The information contained in ASCO-SEP® is provided solely for educational purposes. The information and opinions herein do not constitute medical or legal advice. It is the responsibility of oncologists and other health care professionals to determine, based on their individual judgment and experience, the appropriate course of treatment for each patient. Physicians should not substitute this curriculum for the advice of legal counsel. ASCO assumes no responsibility for errors or omissions in this publication. Specific therapies discussed may not be approved and/or specified for use as indicated. Before prescribing any medication, it is the responsibility of individual physicians to review the complete prescribing information, including indications, contraindications, warnings, precautions, and adverse effects.

Cover art, titled *From Data to Dawn*, by Ann Meredith Garcia Trinidad, MD. Used with permission.

About the cover art: Ann Meredith Garcia Trinidad is Head of the Section of Medical Oncology at Dagupan Doctors Villaflor Memorial Hospital in the Philippines. She received an ASCO International Development and Education Award in 2020, and has served as an Advisory Panelist for Cancer.Net. Inspired by her work in oncology and patient education, she uses paper quilling to transform the science of cancer into a visual narrative of healing. Her featured piece, *From Data to Dawn*, intersperses Kaplan-Meier curves, DNA helices, antibodies, and the tumor microenvironment to symbolize precision oncology. The cancer ribbon and the path towards the sunrise represent the patient journey—anchored in hope, guided by evidence, and sustained by care.

CONTINUING EDUCATION AND CONFLICT-OF-INTEREST DISCLOSURES

CONTINUING EDUCATION

ASCO-SEP® Medical Oncology Self-Evaluation Program does not award continuing education credit and MOC points from ABIM. Please visit ASCO Education for more information.

CONFLICT-OF-INTEREST DISCLOSURES

ASCO is committed to balance, objectivity, and scientific rigor in the management of financial interactions with for-profit health care companies that could create real or perceived conflicts of interest. Participants in the Program have disclosed their financial relationships in accordance with ASCO's Policy for Relationships with Companies; review the policy at asco.org/rwc. ASCO offers a comprehensive disclosure management system, using one disclosure for all ASCO activities. Members and participants in activities use coi.asco.org to disclose all interactions with companies. Their disclosure is kept on file and can be confirmed or updated with each new activity. Please email coi@asco.org with specific questions or concerns.

All financial relationships reported by contributors to this activity are available to learners at ASCO Education. During planning and development of the activity, relevant financial relationships were mitigated for all contributors. Relationships are considered self-held and compensated unless otherwise noted (I= Immediate family member; Inst= My Institution). Disclosures are submitted per the ASCO Policy for Relationships with Companies.

EPIDEMIOLOGY AND PREVENTION

1

Christin B. DeStefano, MD, and John L. Vaughn, MD, MS

RECENT UPDATES

- Blood-based cancer screening uses fragments of DNA shed by tumors into the bloodstream to detect cancer early and noninvasively. Validated tests for colorectal cancer show high sensitivity (83.1%) and specificity (89.6%) in average-risk adults.[1] Emerging multicancer early detection (MCED) platforms analyze DNA fragment patterns, chromatin, and methylation patterns to identify dozens of cancers and predict where they started, offering a single-test approach to broad cancer screening for high-risk populations.
- The National Cancer Institute Vanguard Study (NCT06995898) is a feasibility trial enrolling up to 24,000 participants across multiple sites to assess the operational viability of using MCED blood tests for population-based screening of cancers including pancreatic, ovarian, liver, lung, bladder, breast, colorectal, esophageal, stomach, and prostate. Primary endpoints focus on feasibility of recruitment, adherence, and representative enrollment, while secondary endpoints assess timeliness of result return, diagnostic resolution of abnormal tests, and impact of blinding on adherence and screening behavior.[2]

OVERVIEW

Cancer providers who are charged with the diagnosis, treatment, and management of cancer and related treatments operate at the far end of the cancer life cycle. However, the origins of cancer lie far before these clinical encounters, rooted in an individual's genetic background, environmental exposures, behaviors, and the complex interplay between these factors. Although the care of patients with cancer is crucial for improving outcomes of current and potentially future patients, individual oncology services are insufficient to alter the cancer's impact at the population level. Epidemiology provides the tools to understand cancer at the population level and the opportunity for interventions to reduce the impact of cancer and ultimately improve the outcomes of cancer. Understanding epidemiology empowers clinicians to extend care beyond the patient to the population through targeted interventions in patients' communities. For example, collection of risk factor information, such as tobacco and alcohol use, body mass index, and family history of cancer, can be used to provide advice and guidance to patients (eg, tobacco use cessation) and to guide recommended strategies for primary prevention, secondary prevention (eg, early detection), and tertiary prevention (improving outcomes).

DISTRIBUTION OF CANCER IN POPULATIONS

Epidemiology is the study of the distribution of disease (descriptive epidemiology) and disease determinants (analytic epidemiology) in populations. Characterizing the distribution of cancer in populations is a critical first step to understanding the scope of the problem posed by cancer. Central to this process are ongoing surveillance activities to rigorously track the occurrence of cancer in defined populations according to characteristics of patients with cancer, including where they live and the disease onset. Population-based cancer registries are ongoing surveillance systems designed to ascertain newly diagnosed cases of cancer and deaths resulting from cancer or other etiologies such as secondary cancers or complications of cancer therapy. In the United States, the National Cancer Institute (NCI) sponsors the Surveillance, Epidemiology, and End Results (SEER) Program, which provides data (45.9% of the US population) on cancer incidence, survival, treatment patterns, and county-level data, facilitating epidemiology research.[3] The NCI's Virtual Pooled Registry (VPR) enables secure linkage between external research cohorts and state cancer registries, further supporting epidemiological cancer research and longitudinal cancer surveillance.

MEASURING THE DISTRIBUTION OF CANCER

Cancer statistics use population rates, typically expressed as cases per 100,000 people per year, to describe both the number of new diagnoses and the overall burden of the disease. These rates are age adjusted to allow for meaningful comparisons because

cancer incidence frequently rises with age. Variations in the prevalence of risk factors contribute to differences in how often cancer occurs and its resulting outcomes. The population-attributable risk represents the proportion of new cancer cases that can be linked to specific risk factors within a population. Cancer incidence and survival data are reported in cancer registries throughout the world. These data may be limited by lag times in reporting and missing data.

Key measures include the following:

- Incidence: New cancer cases (reflects effectiveness of primary and secondary prevention, the former will decrease incidence, while the latter will increase incidence).
- Mortality: The cancer mortality includes deaths from cancer (influenced by stage at diagnosis, tumor biology, treatments received, and access to care), and non-cancer mortality includes deaths from competing etiologies (such as cardiovascular disease, motor vehicle accident, etc.).
- Survival: The percentage of patients alive after a specific time (reflects treatment effectiveness). Overall survival takes into consideration deaths from any cause. Overall survival is a common endpoint in clinical trials. Relative survival is a measure of cancer survival that is commonly used in population-based cancer studies. The SEER Program reports relative survival.
- Prevalence: The total number of people living with active cancer (reflects new cases and survival time).

Further information on cancer statistics can be found at the SEER Program.

DESCRIBING THE DISTRIBUTION OF CANCER

An initial step to describe the distribution of cancer in a population involves describing it according to the characteristics of patients (person), including where they live (place), and when they are diagnosed (time).

Real-World Example

A compelling real-world example highlights the importance of detailed analysis: although the overall incidence of colorectal cancer had been decreasing,[4] further analysis based on age groups revealed a concerning trend: an increasing incidence among people younger than 50 years.[5] This observation was corroborated by data from other regions globally[6] and ultimately served as a key factor in the decision to lower the recommended starting age for colon cancer screening in the United States from 50 to 45 years.[7]

Person. Understanding the characteristics of people diagnosed with cancer, such as age, sex, race, ethnicity, and occupation, is crucial for identifying disparities and tailoring interventions. Characteristics of persons measured in US cancer registries principally include age at diagnosis, sex, race, and Hispanic ethnicity. For most cancer types, survival rates are observed to be lower for Black people compared with White people. Exceptions include pancreatic and kidney cancers, where survival rates are similar between these two groups. However, after adjusting for sex, age, and stage at diagnosis, the risk of death from cancer is 33% higher in Black people and 51% higher in American Indian/Alaska Native people compared with their White counterparts.[8] Identification of populations experiencing disparities in incidence and/or mortality has led to research to determine the root causes of these disparities so that they can be reduced. Disparities research entails multilevel assessments to identify and address factors such as social determinants of health, individual socioeconomic characteristics, structural racism, access to and use of health care, lifestyle and behavioral factors, and biological factors that affect outcomes. In the equal-access US military health system, where active-duty service members maintain regular physical fitness, undergo routine drug testing, and receive free unlimited comprehensive care, cancer mortality is significantly lower than in matched civilian populations, and disparities by race or socioeconomic status are markedly smaller than in the standard US health care system.[9,10]

Place. Comparing cancer rates between populations in different locations can distinguish high- and low-risk areas. Age-adjusted breast cancer mortality among non-Hispanic Black women ranges from 33.6 per 100,000 in the District of Columbia to 19 per 100,000 in Massachusetts, reflecting differences in prevalence of risk factors as well as access to and use of prevention and treatment services.[11] Geographic variations in cancer incidence and mortality could reflect access to care, risk factors such as obesity and smoking, environmental exposures, policy differences, and infrastructure for regional screening and clinical trials.

Time. Documentation of the cancer occurrence in populations across time may lead to new hypotheses about the etiology and outcomes of cancer. Increases in incidence may result from population-level increases in risk factors, decreases in protective factors, or both. Compliance with secondary preventive strategies, such as screening for lung, breast and prostate cancer, will also lead to increased cancer incidence. Decreases in incidence may result from large-scale primary prevention interventions or other determinants of population-level decreases in risk factors. Decreases in mortality rates may result from decreased incidence, improved screening that detects cancer at earlier stages, novel treatments, and/or adoption of lifestyle changes such as weight loss and structured exercise that promote longer survival or more effective cures.

- The rapid rise in prostate cancer incidence after 1985 and subsequent fall are largely attributed to the introduction and widespread use of the prostate-specific antigen (PSA) test for screening.[12]
- The COVID-19 pandemic led to a decline in the diagnosis of six major cancers, including localized breast, colorectal, lung, prostate, thyroid, and pancreatic cancers, between March and May 2020. The decline has been attributed to missed or delayed cancer screenings and preventive care visits that occurred in 2020 because of the suspension of nonessential medical care to help control the spread of the disease.[13]

Analyzing cancer trends across time is therefore essential for understanding disease etiology, evaluating interventions, and anticipating future challenges.

DETERMINANTS OF CANCER

Cancer research seeks to identify causes for prevention. A "cause" in epidemiology increases disease frequency when present and decreases it when absent. Cancer typically has multiple causes, and truly necessary causes (eg, human papillomavirus [HPV] for cervical cancer) are uncommon. Modifiable factors play a role in attribution of about 40% of cancers,[14,15] and in almost half of cancer-related deaths worldwide. Establishing a causal link requires a strong association between the factor and the disease, the factor preceding the disease (temporality) with latency considered, and consistent findings across different studies. Epidemiologists use observational studies (cohort, case-control, and cross-sectional studies) to investigate these associations. These studies analyze exposures (eg, diet, environment, occupation) and measure the link to disease using relative risk, odds ratios, hazard ratios, or standardized incidence ratios. Each study type has advantages and disadvantages related to time, resources, and potential biases (Table 1-1). Cohort studies are best for establishing temporality. Replicating findings across various studies, populations, and time periods is crucial for confirming robust causal relationships. Additional details summarizing study designs can be found at the Centre for Evidence-Based Medicine website by the University of Oxford.[14]

Table 1-1 Hierarchy of Evidence by Study Design

Study Type	Evidence
Pooled analysis/ meta-analysis	One of the highest levels of evidence and more generalizable given that it uses multiple data sources, provided inclusion of high-quality studies. Meta-analysis uses published results, whereas pooled analysis reanalyzes individual-level data
Randomized clinical trial	Highest-quality evidence, but use is limited to testing health-enhancing interventions (new treatments, preventive or screening interventions)
Cohort (prospective or retrospective)	Highest-quality observational evidence because of measurement of exposure and follow-up for occurrence of the outcome
Case-control	Useful for studying rare diseases, such as specific cancer types, but susceptible to information and selection biases because of measurement of exposure after the occurrence of disease and challenges of selecting and recruiting a control group representative of the population from which the cases arose
Cross-sectional	Limited by studying only prevalent cancer and measurement of exposure and outcome at a point in time
Ecologic	Unit of observation is group-level data (typically geographically defined), not individuals; results can be useful for evaluating policies aimed at reducing cancer risk factor prevalence that vary geographically
Case series	Commonly used clinical design, but lack of a comparison group severely limits inferences

Study designs higher up in the table tend to provide stronger evidence because of higher internal validity (or lower likelihood of bias).
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

KEY POINTS

- Epidemiology is the study of the distribution and determinants of disease in populations.
- The distribution of cancer incidence, prevalence, mortality, and survival can be compared across demographic characteristics of populations to identify high-risk populations and cancer disparities.
- Criteria for a casual inference in cancer epidemiology include consistency, strength of association, temporal precedence, and latency.

EXTRINSIC AND INTRINSIC FACTORS ASSOCIATED WITH CANCER RISK

Cancer risk is a result of both extrinsic influences (environmental exposures, lifestyle, infectious agents) and intrinsic factors (genetic predisposition, internal biological factors). Although the relative importance of each is still debated, both contribute significantly. The fact that only some smokers develop lung cancer, despite the strong extrinsic factor of smoking, suggests the involvement of intrinsic genetic susceptibility. Therefore, an individual's risk of cancer reflects both their levels and duration of exposure to carcinogens and their own susceptibility, including their genetic predispositions to metabolize exposures or to repair damage induced by a carcinogenic exposure. This interaction between genes and the environment is a central focus of study in molecular epidemiology.[16]

EXTRINSIC FACTORS

Epidemiological studies have identified associations between many extrinsic factors and cancer risk (Table 1-2). For some extrinsic factors, clear-cut causal associations have been established. These are discussed in more detail in the "Interventions for Preventing Cancer" section of this chapter.

Table 1-2 Associations Between Extrinsic Factors and Cancer Risk

Exposure	Cancer Type(s)	Notes
Cigarette smoking	Lung, oral cavity, larynx, esophagus, bladder, kidney, pancreas, stomach, cervix, colon, rectum, liver, acute myeloid leukemia	Causal association; estimated 48% of deaths from cancer in the United States attributable to smoking[17]
Ionizing radiation	Leukemia, non-Hodgkin lymphoma, thyroid, breast (female), lung, colon, bladder	Established cause[18,19] In the Life Span Study on Japanese atomic bomb survivors, after high-dose radiation there was an elevated leukemia risk early on, and an elevated solid tumor risk long-term. A heightened risk of hematological malignancies has been established after lower doses of radiation exposure from medical imaging in children and adolescents[20-22]
UV radiation	Melanoma, nonmelanoma skin cancers	Major cause (sunlight, tanning devices)[18]
HPV (oncogenic strains)	Cervix, penis, vagina, anus, oropharynx	Strong association[23]
Hepatitis B and C viruses	Liver, splenic marginal zone lymphoma	Strong association[23]
Epstein-Barr virus	Burkitt lymphoma, nasopharyngeal carcinoma	Strong association[23]
Helicobacter pylori	Gastric cancer	Strong association[23]
High BMI/obesity	Endometrial, esophageal, meningioma, breast, multiple myeloma, gallbladder, gastric, colorectal, kidney, liver, ovarian, pancreatic, and thyroid cancer[25]	Strong association; 4%-9% of new cancer cases in adults attributable to high BMI[24] Glucagon-like peptide 1 receptor agonists may decrease the risk of obesity associated cancers[26]
Alcohol	Breast cancer, liver, colorectal, oral cavity, esophageal (squamous cell)	Causal association[27,28]
Occupational exposures	Various (eg, melanoma and prostate cancer in pilots/aviators,[29] scrotal carcinomas in chimney sweeps)	2%-8% of cancers attributable to occupational causes[30,31]
Particulate matter (air pollution)	Lung	Classified as human lung carcinogen[32]
HIV infection	Non-Hodgkin lymphoma, cervical cancer, Kaposi sarcoma, anal cancer, Hodgkin lymphoma, lung cancer, skin cancer, oropharyngeal cancers, liver cancer[33]	Risk of non-AIDS-defining cancers (eg, Hodgkin lymphoma, liver, anal, lung) remains elevated even with immune reconstitution on ART. Therefore effective ART reduces, but does not eliminate, excess cancer risk. Coinfections (HPV, HBV, HCV) and lifestyle factors (eg, smoking, alcohol use) further modify risk

Exposure	Cancer Type(s)	Notes
Medications	Immunosuppression or immunomodulators such as lenalidomide can heighten the risk of lymphoid and other malignancies,[34] tamoxifen and uterine cancer risk[35]	Lenalidomide plus high-dose melphalan with autologous stem cell rescue increases the risk of therapy- related myeloid neoplasms[36]
Sedentary lifestyle	Increases the risk of multiple cancers as well as cancer-related mortality[37,38]	The CHALLENGE trial reported a significant reduction in disease-free survival as well as long-term overall survival in colon cancer survivors who underwent a 3-year structured exercise program. Reduced cancer mortality in patients physically fit is exemplified by the healthy soldier effect[39,40]
Circadian rhythm disruptions	Breast, prostate, colorectal, liver, lung cancers	The International Agency for Research on Cancer (IARC) has identified night shift work as a probable carcinogen (group 2A); it is hypothesized that DNA repair, apoptosis, and cell cycle regulation are regulated by circadian genes[41]
Diet	Colorectal cancer	Processed red meat has been linked with an increased colorectal cancer risk[42]

Abbreviations: ART, antiretroviral therapy; HBV, hepatitis B virus; HCV, hepatitis C virus; HPV, human papillomavirus.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

INTRINSIC FACTORS

In addition to external influences, a range of intrinsic factors inherent to a person significantly contributes to their cancer risk (Table 1-3): age, sex, ethnicity, family cancer history, and molecular characteristics encompassing inflammation, immune function, hormones, oxidative stress, and genetic/epigenetic variations.

Table 1-3 Associations Between Intrinsic (Host) Factors Related to Cancer Risk

Intrinsic Factor Category/ Specific Factor	Description/Examples	Cancer Type(s) Associated	Notes
Nonmolecular			
Age	Cancer risk generally increases with age for most cancer types	Most cancers increase in incidence with increasing age	Strong association because of accumulated exposures and cellular changes over time
Sex	Differences in cancer incidence and mortality exist between sexes because of hormonal, genetic, and other factors	Various (eg, breast cancer in women, prostate cancer in men)	Strong; sex-specific cancers, hormonal influences, and other biological differences
Ethnicity/race	Cancer rates can vary across different ethnic and racial groups because of genetic, environmental, and socioeconomic factors	Various	Complex interplay of genetics, environment, and social determinants of health
Family history	Positive family history of cancer can increase risk, particularly for cancers with strong genetic components	Various (eg, breast, ovarian, colon)	Suggests shared genetic susceptibility and/or environmental exposures within families
Personal history	A personal history of cancer increases the risk of a subsequent malignant neoplasm[43,44]	Various	Increased risk likely multifactorial from an elevated baseline inherent risk, immunosuppression from therapy, and DNA damage from certain chemotherapeutic agents or radiotherapy

Intrinsic Factor Category/ Specific Factor	Description/Examples	Cancer Type(s) Associated	Notes
Molecular			
Inflammation and immune dysregulation	Inflammation and autoimmunity can contribute to cancer development; immune system dysfunction can increase cancer risk	Various (marginal zone lymphoma, gastric cancer with autoimmune gastritis, large granular lymphocytic leukemia)	Strong; inflammation can damage DNA and promote cell growth; immune system surveillance plays a role in cancer prevention
Endogenously produced hormones	Hormones play a role in the development of some cancers	Breast, endometrial, prostate, and so on	Strong for hormone-sensitive cancers
Oxidative stress	Imbalance between free radicals and antioxidants can damage DNA and contribute to cancer	Various	Implicated in cancer development, but precise role is still being researched
Host genetic variation			
Rare, moderate or high-penetrance mutations	Mutations with low frequency but high impact on cancer risk (eg, *BRCA1, BRCA2, TP53, ATM, PALB2, CHEK2, CDH1*)	Breast, ovarian, prostate (*BRCA1/2*), Li-Fraumeni syndrome (*TP53*), and so on	Significantly increased inherited susceptibility
Common, low-penetrance polymorphisms (SNPs)	Common DNA sequence variations with small individual effects (often identified through GWAS)	Various	Small individual risk contribution; large potential public health impact; used in polygenic risk scores
Epigenetic variations	Changes in gene expression that do not involve alterations to the DNA sequence itself	Various	Can influence cancer risk, but mechanisms and specific roles are still being studied

Abbreviations: GWAS, genome-wide association study; SNP, single nucleotide polymorphism.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

About 5% to 10% of cancers are hereditary. Genetically, cancer susceptibility can be categorized by the frequency and impact of gene variations. Rare, high-penetrance mutations, such as germline pathogenic *BRCA1/2* mutations significantly elevate inherited risk. In contrast, more common low-or moderate penetrance germline pathogenic mutations, such as in *CHEK2* or *PALB2*, have a smaller effect on an individual's risk, but their widespread prevalence means they could still have a substantial impact on public health. Although common variations may interact with environmental factors—for example, CYP450 enzymes and smoke carcinogens—strong evidence for many such interactions is still needed. Data from genome-wide studies have identified numerous genetic variations linked to cancer, although their precise biological roles often remain unclear. This information can be used to develop polygenic risk scores for potential risk prediction.[45,46]

To illustrate the interplay of these intrinsic and extrinsic factors in real-world scenarios, the following case studies will explore how these influences can contribute to cancer development and outcomes.

PRESENTING CASE STUDIES

Patient 1

A 65-year-old postmenopausal woman presents to the oncology clinic to discuss next steps after undergoing lumpectomy for pT2pN0cM0, estrogen receptor (ER)–positive, progesterone receptor (PR)–positive, HER2–negative invasive ductal carcinoma of the left breast, with a low-risk gene expression score. She has a history of obesity (body mass index [BMI], 32 kg/m^2), hypertension, which she manages with amlodipine, and prediabetes. Menarche occurred at age 12, menopause at age 52, and first pregnancy at age 24. She has been on estrogen replacement therapy (ERT) with estradiol since age 54. She has three sisters and two daughters but reports no family history of breast or ovarian cancer. She consumes approximately 6 ounces of wine four evenings per week and leads a sedentary lifestyle. Physical

examination reveals well-healed surgical sites from the lumpectomy and axillary dissection, and vital signs are within the reference range. She is looking for guidance on adjuvant therapy and risk reduction.

Patient 2

A 35-year-old premenopausal woman seeks to understand her recent diagnosis of pT2pN0cM0, ER-positive, PR-positive, HER2-negative invasive ductal carcinoma of the left breast after she sought care for a palpable breast mass. Despite maintaining a healthy lifestyle with a Mediterranean diet and regular cardiovascular exercise, she is concerned about potential contributing factors, particularly given her family history of breast cancer in her mother at age 45 and ovarian cancer in her sister at age 37. Her only medication is an oral contraceptive pill, and she reports moderate alcohol consumption. A gene expression assay reveals a low-risk score. Physical examination reveals well-healed surgical sites, and vital signs are within the reference range. She would like to discuss adjuvant therapy and risk assessment.

Compare and contrast the potential extrinsic and intrinsic risk factors that may have contributed to the development of breast cancer in these two patients, considering their differences in age, lifestyle, family history, and medical history.

These patient cases emphasize the multifactorial nature of cancer risk, highlighting the interplay between extrinsic and intrinsic factors. Extrinsic factors include environmental exposures, lifestyle choices, or external agents that influence cancer development. Intrinsic factors, in contrast, are inherent to a person's physiology, such as genetic predispositions or inherited traits. Both types of factors contribute to a patient's overall cancer risk.

Comparative analysis of cases

Patient 1 presents several notable extrinsic risk factors:

- Obesity: Her BMI of 32 kg/m^2 indicates obesity, which is linked to increased estrogen levels and chronic inflammation, both implicated in breast cancer development. Adipose tissue acts as an endocrine organ, producing estrogen and inflammatory cytokines that can promote tumor growth. Research suggests a clear association between obesity and postmenopausal breast cancer risk, with a relative risk increase ranging from 1.5 to 2.5.
- ERT: Long-term ERT use, particularly for more than 10 years, is associated with an increased risk of breast cancer. The estrogen component of ERT stimulates breast tissue proliferation, potentially increasing the risk of developing malignant cells. Studies have shown a relative risk increase of 1.33 for breast cancer in women using combined estrogen-progestin ERT for 5 years or longer.
- Sedentary lifestyle: Physical inactivity can contribute to hormonal imbalances, reduced immune function, and increased inflammation, potentially influencing breast cancer risk. Regular exercise has been shown to have protective effects against various cancers, including breast cancer.
- Alcohol consumption: Although her alcohol intake is moderate, it is worth noting that even moderate alcohol consumption can affect estrogen metabolism, potentially increasing breast cancer risk.[47]

Intrinsic factors may also play a role, but they are less prominent in this case. Although the patient has no family history of breast or ovarian cancer, it is important to remember that a significant proportion of breast cancers occur in women without a known genetic predisposition. Age is also an intrinsic factor, because breast cancer risk increases with age.

In contrast to Patient 1, Patient 2's risk profile leans more heavily toward intrinsic factors:

- Family history: Her family history of breast cancer (mother diagnosed at age 45) and ovarian cancer (sister diagnosed at age 37) raises significant concern for a potential genetic predisposition. Pathogenic germline mutations in high-penetrance genes like *BRCA1* and *BRCA2*, associated with hereditary breast and ovarian cancer syndrome, could be contributing factors. Although a low-risk gene expression assay was performed, it did not rule out all possible genetic risks. Other genes and mutations may be involved, and further genetic counseling and testing are warranted to explore this possibility.

- Age: Although she is relatively young for personal history of cancer, her strong family history substantially elevates her breast cancer risk at an earlier age than typically expected.

Extrinsic factors are less prominent in this case because of her healthy lifestyle, including a balanced diet and regular exercise. However, it is important to consider the potential impact of the following:

- Oral contraceptives: Although oral contraceptives have been associated with a slightly increased risk of breast cancer, the absolute risk remains low, particularly in younger women. It is crucial to discuss the risks and benefits with patients who have a family history of cancer.
- Alcohol consumption: Even moderate alcohol consumption can increase breast cancer risk.

Contrasting analysis of cases

These cases illustrate the diverse nature of breast cancer risk. Patient 1's case highlights the impact of modifiable lifestyle factors, whereas Patient 2's case emphasizes the significance of genetic predisposition. It is crucial to recognize that both extrinsic and intrinsic factors can interact and contribute to an individual's overall risk.

Personalized cancer risk assessment

Understanding the interplay between extrinsic and intrinsic risk factors is essential for personalized risk assessment and management. By identifying and addressing modifiable risk factors, such as obesity, ERT use, and sedentary lifestyle, the risk of breast cancer can be reduced. For people with a strong family history or other indications of genetic predisposition, genetic counseling and testing are crucial for informed decision-making regarding risk-reduction strategies, such as increased surveillance or chemoprevention. Both patients should be encouraged to engage in shared decision-making with their health care providers to develop personalized plans that address their unique risk profiles and preferences.

INTERVENTIONS FOR PREVENTING CANCER

Cancer primary prevention aims to reduce the incidence of cancer, secondary prevention aims to detect cancer early, which will inadvertently result in an increased cancer incidence, and tertiary prevention aims to reduce cancer mortality. Therefore, the cancer prevention paradigm operates on a continuum. Epidemiology and basic sciences contribute to the discovery of cancer risk factors, the mechanisms by which they cause cancer, and factors that contribute to cancer-related morbidity and mortality. This knowledge helps to identify opportunities to (1) predict future risk based on combinations of risk factors, (2) detect cancer before the development of symptoms (cancer screening), (3) diagnose cancer early in symptomatic persons (early detection), and (4) address gaps in health care access or social determinants of health. This section reviews the risk factors and the different strategies currently available for the prevention of specific cancers.

TOBACCO

- Cigarette smoking is the leading cause of preventable morbidity and premature mortality in the United States and is causally associated with 13 different malignancies: cancers of the lung, oral cavity, larynx, esophagus, bladder, kidney, pancreas, stomach, cervix, colon, rectum, and liver, as well as acute myeloid leukemia.[17] An estimated 48% of all cancer deaths in the United States are attributable to cigarette smoking. Secondhand smoke is a known cause of lung cancer in nonsmokers, indicating that there is no safe level of exposure to cigarette smoke.[17]
- The risks of malignancy and death caused by cigarette smoking are dose dependent; the risk of most smoking-associated cancers increases with both the duration of smoking (years) and the intensity (cigarettes per day). Quitting smoking is associated with an immediate decrease in cancer risk compared with continued smoking. However, former smokers remain at a higher risk for most smoking-associated cancers compared with never-smokers, even after decades of cessation.
- Pipes and cigars are strongly linked to lung cancer risk although the associations are generally weaker than those for cigarette smoking. This is primarily because these products are typically used less frequently, and the smoke is often inhaled less deeply than with cigarettes.[17] The tobacco marketplace has changed significantly in the last 15 years, most notably with a surge in e-cigarette use (ie, vaping), particularly among youth and young adults.[48] The long-term health effects of e-cigarettes are still under investigation, but the vapor contains known carcinogens, raising concerns that e-cigarette use may increase cancer risk.[48]

Smoking Cessation

Smoking cessation at any point, before, during, or after cancer treatment, improves survival, reduces treatment complications, and lowers the risk of second primary malignancies. Most US adult smokers initiate smoking before the age of 18. Therefore, smoking prevention interventions targeting pediatric and adolescent populations are a major public health priority. Research indicates that a physician's simple advice to avoid or quit smoking can substantially increase the likelihood of a quit attempt and successful cessation.[49,50] Despite this evidence, a survey reported that although more than 80% of oncologists assess their patients' smoking behavior, fewer than 20% feel confident in intervening effectively in this critical area.[51] Given the well-documented negative impact of cigarette smoking on the prognosis of patients with cancer, providing smoking cessation services is essential in the oncology setting.[50] Smoking is an addiction, and evidence shows that smokers are most likely to succeed with a multifaceted cessation program that includes counseling, behavioral strategies, and drug therapy. Recommended first-line drug therapies include nicotine replacement therapy, bupropion, and varenicline, with clonidine and nortriptyline as potential second-line options. Even a small amount of encouragement from a health care provider can significantly enhance smoking cessation efforts. The process of quitting involves identifiable stages for the smoker, including contemplation, action, and maintenance. Numerous effective strategies beyond counseling exist for advising and assisting motivated patients in achieving their goal.[49,50,52]

In addition to individual-level tobacco control, policy-level interventions have demonstrated a reduction in smoking prevalence. Important examples of tobacco control policies include tax increases on cigarettes, smoke-free workplace legislation, and raising the minimum legal age for tobacco product access. Comprehensive tobacco control policies have led to substantial progress in reducing smoking prevalence. Currently, approximately 12.5% of the US population are smokers, which should contribute to continued downward trends in the burden of smoking-caused cancer.[53] Regardless, cigarette smoking remains a major cancer risk factor, and lung cancer is the leading cause of cancer mortality worldwide.

E-CIGARETTE USE (VAPING)

The potential role of e-cigarettes and heated tobacco products in tobacco control is controversial. In the United States, the prevalence of e-cigarette use among youth has increased markedly. Evidence strongly indicates that, beyond the direct harmful effects of e-cigarettes (both known, such as nicotine addiction, cough, and wheezing, and those still under investigation), e-cigarette use is a significant risk factor for the initiation of combustible tobacco cigarette smoking among never-smokers.[48] However, among adult addicted smokers, e-cigarettes have the potential to be a tool to enhance smoking cessation.[54] Nevertheless, the known and potential adverse effects of e-cigarettes preclude their use as a first-line smoking cessation strategy; the full extent of these adverse health effects is still being characterized. In addition to nicotine, e-cigarettes contain numerous compounds with adverse health effects although these are substantially fewer than those found in combustible tobacco cigarettes.[54]

The Centers for Disease Control and Prevention (CDC) recommends "not using e-cigarette, or vaping, products that contain THC [tetrahydrocannabinol] or any e-cigarette, or vaping, products obtained from informal sources. E-cigarette, or vaping, products should never be used by youths, young adults, or pregnant women."[55,56] The CDC provides additional guidelines on the risks of using e-cigarettes.[57] Heated tobacco products, also known as noncombusted cigarettes, differ from e-cigarettes in that they heat, but do not burn, processed tobacco leaf sufficiently to release a vapor containing nicotine. A recent review of randomized clinical trials among cigarette smokers concluded that these products reduce exposure to tobacco carcinogens. However, there was insufficient evidence to conclude that heated tobacco products are effective for smoking cessation.[58]

No data currently exist on the short- or long-term health effects of heated tobacco products. The CDC recommends that people not use heated tobacco products as alternatives to cigarette smoking or e-cigarettes.[59,60]

MARIJUANA

Given evolving legalization and increasing use, continued surveillance and mechanistic research are needed to clarify marijuana's long-term effects on cancer risk. Forty states and the District of Columbia have passed laws legalizing marijuana use in some form. Although most studies on marijuana use and cancer risk have focused on the upper aerodigestive tract and lung, current evidence does not establish a clear positive association between marijuana use and these cancers.[61] Additionally, an association between marijuana use and testicular germ cell tumors has been observed in three case-control studies although a biological explanation for this association has not been established.[61]

ALCOHOL

Moderate alcohol consumption is associated with an elevated risk of breast cancer compared to never consuming alcohol, and heavy consumption is a well-established cause of liver cancer. Although alcohol consumption has previously been associated with cancers of oral cavity, pharynx, larynx, esophagus, and colorectum, the National Academies of Science, Engineering and Medicine recently found insufficient evidence to confirm these associations.[28] The associations between alcohol consumption and cancer are often dose dependent[27] and do not vary substantially based on whether beer, wine, or liquor is ingested.[62] It has been estimated that alcohol consumption is responsible for approximately 6% of all cancer cases and 6% of deaths resulting from cancer globally.[27]

Based on this evidence, ASCO guidelines for alcohol use recommend no more than two drinks per day for men and one drink per day for women, and those who do not drink alcohol are advised to continue to abstain.[27] Furthermore, synergistic interactions between cigarette smoking and alcohol consumption have been established. The ASCO statement on alcohol and cancer emphasizes the importance of alcohol screening and intervention within the oncology setting.[27]

UV RADIATION EXPOSURE

Exposure to UV radiation, either from sunlight or from indoor tanning devices, is the predominant cause of both melanoma and nonmelanoma skin cancers.[18] The major determinant of the occurrence of skin cancer in populations is cumulative UV radiation exposure in combination with sun-sensitive phenotypes (eg, propensity to sunburn on UV radiation exposure, fair skin, freckles). UV radiation exposure in childhood and adolescence is associated with an increased risk of skin cancer in adulthood. The use of tanning beds is causally associated with the risk of melanoma,[63] and the associations between tanning bed use and nonmelanoma skin cancer are also consistent with a causal association. Reduction in sun exposure throughout life by using protective clothing and sunscreen and avoidance of the most intense and direct sunlight (between 10:00 AM and 4:00 PM in the continental United States) are recommended as ways to lower the risk of skin cancer.[64] Interventions to prevent the use of UV radiation–emitting tanning devices include educational interventions and policy-level interventions, such as issuing health warnings and increasing the minimum legal age of access.

OBESITY

Obesity is classically defined as a body mass index (BMI) of at least 30 kg/m^2.[65] Although BMI remains the most common definition of obesity, abdominal obesity is defined as waist circumference of 102 cm or larger for men and 88 cm or larger for women, independent of BMI, and increases health risks and all-cause mortality.[66] Obesity and overweight are epidemic in the United States. Currently, less than one-third of the US adult population is within the normal BMI range. The International Agency for Research of Cancer (IARC) concluded that there is sufficient evidence demonstrating risk associations for obesity and 13 cancers, including esophageal adenocarcinoma, meningioma, multiple myeloma,[24] gastric cardia, colorectal, liver, gall bladder, pancreatic, postmenopausal breast, uterine, ovarian, renal cell, and thyroid cancers. Additionally, IARC concluded that limited evidence supports risk associations for obesity and three additional cancers, including male breast and prostate cancers and diffuse large B-cell lymphoma. Importantly, excess adiposity in people with normal BMI is associated with an increased risk of postmenopausal breast,[67,68] endometrial,[69] and colorectal cancers, suggesting that the public health burden of obesity-related cancers is even higher than that estimated by BMI. Excess adiposity also increases cancer recurrence risk and cancer-specific mortality and reduces treatment efficacy in multiple cancers.[70,71] Excess adiposity drives insulin resistance, cytokine synthesis, and related adipokines, potentially from the adipocyte or macrophages within the adipose tissue, to establish a proinflammatory state.[72,73] Humoral products stimulate both cancer and epithelial stem cell self-renewal.

Weight loss and bariatric surgery are associated with reduced risks of multiple cancers.[74] For example, a study of approximately 37,000 postmenopausal women in the Women's Health Initiative showed that intentional weight loss was associated with a reduced risk of endometrial cancer. During an 11-year follow-up, women who had a greater than 5% intentional weight loss over a 3-year period had a 29% lower risk of endometrial cancer compared with women with a stable weight (hazard ratio [HR], 0.71; 95% CI, 0.54-0.95). Those who gained weight had an increased risk of endometrial cancer.[75] The metabolic effects of bariatric surgery rapidly precede clinical weight loss. These effects include shifting of adipokines and the hormonal environment toward a lower level of chronic inflammation, thus reducing the inflammatory state resulting from obesity-associated metabolic syndrome.[74,75] Observational data indicate that medical weight loss therapy with incretin mimetics, specifically GLP1 receptor agonists, is associated with relative risk reductions for several obesity-associated conditions.[26]

DIET

The observation that rates of breast, colon, endometrium, and prostate cancers are notably higher in North America and Western Europe compared with Asia suggests a potential role for environmental factors. This is further supported by the finding that Asian immigrants and their offspring tend to acquire a greater risk of these cancers after residing in the United States for some time. These epidemiologic patterns, in conjunction with data from studies on model organisms, underpin the hypothesis that dietary modifications could significantly reduce cancer risk in the US population.[76]

Diet represents a complex and multifaceted exposure involving a vast array of nutrients and chemical compounds. Within this complexity, certain dietary components have been identified as potentially protective against cancer. These include polyphenolics, found in foods like those containing curcuminoids, resveratrol, and ginger, as well as sulfur-containing compounds present in green vegetables, such as sulforaphane and flavones.[77] Furthermore, dietary patterns characterized by low-fat content, typically involving reduced consumption of processed red meat and increased intake of fruits and vegetables, may also offer some protection. This benefit is likely attributable to the high levels of antioxidants found in vegetables, fruits, legumes, nuts, and grains.

However, despite these promising epidemiologic associations and supporting biomarker data, establishing a definitive causal link between overall dietary fat intake and cancer has proven challenging.[78] Case-control and cohort studies investigating this relationship have yielded inconsistent results. Moreover, no prospective clinical trial to date has conclusively demonstrated that reducing dietary fat can prevent cancer. For instance, the large-scale Women's Health Initiative randomized trial found no significant effect of a low-fat diet on the incidence of breast or colon cancer.[79,80]

Interestingly, although the broad link between low-fat diets and overall cancer prevention remains unclear, a more specific benefit has emerged in certain contexts. Among women diagnosed with early-stage breast cancer, a low-fat dietary approach seems to offer a survival advantage. The Women's Health Initiative randomized trial involving more than 2400 women with early-stage breast cancer indicated that those assigned to a low-fat diet, in addition to receiving standard adjuvant therapy, experienced a meaningful improvement in survival compared with women maintaining a regular diet (HR, 0.76; 95% CI, 0.60-0.98).[81]

Beyond the focus on overall fat intake, specific dietary patterns and food groups have also been implicated in cancer risk. For example, a high intake of smoked and cured meats, coupled with limited consumption of fresh fruits and vegetables, is associated with an increased risk of gastrointestinal malignancies.[8]

Another significant area of concern involves the consumption of sugar-sweetened beverages and energy-dense foods, such as traditional fast food or heavily processed items. The increased intake of these products elevates the risk of excess adiposity, which is itself a well-established risk factor for at least 13 different malignancies. Importantly, beyond their contribution to obesity and metabolic syndrome, the independent metabolic effects of glucose and fructose, the primary sugars in these products, also seem to contribute to cancer risk.

The potential impact of sugar-sweetened beverages on cancer risk is further underscored by the findings of a comprehensive meta-analysis. This analysis, which included 27 cohort and case-control studies, revealed a positive association between higher intake of sugar-sweetened beverages and an increased risk of both breast cancer (relative risk, 1.14; 95% CI, 1.01-1.30) and prostate cancer (relative risk, 1.18; 95% CI, 1.10-1.27). The meta-analysis also found a positive link between higher fruit juice intake and an elevated risk of prostate cancer (relative risk, 1.03; 95% CI, 1.01-1.05) when comparing the highest and lowest intake categories defined in the individual studies.[82] Furthermore, positive associations were observed between sugar-sweetened beverage consumption and the risk of colorectal and pancreatic cancers.

In light of this growing body of evidence, global health organizations, including the American Cancer Society and the World Cancer Research Fund/American Institute for Cancer Research, have issued recommendations to limit the consumption of sugar-sweetened beverages as a key strategy for the prevention of several obesity-related cancers.[83]

VITAMINS AND SUPPLEMENTS

Most randomized trials of vitamin supplements have not shown cancer prevention benefit; indeed, in some instances, they have shown harm.[84] Table 1-4 lists examples of data demonstrating that supplementation of micronutrients beyond basic dietary requirements has not been associated with reduced incidence of common cancers. Therefore, dietary supplements are not recommended for cancer primary prevention. Additionally, because concomitant use of herbal supplements or certain vitamins during cancer treatment may lead to adverse interactions, discontinuing dietary supplements after a cancer diagnosis is advised.[85]

Table 1-4 Contrast Between Observational and Randomized Studies for Supplements

Supplement/Outcome	Observational Study Findings	Randomized Study Findings	Notes
Selenium and vitamin E/prostate cancer	High intake of selenium and vitamin E were associated with lower risk of prostate cancer	SELECT trial (large, placebo controlled): no reduction in incidence. Small skin cancer trial and secondary analysis of ATBC trial: supported observational findings	Conflicting results; large, well-designed trial showed no benefit[86-88]
Calcium/colon cancer	High-calcium diets were associated with lower risk of colon cancer	Women's Health Initiative and VITAL trial: no lower incidence of colorectal cancer. Two trials: supplemental calcium reduces adenomatous polyps risk (~25%). One trial: calcium supplementation decreased polyp recurrence, but a more recent trial failed to confirm	Mixed results; some benefit seen for polyp reduction but not for overall colorectal cancer incidence[89-95]

Supplement/Outcome	Observational Study Findings	Randomized Study Findings	Notes
Carotenoids and beta-carotene/lung cancer	High intake of carotenoid-rich fruits and vegetables and beta-carotene were associated with lower risk of lung cancer	ATBC and CARET trials (high-risk patients): increased lung cancer incidence and mortality in beta-carotene groups	Clear example where observational studies suggested benefit, but randomized trials showed harm[96,97]
Retinoids/squamous cell cancer (head and neck)	Limited efficacy as preventive agents	One trial: 13-*cis*-retinoic acid reduced second primary head and neck cancer. Two follow-up trials (lower doses): no clinical effectiveness	Initial positive result not replicated with lower, less toxic doses[98-101]
Vitamin D and cancer	Low levels of vitamin D were associated with increased risk of cancer[102]	VITAL trial: Vitamin D supplementation did not result in a lower incidence of cancer[91,103]	Observational studies were likely confounded by multiple variables including outdoor physical activity
Nicotinamide and skin cancer	Nicotinamide use was associated with a 14% reduction in risk of skin cancer[104]	One trial found that nicotinamide was effective at reducing the rates of new nonmelanoma skin cancers and actinic keratoses in high-risk patients.[105] Another trial of solid organ transplant patients did not observe a benefit[106]	The trial in transplant patients was stopped early due to poor accrual

PHYSICAL ACTIVITY

Approximately 25% of the US population is considered sedentary, and this aspect of lifestyle is considered responsible for up to 5% of cancers.[107] Most of these associations were independent of body size or smoking history.[108] In addition to the role of physical activity in reducing cancer risk, increases in physical activity may be helpful for cancer survivors. Evidence suggests a potential dose-response relationship, where greater amounts of physical activity are associated with a reduced risk of various cancers. For instance, a study by Matthews et al[109] indicated that engaging in 150 to 300 minutes of physical activity per week is linked to a lower risk of many cancer types.

Furthermore, among cancer survivors, physical activity has been associated with decreased cancer recurrence and progression, as well as improved overall survival. The most pronounced benefits of physical activity in this population have been reported for survivors of colorectal, breast, and prostate cancers.[107,110,111]

In the CHALLENGE trial, structured exercise after adjuvant chemotherapy for high-risk colon cancer, defined as stage III or stage II with poor prognostic features, improved 5-year disease-free survival (HR 0.72) and reduced overall mortality (HR 0.63) supporting exercise as a critical survivorship intervention.[39]

INFECTIONS

HPV vaccination using the nine-valent vaccine effectively reduces the incidence of cervical carcinoma. HPV vaccination proportions in the United States for adolescents, especially those in the target age range of 9 to 13 years, remain low (coverage of at least one dose: girls, 22%; boys, 24%).[112] Adolescents 13 to 19 years have higher coverage proportions (girls, 69%; boys, 44%).[113] Because these same viruses are involved in other cancers, the incidence of anal, vaginal, penile, and oropharyngeal cancers may also decrease if a sufficient percentage of the population can be protected from HPV through vaccination.

An estimated 1 million deaths in the world annually are attributed to chronic hepatitis B infection. Since the hepatitis B vaccine was introduced in Taiwan in 1984, the risk of hepatocellular carcinoma (the leading cancer in that country) has dropped more than 70% among those vaccinated.[114] The hepatitis C virus (HCV) infects 1.3% of the population in the United States. Antiviral therapy for HCV with direct-acting viral protease inhibitors eradicates the virus. Treatment with viral protease inhibitors is associated with a 54% reduction in all-cause mortality, including reduced mortality as a result of hepatocellular carcinoma.[115] Similarly, it is possible that regular screening and treatment of HCV will result in a lower incidence of HCV-related lymphomas.

Prior to World War II, gastric adenocarcinoma was a prevalent malignancy in the United States. Infection with *Helicobacter pylori* is recognized as a risk factor for gastric cardia carcinoma. However, the effectiveness of eradicating *H. pylori* to lower the

risk of this specific type of stomach cancer differs across populations. Studies have shown that eliminating *H. pylori* is linked to a decreased risk of gastric cancer in Asian populations. In contrast, this protective association has not been consistently demonstrated in studies conducted in US populations.[116-119]

H. pylori is also strongly associated with the development of gastric extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma).[120] *H. pylori* infection causes gastritis that leads to T-lymphocyte activation and B-cell expansion. In some cases, this may result in the development of MALT lymphoma.[121] Eradication of *H. pylori* infection has emerged as the standard first-line treatment option for patients with concomitant *H. pylori* infection and gastric MALT lymphoma,[122] supporting a causative relationship between *H. pylori* and gastric MALT lymphoma.

DRUGS/MEDICATIONS

Compounds of interest in clinical cancer prevention include anti-inflammatory agents, antioxidants, differentiating agents, hormone modulators, obesity medications, and vaccines. A long-term randomized placebo-controlled clinical trial is generally necessary to establish the efficacy of a clinical preventive agent.

Nonsteroidal Anti-inflammatory Drugs and Colorectal Cancer Prevention

Nonsteroidal anti-inflammatory drugs (NSAIDs) encompass both aspirin and nonaspirin compounds. Meta-analyses of randomized controlled trials have demonstrated the effectiveness of aspirin in preventing colorectal cancer.[89,123] Although trials evaluating COX-2 inhibitors and other nonaspirin NSAIDs have shown promise in preventing the development of colorectal adenomas, their use for colorectal cancer prevention is currently not recommended because of an associated increased risk of cardiovascular disease.

Notably, the ASCOLT trial, a large randomized study, did not find that daily 200 mg of acetylsalicylic acid (ASA) improved disease-free survival in patients with stage III or high-risk stage II colon cancer. However, in the ALASCCA trial, low-dose aspirin reduced recurrence in patients with PI3K pathway altered stage I–III colorectal cancer (HR 0.49, 95% CI: 0.24-0.98; $P = .04$) for those with somatic *PIK3CA* hotspot mutations.[124]

Despite the lack of broad recommendations for aspirin in colorectal cancer prevention, data suggesting that NSAIDs can reduce neoplastic progression in patients with familial nonpolyposis colon cancer (Lynch syndrome) indicate that interventions targeting inflammatory pathways may be beneficial in high-penetrance genetic syndromes. Furthermore, the use of NSAIDs for patients with familial adenomatous polyposis after colectomy may be a reasonable consideration in conjunction with ongoing endoscopic screening. Looking ahead, the results of a randomized study evaluating eflornithine and sulindac in patients with treated colorectal cancer are anticipated in the coming years (ClinicalTrials.gov identifier NCT01349881).

Hormone and Testosterone Replacement Therapy

The Women's Health Initiative reported an increased risk of breast cancer (odds ratio, 1.24; 95% CI, 1.01-1.54) among postmenopausal women taking active hormone replacement estrogens with progestins.[125] A parallel trial of estrogen alone compared with placebo for women with prior hysterectomy did not show an increased risk of breast cancer among women taking estrogen.[126] There is no benefit of postmenopausal estrogens for women beyond a short-term reduction in perimenopausal symptoms.[127]

Testosterone therapy is increasingly common in the United States, with millions of men receiving some form of replacement. No cohort study large enough has been conducted to date to adequately address the question of whether this low-dose of androgen supplementation increases the risk of prostate cancer incidence or mortality. The American Urologic Association recommends that clinicians obtain baseline PSA level in men > age 40 and hemoglobin/hematocrit before starting testosterone replacement therapy (TRT), and engage in shared decision-making particularly for men with a history of prostate cancer given that evidence is insufficient to quantify the risk/benefit in this group.

Selective Estrogen Receptor Modulators and Aromatase Inhibitors

Expert guidance from the USPSTF and ASCO recommends either tamoxifen (20 mg/d for 5 years) or raloxifene (60 mg/d for 5 years) to reduce the incidence of estrogen receptor–positive invasive breast adenocarcinoma in high-risk populations including those with breast cancer precursor conditions.[128-130] Notably, neither drug reduces estrogen receptor–negative invasive breast adenocarcinoma incidence nor breast cancer–specific or all-cause mortality. Low-dose tamoxifen (5 mg/d) seems to have similar preventative efficacy to high-dose tamoxifen (20 mg/d), with reduced toxicity.[131] Although aromatase inhibitors have not been approved by the US Food and Drug Administration for chemoprevention, they are included in the ASCO guidelines for preventive therapy and are a reasonable option for postmenopausal women.

ASCO patient selection guidelines for offering preventive therapy:

- All women with atypical hyperplasia (ductal or lobular) or lobular carcinoma in situ who are age 35 or older, have completed childbearing, and have no medical contraindications should be offered preventive therapy.

- Women who are 35 to 59 years with a calculated 5-year risk of at least 3% or with a 10-year absolute risk of at least 5% (based on the National Cancer Institute Breast Cancer Risk Assessment Tool or equivalent measures) should be offered preventive therapy.
- For women who are 60 to 69 years with a 5-year absolute risk of 3% (based on the National Cancer Institute Breast Cancer Risk Assessment Tool or equivalent measures), the risks versus benefits are less clear, and the risk of serious adverse effects is higher than that in younger women.

Antiandrogens: Targeting Androgen Signaling in Prostate Cancer

Given the crucial role of androgens in stimulating prostate cell proliferation and driving prostate carcinogenesis, strategies to reduce androgen signaling are vital. Finasteride and dutasteride achieve this by inhibiting 5-alpha reductase, the enzyme responsible for converting testosterone into its more active form, dihydrotestosterone, within the prostate. Randomized, placebo-controlled clinical prevention trials have demonstrated that these 5-alpha reductase inhibitors can reduce the incidence of prostate cancer by approximately 20%.[132]

An initial finding from early studies suggested a potential concern: men treated with finasteride who developed invasive prostate cancer seemed to have lesions with a higher Gleason score (7-10) compared with those in the placebo group.[133] However, this observation was not supported by longer-term follow-up data.[134] In fact, after 18 years of follow-up, treatment with the 5-alpha reductase inhibitor finasteride showed no significant impact on overall survival.[135] Furthermore, the use of finasteride and dutasteride was associated with a higher incidence of sexual function adverse effects, including erectile dysfunction, loss of libido, and gynecomastia.

Medications to Treat Hematologic Precursor Conditions

The future of treating plasma cell precursor conditions is shifting toward proactive cancer prevention, especially in patients with plasma cell precursor conditions such as smoldering myeloma or high-risk clonal hematopoiesis or clonal cytopenia. While clinical trials are assessing therapeutic drug interventions for patients with monoclonal gammopathies, emerging evidence suggests that dietary or microbiome-directed interventions could modulate antigenic drive and reduce the risk of progression.

PROCEDURAL AND SURGICAL PREVENTION

Esophageal adenocarcinoma is a growing health problem because of its rapidly rising incidence, substantial morbidity, and high mortality. Barrett esophagus, a serious complication of gastroesophageal reflux disease caused by persistent esophageal columnar cell exposure to gastric and duodenal contents, is the only known precursor of esophageal adenocarcinoma. Esophageal adenocarcinoma develops in patients with Barrett esophagus at an annual rate of 0.12%.[136] Endoscopic eradication therapies consisting of mucosal resection, radiofrequency ablation, and cryotherapy are now recommended in patients with dysplastic Barrett esophagus.[137] Such therapies fail in 10% of patients with high-grade dysplasia, and 40% of patients develop recurrence of dysplasia or metaplasia.[96] Cervical cancer is another example in which procedures directed to precursor lesions, cervical dysplasia, or intraepithelial neoplasia can reduce progression to invasive malignancy. Options include conization, loop electrosurgical excision procedure, cryosurgery, electrocauterization, and laser ablation.

Prospective studies in which women self-select for mastectomy or close surveillance have found that the short-term risk of breast cancer is lower for women with certain *BRCA1* and *BRCA2* mutations who choose prophylactic mastectomy. However, prophylactic bilateral mastectomy to prevent breast cancer has not been assessed in a rigorously randomized trial. Because this surgery leaves some breast tissue behind, a patient's risk is reduced by approximately 95%.[138] A Cochrane review concluded that bilateral prophylactic mastectomy for those at very high risk of breast cancer (eg, those with deleterious *BRCA* mutations) was effective in reducing the incidence and subsequent mortality resulting from breast cancer.[139] Colectomy is used as a preventive measure for patients at extremely high risk of colorectal cancer as a result of a history of ulcerative colitis or a genetic predisposition to the disease, such as familial adenomatous polyposis.[128] For women at a very high risk of ovarian cancer because of a *BRCA* genetic mutation, bilateral salpingo-oophorectomy after completion of childbearing remains the treatment of choice.[140] Women with Lynch syndrome associated with large and small bowel polyps and cancers are at an elevated risk of endometrial and ovarian cancers. For these women, prophylactic hysterectomy and bilateral salpingo-oophorectomy may also be recommended. Additionally, in MEN2A and MEN2B syndromes, prophylactic thyroidectomy is recommended before age 5 or even before age 1, respectively, based on germline *RET* mutation risk level, to prevent medullary thyroid carcinoma.[141]

KEY POINTS

- Physical activity and avoidance of obesity are associated with a lower risk of at least 13 cancers.
- Most randomized trials of vitamins or nutritional supplements as clinical preventive agents have had negative results.
- Tamoxifen, raloxifene, and aromatase inhibitors are established breast cancer preventative agents.

- Aspirin and other nonsteroidal anti-inflammatory drugs are not recommended for a majority of patients with colorectal cancer although recent data suggest a benefit for colorectal cancers harboring a somatic *PI3K* mutation.
- Vaccination or antiviral therapy for cancer-causing infectious agents, such as hepatitis B and C and HPV, has led to reduced incidence of and/or mortality as a result of associated cancers (hepatocellular carcinoma, cervical, and other anogenital cancers).
- Risk-reducing surgeries are an appropriate and effective intervention for select high-risk patients, such as those with deleterious *BRCA* mutations or Lynch syndrome.

SECONDARY PREVENTION: CANCER SCREENING AND EARLY DETECTION

RATIONALE AND CONCEPTS

Screening is an attempt to detect preneoplastic lesions and noninvasive or invasive neoplasms in asymptomatic patients with the goal of intervening and decreasing morbidity and mortality. A screening test is not typically diagnostic for cancer; rather, it determines whether a neoplastic lesion has a high probability of being present and whether additional definitive testing, such as imaging or biopsy, is necessary. To be of benefit, screening must lead to earlier treatment that offers a better outcome, usually reduced mortality, compared with treatment that starts at the onset of symptoms. The ideal evaluation of a screening approach is through the assessment of disease-specific and overall mortality in a randomized clinical trial. The ability of a screening test to detect a localized invasive neoplasm does not automatically imply benefit, because (1) not all locally invasive neoplasms can be treated effectively, and (2) some locally invasive neoplasms never progress to cause symptoms (ie, overdiagnosis; Fig. 1-1; Table 1-5).

POTENTIAL BIASES

The evaluation of the benefits of a screening test is subject to several potential biases, including lead time, length time, and healthy volunteer effect biases. Lead and length time biases both can make it seem that there is a benefit to a screening test, when there is actually none; there may even be a net harm. Lead time bias results when screening detects a cancer earlier in its natural history (ie, at an earlier stage) than had it not been detected through screening. Patients with screen-detected cancer therefore will always seem to have longer survival than those whose cancer was not detected early, even if the treatment of the cancer is ineffective. Length bias occurs because, at any point in time, screening is more likely to identify cancers that are relatively slow growing. These cancers are also less likely to contribute to a patient's death. The early detection of mostly slow-growing cancers will seem to improve survival statistics without reducing mortality. The healthy volunteer effect, a type of selection bias, occurs because volunteers for cancer prevention trials are more health conscious and are likely to have better prognoses or lower mortality rates, regardless of whether they are screened. The influences of these biases are substantially reduced in a properly designed and executed randomized trial.[142] Finally, screening, regardless of benefit, will usually increase the number of specific cancers diagnosed, resulting in an increased cancer incidence. Overdiagnosis occurs when a slow-growing invasive neoplasm fulfills the histological criteria for cancer but has a clinically indolent course and is not life threatening.[143] Older people may be more likely to die from competing comorbidities, such as heart disease, than of an indolent cancer.

ACCURACY

The results of screening tests can be classified into four categories. The accuracy of any medical test is usually described by sensitivity and specificity. Positive predictive value and negative predictive value measure test performance as applied to a specific population. Sensitivity and specificity are relatively independent of the underlying prevalence or risk in the population being screened, but the positive predictive value is highly dependent on cancer prevalence. In other words, cancer screening programs are most effective—in terms of benefit, efficiency, and cost—when they target either a cancer that occurs frequently in the overall population or specific groups within the population who are already known a priori to have a higher risk of developing that particular cancer. Sensitivity need not be extremely high. The key criterion for the public health recommendation of a screening test is that it can reduce cancer mortality (Table 1-5).

If a screening test is not effective in reducing mortality in people at average risk of a particular cancer, it will also not be effective in reducing mortality if used in a population with a higher risk of that same cancer. On the other hand, if a screening test does demonstrate effectiveness in reducing mortality, it is undoubtedly more beneficial to prioritize its use in populations at higher risk (for example, those with a family history of the disease).

POTENTIAL HARMFUL EFFECTS

People can be harmed because of screening. Harm can result from the test itself, the workup of positive results of screening tests (both true-positive and false-positive results), and adverse events from the treatment of true-positive results. Screening can detect some cancers that would never have caused medical problems; unnecessary treatment of these cancers can be harmful.

Figure 1-1 Deriving Specificity: Organized Data From a Hypothetical Mammogram Study

Table 1-5 **Indices for Describing Accuracy of Screening Tests**

Term	Definition	Ability of Test	Equation
Sensitivity	Proportion of people with the disease who have a positive result on a screening test	To detect disease when it is present	A/(A + C)
Specificity	Proportion of people who do not have the disease who have a negative result on a screening test	To correctly identify the absence of disease	D/(B + D)
Positive predictive value	Proportion of people with a positive result on a screening test who have the disease; increases as disease prevalence in a population increases	To accurately predict the presence of disease	A/(A + B)
Negative predictive value	Proportion of people who have a negative result on a screening test who truly do not have the disease; increases as disease prevalence in a population decreases	To accurately predict the absence of disease	D/(C + D)

A, true-positive result; B, false-positive result; C, false-negative result; D, true-negative result.

In addition to the adverse health effects of screening, financial and emotional costs are associated with screening and with all the additional diagnostic tests and treatments. A good example is low-dose computed tomography (CT) for the early detection of lung cancer. In 1.7% of patients screened, false-positive results lead to invasive procedures (eg, needle biopsy, bronchoscopy, thoracotomy).[144]

KEY POINTS

- Evaluation of the benefits/efficacy of a cancer screening test is far more complicated than simply performing the test and detecting localized cancers.
- Biases that complicate the assessment of screening benefits are lead time, length, and healthy volunteer effect.
- These biases can make a screening test seem beneficial when there is no benefit, or the test may even cause harm.
- Overdiagnosis occurs when a screening test identifies indolent cancers that do not pose a mortal threat. The costs of overdiagnosis are high: unnecessary screening of large populations, unnecessary medical procedures, and emotional and financial harm.
- To offset these biases, a randomized trial is the best way to assess a screening test, with the endpoint of reduction in cancer-related mortality.
- Sensitivity, specificity, and positive predictive value can be important measures of the accuracy of a screening test and the rate of false-positive and false-negative results. However, these metrics are not used to decide whether a screening test should be used on a large-scale; the main criterion for this purpose is reduction in mortality.

CURRENT SCREENING AND EARLY DETECTION GUIDELINES BY ORGAN SITE

There is convincing evidence that screening for cervical, colorectal, lung, and breast cancers is beneficial at certain ages for people at average risk. Although increased surveillance of people at high risk of specific cancers due to family history or genetic risk may be prudent, few studies have been performed to assess the benefits of this approach. The USPSTF[145-148] and American Cancer Society[149] are among the more prominent organizations publishing screening recommendations after rigorous independent review processes consisting of a structured evaluation of the literature by experts (Table 1-6).

Table 1-6 **Screening Recommendations for Asymptomatic Patients With Average Risk by Guideline Setting Organization**

Test or Procedure	Organization		
	US Preventative Services Task Force[150]	**Canadian Task Force on Preventive Health Care**[151]	**American Cancer Society**[152]
Colorectal	2021	2016	2018
HSgFOBT or FIT	Annual HSgFOBT or FIT, starting at age 45 years	FOBT or FIT every 2 years, starting at age 50 years	Annual FOBT or RT, starting at age 45 years (qualified recommendation); age 50 years (strong recommendation: FIT preferred)
Flexible sigmoidoscopy	Every 5 years starting at age 45 years	Flexible sigmoidoscopy every 10 years, starting at age 50 years	Every 5 years, starting at age 45 years (qualified recommendation); age 50 years (strong recommendation)
Flexible sigmoidoscopy plus FIT	Every 10 years plus annual FIT, starting at age 45years	Not recommended	Not recommended
Colonoscopy	Every 10 years, starting at age 45 years	Not recommended	Every 10 years, starting at age 45 years (qualified recommendation); age 50 years (strong recommendation)
CT colonography	Every 5 years starting at age 45 years	Not recommended	Every 5 years, starting at age 45 years (qualified recommendation); age 50 years (strong recommendation)
Prostate	2018[a]	2014	2023
DRE	No change	No change	May be performed in men who want to be screened with PSA
PSA	No change	No change	Shared decision-making starting at age 50 years in men at average risk of prostate cancer who have a life expectancy of 10 years or more; men who choose to be tested and have a PSA level <2.5 ng/mL may only need to be retested every 2 years; men whose PSA level is ≥2.5 ng/mL should be screened annually
Cervical	2018	2013	2020
Pap cytology	Women aged <21 years should not be screened; for women age 21-29 years, Pap test every 3 years; for women aged 30 to 65 years, screening every 3 years with Pap cytology alone; women aged 65+ years who have had adequate prior screening and are not otherwise at high risk of cervical cancer should not be screened; women who have had a hysterectomy with removal of the cervix and do not have a history of a high-grade precancerous lesion (ie, CIN grade 2 or 3) or cervical cancer should not be screened	Women aged <25 years should not be screened; starting at age 25years, screen every 3 years to age 69 years; for women aged 70+ years who have been adequately screened (eg, three successive negative Pap tests in the last 10 years), routine screening may cease; for women aged ≥70 years who have not been adequately screened, continue screening until three negative test results have been obtained	Women aged 25-65 years: a Pap test alone every 3 years; women aged 65+ years who have had three normal Pap tests and no abnormal tests in the last 10 years and no history of CIN II or more serious diagnosis within the last 25 years should stop screening; women who have had total hysterectomy (unless hysterectomy was done as treatment for cervical cancer or precancer) should not be screened

Test or Procedure	Organization		
	US Preventative Services Task Force[150]	Canadian Task Force on Preventive Health Care[151]	American Cancer Society[152]
HPV DNA	For women aged 30-65 years, every 5 years with hrHPV testing alone or every 5 years with hrHPV testing in combination with Pap cytology (ie, cotesting)	No recommendation	Women aged 25-65 years: primary hrHPV test every 5 years; if a primary hrHPV test is not available, acceptable options include a cotest (hrHPV test done at the same time as a Pap test) every 5 years
Breast	2024	2018	2015
BSE	No change	No change	No change
CBE	No change	No change	
Mammography	Women aged 40-74 years: screen every 2 years; for women aged ≥75 years, there is insufficient evidence to form a recommendation	No change	No change
Lung	2021	2016	2023
LDCT	Adults aged 50-80 years: annual screening if the patient also has at least a 20-pack-year smoking history and currently smokes or quit smoking <15 years ago	Adults aged 55-74 years: three consecutive annual screenings if the patient also has at least a 30-pack-year smoking history and smokes or quit smoking <15 years ago	Adults aged 50-80 years: annual screenings if the patient also has at least a 20-pack-year smoking history and smokes or previously smoked

Abbreviations: BSE, breast self-examination; CBE, clinical breast examination: CIN, cervical intraepithelial neoplasia; DRE, digital rectal examination; FIT, fecal immunochemical test; FOBT, fecal occult blood testing; HPV, human papillomavirus: hrHPV, high-risk human papillomavirus; HSgFOBT, high-sensitivity guaiac fecal occult blood testing; LDCT, low-dose CT; Pap, Papanicolaou; PSA, prostate-specific antigen; RT, radiation therapy.

COLORECTAL CANCER

Fecal Occult Blood Test Screening

Fecal occult blood tests (FOBTs) screen for colorectal neoplasms by detecting traces of blood in the stool. Positive FOBT results require follow-up screening using colonoscopy. There are two main types of FOBTs: guaiac-based FOBT (gFOBT) and immunohistochemistry-based FOBT (iFOBT) or fecal immunochemical test (FIT).

gFOBT

Annual or biennial screening with gFOBTs has been shown to reduce colorectal cancer mortality by 15% to 33%.[153-155] Furthermore, this reduction in colorectal cancer mortality resulting from gFOBT screening is durable over at least three decades.[156] However, it is important to note that gFOBTs are not specific for human blood. Consequently, they tend to generate a relatively high proportion of false-positive results.

iFOBT (FIT)

FITs offer an advantage over gFOBTs by specifically detecting human hemoglobin. This specificity eliminates false-positive results generated from gFOBTs because of nonhuman hemoglobin present in the diet.[157]

Although FITs demonstrate higher sensitivity for detecting colorectal cancers (ranging from 61% to 91%), their sensitivity for detecting adenomas (precancerous polyps) is lower, ranging from 16% to 31%.[158,159]

A comprehensive meta-analysis, pooling data from 19 randomized trials or observational cohorts that used 8 different commercially available FITs, reported an overall sensitivity of 79% for the detection of colorectal adenocarcinoma and a specificity of 94%.[160]

It is also worth noting a multitarget stool DNA test, which combines the FIT with multiplexed methylated DNA markers. This test exhibits high sensitivity for detecting colorectal cancer. However, currently, there are no published data demonstrating that Cologuard reduces the incidence or mortality of colorectal cancer. Furthermore, the test's performance in detecting adenomas decreases significantly.[161]

Endoscopy and Imaging

Several techniques allow for the visual inspection of the inner lining of the colon and rectum to detect and remove polyps, thereby reducing an individual's risk of developing colorectal cancer. These primary methods include flexible sigmoidoscopy, colonoscopy, and CT colonography.

Flexible Sigmoidoscopy

Screening with flexible sigmoidoscopy, which examines the lower (distal) portion of the colon and the rectum, has been shown to reduce the incidence and mortality of distal colon cancer by 22% to 26%.[162,163] However, this method does not provide a benefit for cancers located in the upper (proximal) colon.

Colonoscopy

Population-based cohort studies evaluating colonoscopy screening, which allows for the visualization of the entire colon, have also demonstrated a reduction in colorectal cancer mortality. Interestingly, this benefit has been observed primarily in the distal colon, with less clear evidence of mortality reduction in the proximal colon.[164-166] This discrepancy has been attributed to factors such as variations in endoscopic quality, the technical challenges of detecting lesions in the right-sided colon, and the more frequent occurrence of flat and depressed precancerous lesions in that region.[164,167-169]

CT Colonography

CT colonography, a noninvasive imaging technique, has demonstrated a reported sensitivity ranging from 67% to 94% for detecting adenomas (precancerous polyps) measuring at least 10 mm. The specificity of CT colonography for these larger adenomas ranges from 86% to 98%.[167] However, there are currently no published studies that directly compare the mortality benefit of CT colonography with that of standard colonoscopy. Although CT colonography appear to be capable of adequately detecting precursor lesions 6 mm or larger (similar to colonoscopy), potential harms associated with this technique include cumulative radiation exposure from repeated examinations and the detection of incidental, often noncancerous, findings.[170]

Guidelines

Among the various screening tests available for colorectal cancer, the USPSTF has concluded that no single test demonstrates superiority to others.[145] Consequently, its guidelines recommend screening for colorectal cancer in average-risk people, defined as those without a history of polyps or precancerous lesions on prior endoscopic examinations, from age 45 to 75 years. This screening should be conducted using a shared decision-making approach, where patients are offered the following options:

- **Annual stool-based screening.** This includes either a high-sensitivity standard gFOBT performed annually or an FIT or a combined FIT-DNA test performed every 1 to 3 years.
- **Endoscopic procedures.** These options include flexible sigmoidoscopy screening conducted once every 5 years in conjunction with an annual FIT or a colonoscopy performed every 10 years.
- **CT colonography.** For people at high risk of colorectal cancer, such as those with a genetic predisposition, a personal history of colorectal cancer or large adenomatous polyps, or inflammatory bowel disease, colonoscopy is the recommended screening method.

Over the last two decades, the incidence and mortality rates of colorectal cancer in the United States have generally decreased. However, more recent data from the SEER Program have revealed a concerning trend: a significant increase in colorectal cancer incidence among younger people. Currently, 20% of all colorectal cancers and 30% of all rectal cancers are diagnosed in patients younger than the age typically associated with this disease.[171]

Recognizing the disproportionately higher mortality and risk of early-onset colorectal cancer among Black people, the US Multisociety Task Force (representing three gastroenterological societies) issued a recommendation in 2017 to begin colorectal cancer screening for Black patients at age 45. Subsequently, in 2018, the American Cancer Society also updated its guidelines to recommend that average-risk people, including Black people, begin colorectal cancer screening at age 45.[172]

PROSTATE CANCER: BALANCING EARLY DETECTION WITH RISK OF OVERDIAGNOSIS

Digital rectal examination (DRE) and measurement of serum PSA levels are commonly used in the United States for the early detection of prostate cancer. However, most professional organizations advocate for a cautious approach to the use of these screening tools. Although PSA testing and DRE can identify many asymptomatic prostate cancers, their ability to reliably distinguish between indolent tumors that pose minimal threat and aggressive, potentially lethal yet curable cancers is limited. Indeed, the USPSTF estimates that a substantial proportion, ranging from 22% to 42%, of screen-detected localized prostate cancers represent overdiagnosis.[146]

The treatment of screen-detected prostate cancers is not without potential harm, often leading to excess morbidity, such as impotence and urinary incontinence, and carrying a small but definite mortality risk. Current screening guidelines have been

significantly influenced by the findings of two large, randomized prostate cancer screening trials: the PLCO (Prostate, Lung, Colorectal and Ovarian) screening trial and the ERSPC (European Randomized Study of Screening for Prostate Cancer). Notably, the PLCO trial found no reduction in prostate cancer mortality,[171] whereas the ERSPC reported a 21% reduction in cancer-specific mortality associated with screening.[172]

The discrepancy in outcomes between the PLCO and ERSPC trials has been attributed to at least two key differences in their designs. First, a significant proportion (estimated at 80%) of the control arm in the PLCO trial underwent PSA screening outside of the study protocol, effectively reducing the observed difference between the screened and unscreened groups. In contrast, such off-protocol screening was comparatively uncommon in the ERSPC control arm. Second, the PLCO trial focused on absolute mortality reduction, which represents the actual likelihood of a patient avoiding death from prostate cancer. Conversely, the ERSPC reported relative mortality reduction, which reflects the proportional decrease in the risk of dying from prostate cancer compared with the risk in the absence of screening.

Based on its assessment of the balance between risks and benefits, the USPSTF concluded that population-based, PSA-based screening did not offer sufficient net benefit to warrant a universal recommendation. Their current (2018) recommendations state: "For men aged 55 to 69 years, the decision to undergo periodic PSA-based screening for prostate cancer should be an individual one. Before deciding whether to be screened, men should have an opportunity to discuss the potential benefits and harms of screening with their clinician. Screening offers a small potential benefit of reducing the chance of death from prostate cancer in some men."[146,173]

To address the challenge of overdiagnosis associated with PSA screening, alternative approaches are being explored. One such strategy involves the use of a prostate cancer risk calculator, developed from long-term longitudinal data from the Prostate Cancer Prevention Trial. This tool enables the prediction of both low-grade (Gleason score <7) and high-risk cancers, thereby aiding in informed biopsy and treatment decisions.[174] Another approach uses risk stratification algorithms that integrate age-specific PSA levels along with other epidemiologic risk factors to identify men who would benefit most from frequent screening and additional diagnostic procedures.[175]

In men presenting with clinical symptoms suggestive of prostate cancer, magnetic resonance imaging (MRI) of the prostate prior to biopsy consideration has demonstrated the potential to reduce biopsy rates[176] and the incidence of overdiagnosis.[177] Extending this to the screening setting, among men with elevated PSA levels (>3 ng/mL), MRI of the prostate with MRI-targeted biopsy, compared with traditional biopsy based on risk-prediction models, resulted in a lower detection rate of clinically insignificant cancers. This suggests that prebiopsy MRI may offer an avenue to mitigate the harms associated with PSA screening.[178]

CERVICAL CANCER: CYTOLOGY AND HPV DNA TESTING

For the past 60 years in high-income countries, early detection of cervical neoplasia, both noninvasive and invasive, has primarily relied on cervical cytology, also known as the Papanicolaou (Pap) test. This method has a reported sensitivity of 78% (range, 30%-87%) and a specificity of 62% (range, 61%-94%).[179]

However, cytological screening is susceptible to limitations, including tissue sampling errors, issues with cellular preservation, and the inherent subjectivity of cytotechnologist interpretation. Furthermore, because colposcopy referral is typically triggered only by positive cytology results, the rate of false-negative findings is challenging to accurately measure but has been reported to be as high as 50%.[179]

In contrast, the HPV DNA test has emerged as another important screening modality. A meta-analysis of 8 studies involving more than 3,700 women demonstrated that a single HPV DNA test yielded a pooled sensitivity of 90% (95% CI, 88%-93%) for cervical intraepithelial neoplasia grade 2 (CIN 2) and 95% (95% CI, 93%-97%) for cervical intraepithelial neoplasia grade 3 (CIN 3), both of which are considered precancerous lesions. Although highly sensitive, HPV testing demonstrated consistently lower specificity when directly compared with parallel cervical cytology: 88.5% (95% CI, 87%-90%) for CIN 2 and 89% (95% CI, 87.2%-88.5%) for CIN 3.[180]

USPSTF Guidelines

The USPSTF provides the following recommendations for cervical cancer screening[148]:

- **Women who are 21 to 29 years:** cervical cytology screening every 3 years
- **Women who are 30 to 64 years:** one of the following:
  - Cervical cytology alone every 3 years; or
  - High-risk HPV DNA molecular testing alone every 5 years; or
  - Combined cervical cytology and high-risk HPV DNA molecular testing every 5 years.

Rationale for Guidelines

In women younger than 30 years, the high prevalence of transient HPV infections, which carry minimal long-term risk of disease progression, reduces the specificity of HPV testing. More frequent screening in this age group can lead to unnecessary additional procedures and treatment of these transient lesions without providing incremental clinical benefit.

The decreasing cost and increasing accessibility of HPV DNA molecular testing have contributed to higher rates of women being screened. Importantly, screening remains recommended even for women who have received the prophylactic HPV vaccine. This is because the original quadrivalent vaccine does not offer protection against all high-risk HPV types. It is anticipated that this recommendation may be revised as the nine-valent vaccine, which provides broader protection, becomes more widely used globally. Notably, ASCO cervical screening guidelines are consistent with those of the USPSTF.[181]

BREAST CANCER SCREENING: MAMMOGRAPHY AND BREAST SELF-EXAMINATION

Breast Self-Examination

The results of the largest randomized controlled study of breast self-examination conducted to date, in a population without access to mammography, demonstrated an increased rate of biopsy and enhanced detection of benign lesions. However, the study showed little to no stage shift in cancer diagnosis and no reduction in breast cancer mortality.[182]

Mammography

Multiple randomized clinical trials have consistently shown that screening women at average risk using mammography alone or mammography combined with clinical breast examination every 1 to 2 years leads to a reduction in breast cancer mortality ranging from 20% to 30%. Although individual trials have faced specific methodologic criticisms, the consistency of these observations across numerous studies outweighs these concerns. The introduction of mammographic screening in the United Kingdom starting in 1991 for women aged 49 to 64 years has been associated with an estimated overall reduction in breast cancer mortality of 21%.[179] Consensus publications from the USPSTF[183] and the Canadian Task Force on Preventive Health Care[148] recommend mammographic screening every 2 to 3 years for average-risk women between the ages of 50 and 69 years (Canadian recommendation) or 50 and 74 years (US recommendation).

The role of mammographic screening for women aged 40 to 49 years at average risk remains a subject of debate. Although studies have shown an approximately 18% reduction in breast cancer mortality in this age group, the accompanying high number of false-positive screening results was a significant factor in the Canadian Task Force on Preventive Health Care and the 2016 USPSTF recommendations against routine population-based screening in this age range. However, in 2024 the USPSTF issued new recommendations that lowered the starting age for biennial screening mammography to 40 years.[184] This change in the USPSTF recommendation was not primarily due to a change in the moderate net benefit of screening mammography in this age group. Instead, it reflected a consideration of the increasing incidence of breast cancer among women in their 40s and the higher mortality rate of breast cancer observed among Black women. In contrast, the American Cancer Society currently recommends that screening for women at average risk begin at age 45.[180]

MRI for Breast Cancer Screening in High-Risk Populations

MRI has demonstrated better sensitivity compared with mammography or ultrasound in detecting breast cancer among women carrying *BRCA1* or *BRCA2* mutations. Although its high cost and the lack of proven mortality benefit make it unsuitable for average-risk women, MRI can be a cost-effective tool for increasing cancer detection yield in younger *BRCA* mutation carriers and other women at very high risk of breast cancer.[185]

The American Cancer Society has established guidelines for MRI use in women who have a calculated lifetime risk of breast cancer of at least 20%, as determined by one of several validated mathematic models. Another group of women considered to be at an elevated risk includes those with dense breasts. Recommendations for screening these women are varied and sometimes include supplemental imaging with ultrasound, MRI, or other tests in addition to mammography. However, the 2024 recommendation from the USPSTF acknowledges the enhanced detection capabilities of these additional imaging procedures but does not recommend their routine use for screening women with dense breasts. This stance is based on concerns regarding increased false-positive results and imprecisely estimated clinical endpoints because of limited available data.[184]

LUNG CANCER: THE ROLE OF LOW-DOSE CT

Lung cancer is a compelling target for screening initiatives because of the existence of a well-defined high-risk group, composed primarily of heavy cigarette smokers, and its characteristically long preclinical phase. This extended preclinical period offers a significant window of opportunity during which treatment interventions could be particularly effective in reducing mortality. Consequently, the primary screening strategy that has been extensively investigated involves imaging of the lungs.

Initial investigations into lung cancer screening using chest radiography combined with sputum cytology failed to demonstrate any reduction in lung cancer mortality.[186] However, subsequent research has yielded more promising results. Notably, screening with low-dose spiral CT scanning has been shown to reduce lung cancer mortality by approximately 20%.[187]

Although low-dose spiral CT scans increase the number of pulmonary lesions diagnosed, which inevitably leads to a greater number of diagnostic and therapeutic procedures being performed, cost-benefit analyses for this screening modality have generally concluded that the benefits for specific subgroups of heavy smokers outweigh the potential harms associated with overdiagnosis and false-positive results.[188]

Based on this evidence, most expert organizations now recommend CT screening for people who are current or former heavy smokers with a smoking history of at least 20 pack-years. The USPSTF recommends initiating screening at age 50 for persons with a smoking history of 20 or more pack-years.[189] The American Cancer Society provides a similar recommendation in their updated 2023 guidelines.[172]

HEPATOCELLULAR CARCINOMA: TARGETING HIGH-RISK POPULATIONS

The USPSTF recommends screening for hepatitis B virus (HBV) infection in populations identified as being at high risk. This high-risk designation includes people who have immigrated to the United States or whose parents originated from countries with a prevalence of hepatitis B surface antigen (HBsAg) of at least 2%.[187] Screening is also recommended for other high-risk groups defined by clinical and behavioral characteristics associated with an HBsAg prevalence of 2% or greater.[187] Although the optimal frequency of screening is not definitively established, intervals based on clinical judgment are recommended. In addition to educational interventions, a significant proportion, ranging from 20% to 40%, of positive screening results will require treatment. International screening recommendations for hepatocellular carcinoma are further detailed in the "Screening for Other Cancers Globally" section of this chapter.

OVARIAN CANCER: LACK OF EFFECTIVE STRATEGIES FOR MORTALITY REDUCTION

Several modalities, including adnexal palpation, transvaginal ultrasound, and measurement of serum cancer antigen 125 (CA-125), have been investigated for their potential in screening for ovarian cancer. However, randomized trials evaluating these approaches, whether used individually or in combination, have consistently failed to demonstrate a reduction in ovarian cancer mortality.[190]

A significant challenge in developing effective ovarian cancer screening is the relatively low incidence of the disease within the general population. Consequently, any screening modality used would likely result in an unacceptably high rate of false-positive findings. These false positives could then lead to expensive and potentially risky invasive diagnostic procedures, such as laparotomy, in women who do not have cancer.

SKIN CANCER SCREENING: LACK OF EVIDENCE FOR MORTALITY REDUCTION WITH VISUAL EXAMINATION

Although nonmelanoma skin cancers (basal and squamous cell carcinomas) represent the most common cancer types in the United States, they are rarely fatal. In contrast, cutaneous melanomas are associated with significant mortality. To date, no randomized controlled study has definitively assessed whether a clinical skin examination screening program reduces melanoma-specific mortality. A nationwide routine screening program implemented in Germany reported a higher proportion of melanoma-related deaths in the unscreened group compared with the screened group; however, this difference was diminished after multivariable adjustment.[191]

Furthermore, potential harms associated with routine skin cancer screening may be considerable, including the need for repeated biopsies and the risk of overdiagnosis and subsequent overtreatment. Considering these factors, the USPSTF 2023 recommendations conclude that the current evidence remains insufficient to determine the balance of benefits and harms of visual skin examination by a clinician for screening for skin cancers in adults.[192]

LOWER-ESOPHAGEAL ADENOCARCINOMA SCREENING: ADDRESSING THE RISING INCIDENCE

The substantial increase in the incidence of esophageal adenocarcinoma over the last two decades has raised significant concerns regarding prevention strategies. Barrett esophagus is recognized as the primary precursor lesion to esophageal adenocarcinoma. Consequently, preventing the development of Barrett esophagus or using ablation techniques for dysplastic mucosa arising within Barrett metaplastic epithelium could potentially reduce an individual's risk of this cancer. A major risk factor for Barrett esophagus is gastroesophageal reflux disease (GERD), a condition that has also seen a dramatic rise in prevalence,[193] possibly linked to the increasing rates of obesity.

Guidelines from the American College of Gastroenterology (ACG) recommend upper endoscopic screening in people identified as being at high risk of Barrett esophagus. Its criteria for high risk include men with chronic GERD (defined as >5 years' duration) and the presence of three or more additional risk factors: age older than 50 years, White race, central obesity (waist circumference >102 cm or waist-to-hip ratio >0.9), current or past history of smoking, and a confirmed first-degree family history of Barrett esophagus or esophageal adenocarcinoma.[194] It is important to note that current evidence from both randomized controlled trials and observational studies does not support a mortality benefit associated with upper endoscopic screening, even in these high-risk people.

Cancer Screening Based on Genetic Risk

NCCN guidelines on Genetic/Familial High-Risk Assessment are rapidly evolving and expanding and include cancer screening based on genetic risk. As we learn more about the effects on cancer risk in various patient populations with specific pathogenic or

likely pathogenic germline mutations in high- or moderate-penetrance genes, guidelines are evolving to include cancer screening recommendations. For example, tailored cancer screening recommendations are included for patients with known variants in genes such as *BRCA1/2, TP53, ATM, BARD1, BRIP1, CDKN2A, CHEK2, NF1, PALB2, PTEN, STK11, CDH1, MSH2, MLH1, PMS2, EPCAM*, and *RAD51C/D*. For some germline variants, screening for cancers not typically screened for are now recommended, including pancreatic cancer screening at experienced centers with magnetic resonance cholangiopancreatography (MRCP) or endoscopic ultrasound. The age at which to begin screening depends on the specific mutation and family history.

SCREENING FOR OTHER CANCERS GLOBALLY

This chapter primarily focuses on cancer screening practices in the United States. However, it is important to recognize that global variations in cancer incidence and prevalence lead to corresponding geographic differences in screening recommendations. The following examples illustrate cancer screening guidelines implemented outside of the United States.

India

Oral cavity cancer is the most prevalent malignancy among men in India, largely attributable to the widespread use of tobacco products and betel quid (with or without tobacco). A randomized controlled trial demonstrated that visual screening of the oral cavity resulted in an approximate one-third reduction in mortality among people who used alcohol, tobacco, or both.[195]

East Asia and Africa

The Shanghai trial, involving more than 18,000 carriers of HBV, randomly assigned participants to either a serum α-fetoprotein (AFP) test plus ultrasonography every 6 months or no screening for hepatocellular carcinoma. This study found a 37% reduction in mortality in the screened group.[196] Furthermore, the combined use of ultrasonography and MRI has been shown to detect most hepatocellular carcinomas at an early stage when surgical resection is more likely to be feasible.[197]

Japan

Gastric cancer screening guidelines in Japan recommend either radiographic upper gastrointestinal imaging or endoscopy. These recommendations are primarily based on observational studies because no randomized controlled trials have yet confirmed the efficacy of these tests in reducing gastric cancer mortality.[198]

China

An observational cohort study reported that endoscopic screening for squamous cell carcinoma of the esophagus in endemic regions of China was associated with a 50% reduction in mortality.[194] Additionally, screening for exposure to Epstein-Barr virus (EBV) using a plasma EBV DNA test can identify persistently positive patients who may benefit from further nasopharyngeal cancer screening. In an observational cohort of 20,174 plasma screens conducted in Shanghai, 5.5% yielded positive results, with approximately one-quarter of these being persistently positive. These persistently positive patients underwent further endoscopic evaluation, and 34 cases of nasopharyngeal carcinoma were detected, predominantly at an early stage. Notably, only one carcinoma developed among patients who were EBV negative.[197] A randomized clinical trial is warranted to definitively determine whether plasma screening for EBV DNA reduces mortality from nasopharyngeal carcinoma.

THE FUTURE OF CANCER SCREENING: MULTICANCER EARLY DETECTION TESTS

Current recommendations for cancer screening are largely specific to individual organs and diseases. However, advancements in genomics and computational power have opened the possibility of blood-based screening using cell-free DNA for multiple cancers, regardless of their origin. Multicancer early detection (MCED) tests are among those currently under development. Using a single blood sample, these tests aim to detect signals from over 50 different cancers and predict the organ of origin if a cancer signal is identified. In a large US-based study of the Galleri test, cancer was detected in 1.4% of the 6621 participants who had a positive cancer signal, with 38% of these being true positives. Importantly, many of the cancers detected in this study would not have been identified under current standard screening paradigms. This test, along with other similar ongoing research efforts, suggests the potential for successful development and implementation of multicancer detection tests in the near future.[2] The NCI Vanguard Study (NCT06995898) is a feasibility trial enrolling up to 24,000 participants across over 20 US sites to assess the operational viability and potential harms of using MCED blood tests for population-based screening of cancers including pancreatic, ovarian, liver, lung, bladder, breast, colorectal, esophageal, stomach, and prostate. Primary endpoints focus on feasibility of recruitment, adherence, and representative enrollment, while secondary endpoints assess timeliness of result return, diagnostic resolution of abnormal tests, impact of blinding on screening behavior, and potential harms such as unnecessary procedures or anxiety triggered by false positives.

It is possible that in the future, MCED could be used to complement traditional cancer screening in high-risk populations, such as based on age, a history of toxic exposures, high-risk occupations (such as aviators or space travelers), and germline predisposition.

KEY POINTS

- Evidence-based screening information for cancers of the lung, colorectum, prostate, and ovary includes the following:
- Chest radiography is ineffective as a lung cancer screening tool.
- Sigmoidoscopy and colonoscopy are effective in reducing mortality resulting from colorectal cancer.
- CA-125 and transvaginal ultrasonographic screening for ovarian cancer are not effective in reducing mortality.
- The effectiveness of PSA screening for prostate cancer in reducing mortality remains uncertain.
- Mammographic screening for breast cancer among women aged 50 years or older reduces mortality; however, whether mammographic screening meaningfully reduces mortality in women younger than 50 years remains unclear.
- Decisions regarding PSA-based prostate cancer screening should be individualized and involve a thorough discussion of potential risks and benefits between the patient and clinician.
- Low-dose spiral CT screening is an established approach for reducing lung cancer mortality among heavy smokers.
- The use of HPV DNA molecular testing in conjunction with the Papanicolaou test for women aged 30 years or older allows for an extension of the interval between cervical cancer screenings to 5 years.
- Multiple options, specifically FOBT, sigmoidoscopy, and colonoscopy, are recommended as screening modalities for colorectal cancer.

HIGH-YIELD TAKEAWAYS

- Cancer Disparities and High-Risk Populations: Recognize demographic variations in cancer incidence and mortality to guide equitable screening and prevention, especially in hereditary syndromes and underserved groups.
- Evidence-Based Prevention Strategies: Apply established chemopreventive agents (eg, tamoxifen, aspirin), risk-reducing surgeries (eg, *BRCA*), and cancer-preventive vaccines (HPV, HBV) in counseling and clinical decision-making.
- Screening Principles and Biases: Evaluate screening tests using concepts such as lead-time bias, length bias, and healthy volunteer bias; prioritize mortality reduction over surrogate endpoints such as sensitivity or PPV.
- Guideline-Driven Screening: Implement current screening recommendations for lung (LDCT), breast (mammography ± MRI), colorectal (colonoscopy, FOBT), cervical (HPV/Pap), prostate (individualized PSA), and HCC (AFP + ultrasound in HBV carriers).
- Avoid Harmful or Ineffective Screening: Recognize when screening lacks mortality benefit (eg, ovarian cancer in average-risk women, melanoma via routine clinical exams, and esophageal adenocarcinoma outside high-risk GERD populations) to prevent overdiagnosis and unnecessary procedures.

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

EPIDEMIOLOGY AND PREVENTION

1

CHAPTER SUMMARY GUIDE

KEY POINTS

- Epidemiology is the study of the distribution and determinants of disease in populations.
- The distribution of cancer incidence, prevalence, mortality, and survival can be compared across demographic characteristics of populations to identify high-risk populations and cancer disparities.
- Criteria for a casual inference in cancer epidemiology include consistency, strength of association, temporal precedence, and latency.
- Physical activity and avoidance of obesity are associated with a lower risk of at least 13 cancers.
- Most randomized trials of vitamins or nutritional supplements as clinical preventive agents have had negative results.
- Tamoxifen, raloxifene, and aromatase inhibitors are established breast cancer preventative agents.
- Aspirin and other nonsteroidal anti-inflammatory drugs are not recommended for a majority of patients with colorectal cancer although recent data suggest a benefit for colorectal cancers harboring a somatic *PI3K* mutation.
- Vaccination or antiviral therapy for cancer-causing infectious agents, such as hepatitis B and C and HPV, has led to reduced incidence of and/or mortality as a result of associated cancers (hepatocellular carcinoma, cervical, and other anogenital cancers).
- Risk-reducing surgeries are an appropriate and effective intervention for select high-risk patients, such as those with deleterious *BRCA* mutations or Lynch syndrome.
- Evaluation of the benefits/efficacy of a cancer screening test is far more complicated than simply performing the test and detecting localized cancers.
- Biases that complicate the assessment of screening benefits are lead time, length, and healthy volunteer effect.
- These biases can make a screening test seem beneficial when there is no benefit, or the test may even cause harm.
- Overdiagnosis occurs when a screening test identifies indolent cancers that do not pose a mortal threat. The costs of overdiagnosis are high: unnecessary screening of large populations, unnecessary medical procedures, and emotional and financial harm.
- To offset these biases, a randomized trial is the best way to assess a screening test, with the endpoint of reduction in cancer-related mortality.
- Sensitivity, specificity, and positive predictive value can be important measures of the accuracy of a screening test and the rate of false-positive and false-negative results. However, these metrics are not used to decide whether a screening test should be used on a large-scale; the main criterion for this purpose is reduction in mortality.
- Evidence-based screening information for cancers of the lung, colorectum, prostate, and ovary includes the following:
- Chest radiography is ineffective as a lung cancer screening tool.
- Sigmoidoscopy and colonoscopy are effective in reducing mortality resulting from colorectal cancer.
- CA-125 and transvaginal ultrasonographic screening for ovarian cancer are not effective in reducing mortality.
- The effectiveness of PSA screening for prostate cancer in reducing mortality remains uncertain.
- Mammographic screening for breast cancer among women aged 50 years or older reduces mortality; however, whether mammographic screening meaningfully reduces mortality in women younger than 50 years remains unclear.
- Decisions regarding PSA-based prostate cancer screening should be individualized and involve a thorough discussion of potential risks and benefits between the patient and clinician.
- Low-dose spiral CT screening is an established approach for reducing lung cancer mortality among heavy smokers.
- The use of HPV DNA molecular testing in conjunction with the Papanicolaou test for women aged 30 years or older allows for an extension of the interval between cervical cancer screenings to 5 years.
- Multiple options, specifically FOBT, sigmoidoscopy, and colonoscopy, are recommended as screening modalities for colorectal cancer.

CHAPTER TABLES AND IMAGES

Table 1-1 Hierarchy of Evidence by Study Design

Study Type	Evidence
Pooled analysis/ meta-analysis	One of the highest levels of evidence and more generalizable given that it uses multiple data sources, provided inclusion of high-quality studies. Meta-analysis uses published results, whereas pooled analysis reanalyzes individual-level data
Randomized clinical trial	Highest-quality evidence, but use is limited to testing health-enhancing interventions (new treatments, preventive or screening interventions)
Cohort (prospective or retrospective)	Highest-quality observational evidence because of measurement of exposure and follow-up for occurrence of the outcome
Case-control	Useful for studying rare diseases, such as specific cancer types, but susceptible to information and selection biases because of measurement of exposure after the occurrence of disease and challenges of selecting and recruiting a control group representative of the population from which the cases arose
Cross-sectional	Limited by studying only prevalent cancer and measurement of exposure and outcome at a point in time
Ecologic	Unit of observation is group-level data (typically geographically defined), not individuals; results can be useful for evaluating policies aimed at reducing cancer risk factor prevalence that vary geographically
Case series	Commonly used clinical design, but lack of a comparison group severely limits inferences

Study designs higher up in the table tend to provide stronger evidence because of higher internal validity (or lower likelihood of bias).

Table 1-2 **Associations Between Extrinsic Factors and Cancer Risk**

Exposure	Cancer Type(s)	Notes
Cigarette smoking	Lung, oral cavity, larynx, esophagus, bladder, kidney, pancreas, stomach, cervix, colon, rectum, liver, acute myeloid leukemia	Causal association; estimated 48% of deaths from cancer in the United States attributable to smoking[17]
Ionizing radiation	Leukemia, non-Hodgkin lymphoma, thyroid, breast (female), lung, colon, bladder	Established cause[18,19] In the Life Span Study on Japanese atomic bomb survivors, after high-dose radiation there was an elevated leukemia risk early on, and an elevated solid tumor risk long-term. A heightened risk of hematological malignancies has been established after lower doses of radiation exposure from medical imaging in children and adolescents[20-22]
UV radiation	Melanoma, nonmelanoma skin cancers	Major cause (sunlight, tanning devices)[18]
HPV (oncogenic strains)	Cervix, penis, vagina, anus, oropharynx	Strong association[23]
Hepatitis B and C viruses	Liver, splenic marginal zone lymphoma	Strong association[23]
Epstein-Barr virus	Burkitt lymphoma, nasopharyngeal carcinoma	Strong association[23]
Helicobacter pylori	Gastric cancer	Strong association[23]
High BMI/obesity	Endometrial, esophageal, meningioma, breast, multiple myeloma, gallbladder, gastric, colorectal, kidney, liver, ovarian, pancreatic, and thyroid cancer[25]	Strong association; 4%-9% of new cancer cases in adults attributable to high BMI[24] Glucagon-like peptide 1 receptor agonists may decrease the risk of obesity associated cancers[26]
Alcohol	Breast cancer, liver, colorectal, oral cavity, esophageal (squamous cell)	Causal association[27,28]
Occupational exposures	Various (eg, melanoma and prostate cancer in pilots/aviators,[29] scrotal carcinomas in chimney sweeps)	2%-8% of cancers attributable to occupational causes[30,31]
Particulate matter (air pollution)	Lung	Classified as human lung carcinogen[32]
HIV infection	Non-Hodgkin lymphoma, cervical cancer, Kaposi sarcoma, anal cancer, Hodgkin lymphoma, lung cancer, skin cancer, oropharyngeal cancers, liver cancer[33]	Risk of non-AIDS-defining cancers (eg, Hodgkin lymphoma, liver, anal, lung) remains elevated even with immune reconstitution on ART. Therefore effective ART reduces, but does not eliminate, excess cancer risk. Coinfections (HPV, HBV, HCV) and lifestyle factors (eg, smoking, alcohol use) further modify risk
Medications	Immunosuppression or immunomodulators such as lenalidomide can heighten the risk of lymphoid and other malignancies,[34] tamoxifen and uterine cancer risk[35]	Lenalidomide plus high-dose melphalan with autologous stem cell rescue increases the risk of therapy- related myeloid neoplasms[36]
Sedentary lifestyle	Increases the risk of multiple cancers as well as cancer-related mortality[37,38]	The CHALLENGE trial reported a significant reduction in disease-free survival as well as long-term overall survival in colon cancer survivors who underwent a 3-year structured exercise program. Reduced cancer mortality in patients physically fit is exemplified by the healthy soldier effect[39,40]

Exposure	Cancer Type(s)	Notes
Circadian rhythm disruptions	Breast, prostate, colorectal, liver, lung cancers	The International Agency for Research on Cancer (IARC) has identified night shift work as a probable carcinogen (group 2A); it is hypothesized that DNA repair, apoptosis, and cell cycle regulation are regulated by circadian genes[41]
Diet	Colorectal cancer	Processed red meat has been linked with an increased colorectal cancer risk[42]

Abbreviations: ART, antiretroviral therapy; HBV, hepatitis B virus; HCV, hepatitis C virus; HPV, human papillomavirus.

Table 1-3 **Associations Between Intrinsic (Host) Factors Related to Cancer Risk**

Intrinsic Factor Category/ Specific Factor	Description/Examples	Cancer Type(s) Associated	Notes
Nonmolecular			
Age	Cancer risk generally increases with age for most cancer types	Most cancers increase in incidence with increasing age	Strong association because of accumulated exposures and cellular changes over time
Sex	Differences in cancer incidence and mortality exist between sexes because of hormonal, genetic, and other factors	Various (eg, breast cancer in women, prostate cancer in men)	Strong; sex-specific cancers, hormonal influences, and other biological differences
Ethnicity/race	Cancer rates can vary across different ethnic and racial groups because of genetic, environmental, and socioeconomic factors	Various	Complex interplay of genetics, environment, and social determinants of health
Family history	Positive family history of cancer can increase risk, particularly for cancers with strong genetic components	Various (eg, breast, ovarian, colon)	Suggests shared genetic susceptibility and/or environmental exposures within families
Personal history	A personal history of cancer increases the risk of a subsequent malignant neoplasm[43,44]	Various	Increased risk likely multifactorial from an elevated baseline inherent risk, immunosuppression from therapy, and DNA damage from certain chemotherapeutic agents or radiotherapy
Molecular			
Inflammation and immune dysregulation	Inflammation and autoimmunity can contribute to cancer development; immune system dysfunction can increase cancer risk	Various (marginal zone lymphoma, gastric cancer with autoimmune gastritis, large granular lymphocytic leukemia)	Strong; inflammation can damage DNA and promote cell growth; immune system surveillance plays a role in cancer prevention
Endogenously produced hormones	Hormones play a role in the development of some cancers	Breast, endometrial, prostate, and so on	Strong for hormone-sensitive cancers
Oxidative stress	Imbalance between free radicals and antioxidants can damage DNA and contribute to cancer	Various	Implicated in cancer development, but precise role is still being researched
Host genetic variation			
Rare, moderate or high-penetrance mutations	Mutations with low frequency but high impact on cancer risk (eg, *BRCA1, BRCA2, TP53, ATM, PALB2, CHEK2, CDH1*)	Breast, ovarian, prostate (*BRCA1/2*), Li-Fraumeni syndrome (*TP53*), and so on	Significantly increased inherited susceptibility
Common, low-penetrance polymorphisms (SNPs)	Common DNA sequence variations with small individual effects (often identified through GWAS)	Various	Small individual risk contribution; large potential public health impact; used in polygenic risk scores
Epigenetic variations	Changes in gene expression that do not involve alterations to the DNA sequence itself	Various	Can influence cancer risk, but mechanisms and specific roles are still being studied

Abbreviations: GWAS, genome-wide association study; SNP, single nucleotide polymorphism.

Table 1-4 **Contrast Between Observational and Randomized Studies for Supplements**

Supplement/Outcome	Observational Study Findings	Randomized Study Findings	Notes
Selenium and vitamin E/prostate cancer	High intake of selenium and vitamin E were associated with lower risk of prostate cancer	SELECT trial (large, placebo controlled): no reduction in incidence. Small skin cancer trial and secondary analysis of ATBC trial: supported observational findings	Conflicting results; large, well-designed trial showed no benefit[86-88]
Calcium/colon cancer	High-calcium diets were associated with lower risk of colon cancer	Women's Health Initiative and VITAL trial: no lower incidence of colorectal cancer. Two trials: supplemental calcium reduces adenomatous polyps risk (~25%). One trial: calcium supplementation decreased polyp recurrence, but a more recent trial failed to confirm	Mixed results; some benefit seen for polyp reduction but not for overall colorectal cancer incidence[89-95]
Carotenoids and beta-carotene/lung cancer	High intake of carotenoid-rich fruits and vegetables and beta-carotene were associated with lower risk of lung cancer	ATBC and CARET trials (high-risk patients): increased lung cancer incidence and mortality in beta-carotene groups	Clear example where observational studies suggested benefit, but randomized trials showed harm[96,97]
Retinoids/squamous cell cancer (head and neck)	Limited efficacy as preventive agents	One trial: 13-*cis*-retinoic acid reduced second primary head and neck cancer. Two follow-up trials (lower doses): no clinical effectiveness	Initial positive result not replicated with lower, less toxic doses[98-101]
Vitamin D and cancer	Low levels of vitamin D were associated with increased risk of cancer[102]	VITAL trial: Vitamin D supplementation did not result in a lower incidence of cancer[91,103]	Observational studies were likely confounded by multiple variables including outdoor physical activity
Nicotinamide and skin cancer	Nicotinamide use was associated with a 14% reduction in risk of skin cancer[104]	One trial found that nicotinamide was effective at reducing the rates of new nonmelanoma skin cancers and actinic keratoses in high-risk patients.[105] Another trial of solid organ transplant patients did not observe a benefit[106]	The trial in transplant patients was stopped early due to poor accrual

Table 1-5 **Indices for Describing Accuracy of Screening Tests**

Term	Definition	Ability of Test	Equation
Sensitivity	Proportion of people with the disease who have a positive result on a screening test	To detect disease when it is present	A/(A + C)
Specificity	Proportion of people who do not have the disease who have a negative result on a screening test	To correctly identify the absence of disease	D/(B + D)
Positive predictive value	Proportion of people with a positive result on a screening test who have the disease; increases as disease prevalence in a population increases	To accurately predict the presence of disease	A/(A + B)
Negative predictive value	Proportion of people who have a negative result on a screening test who truly do not have the disease; increases as disease prevalence in a population decreases	To accurately predict the absence of disease	D/(C + D)

A, true-positive result; B, false-positive result; C, false-negative result; D, true-negative result.

Table 1-6 **Screening Recommendations for Asymptomatic Patients With Average Risk by Guideline Setting Organization**

Test or Procedure	Organization		
	US Preventative Services Task Force[150]	**Canadian Task Force on Preventive Health Care**[151]	**American Cancer Society**[152]
Colorectal	2021	2016	2018
HSgFOBT or FIT	Annual HSgFOBT or FIT, starting at age 45 years	FOBT or FIT every 2 years, starting at age 50 years	Annual FOBT or RT, starting at age 45 years (qualified recommendation); age 50 years (strong recommendation: FIT preferred)
Flexible sigmoidoscopy	Every 5 years starting at age 45 years	Flexible sigmoidoscopy every 10 years, starting at age 50 years	Every 5 years, starting at age 45 years (qualified recommendation); age 50 years (strong recommendation)
Flexible sigmoidoscopy plus FIT	Every 10 years plus annual FIT, starting at age 45years	Not recommended	Not recommended
Colonoscopy	Every 10 years, starting at age 45 years	Not recommended	Every 10 years, starting at age 45 years (qualified recommendation); age 50 years (strong recommendation)
CT colonography	Every 5 years starting at age 45 years	Not recommended	Every 5 years, starting at age 45 years (qualified recommendation); age 50 years (strong recommendation)
Prostate	2018[a]	2014	2023
DRE	No change	No change	May be performed in men who want to be screened with PSA
PSA	No change	No change	Shared decision-making starting at age 50 years in men at average risk of prostate cancer who have a life expectancy of 10 years or more; men who choose to be tested and have a PSA level <2.5 ng/mL may only need to be retested every 2 years; men whose PSA level is ≥2.5 ng/mL should be screened annually
Cervical	2018	2013	2020
Pap cytology	Women aged <21 years should not be screened; for women age 21-29 years, Pap test every 3 years; for women aged 30 to 65 years, screening every 3 years with Pap cytology alone; women aged 65+ years who have had adequate prior screening and are not otherwise at high risk of cervical cancer should not be screened; women who have had a hysterectomy with removal of the cervix and do not have a history of a high-grade precancerous lesion (ie, CIN grade 2 or 3) or cervical cancer should not be screened	Women aged <25 years should not be screened; starting at age 25years, screen every 3 years to age 69 years; for women aged 70+ years who have been adequately screened (eg, three successive negative Pap tests in the last 10 years), routine screening may cease; for women aged ≥70 years who have not been adequately screened, continue screening until three negative test results have been obtained	Women aged 25-65 years: a Pap test alone every 3 years; women aged 65+ years who have had three normal Pap tests and no abnormal tests in the last 10 years and no history of CIN II or more serious diagnosis within the last 25 years should stop screening; women who have had total hysterectomy (unless hysterectomy was done as treatment for cervical cancer or precancer) should not be screened

Test or Procedure	Organization		
	US Preventative Services Task Force[150]	**Canadian Task Force on Preventive Health Care**[151]	**American Cancer Society**[152]
HPV DNA	For women aged 30-65 years, every 5 years with hrHPV testing alone or every 5 years with hrHPV testing in combination with Pap cytology (ie, cotesting)	No recommendation	Women aged 25-65 years: primary hrHPV test every 5 years; if a primary hrHPV test is not available, acceptable options include a cotest (hrHPV test done at the same time as a Pap test) every 5 years
Breast	2024	2018	2015
BSE	No change	No change	No change
CBE	No change	No change	
Mammography	Women aged 40-74 years: screen every 2 years; for women aged ≥75 years, there is insufficient evidence to form a recommendation	No change	No change
Lung	2021	2016	2023
LDCT	Adults aged 50-80years: annual screening if the patient also has at least a 20-pack-year smoking history and currently smokes or quit smoking <15 years ago	Adults aged 55-74years: three consecutive annual screenings if the patient also has at least a 30-pack-year smoking history and smokes or quit smoking <15 years ago	Adults aged 50-80 years: annual screenings if the patient also has at least a 20-pack-year smoking history and smokes or previously smoked

Abbreviations: BSE, breast self-examination; CBE, clinical breast examination: CIN, cervical intraepithelial neoplasia; DRE, digital rectal examination; FIT, fecal immunochemical test; FOBT, fecal occult blood testing; HPV, human papillomavirus: hrHPV, high-risk human papillomavirus; HSgFOBT, high-sensitivity guaiac fecal occult blood testing; LDCT, low-dose CT; Pap, Papanicolaou; PSA, prostate-specific antigen; RT, radiation therapy.

MOLECULAR BIOLOGY 2

Andrew B. Nixon, PhD, MBA, and Uta Schmidt-Strassburger, PhD

RECENT UPDATES

- US FDA oncology drug approvals in 2025 include molecularly targeted agents, such as an alkylating agent, a hormone receptor-antagonist, small-molecule inhibitors against different kinases, as well as monoclonal antibodies, antibody-drug conjugates, a bispecific T-cell engager, a proteasome activator, and berahyaluronidase alfa-pmph, an endoglycosidase.
- Pathways targeted by these drugs include hormone signaling (estrogen receptor), cell survival (hepatocyte growth factor receptor [HGFR/cMET], receptor tyrosine-protein kinase erbB-2 [ERBB2/HER-2], epidermal growth factor receptor [EGFR], exon 20 insertions [mutated *EGFR*], histone mutation [H3 K27M], mitogen-activated protein kinase 1/2 [MEK1/2], rapidly accelerated fibrosarcoma kinase [RAF], focal adhesion kinase [FAK], proline-rich tyrosine kinase-2 [Pyk2]), improper cell function attenuation (programmed cell death 1, programmed death-ligand 1), and immune cell engagement (B-cell maturation antigen).
- Technological advances continue to revolutionize molecular biology, offering deeper insights into the intricacies of cellular processes. Techniques such as single-cell sequencing, clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9) gene editing, and advanced imaging technologies now enable researchers to better understand the molecular mechanisms underlying diseases. This increased precision allows for the development of targeted therapies tailored to individual genetic profiles, and breakthroughs in computational biology and artificial intelligence are facilitating the analysis of vast data sets, accelerating the identification of potential drug targets and biomarkers.[1]

OVERVIEW

The clinical applications of insights into molecular oncology and the technologies linked to them are rapidly evolving, and our understanding of the genes and processes that drive tumorigenesis continues to expand. Recent studies have taken advantage of these technological advances, particularly high-throughput sequencing of DNA and RNA, which provides unprecedented depth and breadth of analysis of individual cancer samples. Identification of rare yet important cancer genes has revealed surprising new cancer pathways, and this knowledge has fueled the development of therapeutics that target specific oncogenic processes.

It is now both feasible and rational to perform detailed molecular analyses of each patient's cancer sample in a matter of days to weeks. This improvement in turnaround time has enabled clinicians to rationally select targeted therapies to treat individual cancers when locally confined approaches like surgery or radiotherapy have been exhausted or are no longer applicable because of the generalized nature of the cancer. In addition, DNA sequencing can provide phenotypic information, such as microsatellite instability (MSI) and tumor mutation burden, both of which may predict the benefit of therapy with immune checkpoint inhibitors, independently of tumor type or location. As our therapeutic armamentarium continuously expands to include new molecularly targeted agents to complement older traditional cytotoxic compounds, it is essential that cancer care providers have at least a basic understanding of the molecular basis of cancer, as well as the established and emerging technologies used to aid in cancer diagnosis, prognosis, and therapy.

The information selected for this chapter aims to provide the reader with an understanding of cancer's proclivity to constantly evolve and provide a scientific rationale at the molecular level for how diagnostic testing and drugs can be deployed most effectively. It has become essential as well as practical for oncologists at any level and in any practice setting to acquire a basic understanding of the biology to comprehend the torrent of targeted and other drugs coming down the pipeline and increasingly being approved for daily use in patient care.

MULTISTEP TUMORIGENESIS

The development of fully malignant cancers requires many independent genetic and epigenetic events that dysregulate normal cellular processes sufficiently to transform the cells into a malignant state. Although the mutations that cause

human cancers vary greatly among cancer types and individuals, the broad consequences of these mutations are abnormal phenotypes that are shared by most cancers. Hanahan and Weinberg[2] originally proposed six hallmarks of cancer that they defined as "distinctive and complementary capabilities that enable tumor growth and metastatic dissemination."[3] These include the following:

1. Sustained proliferative signaling
2. Evading growth suppressors
3. Resisting cell death
4. Enabling replicative immortality
5. Inducing angiogenesis
6. Activating invasion and metastasis

These capabilities can be acquired in a different order, and in some cases, a single genetic mutation might provide more than one capability. This conceptualization provides a framework within which to consider multistep tumorigenesis. The first three of these acquired capabilities involve mutations within the mitogenic signaling, cell cycle, and cell death pathways. The activation of mitogenic signaling pathways promotes uncontrolled cell proliferation, whereas dysregulation of cell-cycle pathways leads to unchecked cell division, contributing to tumor growth. Simultaneously, impairment of cell death pathways allows cancer cells to evade apoptosis, facilitating their survival and progression. The fourth category involves the acquisition of cellular immortality in tumors. Normal cells are limited in the number of times they can divide, even when they are provided with all the normal mitogenic stimuli required for cell division. By contrast, many cancer cells can divide with apparently limitless potential. One fundamental mechanism that limits human cell division involves repetitive nucleotide sequences, called telomeres, at the ends of chromosomes. Telomeres protect the ends of chromosomes from deterioration. They shorten with each cell division (the length of the telomeres of a cell reflects the number of divisions it has undergone) and eventually are shortened to the point where they can no longer protect the chromosome ends. This leads to a condition termed telomere crisis and, ultimately, to cell death. Unlike normal cells, cancer cells maintain their telomere length during cell division. Maintenance of telomere length usually results from expression of the enzyme telomerase that adds nucleotides back to the telomere. Telomerase activity can be detected in 85% to 90% of cancers, and the remaining tumors maintain their telomeres through a mechanism involving recombination (Fig. 2-1).

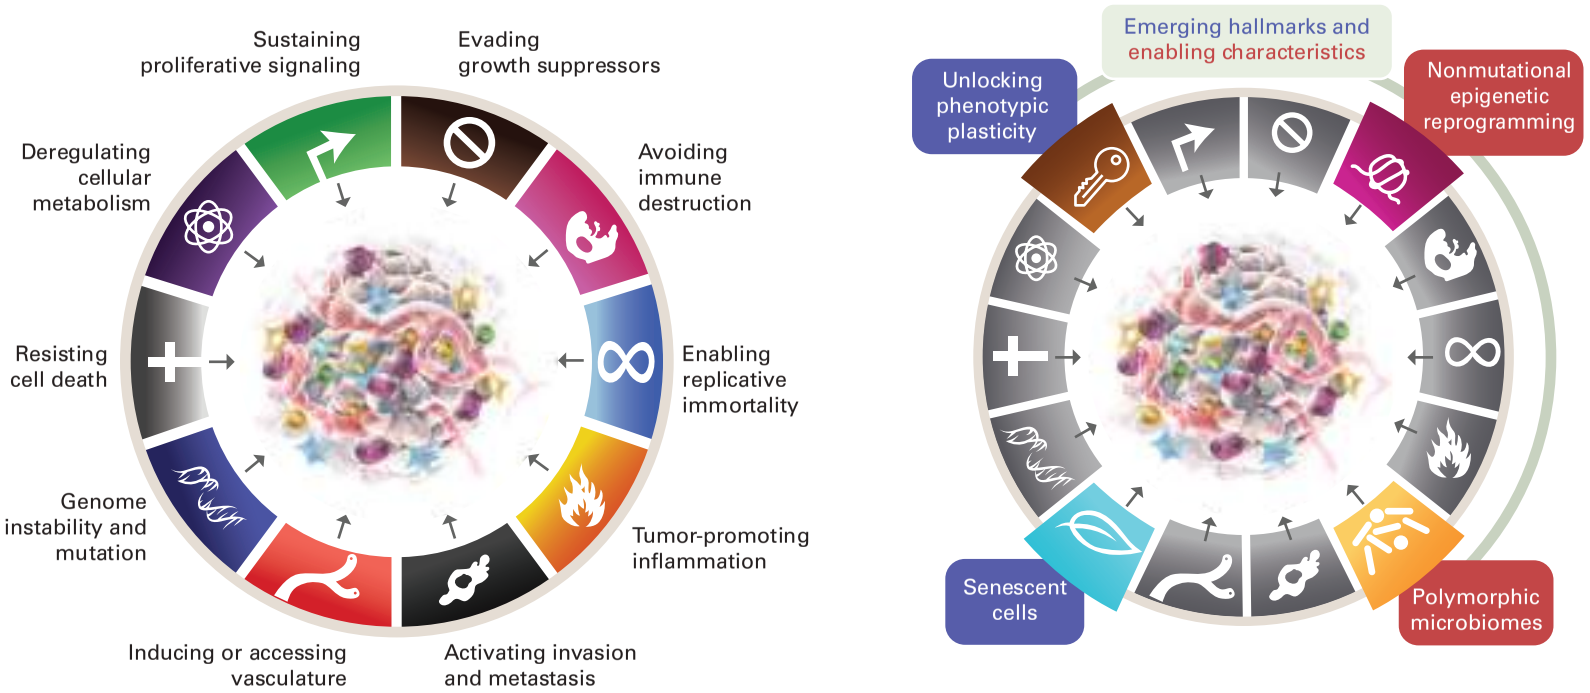
The fifth capability of induced angiogenesis reflects the need of tumors to actively recruit vasculature to grow once they have outgrown their existing oxygen/blood supply. In normal tissues, the development of new blood vessels is highly regulated by both positive and negative signals. Tumor cells promote angiogenesis by upregulating the pathways that promote blood vessel formation (eg, increased expression of angiogenic factors, such as vascular endothelial growth factor [VEGF] and fibroblast growth factor [FGF]) and reducing the activity of inhibitory pathways. Some of these pathways involve transcriptional networks under the control of other genes, such as *VHL* mutations in renal cell carcinoma. The 2021 Food and Drug Administration (FDA) approval of belzutifan underlines the practical implications of the hallmarks.[4] So far, targeting the different hallmarks is challenging because of the involvement of the targets in physiologic functions, and it remains the essence of basic oncology research. The importance of these pathways in tumor cell growth is well established, and a multitude of drugs have been developed that target angiogenesis, including both antibody and small-molecule inhibitors of the VEGF pathway.

The sixth hallmark comprises tissue invasion and metastasis, accounting for most cancer fatalities. Specific gene products are associated with the ability of tumor cells to metastasize to different organ sites. The composition of the tumor stroma, which is a complex mixture of extracellular matrix components and various cell populations, including fibroblasts, endothelial cells, and immune cells, has a major influence on metastasis as well. Elegant animal models as well as transcriptional profiling of human cancers show that metastasis includes alterations in genes involved in cell adhesion, cell fate, integrin signaling, growth factor and chemokine signaling, and extracellular proteolysis.

Ten years after their initial report on cancer hallmarks,[2] Hanahan and Weinberg[3] expanded on their original work, defining two emerging hallmarks and two enabling characteristics that make it possible for tumor cells to acquire the six core hallmarks. The two emerging hallmarks are deregulating cellular energetics and avoiding immune destruction. These two are now regarded as sufficiently validated to be part of the core set of cancer hallmarks.[5]

- Deregulating cellular energetics is based on growing knowledge that tumors deregulate metabolism to facilitate growth. Whereas normal cells tend to use mitochondrial oxidative phosphorylation for energy production, cancer cells use glycolysis, even when oxygen is available, a process termed aerobic glycolysis, also known as the Warburg effect. Other metabolic pathways are similarly altered in cancers.[6]
- Evading immune destruction is now validated as an effective strategy to overcome this evasion. Immunotherapies are key components of current therapy for cancer in many organ sites and are discussed in other chapters in this book.

Figure 2-1 Hallmarks of Cancer



The latest version of the hallmarks of cancer includes two emerging hallmarks and two enabling characteristics (right). These include unlocking phenotypic plasticity and senescent cells (emerging hallmarks) and non-mutational epigenetic reprogramming and polymorphic microbiomes (emerging enabling characteristics).
Reprinted from *Cancer Discov*. 2022;12(1):31-46, Hanahan D, Hallmarks of cancer: new dimensions, with permission from AACR.

The two enabling characteristics are properties of cancer cells that facilitate the acquisition of the core hallmarks:

- Genomic instability drives the acquisition of multiple mutations required for multistep tumorigenesis.
- Tumor-promoting inflammation reflects the rapidly advancing concept that inflammatory responses can facilitate tumor initiation and progression.

In the 2022 revision, two emerging enabling characteristics and two emerging hallmarks were identified[5]:

- Non-mutational epigenetic reprogramming is an emerging enabling characteristic of cancer that allows gene expression to be shaped through its interaction with the tumor microenvironment. Examples include hypoxia-modulating ten-eleven translocation (TET) demethylases or reversible induction of tumor invasiveness during epithelial-to-mesenchymal transition.
- Polymorphic microbiomes are an emerging enabling characteristic, based on the impacts of the microbiome from the gut and other barrier tissues on cancer biology. The most direct evidence supporting this emerging hallmark has been observed with the gut microbiota affecting colorectal cancer.
- Senescence is an emerging hallmark of cancer. Senescence is a type of cellular aging characterized by irreversible proliferative arrest. This process has historically been considered protective against cancer because these cells cannot proliferate or act aggressively. However, this view has been called into question by studies that have found that the presence of senescent cells may stimulate or activate cancer programs in adjacent tumor cells, leading to their provisional addition as an emerging cancer hallmark. Efforts to develop therapeutics that either induce the death of senescent cells (senolytics) or specifically attenuate the functionality of senescent cells (senomorphics) are currently underway.
- Unlocking phenotypic plasticity is another emerging hallmark of cancer. It is increasingly recognized that various cancer deregulations can release cancers from a limited potential differentiated state to a less-differentiated state in which they more freely proliferate and invade. Examples include dedifferentiation in colorectal cancer, blocked differentiation in acute promyelocytic leukemia, and transdifferentiation of prostate adenocarcinoma into neuroendocrine tumors through loss of retinoblastoma (RB) protein. In addition, the use of *KRAS* G12C inhibitors in non–small cell lung cancer (NSCLC) has been associated with histologic transformation, where adenocarcinoma exhibits plasticity by transitioning into a squamous histology, affecting the phenotypic landscape.[7]

One important aspect of the enabling characteristics concept is that it also provides a framework for the development of mechanism-based targeted therapies, which target both hallmarks and enabling characteristics. Examples of such combinatorial therapies include angiogenesis inhibitors and immune checkpoint inhibitors, as discussed here as well as in other chapters of this book.

KEY POINTS

- Tumorigenesis is a multistep process that requires the gain of multiple mutations or characteristics that subvert safeguards preventing normal cells from transforming into cancer cells.
- All tumors share a number of hallmarks that contribute to their malignant phenotypes, but the specific molecular events that produce these phenotypes vary greatly among tumor types and individuals.
- Understanding of the hallmarks of cancer informs the development of targeted therapies.

PRECISION ONCOLOGY

Large studies using next-generation sequencing (NGS) to study cancer genetics have radically altered our understanding of the genomic landscape of cancers and demonstrated the immediate effect of targeted gene panels and genome-scale analyses on clinical oncology.

A comprehensive review of the explosion of cancer genomic studies enabled by NGS and other technologies is beyond the scope of this chapter, but some examples follow to highlight the power and importance of these approaches. Also, two databases have been introduced that permit individual exploration of publicly funded research (the Catalogue of Somatic Mutations in Cancer [COSMIC][8] and cBioPortal, which focuses particularly on the publicly funded and available American Association for Cancer Research GENIE data set). Two early studies described an integrative approach that included the sequencing of protein-coding genes (exome sequencing), analyses of DNA copy number, and RNA sequencing to assess gene expression, which led to an in-depth understanding of the genes and pathways mutated in pancreatic cancers and glioblastomas.[9,10] The use of these combined modalities has helped distinguish mutations that likely play a causal role in tumorigenesis (driver mutations) from mutations that may be irrelevant (passenger mutations). Importantly, one of these studies[10] found that an isocitrate dehydrogenase

(*IDH*) gene, previously unrecognized as an oncogene, was mutated in 12% of glioblastomas. *IDH1* and *IDH2* mutations have subsequently been found in other cancers, including acute myeloid leukemia (AML), chondrosarcoma, and cholangiocarcinoma. Importantly, *IDH1*/*IDH2* mutations cause epigenetic dysregulation and DNA hypermethylation,[11] and pharmacologic IDH inhibitors are proving successful in the clinic; ivosidenib and enasidenib were approved for use in patients with *IDH*-mutated AML.

Dozens of large-scale cancer genomic studies, many of which have been coordinated by The Cancer Genome Atlas (TCGA; a consortium sponsored by the National Institutes of Health), have identified the molecular features of the most common and many uncommon cancer types.[12] The molecular features that have been catalogued include whole-exome sequencing, RNA sequencing/RNA expression, copy-number variation, DNA methylation, microRNA (miRNA) expression, and protein analysis. These studies have provided unprecedented insights into cancer biology and revealed many new targets for therapeutic interventions. TCGA initially studied tumor types individually, revealing drivers of specific diseases. For example, TCGA analysis of adult AMLs revealed that AMLs contain fewer mutations than other adult cancers, with an average of 13 mutations per sample, only five of which involve recurrently mutated genes.[13] As these studies of individual tumors were completed, TCGA went on to perform combined cross-cancer analyses across all tumor types, generating the PanCanAtlas. One common theme that has emerged from this work is that although specific organ sites exhibit unique mutational spectra, other pathways are mutated in many types of cancer.[14,15]

These global approaches set the stage for the use of NGS, in real time, to assist with clinical decision-making. Indeed, basing treatments on specific mutations present in a given patient's tumor is a key feature of personalized cancer medicine. Assays can include focused molecular diagnostic assays with clearly defined therapeutic implications, namely, identifying known driver mutations, such as *EGFR*, anaplastic lymphoma kinase (*ALK*), and other genes in lung cancers; identifying human epidermal growth factor receptor 2 (HER2) overexpression in breast and gastroesophageal cancers; or evaluating rat sarcoma virus protein (*RAS*) status in colorectal cancers. In contrast to these focused approaches, individual patient tumor samples can be studied with NGS panels, which analyze up to several hundred known and often targetable cancer genes for genetic alterations. These panels identify rare driver mutations that suggest treatment with specific targeted agents may be clinically beneficial, even if these agents have not been previously evaluated in the tumor type. This trend toward tumor-agnostic therapies, which are based on molecular mutations rather than tissue of origin, is another advancement of precision medicine. Larger-scale sequencing, such as whole-exome sequencing or even whole-genome sequencing, is emerging to further inform and potentially guide therapies for individual patients. The high cost and extended turnaround time required for these approaches were previously prohibitive, but this is no longer the case. Although the complexity of data analysis remains a barrier, it is anticipated that an increasing number of patients with cancer will have their tumors analyzed with more comprehensive approaches in the future.

All these techniques are based on basic principles of molecular biology, which will be introduced/reviewed in subsequent subchapters. It is important to understand the underlying principles and caveats to be able to discuss molecular diagnoses in an informed manner to provide patients and their families with the best available evidence for shared decision-making.

BASIC PRINCIPLES OF MOLECULAR BIOLOGY

The human genome contains approximately 3 billion nucleotides partitioned among 23 chromosomes. Approximately 1% of the genome is composed of coding DNA, which contains the gene sequences that encode proteins. The other 99% is considered noncoding DNA, which contains instructions for the formation of specialized RNA molecules (eg, transfer RNA and ribosomal RNA), as well as structural (eg, centromeres, telomeres, and G-quadruplexes), regulatory (eg, promoters, enhancers, and silencers), and other elements (eg, transposons, retrotransposons, and interspersed nuclear elements). Most human cells contain a complete genomic copy of DNA, but there are exceptions. As examples, erythrocytes contain no genomic DNA, mature lymphocytes delete fragments of DNA within either immunoglobulin or T-cell receptor genes to generate antigen-recognition proteins, and megakaryocytes contain extra copies of the genome that result from the process of endoreduplication (ie, successive duplications of the genome without intermediary mitosis).

DNA is a macromolecule comprising nucleotides containing one of four bases (adenine [A], guanine [G], cytosine [C], or thymine [T]) plus a deoxyribose sugar and a phosphate group. Each nucleotide base is connected to a deoxyribose sugar, forming a nucleoside, and phosphodiester bonds between the sugar moieties form the DNA strand. The nucleosides of one DNA strand form hydrogen bonds with nucleosides on the complementary strand (C pairs with G, and A pairs with T) to create a DNA double-strand helix. When DNA is replicated, the strands separate, and each provides a template for an exact complement to be synthesized, thereby generating two identical helices, a process that occurs in normal and tumor cells alike.

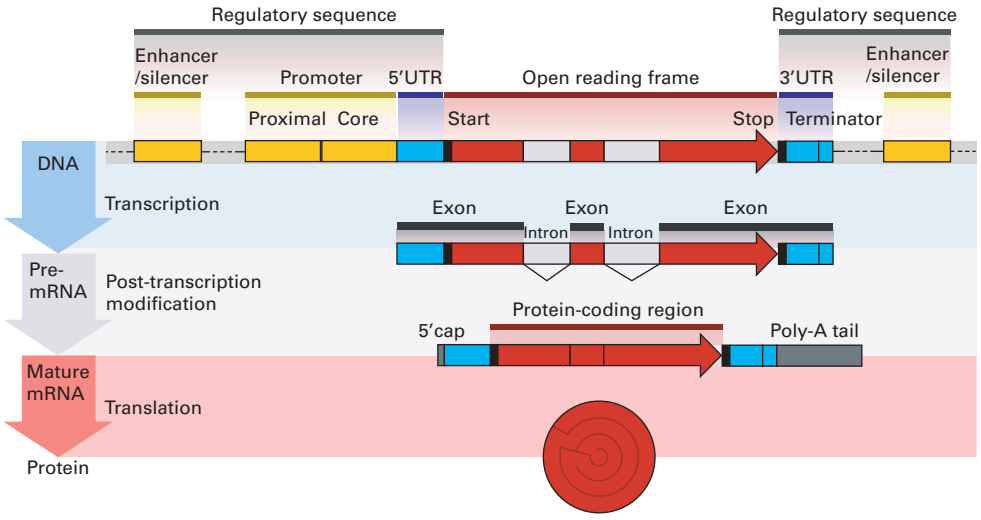
GENES AND GENE EXPRESSION

A gene is a DNA sequence that encodes a protein or functional RNA.[16] Gene expression refers to the process by which specific genetic sequences direct the synthesis of these gene products. This process is highly regulated, and individual cell types express only a subset of the full complement of genes. Specific gene expression programs fundamentally drive many biological processes, including growth and development, cellular differentiation, and neoplastic transformation.

Although protein-coding genes account for only a small portion of chromosomal DNA, they are regarded as the central determinants of cellular and organismal phenotypes. Most clinically relevant DNA mutations occur within such genes, and many targeted cancer therapies are directed against specific genetically encoded protein pathways (Fig. 2-2).

- The first step in protein synthesis is transcription of the DNA template into a linear RNA copy, known as messenger RNA (mRNA).
- Most protein-coding genes are arranged in segments, with coding elements called exons and noncoding elements called introns.
  - Additional noncoding DNA elements that dictate gene expression include regulatory elements, such as promoters (which direct the site of transcription initiation) and enhancers (which increase transcription).[17]
  - Regulatory elements are recognized by proteins, called transcription factors, which establish the timing and tissue-specific characteristics of gene expression. Many transcription factors bind directly to these regulatory elements and recruit additional regulatory proteins into the transcription complex.
  - Proteins that mediate the assembly of active transcription complexes by recruiting factors or facilitating chromatin changes that promote transcription are termed coactivators, and those that inhibit transcription are corepressors.[18]

Figure 2-2 Schematic Diagram of an Idealized Gene



Schematic diagram of an idealized gene, including promoter elements, an enhancer, and the transcribed region of the gene. Regulatory sequences control when and where the protein-coding region is expressed. Promoter and enhancer regions regulate the transcription of the gene into a pre-mRNA, which is modified to add a 5′ cap and poly-A tail and remove introns. The mRNA 5′ and 3′ UTRs regulate translation of the final protein product.
Abbreviations: mRNA, messenger RNA; UTR, untranslated region.
Reproduced under Creative Commons license. Source: Shafee T, Lowe R. Eukaryotic and prokaryotic gene structure. *WikiJournal Med*. 2017;4, figure 1. doi:10.15347/WJM/2017.002

Gene transcription first results in pre-mRNA, which contains both exons and introns. The introns are spliced out to generate a mature mRNA that contains a continuous coding sequence. Importantly, alternative splicing of pre-mRNAs can generate distinct mRNA molecules that include or exclude distinct sets of exons, effectively allowing a single gene to encode multiple related mRNAs that, in turn, translate to multiple protein products, termed isoforms. Another feature of mature mRNAs is that they comprise the 5′- and 3′-untranslated regions, which extend beyond the coding regions and regulate mRNA stability and translational efficiency.

After a mature mRNA is produced, the process of protein translation uses the mRNA sequence to guide the production of a protein. This process requires ribosomes, which are protein- and RNA-containing structures that bind mRNAs and read nucleotide triplets, termed codons, that specify which amino acids will be incorporated into a nascent polypeptide chain. Once a complete protein is produced, the amino acid sequence can be further modified by posttranslational processes, such as phosphorylation, acetylation, ubiquitination, or methylation. These dynamic and often reversible changes can control protein activity, stability, cellular localization, and multiprotein complexes.

Even with the completion of the Human Genome Project in 2003, the exact number of human protein-coding genes remains unclear. Currently, it is estimated that there are approximately 20,400 protein-coding genes; however, the total number of distinct human proteins is considerably greater. Genes can be alternatively spliced into distinct mRNAs to produce multiple protein

isoforms, and proteins can undergo posttranslational modification to produce multiple forms of proteins, called proteoforms. It is estimated that the full set of human proteins, known as the proteome, contains 250,000 to 1 million distinct proteoforms.

Protein-coding genes are often emphasized; however, there is another major class of genes termed noncoding RNAs. As their name suggests, these transcriptional units generate RNA sequences that do not code for proteins but have important cellular functions. These classically include ribosomal RNA and transfer RNA, which comprise key components of the translational machinery, as well as part of the spliceosome. Additional functional noncoding RNA units include miRNAs and long noncoding RNAs, both of which regulate gene expression and other cellular processes, in part by interacting with mRNA.

- miRNAs are short (21-23 nucleotides) RNA molecules encoded within longer primary RNA transcripts.
- More than 2,000 miRNA genes have been identified in humans, where they regulate diverse cellular processes, including differentiation, migration, proliferation, and apoptosis.[19]
- miRNAs decrease the expression of specific protein-coding genes through direct interaction with mRNA molecules with complementary sequences, which leads to degradation and/or modified translation of target mRNAs.[20,21]
- miRNA analyses have been developed as molecular tools in cancer diagnosis and prognosis.[22,23] It has long been hypothesized that miRNA signatures would serve as ideal biomarkers because of the stability of miRNA over time.[22,23]

Long noncoding RNAs are a second group of noncoding RNAs that affect many diverse cellular processes.[24]

- These RNAs are generally longer than 200 nucleotides, but they can vary in length.
- Long noncoding RNAs have the ability to repress gene expression through increased degradation of mRNAs; however, they have much more varied functions, including silencing transcription, modulating chromatin in time and space, altering mRNA splicing, regulating mRNA translation, and influencing posttranslational modifications of proteins.
- Several long noncoding RNAs are implicated in carcinogenesis in experimental models, including the following:
  - NKILA, which modulates breast cancer phenotype through altered protein phosphorylation;
  - MALAT1, which regulates mRNA splicing and may play a role in multiple cancers;
  - TERC, which influences telomere length to increase cell lifespan and is amplified in multiple cancer types[25]; and
  - One of the largest known long noncoding RNAs, the 17,000-nucleotide RNA expressed from the X-inactive specific transcript (*XIST*) gene, which serves to inactivate one X chromosome in female cells to ensure proper levels of expression from the single active X.[26]

EPIGENETIC GENE REGULATION

Epigenetic gene regulation, or epigenetics, refers to heritable processes that profoundly influence gene expression without changing the DNA nucleotide sequence. Epigenetic gene regulation occurs primarily through two processes: DNA methylation and histone modification.[27] DNA methylation occurs when DNA methyltransferases catalyze the addition of methyl groups onto CG dinucleotides in genomic DNA.[28] When CGs lie in gene promoters or other regulatory regions, methylation represses gene transcription. Distinct DNA methylation patterns can be seen in cells at different stages of development or between different cell types, suggesting that DNA methylation controls global gene transcription to define cell identity. Similarly, DNA methylation patterns are altered in various disease states, including cancer, where many tumor suppressor genes are silenced by promoter methylation. Prominent examples include the *MLH1* gene promoter, which is methylated in a variety of cancers, suppressing the expression of this DNA mismatch repair (MMR) enzyme, and the *CDKN2A* gene promoter, which is methylated in many tumor types, leading to decreased expression of the p16 tumor suppressor protein. Although some genes can be inactivated by either mutation or gene silencing, it is now understood that certain cancer-associated genes are inactivated only through genetic mutation, whereas others can also be inactivated through epigenetic gene silencing resulting from aberrant methylation. Thus, the study of methylation patterns in human cancer genomes has identified previously unknown tumor suppressor genes.

The second major type of epigenetic regulation results from modifications of highly abundant DNA-associated proteins known as histones.[29] Human DNA is packaged and condensed through association with histones and other nuclear proteins to form chromatin. Within a chromatin fiber, DNA is wrapped around octamers of eight histone proteins to form a nucleosome.[30] This not only compacts DNA sufficiently to allow it to fit within the cell nucleus but also adds another level of control over which regions of the genome are transcriptionally active or silent at any given time. Histones are modified covalently (eg, by acetylation, methylation, phosphorylation, and ubiquitylation), by changes in subunit composition (eg, replacement of core histones by specialized histones), and by repositioning. Each of these modifications renders DNA either more or less accessible to transcription by RNA polymerase. Histone methylation and acetylation are particularly important. Histone methylase and demethylase enzymes regulate methyl-, dimethyl-, or trimethylation of lysine residues; methylation on some sites facilitates transcription, whereas on others, it represses transcription. Histone acetylation is also regulated by opposing enzymes; acetylation is found in actively transcribed genes, whereas histone deacetylation correlates with repression.

Because of their influence on gene expression, the enzymes that catalyze epigenetic modifications are themselves important targets for cancer therapeutics. The hypomethylating agents 5-azacytidine and 5-aza-2′-deoxycytidine (decitabine) inhibit DNA methyltransferase enzymes, which leads to lower methylation of gene promoters. These drugs are used to treat myelodysplastic syndromes and other hematologic malignancies and are thought to function in part by reestablishing the expression of tumor suppressor genes repressed by methylation.[31] Histone deacetylase inhibitors, including vorinostat, panobinostat, and belinostat, constitute another example of epigenetic therapy.[32,33] These drugs have global effects on histone modification and can broadly alter gene expression to inhibit the growth of some cancers, including T-cell lymphoma and multiple myeloma. In addition to these global inhibitors, there has been progress in more selective inhibitors of specific methyltransferases. Tazemetostat is a specific inhibitor of EZH2 methyltransferase, which is approved for follicular lymphoma.[33] Tulmimetostat, a next-generation EZH2/1 inhibitor, received FDA fast-track designation for the treatment of patients with advanced, recurrent, or metastatic endometrial cancer[34] harboring *ARID1A* mutations. Other clinical trials are testing inhibitors of specific histone methyltransferases, such as DOT1L and KDM1A, which are upregulated in distinct cancer types.[31] These agents have so far been less active in solid tumors.

KEY POINTS

- Genes are functional units of DNA that control the production of RNAs and proteins.
- Cells express only a subset of the genes contained within their genomes. Protein-coding genes are transcribed into mRNA in a process that is controlled by regulatory DNA elements (eg, enhancers and promoters).
- Noncoding RNAs, including miRNAs and long noncoding RNAs, are important regulators of gene expression and are often deregulated in human cancers.
- Gene expression is also regulated by epigenetic modifications of DNA and histones. Such chromatin modifications, which include methylation and acetylation, play a major role in determining the timing and extent of gene expression.
- Enzymes that catalyze epigenetic modifications are potential targets for cancer therapeutics.

DNA

DNA Polymorphisms Facilitate Genetic Analysis of Complex Diseases

Before the development of modern DNA amplification and sequencing techniques, the analysis of cancer genetics on a broad scale was largely limited to familial cancer syndromes. This research was painstaking and imprecise, but resulted in the identification of cancer genes in cancer-prone families. This work was facilitated by the study of genetic polymorphisms, which are DNA sequences that exhibit substantial variability in a population. Genome-wide maps of polymorphic markers were important tools in the analysis of genetic traits. Through linkage analysis of pedigrees in which family members did or did not develop early-onset cancer, the genetic polymorphisms that segregated with the cancer-development phenotype identified many hereditary cancer genes, including those involved in breast cancer (eg, *BRCA1* and *BRCA2*).

- DNA sequencing technologies are the predominant method for cataloguing single-base changes throughout the genome, termed single-nucleotide variations (SNVs; formerly single-nucleotide polymorphisms).
- SNVs are the most common polymorphisms and represent approximately 1% of the human genome.[35,36]
- Geneticists can now apply complex statistical methods of analysis to large populations of people to determine the associations of specific SNVs with specific phenotypes, including cancer.
- Experimental validation has confirmed hypotheses generated through genome-wide association studies (eg, common polymorphisms can affect cellular proliferation, gene transcription and silencing, and sensitivity to specific cancer therapeutics in vitro).
- Importantly, these polymorphisms are rarely found in the coding regions of the affected genes, but rather, they are more likely to be located in close proximity to the functional gene or mutation. Therefore, we mostly consider them to be indicators but not the causes of cancer risk.
- SNVs may also affect cancer therapy (eg, several inactive or less active variants of dihydopyrimidine dehydrogenase [DPD], the enzyme responsible for the turnover of fluoropyrimidines, a class of widely used chemotherapeutic drugs).[37] The presence of these variants may result in life-threatening toxicities in such patients. The FDA has issued the requirement to test for DPD heterozygosity and homozygosity in October 2025, and an amendment in the capecitabine and 5-fluorouracil prescribing information.
- Another relatively common type of polymorphism occurs in the microsatellite regions of DNA, which are tandem repeats of two to six nucleotides that occur in thousands of locations in the genome.[38] One common type of microsatellite is composed of cytosine and adenine (CA) dinucleotide repeats, mainly located near the end of the chromosome. These regions of the genome are susceptible to imperfect DNA replication, thus leading to a higher mutation rate, creating genetic variation

among individuals and allowing for facile DNA genotyping. These microsatellite polymorphisms allow for the fingerprinting of DNA, and the shorter ones have long been used in forensic examinations, because they can distinguish DNA from individuals with simple analyses. Under ordinary circumstances, these satellite repeats differ among individuals but are uniform in all somatic cells. Somatic variations in microsatellite regions can occur in tumors. The primary cause of microsatellite variation is an error in DNA MMR.

- This loss of functional MMR enzymes is a result of either mutation or epigenetic silencing of MLH1, MSH2, MSH6, and PMS2.
- These MMR enzymes that normally suppress DNA replication errors are mutated in some familial cancers, such as hereditary non-polyposis colon cancer/Lynch syndrome.
- Loss of a second functional MMR gene, occurring most commonly in gastrointestinal and endometrial cancers, increases variation in altered microsatellite sequences occurring in tumors.
  - This trait, termed MSI, serves as a harbinger of widespread tumor-specific point mutations throughout other regions of the genome.
  - MSI is highly suggestive of Lynch syndrome, which should prompt genetic counseling; however, it can occasionally occur spontaneously in tumors without a heritable germline mutation.[39]
  - In addition to its value in identifying familial cancer syndromes, MMR deficiency (dMMR)/MSI also predicts the likelihood of response to immune checkpoint inhibitors in diverse cancer types.
  - MMR/MSI is thought to make tumors more immunogenic, because the altered protein products encoded by the highly mutated cancer genome generate novel antigens (neoantigens) that are presented to the immune system on major histocompatibility complex class I.[39]

Polymerase Chain Reaction

Accurate and high-throughput DNA analysis is generally dependent on error-free amplification of partial or whole genomes. The development of the polymerase chain reaction (PCR) was a watershed technological advance because it made the synthesis of large quantities of specific DNA sequence fragments from minuscule quantities of template a routine procedure.[40] PCR was essential for producing the draft sequence of the human genome; amplified copies of countless small fragments of the human genome were cloned, sequenced, and aligned to one another. A wide variety of PCR-based techniques have revolutionized virtually all methods used to manipulate, detect, and analyze nucleic acids.

Next-Generation DNA and RNA Sequencing

NGS technologies have increased the speed and dramatically reduced the cost of DNA and RNA sequencing. NGS methods apply massively parallel sequencing to obtain millions of DNA sequence reads simultaneously.[41] Although technology platforms vary, most read relatively short DNA sequences, typically measuring 100 to 200 bp. The sequence reads are highly specific, allowing millions to be uniquely mapped to specific genes or regions of the human genome, even when they contain mutations or small sequencing errors. NGS detects mutations, alterations, and structural changes in the genome. DNA translocations can also be detected, although they generally require a 100- to 200-bp read to cross the boundary of the translocation, which is difficult because the boundary can differ greatly among cancers. As a complementary approach, assays have been developed that evaluate mRNA sequences, which can more efficiently detect these fusion boundaries.

- One challenge with NGS is that tumors are heterogeneous and composed of both cancer and non-cancer cells, whereas most of the genetic alterations are somatic (ie, they are found only in the cancer cells).
- This issue can be overcome by sequencing at a greater depth, which is the measure of the average number of reads that map to any one region of the genome.
- Sufficient depth of coverage allows for mutation detection in at least some of the reads. The fraction of reads that have the mutation is often reported as the variant allele frequency or simply allele frequency.

The cost and speed of NGS are rapidly improving. For example, in 2008, two human genome sequences could be completed in a few months at a cost of approximately $1 million per genome. By 2019, rapid human genome sequencing was available, with costs in the range of $1,000 and timeframes of less than 1 week. Rapid and low-cost NGS has enormous implications for understanding cancer biology, prognosis, diagnosis, and treatment, enabling individualized treatments based on genome-scale sequence data (ie, precision oncology).[42] In recent years, NGS has given way to comprehensive genomic profiling approaches for testing of clinical tumor specimens for treatment decision-making. Therefore, targeted resequencing approaches that cover actionable somatic mutations are used widely, as is whole-exome sequencing (ie, the totality of expressed genes).

NGS also allows epigenetic studies on a genome-wide scale. For example, chromatin immunoprecipitation (ChIP) followed by sequencing is a method that uses antibodies that recognize specific modifications (eg, histone methylation) to isolate fragments of DNA associated with the modified histone, and NGS is then applied to identify all DNA regions that contain the modification.[43] This strategy has produced highly detailed maps of the epigenetic markers that regulate gene expression. ChIP is used mainly

in basic research for the identification of sites that are hyper- or hypomethylated. Patients with diseases with these features are amenable to epigenetic drugs like azacytidine.[43]

Similar approaches have shown that CG methylation is a highly dynamic process that changes greatly during cellular differentiation and that distinct CG methylation patterns can distinguish between normal and cancerous tissues.[44] The Encyclopedia of DNA Elements (ENCODE) project has used NGS approaches to catalog transcription factor–binding sites as well as chromatin and histone modifications across the human genome.[45] These technologies are expanding our understanding of how gene expression is regulated in health and disease.

RNA

Reverse Transcription and Real-Time PCR

PCR-based methods used for RNA analysis first use reverse transcription, a viral enzyme that converts mRNA to a complementary strand of DNA, called complementary DNA (cDNA). When followed by PCR, the DNA is amplified into many identical double-stranded copies, using primers, which are short synthetic fragments of DNA specific to the sequence of interest. This general strategy is termed reverse transcription PCR to reflect both the reverse transcription and PCR steps.

- Reverse transcription PCR can be used to amplify, detect, or sequence RNA transcripts of interest.
- Quantitative reverse transcription PCR methods are used to precisely measure RNA abundance in cells and tissues.
- Real-time PCR assays use fluorescent dyes to measure the amount of PCR product synthesized in each amplification cycle in real time, as PCR progresses.[46]
- One approved diagnostic test uses real-time PCR to assess the mRNA levels (ie, expression) of 21 genes to predict the benefit of adjuvant chemotherapy in women with early-stage ER-positive breast cancer.[47]

Digital Droplet PCR

Although PCR detects small quantities of specific DNA sequences through amplification, it typically cannot detect specific low-abundance mutations within those sequences, such as one in 10,000 sequence reads. To overcome this limitation, digital droplet PCR uses water-in-oil droplets, which partition the DNA into thousands of droplets, each of which is PCR amplified separately. After amplification, specific mutations are detected by the TaqMan fluorescent assay. In this manner, rare mutations can be detected and quantified in samples, determined by their presence in a limited fraction of droplets. Examples of this would be the use of circulating DNA to detect mutations of *ALK, PIK3CA*, or *ESR1*. Although modern NGS methods can now directly sequence mutations at a high depth, there are tradeoffs in efficiency that still favor digital droplet PCR in specific circumstances, such as ultrasensitive detection (eg, in minimal residual disease), routinely applied for hematologic malignancies, and quantification of specific point mutations (eg, for therapeutic monitoring of resistance development toward a particular drug).

Microarrays, NGS, and Global Analyses of Transcription

Some RNA analyses measure the expression of thousands of genes simultaneously, and these typically use microarray chips or, more commonly today, NGS (Fig. 2-3).

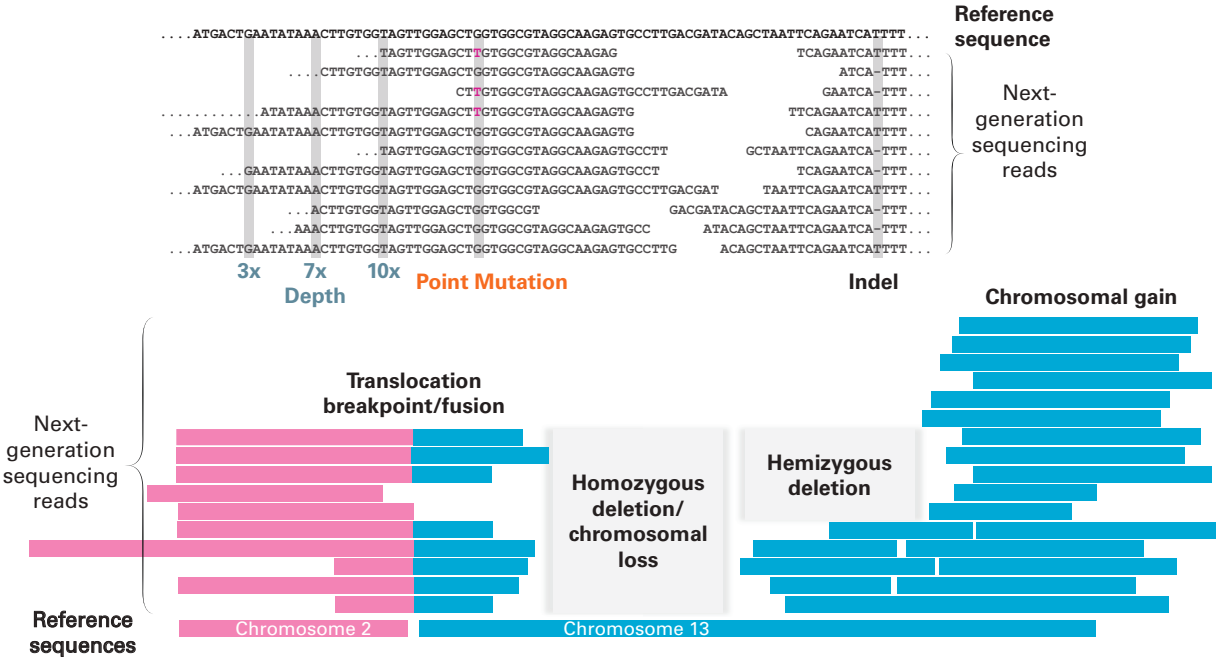
- Microarray chips are small slides on which either oligonucleotides or cDNA probes are spotted in a defined array. By hybridizing cDNA from different conditions onto the oligonucleotides on the chip, each labeled with a different fluorescent dye, it is possible to uncover relative differences in gene expression.
- NGS has largely supplanted array technologies for gene expression analyses, because reads can be mapped to specific gene mRNAs, providing quantitative measures of gene expression.
- Whole-transcriptome sequencing overcomes many of the technical limitations of microarrays by taking an untargeted approach to sequencing that quantifies all transcripts within a given tumor sample.
- RNA sequencing can now be used routinely in some assays for cancer diagnosis and treatment, including separating large-cell lymphomas into high- and low-risk groups and predicting outcomes and therapeutic benefits for women with breast cancer.

Single-cell genomics is now providing crucial insights into tumor heterogeneity and the interactions between tumor cells and stroma. Several technological advances have enabled the application of sequencing to single cells.

- Improved NGS technologies: sequencers such as NovaSeq can provide 20 billion nucleic acid reads of up to 120 bp per run.
- Improved reagents for library preparation: these effectively amplify DNA from single cells, whether genomic DNA or cDNA reverse transcribed from RNA extracted from single cells.
- Cells are barcoded with unique synthesized DNA sequences ligated to each DNA or cDNA before amplification.
- DNAs from all cells are pooled to go on a large sequencing run, and their relationship with each cell is determined by sequencing.

- Unique molecular identifiers are an extension of this concept that overcomes unpredictable biases occurring in nucleic acid amplifications.
- A distinct molecular identifier unique to each DNA molecule is included in the ligated DNA sequence. If a given molecule of DNA or cDNA is amplified in a biased fashion, the repeated unique molecular identifier will allow it to be counted only once.
- Improved microfluidic platforms, such as Drop-seq and the 10× microfluidics platform, allow single cells to be efficiently isolated for nucleic acid extraction, ligation, cDNA preparation, and amplification.
- Emerging techniques include spatial barcoding to preserve spatial relationships through additional barcodes.[48,49]

Figure 2-3 Types of Mutations Discovered by Next-Generation Genomic Sequencing



The upper diagram illustrates the alignment of different sequence reads created during NGS. Sequences are aligned to cover the reference genome. Sequencing depth describes the number of sequences produced, identified, and aligned around a specific region. The point mutation example shows the *KRAS* complementary DNA sequence as a reference and a c.34G > T mutation that results in the G12C variant of *KRAS*. Note that the mutation is not present in all reads of this analysis. Less common variants require a higher number of reads (ie, greater depth of sequencing). The small deletion (indel) has been inserted for illustration purposes only. The lower diagram presents a broader perspective of NGS results. It illustrates the translocation t(2;13) of *PAX3* on chromosome 2 with *FKHR* on chromosome 13, a translocation frequently found in alveolar rhabdomyosarcoma. Also shown are examples of a homozygous or hemizygous loss of chromosome 13, which occurs frequently in retinoblastoma, breast cancer, and prostate cancer, among others. In addition, chromosomal gain may occur in other settings, such as metastatic colorectal cancer.

Single-cell methods are being used to generate comprehensive tumor atlases characterizing the genomic, epigenetic, transcriptomic, and spatial relationships between individual cells within tumors.[50,51] These analyses generate a truly staggering amount of data, with a goal, for example, of providing unprecedented insights into how tumors recruit or evade the immune system, a problem particularly suited for single-cell analyses. Single-cell NGS analyses have been proposed to improve the prediction of which patients may benefit from immunotherapy.[52] These efforts transcend oncology and include atlases such as the Human Biomolecular Atlas Program (HuBMAP) and the Cellular Senescence Program (SenNet) at the National Institutes of Health, which seek to provide an open and global map of human cells.

Research Tools for Modulating Gene Expression and Engineering Genomes: Small Interfering RNAs and CRISPR/Cas9

Knowledge of miRNA function has enabled the development of simple yet powerful laboratory techniques for the inhibition of the expression of virtually any gene in the cell. These techniques, termed RNA interference, use synthetic double-stranded

miRNAs known as small interfering RNAs to efficiently catalyze the degradation of their cognate mRNAs in vitro. Although genes can be inhibited individually, RNA interference is readily scalable such that genome-wide small interfering RNA screens can be used to dissect complex biological pathways to ascertain gene function globally and identify drug targets in cancer cells.[53,54] RNA interference is also making its way to the clinic, because small interfering RNAs can serve as drugs to inhibit gene function. The first RNA interference–based therapy was FDA-approved agent in 2018 for complications associated with a rare hereditary disease, transthyretin amyloidosis. Many RNA interference–based cancer therapies are currently being tested in clinical trials,[55] although applications in oncology are limited.

The recent development of simple and robust genome-editing technologies using the clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9) system has revolutionized science. Cas9 was discovered as a component of the adaptive immune system in bacteria. There are two components to this system. Cas9 is a protein that picks up structured guide RNA molecules to identify and bind specific cognate DNA sequences and then destroys them by cleavage catalyzed by a nuclease domain. CRISPR is an adaptive part of the bacterial genome that constitutes a memory of all bacterial viruses (phages) previously encountered. CRISPR produces guide RNAs that target Cas9 to any of the previously encountered phages. This system can be readily applied to elicit double-strand breaks at a specific location in any genome simply by designing a guide RNA targeting the desired region; this advance led to the 2020 Nobel Prize in Chemistry being awarded to Emmanuelle Charpentier and Jennifer Doudna.

- CRISPR/Cas9 is routinely used in the laboratory for genome engineering to delete or knock out a gene of interest by creating specifically directed double-stranded DNA breaks.
- Alternatively, specific DNA edits can be generated to create or repair mutations by introducing separate DNA fragments that serve as repair templates.
- CRISPR/Cas9 has supplanted RNA interference for whole-genome screens, because synthetic RNA libraries are now available targeting all protein-encoding genes.[56] Key uses of this technology include the following:
  - Discovery of *PTPN2* as a gene involved in immune evasion.
  - Functional characterization of all *BRCA1* variants through saturation genome editing, creating virtually all possible mutations, largely eliminating the historical need to classify variants of unknown significance on this gene.[57]
  - CRISPR/Cas9 can also be used for lineage tracing; one study used this system in mice to continuously generate genetic marks over time, from which the ancestral relationships of every cell in a tumor and metastases could be determined.[58]
  - Ongoing clinical trials are using this technology to genetically reprogram T cells to fight cancer; revert disease-causing mutations in specific diseases, such as sickle cell anemia and muscular dystrophy; and knock out dominant oncogenes, such as human papillomavirus (HPV) *E6*/*E7* in cervical cancer.

However, CRISPR/Cas9 technology has some limitations. Unanticipated off-target effects can occur, particularly when an undesired region of the genome has a sequence similar to that of the target site.[59] In addition, Cas9 screens are more readily useful for loss-of-function screens, where they induce gene deletions rather than gene activations. This has been partly overcome by modifying Cas9 to remove the nuclease domain and replace it with other functions that can increase gene expression or even edit DNA sequences through deamination.[60] In this manner, the CRISPR/Cas9 system can be adapted for virtually any desired enzymatic activity at any particular site in the genome.

KEY POINTS

- NGS methods use computational analysis of short nucleic acid sequence reads aligned with reference genome sequence information.
- NGS can define full mutational landscapes of individual tumor samples, including alterations in DNA sequence, as well as structural changes and epigenetic changes.
- Single-cell NGS provides insights into tumor heterogeneity and the complex cellular interactions within the tumor immune microenvironment.
- Analyses of mRNA by techniques such as reverse transcription PCR or RNA sequencing measure the expression of specific genes in tumor samples. This provides insights into cancer biology, as well as important diagnostic and prognostic information.
- Whole-genome genetic screens using small interfering RNA or CRISPR/Cas9 technologies can identify genes that promote or suppress cancer or mediate resistance to chemotherapy.

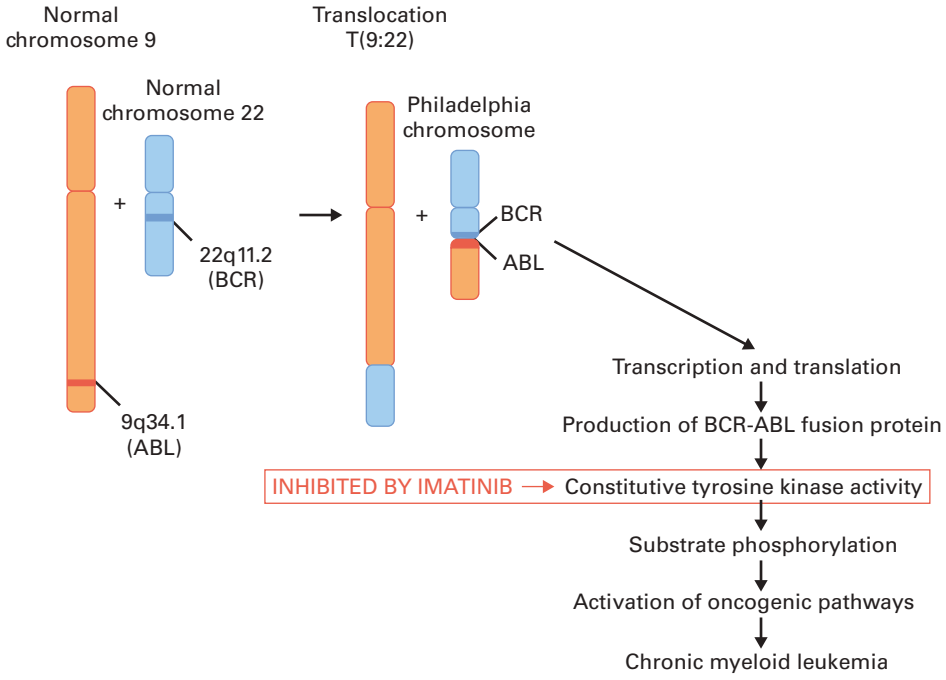
CHROMOSOMAL ANALYSIS

Cytogenetics is the study of chromosomal changes in cells and tissues. Cancer cells often exhibit chromosomal abnormalities that are pathognomonic for specific diseases. Karyotype analyses examine the entire chromosomal complement of a cell or person. Classically, chromosomes are identified from metaphase spreads based on banding patterns and morphology. This process

requires culturing live cells in the laboratory under conditions in which a sufficient number enter mitosis, where they can be captured in metaphase; therefore, this is more suitable for bone marrow specimens and proliferative hematologic malignancies.

Classic karyotyping is often augmented with newer techniques that are more sensitive and can reliably identify specific chromosomes or genetic loci (places on a chromosome that encode a gene). One example is fluorescence in situ hybridization (FISH), which uses fluorescently labeled synthetic nucleic acid probes of prespecified sequences that are incubated with fixed cells and can detect DNA, whether the cell is in interphase (with intact nuclei) or metaphase (with condensed chromosomes). The probes hybridize to their cDNA sequences in the cell, which allows visual inspection of the structure of specific genes using a fluorescence microscope. Chromosome- and gene-specific probes are used to determine the copy number of specific oncogenes. For example, amplification of the *HER2* gene is detected by a high ratio of FISH probe for the HER2 locus (eg, red color) relative to a control region on chromosome 17 (eg, green color); such amplification predicts sensitivity to anti-HER2 therapies. Another common FISH technique uses probes that detect gene fusions (fusion probes) and chromosomal translocations (break-apart probes). For example, the *BCR::ABL* fusion is diagnostic of chronic myeloid leukemia (CML) and is sometimes found in acute leukemias (Fig. 2-4). Similarly, the *EML4::ALK* translocation defines a subgroup of NSCLCs. The identification of these translocations is clinically relevant because it confers sensitivity to tyrosine kinase inhibitors (TKIs). The ability of FISH methods to identify rare cells with abnormal karyotypes makes it useful for detecting residual disease when malignant cells harbor a cytogenetic marker and in diagnostics and treatment stratification (eg, sarcomas with translocations *EWSR1::CREB* [*ATF1, CREB1*], *EWSR1/FUS::NFATC1/2, EWSR1::WT1, ETV6::NTRK3, YAP1::MAML2*, or *EWSR1/FUS::CREB3L1/CREB3L2* or the prominent *MDM2* amplification).[61]

Figure 2-4 Translocation Leading to the Ph Chromosome and Role of BCR::ABL in the Pathogenesis of CML



The Ph chromosome is a foreshortened chromosome 22 resulting from an exchange between the long arms of chromosomes 9 and 22. This leads to the production of a BCR::ABL fusion protein that has constitutive kinase activity and promotes the development of CML. The tyrosine kinase inhibitor imatinib inhibits this constitutive kinase activity and can lead to long-term control of CML.

KEY POINTS

- Karyotyping reveals gross chromosomal structural anomalies in tumor cells, such as translocations and chromosomal deletions.
- FISH techniques detect structural alterations, such as translocations, deletions, fusions, and copy-number variations, directly inside cancer cells.
- Genome alterations identified by FISH are clinically relevant because they can predict sensitivity to molecularly targeted therapies and can be used to detect residual disease in hematologic cancers.

PROTEIN ANALYSIS

As noted, the human genome has approximately 20,400 protein-coding genes yet can generate more than 250,000 distinct proteoforms (protein forms), including exon splicing variants and additional posttranslational modifications, such as phosphorylation, methylation, acetylation, ubiquitination, and sumoylation, among others. Understanding protein production, regulation, and function is integral to understanding cancer. Low-to-intermediate-throughput antibody-based assays for protein detection have been commonly used for decades. Newer methods to study large sets of proteins simultaneously, collectively termed proteomics, are powerful tools to enhance the understanding of cancer and offer the potential for diagnostics that might advance cancer care beyond that achieved with NGS.

ANTIBODY-BASED METHODS

Western Blot and ELISA

- A common laboratory technique for protein analysis is called Western blotting (or immunoblotting), where proteins are solubilized, denatured, and separated by size using gel electrophoresis.
  - After transferring to membranes, the membranes are exposed to detection probes, most commonly antibodies specific to the proteins of interest in the sample.
- Enzyme-linked immunosorbent assay (ELISA) is an analogous technique that allows more precise protein quantification.
  - In ELISA, fixed whole cells or solutions of solubilized proteins from tissue or blood specimens are bound to 96-well plates; specific proteins are then detected using antibodies that have been optimized for sensitivity and specificity.
  - A standard curve can be generated by plating purified protein at various concentrations, thereby allowing quantification of protein levels in test samples.
  - Novel multiplex ELISA technologies measure multiple proteins at one time, allowing for the development of multivariate protein signatures.
- Together, these techniques can detect protein abundance, posttranslational modifications (eg, phosphorylation), and changes in protein size (eg, isoforms of different length).[62]
  - The main limitation of Western blots is the amount of input material, because the target protein cannot be amplified like a nucleic acid. Another limitation is the availability of a specific antibody for the detection of small changes within the protein.

Immunohistochemistry

There are many uses of immunohistochemistry (IHC), especially in tumor subtyping (eg, breast cancer, sarcoma, cancer of unknown primary), prognostic biomarkers (prostate cancer), predictive biomarkers (breast cancer, gastric cancer), diagnosis (lymphoma), detection of molecular alterations, and hormone receptors (prostate cancer, breast cancer; Fig. 2-5).

- Pathology laboratories routinely use antibody-based IHC methods to detect the expression of specific proteins in tumor cells.
  - IHC can be used as a diagnostic tool to define the origins of poorly differentiated cancers or determine squamous cell carcinoma or adenocarcinoma differentiation in lung cancers.
  - IHC is frequently used to subclassify human tumors to refine prognosis and determine treatment.
  - p16 overexpression is a marker for HPV-associated oropharyngeal cancers, which have a more favorable prognosis compared with non-HPV-associated cancers.[63,64]
- HER2 overexpression can be detected by IHC, and this overexpression has both prognostic and therapeutic significance in a subset of breast, gastroesophageal, and other cancers, because these cancers frequently respond to anti-HER2 therapies.[65]
- So far, prognostication and identification for HER2-targeted therapy with anti-HER2 antibodies are limited to cases of strong circumferential membrane staining with IHC alone or a circumferential staining in more than 10% of the cells by IHC, together with a shown amplification as demonstrated by FISH.[66] Amplification of the HER2 locus alone, without detectable overexpression of HER2 at the protein level, does not qualify a patient for anti-HER2 therapy. Despite the positive outcome of the DESTINY-Breast04 trial, further distinction of IHC staining positivity has not been recommended by ASCO in collaboration with the College of American Pathologists (CAP).
- IHC for the detection of MMR proteins has long been used to identify cancers associated with Lynch syndrome, but has now gained much broader use, because clinical data show that dMMR predicts sensitivity to immunotherapy across diverse tumor types.[67]
- IHC largely depends on the preservation method, along with a validated primary antibody. Positive and negative controls are essential, as outlined by CAP.

Flow Cytometry

- Flow cytometry is another important diagnostic technique that can detect multiple proteins on the cell surface.
- Flow cytometry has high sensitivity and throughput and can quantify proteins in individual cells, allowing for the detection of small numbers of tumor cells, such as residual leukemia in normal bone marrow.
- Living or fixed cells are stained with fluorescently labeled antibodies that attach to specific cell-surface proteins. As the cells are applied to the flow cytometer, the fluorescent dyes are excited by a laser with intensity proportional to protein abundance.
- This process, known as immunophenotyping, can classify leukemias and lymphomas based on their cell-surface proteins.
- Flow cytometry can determine eligibility for the rapidly expanding array of monoclonal antibody-based therapies and chimeric antigen receptor T cells, including those targeting CD19 and CD20 (for lymphoma and leukemia), CD30 (for Hodgkin and other lymphomas), CD33 (for acute leukemias), and CD38 (for multiple myeloma).

One limitation of flow cytometry is that the existing fluorescent dyes and lasers are generally limited in the number of proteins that can be simultaneously detected. To extend this, new flow cytometric approaches have been developed to use other methods of detection distinct from fluorescence. One newer technique, known as CyTOF, quantitatively measures up to 100 proteins across thousands of cells, using antibodies each labeled with a distinct mixture of heavy metals that is detected by mass spectrometry (MS).[68] CyTOF is now providing unprecedented high-dimensional information about the many proteoforms detected both in the circulation and in the tumor.

MS-BASED PROTEOMICS

Analogous to the large-scale genomic analyses of DNA sequence or RNA expression, MS is a high-throughput technology that can analyze thousands of proteins simultaneously. MS forms the core of modern proteomics and is used in combination with bioinformatics to quantify and identify the large numbers of proteins present in complex biological samples.[69] These methods are informed by the genome-wide sequencing that allowed the construction of the comprehensive databases used to identify the peptides analyzed by MS. In addition, MS can interrogate protein modifications, such as protein phosphorylation and ubiquitylation, on a large scale.

- MS analysis of tumor samples or serum from patients with cancer can be used to generate proteomic signatures that may influence the selection of therapy.[70]
- Proteomic research involves early cancer detection based on defining protein signatures indicative of early-stage cancers in tissues or peripheral blood.[71]
- Metabolomics, in which MS is used to measure hundreds of cellular metabolites, provides clues as to how metabolic changes affect cancer development and survival, potentially allowing for the development of anticancer therapies.[72]
- MS is most reliable in detecting high-abundance proteins, posttranslational modifications, and cellular metabolites.
- One limitation of MS is that there are no methods to amplify signals comparable to PCR amplification of DNA, affecting the ability to detect small quantities of protein in the sample.

Traditional MS detection of protein involves fragmentation using enzymes such as trypsin to obtain small fragments suitable for MS. The various protein isoforms, truncations, and modifications (eg, methylation, phosphorylation, and acetylation) can then be detected, and the protein forms can be inferred, in what is now termed a bottom-up approach. However, this classic bottom-up approach disallows relating these modifications across a single protein molecule. For example, it is possible that two modifications are present on opposite ends of the protein but are mutually exclusive in a single protein molecule, which could not be detected. To overcome this, top-down proteomics is now becoming available to characterize proteins without trypsin fragmentation. Top-down proteomics can reveal which permutations of modifications exist on each protein molecule; this approach can thereby reveal the many unique proteoforms associated with a given gene.[68]

AFFINITY-BASED HIGH-THROUGHPUT PROTEOMIC APPROACHES

Novel high-throughput proteomic platforms that can measure thousands of proteins have been developed and can better bridge the gap between the proteome and disease. In the past, the gold standard for the detection of growth factors and cytokines in blood was the use of standard ELISAs; however, high-throughput proteomic approaches offer an attractive alternative approach for protein analyses. Platforms such as Olink and SomaLogic allow for the measurement of multiple analytes simultaneously from a single sample. Olink technology is similar to ELISA-based assays in that it uses distinct antibody pairs. However, the system integrates the use of DNA reporter sequences on the antibody pairs, allowing for amplification of the signal via real-time PCR. These additional DNA reporter sequences limit the cross-reactivity of the antibodies and maintain a high degree of sensitivity and specificity. SomaLogic is a different technology that provides high-content protein information. This platform uses aptamers, short synthetic peptide sequences, instead of antibodies for binding to the selected target protein. By modulating the aptamer, key components such as reproducibility, specificity, and sensitivity can be optimized, providing the ability to assess thousands of proteins in a single assay.

KEY POINTS

- Protein analyses reveal protein abundance, as well as functional modifications, such as phosphorylation and acetylation.
- Antibody-based protein detection techniques, such as Western blotting, ELISA, IHC, and flow cytometry, are used in a wide variety of clinical settings, including immunophenotyping for cancer diagnosis and classification, detection of minimal residual disease, and selection of therapy.
- Novel high-throughput protein analyses allow for large numbers of proteins to be analyzed in highly multiplexed fashions.
- MS-based proteomics allows for large-scale analyses of protein expression and modifications in tumor tissues.

ONCOGENES AND TUMOR SUPPRESSORS: ACCELERATORS AND BRAKES ON THE ROAD TO CANCER

Transformation of a normal cell into a malignant cell requires mutations or deletions of genes, termed oncogenes and tumor suppressor genes.[73] To date, several hundred human genes have been implicated as proto-oncogenes, which are genes that have the potential to be converted into oncogenes. Once converted, oncogenes carry dominant gain-of-function mutations (cells with a mutated protein encoded by the oncogene gain a new function, such as evasion of apoptosis), whereas tumor suppressor genes carry recessive mutations that sustain loss of function (tumor suppressor genes cause cancer when they are inactivated by a mutation). Studying oncogene and tumor suppressor gene functions and the processes they control is integral to understanding cancer biology and, increasingly, cancer therapy.

IDENTIFICATION OF ACTIVATED DOMINANT ONCOGENES

Numerous mechanisms, including gene translocations, amplifications, and point mutations, can activate oncogenes. These different types of alterations lead to distinct functional outcomes and often provide important diagnostic and prognostic information.

Chromosomal Translocations and Gene Fusions

Cancers often contain recurrent chromosomal translocations; this is particularly true of many hematologic malignancies, which are characterized by chromosomal translocations that involve immunoglobulin and T-cell receptor genes.[74] Specific translocations have important diagnostic and prognostic implications, serve as molecular markers for the detection of residual disease, and are increasingly recognized as targets for therapeutic intervention. The regions of DNA commonly involved in translocations are termed breakpoints, and they often contain proto-oncogenes that are activated by DNA rearrangement. Although some translocations are evident using conventional cytogenetics or FISH, most clinically relevant translocations in solid tumors have been discovered using NGS technologies, particularly those that cause gene fusion.[75]

Chromosomal translocations can activate proto-oncogenes in two general ways: gene fusion or dysregulated expression without fusion.[76] The more common gene fusion occurs when the translocation joins genes normally separated on the same or different chromosomes into a single translational reading frame, resulting in the production of a novel protein partly encoded by each of the two fused genes. Fusion proteins often involve transcription factors or tyrosine kinases and have biologic activities that differ from those of the parental proto-oncogene. Indeed, several translocations are highly relevant to cancer biology and therapy.

- In hematologic cancers, the *BCR::ABL* fusion that results from the reciprocal exchange of DNA between chromosomes 9 and 22 is known as the Philadelphia chromosome. The resultant gene produces a hybrid mRNA that codes for the BCR::ABL oncoprotein, which constitutively activates the tyrosine kinase activity normally associated with the c-ABL protein.
- In Ewing sarcoma, translocations fuse the *EWS* gene on chromosome 22 to the *FLI1* gene on chromosome 11, and this creates a transcription factor containing a DNA-binding domain derived from FLI1 and a transcriptional activation domain from EWS.[77]
- Alveolar rhabdomyosarcomas also contain pathognomonic translocations, which fuse the *PAX3* or *PAX7* and *FOXO1* transcription factor genes. The presence of these fusions may predict unfavorable clinical outcomes.[78]
- In prostate cancer, translocations that join the androgen-responsive *TMPRSS2* gene with two *ETS* transcription factor genes, *ETV1* and *ERG*, occur frequently and result in abnormal ETS expression driven by the androgen-responsive regulatory elements in the *TMPRSS2* gene.[79]
- In cholangiocarcinoma, *FGFR2* fusions to various upstream partners are commonly found (10%-20%). Tumors with these fusions respond to pemigatinib (overall response rate [ORR] with pemigatinib was 36% in the study that led to FDA approval).[80]
- *NTRK1-3* fusions refer to a highly related group of gene fusions that occur infrequently but can be found across many tumor types. Tumors harboring these fusions are highly responsive (up to 63% ORR) to the TRK inhibitors larotrectinib and entrectinib.[81]
- *RET* fusions to various upstream partners are found in a small fraction of NSCLCs. Tumors harboring these fusions are highly responsive (up to 84% ORR) to selpercatinib.[82]
- Neuregulin 1 (NRG1) fusions with HER3 have been identified to occur in different solid neoplasms, with a frequency of <1%, but are enriched in invasive mucinous adenocarcinoma of the lung and *KRAS* wild-type pancreatic cancer. As of 2024, Zenocotuzumab, a humanized, full-length IgG1 bispecific antibody directed against HER2 and HER3, was approved for these indications.[83-85]

The second type of oncogenic translocation activates proto-oncogenes by deregulating their expression without affecting the structure of the protein they encode.

- An example of this type of translocation is found in Burkitt lymphoma, characterized by translocations that cause the *CMYC* oncogene, located on chromosome 8, to be juxtaposed with immunoglobulin genes that are located on chromosomes 14, 2, and 22. In each case, the translocation deregulates *CMYC* expression by placing it under the control of transcriptional elements contained within the immunoglobulin locus.
- Other examples of proto-oncogenes that are activated by translocations involving immunoglobulin genes include *CCND1*, which encodes the cell-cycle driver cyclin D (found in mantle cell lymphoma and multiple myeloma), and *BCL2*, which encodes the antiapoptotic protein B-cell lymphoma 2 (BCL-2; found in various non-Hodgkin lymphomas).
- Other genomic rearrangements, such as chromosomal segment inversions, create fusion proteins with important therapeutic implications, including the *EML4::ALK* fusion discussed in the previous section.

DNA Amplification

DNA amplification, which results from the duplication and multiplication of the gene locus within the tumor DNA, is another mechanism by which cancer cells increase the expression of a gene product.[74] Amplification is known as high copy number, which describes the excess reads that arise that map to a given oncogene. Normal cells typically harbor two copies of any given gene, but amplification can elevate this to tens or hundreds of copies. Gene amplification can be directly detected, using cytogenetic and

NGS approaches, or indirectly detected, using protein assays, such as IHC, to examine downstream protein expression resulting from the amplification.

- Detection of amplified genes provides important prognostic and treatment-related information, as in cases of HER2 amplification in breast, gastroesophageal, and other cancers, and NMYC amplification in neuroblastoma.
- DNA amplification can also be a mechanism of resistance to targeted therapy. For example, the androgen receptor gene AR is amplified in some castration-resistant prostate cancers.

Point Mutations

Point mutations (changes in only one or a few nucleotides in a gene sequence) can inactivate or impair protein function, and many recurrent point mutations activate dominant oncogenes. Examples of this mechanism of oncogene activation include mutations that alter *KRAS* function in colorectal and other cancers and activating mutations of *EGFR* in lung cancer. Because some common oncogenes, such as *KRAS*, are activated by only a few specific point mutations, these mutations were some of the first that were routinely screened for in cancer specimens.

- NGS can now identify most potentially oncogenic point mutations in primary tumor samples and can do so in timeframes that allow genomic-based treatment decisions.[86]
- One common strategy uses targeted sequencing to interrogate panels of commonly mutated and actionable proto-oncogenes. This approach can provide genomic data in a timeframe and at a cost more concordant with clinical interventions than broader approaches that sequence all protein-coding regions or even whole genomes.

IDENTIFICATION OF TUMOR SUPPRESSOR GENES

Many tumor suppressor genes were first identified through their association with hereditary cancer syndromes. Importantly, the genes responsible for familial cancers are often the same tumor suppressor genes that are inactivated in sporadic cancers. In most familial cancer syndromes, an individual inherits a mutated copy of a tumor suppressor gene and later in life acquires a mutation or deletion of the other normal allele, leaving him or her without a functional copy of the gene, which can lead to cancer development. Recessive oncogenes, in which disruption of both alleles is associated with cancer formation, are known as two-step (Knudson) tumor suppressors, named after classic studies of the *RB* tumor suppressor in RB.[87]

Important exceptions to the Knudson model expand our understanding of how tumor suppressor genes are mutated in cancers. One situation in which a tumor suppressor will not conform to the Knudson model is when the tumor suppressor is inactivated by an epigenetic mechanism, such as when the *CDKN2A* cell-cycle inhibitor gene is silenced by DNA methylation in cancers. In other cases, loss of a single allele of a tumor suppressor is sufficient to confer cancer susceptibility or contribute to neoplastic progression, even when a normal allele persists. This is termed a haploinsufficient tumor suppressor gene.[88] So-called dominant-negative mutations also result in non-canonical tumor suppressor inactivation, because they inhibit the function of the wild-type protein produced by the normal allele, thereby removing the selective pressure to mutate both alleles. As in the haploinsufficient case, only one allele of the tumor suppressor gene will contain a mutation, such as is seen with the *FBXW7* and *SPOP* ubiquitin ligase genes or the *TP53* gene.

Loss of tumor suppressor gene alleles occurs commonly in cancers.[89] In classic studies, delineating a locus involved by allelic loss in a tumor type was often the first step toward identifying a tumor suppressor gene, such as the breast cancer susceptibility gene *BRCA1*.[90] Sites of allelic loss were thus determined by analyzing polymorphic markers, and disease genes were localized to within the smallest common region of allelic loss (Presenting Case Study 1). Today, NGS-based technologies are becoming the method of choice for detecting allelic losses in tumors. NGS approaches also detect numerous other mechanisms that disrupt tumor suppressor gene function, including inactivating point mutations, deletions that lead to premature termination and/or nonfunctional proteins, and promoter methylation.

PRESENTING CASE STUDY 1

A 44-year-old woman presents to her primary care clinician after noticing a left breast lump. Mammography confirms a suspicious lesion in the left breast. Biopsy demonstrates invasive ductal carcinoma that is negative for estrogen receptor, progesterone receptor, and human epidermal growth factor receptor 2 (HER2; ie, triple-negative breast cancer). Her family history is notable for cancer in multiple first-degree relatives, including breast cancer in her maternal aunt and sister and ovarian cancer in her mother. Genetic testing reveals a germline mutation in *BRCA1*.[91] Staging studies demonstrate no evidence of regional or distant disease, and she is treated with surgery and appropriate adjuvant therapy. Three years later, she presents with weight loss, cough, and headache and is found to have extensive metastatic

disease in her lungs, liver, and brain. After brain irradiation, she receives the PARP inhibitor olaparib, which controls her disease for 24 months.[92]

How do the described patient characteristics inform your decision about genetic testing, that is, whole-genome/-exome sequencing?

Tumor sequencing studies have cataloged many different mutations in *BRCA1* or *BRCA2* that can affect the risk of breast and other cancers, including ovarian, prostate, and pancreatic cancers. Importantly, although *BRCA1* was first identified as a cause of familial cancers, rare sporadic tumors also harbor mutations in this gene. The BRCA1 protein is now known to be a key component of the normal cellular response to DNA damage, one of the hallmarks of cancer. The loss of the DNA-damage response results in selective sensitivity to certain drugs, including PARP inhibitors and platinum compounds, and some patients with *BRCA*-mutated cancer show prolonged responses to these agents. Patients with *BRCA* mutations more frequently exhibit triple-negative breast cancer, which is often known to metastasize and does not respond to drugs that work in several other subtypes of breast cancers, like anti-hormones, aromatase inhibitors, or anti-HER2-directed antibodies, as well as chemotherapies. The underlying biology of these tumors calls for a different approach, and PARP inhibitors have shown some benefit.[92]

Because cells can function well with a single copy of a tumor suppressor, these genes are commonly associated with heritable cancer predisposition syndromes, such as RB, Li-Fraumeni syndrome (*TP53*), Cowden syndrome (*PTEN*), and hereditary breast and ovarian cancer syndrome (*BRCA1* and *BRCA2*). Individuals with these syndromes can develop cancer through loss of heterozygosity of the residual gene copy in an at-risk tissue.[93]

Due to the hereditary nature of *BRCA* mutations, patients in this category develop tumors much earlier than people without these mutations, oftentimes before reproduction. Certainty about the nature of a potential tumor predisposition may inform decisions on reproductive health, as well as preemptive surgeries like prophylactic mastectomy or salpingo-oophorectomy.

Information about the heritable nature of this disease might be relevant to any relatives of the patient since it will inform their decisions on genetic testing and its possible consequences.

KEY POINTS

- Proto-oncogenes are normal cellular genes that can be converted into oncogenes by mutations or epigenetic mechanisms, which alter their normal function or expression.
- Oncogenes encode proteins that are activated in tumors by mechanisms such as amplification, point mutation, and translocation. Oncogenes operate dominantly, and alteration of a single gene is sufficient to promote transformation.
- Tumor suppressor genes are inactivated in tumors by mechanisms such as deletion, point mutation, and gene silencing. Because they act in recessive fashion, the other copy of the gene must be deleted, typically by loss of heterozygosity.

CELLULAR FUNCTIONS OF ONCOGENES AND TUMOR SUPPRESSORS

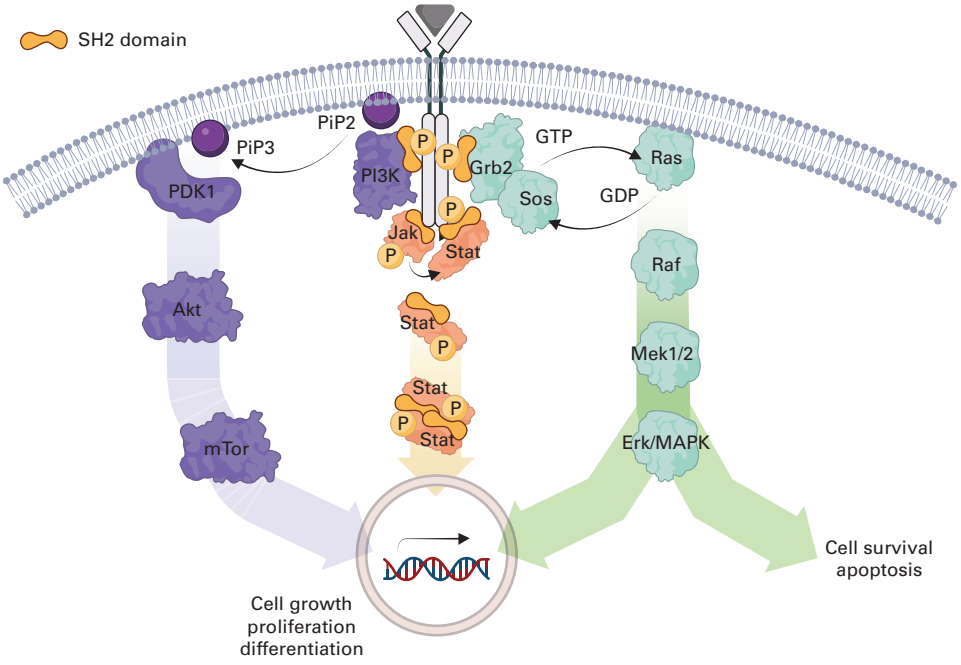
- Many oncogenes are found within the pathways that govern cell division and differentiation in response to specific signals.
- Oncogene mutations also affect other global cellular pathways and processes, including metabolism, programmed cell death (apoptosis), and protein degradation.
- Oncogene alterations are gain of function, which means that only one copy, or allele, of the gene needs to be mutated to impart biologic effects.
- Tumor suppressors serve to counter the effects of oncogenes and have a particularly important role in maintaining the integrity of the genome by suppressing errors during DNA replication and coordinating the response and repair mechanisms triggered by DNA damage.
- Tumor suppressors restrain oncogenic transformation, and typically, their function must be completely lost to confer cancerous transformation. Typically, one copy of a tumor suppressor is mutated, and the other is deleted.
- Deletion is termed loss of heterozygosity because the tumor seems to have only one copy of the gene, which is mutated.

MITOGENIC SIGNAL TRANSDUCTION PATHWAYS

Cell division is triggered by signal transduction pathways that are stimulated when growth factors bind to specific cell-surface receptors. Most growth factor receptors are anchored in the cell membrane such that an extracellular domain is available for

growth factor (ligand) binding and an intracellular domain interacts with downstream signaling molecules (Fig. 2-6). The intracellular portion of a class of growth factor receptors, called receptor tyrosine kinases (RTKs), catalyzes the addition of phosphate to tyrosine residues. Ligand binding causes RTKs to dimerize and autophosphorylate, which recruits signaling proteins that transmit the mitogenic signal down several parallel pathways. Cytoplasmic tyrosine kinases also transduce these mitogenic signals. Kinases are often activated in cancer through dominant mutations, amplifications, and translocations. These genetic alterations lead to overactive signaling, often by nullifying or bypassing negative regulatory processes that would usually attenuate these pathways. Essentially, the checks and balances that are present in normal cells are disrupted in cancer cells, leading to uncontrolled growth.

Figure 2-6 Mitogenic Signaling



This figure shows schematically the binding of an extracellular signal (dark gray triangle) to a transmembrane receptor (light gray structure transversing the cell membrane) that is being phosphorylated in the process, usually on tyrosine residues, yielding phosphotyrosines (Ps in yellow circles). Adapter molecules containing SH2 domains bind to the phosphotyrosines and recruit effector proteins in doing so. The examples in this figure (purple) are phosphoinositide 3-kinase (PI3K) and its downstream target phosphoinositide 3-kinase-dependent kinase (PDK1), which, in turn, activates protein kinase B (Akt). Akt activates the mammalian target of rapamycin (mTor), that is exerting promitogenic transcription, differentiation, or cell growth in the cell nucleus. Also, SH2 domain-containing molecules may recruit (orange pathway) Janus kinases (Jaks) and signal transducers and activators (Stats). Jaks phosphorylates Stats on tyrosine residues, amplifying the original signal from the transmembrane receptors. Stats themselves can shuttle into the nucleus and initiate or promote the described processes. The green route illustrates the amplification of the original phosphotyrosine signal via the growth factor-bound protein 2 (Grb2) and rat sarcoma protein (Ras) and its subsequent effectors. Activation of this route may lead to cell growth, proliferation, and differentiation, or cell survival and diminished apoptosis.

RAS proteins are membrane-tethered intracellular enzymes that transduce signals for cell division. RAS activity is regulated by binding to guanosine triphosphate (GTP) or guanosine diphosphate (GDP).[94] Thus, RAS activity reflects a balance of G nucleotide exchange factors that activate RAS by replacing bound GDP with a new molecule of GTP and GTP-activating proteins, which hydrolyze RAS-bound GTP to GDP. There are three closely related RAS family members (*KRAS, NRAS*, and *HRAS*), and all are mutated in human cancers. Oncogenic *RAS* mutations affect amino acids that interface with GTP-activating proteins at residues 12 and 13, which results in overactivity of proliferative signaling pathways. Furthermore, GTP-activating proteins themselves can function as recessive oncogenes (eg, the *NF1* gene is a GTP-activating protein that acquires a loss-of-function mutation in neurofibromatosis).[94]

Of the *RAS* genes, *KRAS* is most commonly activated through mutation in a variety of cancers, including pancreatic cancer, NSCLC, and colorectal cancer. Most activating *KRAS* mutations mutate the glycine at position 12. Mutations that alter this side chain, most commonly G12D, G12V, or G12C, constitutively activate the GTPase activity of *KRAS*. Tumor cells that harbor this activity are thus not well suited to targeting upstream signaling events (Presenting Case Study 2).

RAS drives mitogenic signaling via three parallel signal transduction pathways: the mitogen-activated protein kinase (MAPK) pathway (which activates transcription factors), the RAL/CDC42 pathway (which regulates membrane and cytoskeletal changes), and the PI3K pathway (which affects many cellular functions, including protein synthesis and apoptosis). In addition to activation by RAS, the MAPK and PI3K pathways can be activated independently of RAS by mutations in other pathways that also use these signaling components.

- The MAPK pathway is stimulated by the RAF serine/threonine kinase and signals to additional downstream cytoplasmic serine/threonine kinases, which ultimately activate MAPKs and other effectors. MAPK signaling activates nuclear proto-oncogenes, which are transcription factors, such as FOS, JUN, and MYC.
- Mutations of the BRAF gene, specifically V600E mutations, are found in approximately 50% of malignant melanomas.
- The PI3K-AKT pathway phosphorylates various target proteins to stimulate transcriptional and translational responses that affect diverse cellular processes, including cell growth and division, apoptosis, protein synthesis, and cellular metabolism.
- AKT is a protein kinase that is downstream of PI3K and is often amplified and/or overexpressed in cancers.[95]
- Cancers exhibit elevated AKT activity caused by mutations in regulatory genes, such as the PTEN tumor suppressor, which is commonly deleted in cancers, opposing PI3K and preventing AKT activation.[95]
- Each of these processes may be abnormal in cancers with PI3K mutations, which are among the most common mutations found in cancer cells.[8,95,96]

PRESENTING CASE STUDY 2

During a routine visit in 2009, a 37-year-old woman who quit smoking 5 years prior was diagnosed with colorectal cancer (CRC) that seemingly infiltrated neighboring structures. The doctor determined that it should be removed surgically and referred the patient accordingly. She received neoadjuvant 5-fluorouracil, leucovorin, and oxaliplatin (FOLFOX) therapy to shrink the tumor, thereby making it amenable to surgery. The left-sided tumor was removed and staged as ypT4aN0.[97]

Postoperatively, she presented for regular follow-up, and after 8 years, a singular 3-cm liver metastasis was discovered and surgically removed. The liver metastasis was analyzed at the molecular level to provide hints for further definitive treatment options. Because molecular testing indicated wild-type *RAS*, wild-type epidermal growth factor receptor (*EGFR*) status, and a mutated p53 gene (*TP53*), she continued with six rounds of FOLFOX with cetuximab within a clinical trial.[98] She remained tumor and metastasis-free for the next 3 years, until an 8-cm lesion was discovered on the liver, with smaller lesions in her lungs. She received external-beam radiation therapy to the lung and six rounds of 5-fluorouracil, leucovorin, oxaliplatin, and irinotecan (FOLFOXIRI) with cetuximab. The liver metastasis shrank to 5 cm in diameter, but major vessels were still in the way of surgery. She then received brachytherapy to the liver. Re-biopsy showed a newly acquired *RAS* mutation. With limited therapeutic options available, she opted to participate in a clinical trial evaluating the combination of pembrolizumab and lenvatinib, an immunotherapy agent combined with a novel tyrosine kinase inhibitor.[99]

One year into the clinical trial, she experienced excruciating stomach pain and decided with her oncologist to continue pembrolizumab and discontinue lenvatinib, owing to its severe side effects and the threat of a perforated stomach. Her stomach pain resolved with antacid and nonsteroidal anti-inflammatory drug usage, and she slowly restarted lenvatinib. Shortly after, she developed severe jaundice. Initial attempts at resolving the biliary obstruction failed, and she was weaned off pembrolizumab and given glucocorticoids to resolve the noninfectious hepatitis. She remained jaundiced and was in and out of the hospital over the next 7 months. Ascites fluids were removed twice before she was hospitalized again with severe hepatitis. Her physicians explained her late palliative situation.

How would recent advancements in tumor biology impact the treatment decisions in this case?

In recent years, there has been a shift in CRC occurrence toward a younger age (<50 years). Often, this shift coincides with the reproductive age of those affected. Surgery is still the mainstay of treatment for locally confined and advanced CRC, perhaps followed and/or preceded by chemotherapy, usually 3 to 6 months of FOLFOX or capecitabine and oxaliplatin (CAPOX), depending on the risk of recurrence. Even today, this approach of surgery and (neo)adjuvant chemotherapy remains the standard of care. However, more comprehensive molecular testing of the tumor would have been performed, now that better tests and more therapeutic agents are available.

When this patient's tumor was initially evaluated, limited testing was available, and precision oncology had limited integration into clinical practices. The tumor showed no microsatellite instability, deeming her eligible for chemotherapy. Wild-type *KRAS* status meant that the tumor would most likely be susceptible to EGFR inhibition. The fact that *KRAS*-mutated clones dominated the subsequent biopsy indicates both the clonal evolution of this tumor and the necessity for a treatment change. Vascular endothelial growth factor (VEGF)-targeted agents had not been part of this patient's previous regimens and seemed a valid option at the time. Her participation in a clinical trial involving pembrolizumab and lenvatinib highlights the ongoing search for effective treatment for CRC in the metastatic setting, yielding negative results more frequently than anticipated.

How does the p53 mutation play a role in the treatment decision?

A p53 mutation conveys an inferior prognosis compared to wild-type p53.[100] Individuals who smoke often exhibit p53 inactivation, either in an epigenetically silenced form or as a somatic mutation.[101]

What about mutated *KRAS*?

Initially, the tumor presented as a KRAS wild-type tumor, but later converted to a KRAS-mutant tumor upon subsequent biopsies. Mutated *KRAS* meant a tumor was no longer amenable to EGFR-directed therapy. However, in the current landscape, this limitation has been overcome using agents that specifically target mutated KRAS. Sotorasib in combination with panitumumab and adagrasib in combination with cetuximab are now approved as *KRAS G12C* inhibitors for patients with metastatic CRC who have undergone FOLFOX/IRI treatment and experienced recurrence. Therapeutic development in this area continues to expand.

Should all possible options be tried?

While pembrolizumab is active in a subset of CRCs, patients with microsatellite instability-high and microsatellite-stable disease have not been shown to benefit from immunotherapy, and in today's therapeutic landscape, a patient with a microsatellite-stable tumor would not receive checkpoint inhibitors. Lenvatinib is a tyrosine kinase inhibitor that primarily acts on the VEGF receptor. Stomach ulceration is a frequent adverse event resulting from lenvatinib, as is noninfectious inflammation with immune checkpoint inhibitors, both of which tend to be difficult to control under real-world conditions. The patient's hope for prolongation of life while enrolling in the trial played a pivotal role in clinical decision-making and all subsequent treatments.[99] Today, knowing the negative results of the trial, we would discourage the patient from participating and opt for the highest quality of life possible, ideally with comfort measures.

TARGETING MITOGENIC KINASES IN CANCER CHEMOTHERAPY

The concept of specifically inhibiting mutated oncoproteins in cancer falls under the umbrella term targeted therapy and has been heavily applied to mitogenic kinases in cancer. In cases where the roles of individual kinases in specific cancers have been recognized for a long time, such as HER2 in breast cancer and BCR::ABL in CML, targeted therapies are already well established. However, the NGS-driven revolution in molecular oncology now allows targeted approaches to be directed against a much larger number of cancers that contain sensitizing gene mutations. Although targeted therapies will be discussed in detail in subsequent chapters in the context of specific organ sites and therapies, a general overview of these concepts is provided here. Several therapeutic strategies that target aberrant RTKs are in clinical use.

- One approach uses antibodies that bind to and inhibit RTK activation. Examples include trastuzumab, which antagonizes HER2 activity and is used in the treatment of breast cancers with *HER2* amplification,[102-104] and cetuximab, an inhibitory antibody that binds to EGFR and is approved for use in metastatic colon cancer and head and neck cancers.[103,104]
- Another important strategy to target RTKs and mitogenic kinases in cancers uses small-molecule inhibitors, such as imatinib, erlotinib, crizotinib, vemurafenib, and larotrectinib, which bind to specific kinases and inhibit their catalytic activity. The most recently approved TKIs are mentioned at the beginning of this chapter.
- Many available inhibitors have improved efficacy in tumors that contain mutations within the target kinase. The concept of directing small-molecule inhibitors against tumors with specific activating gene mutations lies at the crux of precision oncology.
- Kinase inhibitors can also be used to treat tumors that depend on the activity of a kinase pathway but do not have mutations in the kinase itself. Examples of this approach include the treatment of chronic lymphocytic leukemia with idelalisib (which inhibits PI3K-δ) and the treatment of mantle cell lymphoma and chronic lymphocytic leukemia with ibrutinib (which inhibits BTK).[105]

RESISTANCE TO KINASE INHIBITORS

Despite the remarkable activity of small-molecule kinase inhibitors, the development of resistance limits the durability of clinical responses. An exception to this is the use of imatinib and related drugs to inhibit BCR::ABL in CML, where responses are extremely durable, lasting more than 10 years on average.[106] In other cancers, impressive initial responses eventually give way to resistant and progressive disease much more quickly, often in 1 year or earlier (eg, use of BRAF inhibitors in melanoma).[107] However, this is not the case for all situations, because durable responses exceeding 2 years have been reported in *NTRK* fusion cancers treated with larotrectinib and *RET*-altered cancers treated with selpercatinib.[108,109] Tumors acquire resistance to kinase inhibitors in several ways.[14]

- First, new mutations develop in the target kinases, which render the targeted therapy ineffective. In some cases, the mutated kinases can still be effectively inhibited by related small molecules. An example of this mechanism occurs in CML, where the acquisition of *BCR::ABL* mutations leads to the production of proteins that can no longer be inhibited by imatinib, but related agents, such as nilotinib, can reinstate inhibition.
- Second, bypass pathways develop, where tumor cells rewire their mitogenic signaling to use alternative pathways. In this case, although the target kinase is still sensitive to the pharmacologic inhibitors, the tumors have escaped kinase inhibition through the activation of alternative signaling pathways. An example of this mechanism is the activation of alternative RTKs in lung cancers being treated with EGFR inhibitors. One approach to overcome this type of resistance is the use of additional kinase inhibitors to block the bypass pathway, such as targeting both the BRAF and MAPK pathways in melanoma.

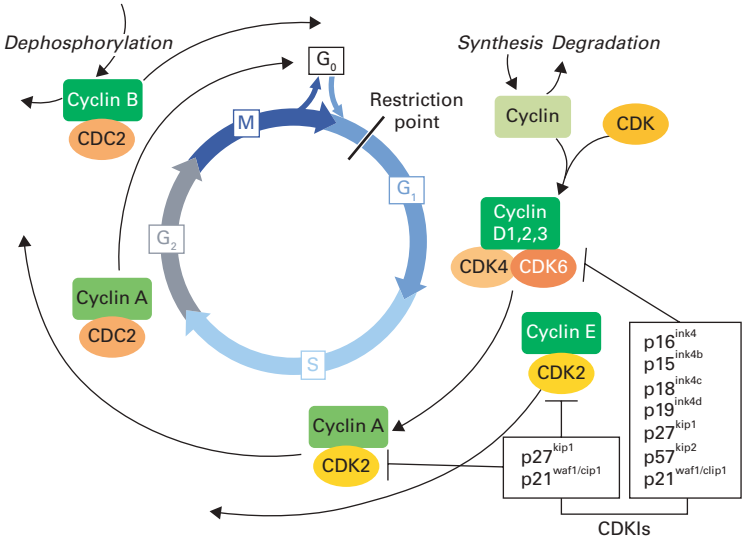
CELL-CYCLE CONTROL

Cell cycles are divided into four phases that coordinate cell growth, DNA replication, and cell division (Fig. 2-7). Under ordinary conditions, cells execute the cell division cycle faithfully, but in cancer, several steps can go awry.

- The G1 phase is a period of growth between mitosis and the onset of DNA synthesis during which cells integrate mitogenic signals and, under certain conditions of mitogenic drive, commit to the onset of DNA replication.
- The S phase is the period of DNA synthesis during which a cell replicates its genomic material.
- The G2 phase follows the S phase and is the second period of cell growth.
- In mitosis, or M phase, chromosomes are segregated to daughter cells, and cell division occurs.

Cyclin-dependent kinases (CDKs) are the master regulators of the cell cycle. CDKs drive cell-cycle transitions by phosphorylating proteins, driving altered functional roles specific to the new phase of cell division. CDKs are composed of two subunits: a catalytic

Figure 2-7 The Cell Cycle



The cell cycle is divided into four phases (G1, S, G2, and M). Progression through the cell cycle is promoted by CDKs, which are regulated positively by cyclins and negatively by CDK inhibitors. The restriction point is the point at which cells progress through the cell cycle independently of external stimuli.
Abbreviation: CDK, cyclin-dependent kinase.
Reproduced with permission from Schwartz GK, Shah MA. Targeting the cell cycle: a new approach to cancer therapy. *J Clin Oncol*. 2005;23:9408-9421. doi:10.1200/JCO.2005.01.5594

subunit (the CDK) and a regulatory subunit (the cyclin) that activates the CDK. Specific CDK-cyclin pairs are involved in distinct cell-cycle transitions. Innate protein CDK inhibitors counteract CDK activity to prevent premature cycling. A balance between these two opposing activities is central to the regulated control of cell growth and division.

- Cyclins and CDKs can act as dominant oncogenes.
- The cyclin D gene (*CCND1*) is rearranged by chromosome inversion in parathyroid adenomas, translocated to the immunoglobulin G heavy-chain locus in mantle cell lymphomas, and amplified in 10% to 15% of solid tumors.
- The cyclin E gene (*CCNE1*) is the second most commonly amplified gene in ovarian cancer,[110] and cyclin E is upregulated in cancers by increased transcription or prolonged protein stability.[111]
- CDKs can also be mutated; for example, the *CDK4* mutation found in familial melanomas prevents its inhibition by INK4 proteins.[112] Pharmacologic inhibitors of CDK4 and CDK6 cancers, including palbociclib, ribociclib, and abemaciclib, are used with antiestrogens to treat hormone receptor–positive breast cancer.[113]
- Genes encoding CDK-inhibiting proteins are often tumor suppressors.

APOPTOSIS

Cell death can occur via multiple mechanisms, including necrosis, which is an unregulated process triggered by various cellular insults, and apoptosis, an active and highly regulated physiologic process whereby complex biochemical pathways control whether a cell lives or dies. Tumor growth is a consequence of both unrestrained cell division and decreased apoptosis, and the pathways that mediate apoptosis contain proto-oncogenes and tumor suppressor genes that are altered in cancers (Fig. 2-8). There are two distinct apoptotic pathways[114]:

- The intrinsic or mitochondrial pathway results from a number of stimuli, such as radiotherapy and chemotherapy, and involves changes in the mitochondrial membrane that affect the release of cytochrome C into the cytoplasm. The intrinsic pathway also activates a caspase cascade that ultimately leads to DNA fragmentation and cell death.
- The extrinsic pathway is signaled when ligands, such as tumor necrosis factor α (TNF-α) and Fas ligand, bind to cell-surface death receptors, such as TNF receptor 1 and FAS. Ligand binding to death receptors initiates a sequence of events leading to activation of proteases, termed caspases, which execute the apoptotic response.

The BCL-2 family comprises proteins that regulate apoptosis, which are either proapoptotic (promote cell death) or antiapoptotic (promote cell survival).[115] *BCL2* was first identified as the gene activated by the t(14;18) translocation that is found in follicular lymphomas. The realization that BCL-2 functions to prevent apoptosis was pivotal to understanding the relationship between aberrant apoptosis and cancer biology. The precise mechanisms by which BCL-2 prevents cell death are not fully elucidated, but they involve interactions with proapoptotic family members, as well as alterations in mitochondrial functions. One important consequence of BCL-2 overexpression in tumorigenesis is that it prevents the apoptosis normally triggered by dominant oncogenes, such as *CMYC*, and this likely underlies the aggressive behavior of double-hit lymphomas, which contain activating translocations of both the *CMYC* and *BCL2* genes.[116] Because of their potential to induce apoptosis in tumor cells, drugs that target the BCL-2 protein family are being widely studied in clinical trials, and venetoclax is now approved for treatment of chronic lymphocytic leukemia and AML (Presenting Case Study 3).[35,117-119]

PRESENTING CASE STUDY 3

A 76-year-old man presents to the clinic with decreasing energy and pallor over the last few weeks. Complete blood count shows pancytopenia. Bone marrow evaluation demonstrates myelodysplasia as well as AML with complex cytogenetics. Chronic medical comorbidities include chronic obstructive pulmonary disease, congestive heart failure, and stroke. The patient is treated with the demethylating agent 5-azacytidine in combination with venetoclax, a B-cell lymphoma 2 (BCL-2) inhibitor.[117] He requires blood and platelet transfusions but otherwise tolerates therapy reasonably well, with no need for hospitalization, minimal decline in performance status, and no dose reductions. The treatment combination leads to a sustained partial response before he eventually develops marked cytopenias. Repeat bone marrow evaluation shows AML progression, and his therapy is discontinued. He dies under hospice care shortly thereafter.

Given the patient's age and comorbidities, which course of action would you have taken?

Usually, the treatment of patients with AML comprises induction therapy to generate remission. Subsequently, patients may undergo further chemotherapy, radiation therapy, or, ideally, a stem cell transplant. This patient's age

and comorbidities disqualify him from induction chemotherapy, for example, with idarubicine and cytarabine.[120] Cytosine methylation inhibitors have long been known to have clinical activity in hematologic cancers, including myelodysplastic syndromes and AML. Furthermore, large-scale analysis of human myelodysplastic syndromes and AML samples with methylation arrays showed that abnormal methylation is an important driver of cancer progression, because early, intermediate, and transformed myelodysplastic syndromes have increasing levels of methylation. This underscores the relevance of an emerging hallmark of cancer, non-mutational epigenetic reprogramming (see Fig. 2-1).

Although abnormal apoptosis, another hallmark of cancer, was not inferred to be a major driver of AML, preclinical laboratory studies showed that inhibitors of the antiapoptotic protein BCL-2 had clear clinical activity. Given the relatively low toxicity associated with methylation inhibitors and BCL-2 inhibitors, trials combining these two approaches were initiated in patients unfit for standard intensive chemotherapy. The dramatic effectiveness of this approach led to trials evaluating this combination in fit patients as well.[35,117]

Many cancer genes interact with the core apoptotic pathways. The most common mutations that impair apoptosis in tumors involve the *TP53* tumor suppressor gene. Apoptosis is one outcome of TP53 activation by cellular stress, and impaired cell death is an important consequence of TP53 loss in cancer. Another signaling pathway that prevents apoptosis is the PI3K-AKT pathway. The interactions of AKT with apoptotic signaling are complex and include direct effects on the mitochondrial membrane, as well as functional interactions with BCL-2 family members, FOXO transcription factors, nuclear factor κB, and p53.

Classically, apoptosis is one of four major types of cell death, the others being autophagy, necrosis, and entosis, the cellular process in which one cell invades and is engulfed by another living cell, leading to the formation of a single hybrid cell.[121] The first two types of cell death were classified as programmed death; however, recent discoveries have upset the ontology of programmed cell death. For example, ferroptosis, discovered in 2012, is an iron-dependent mechanism of programmed cell death.[56] The relevance of ferroptosis and other mechanisms of programmed cell death in cancer therapy is not clear.

KEY POINTS

- Mitogenic signaling pathways contain broadly acting proto-oncogenes, and their products are tyrosine kinases. Small-molecule kinase inhibitors and antibody-based therapeutics target many of these proteins.
- Genes that promote or inhibit the normal cell cycle are commonly mutated in cancer cells and are becoming important targets for cancer treatment.
- Many oncogenic mutations disrupt normal apoptotic responses. Inhibitors of proapoptotic proteins constitute another important new class of anticancer drugs.

UBIQUITIN-MEDIATED PROTEIN DEGRADATION

The precise control of protein abundance within a cell is critical to many cellular processes. The rapid degradation of specific proteins is accomplished through the ubiquitin-proteasome system. This process first requires site-specific modification, typically phosphorylation, of the protein to be degraded, which serves as a flag that the protein is no longer required in the cell. Next, a multienzyme process catalyzes the transfer of chains of the small protein ubiquitin to the phosphorylated target. Families of enzymes, known as E1s, E2s, and E3s, play specific roles in this ubiquitination step. Finally, this polyubiquitination causes the protein to be recognized and then degraded by a proteolytic organelle called the proteasome.[122] Additional control of this process is provided by a family of deubiquitinating enzymes, which can remove polyubiquitin chains before degradation takes place. Furthermore, shorter forms of ubiquitin chains can be added to proteins to signal events in addition to degradation, such as protein-protein interactions and intracellular signaling events.

Given their critical role in the control of protein abundance, enzymes involved in the ubiquitin-proteasome pathway are often altered in cancers. E3 ubiquitin ligases, the enzymes that catalyze the final transfer of ubiquitin to substrates targeted for degradation, are particularly important oncogenes and tumor suppressors.

- The E3 ubiquitin ligase *FBXW7* is one of the most commonly mutated tumor suppressor genes across cancer types.[123] The Fbxw7 protein targets numerous key oncoproteins for degradation, including cyclin E, c-MYC, Notch, and c-JUN, whereas inactivating *FBXW7* mutations prevent degradation of these oncoproteins.
- The *SPOP* ubiquitin ligase gene was recently identified as a tumor suppressor gene and is also involved in the DNA repair process. *SPOP* mutations may predict sensitivity to DNA-damaging agents.[124]

- von Hippel-Lindau (VHL) syndrome is diagnosed by the presence of germline-inactivating *VHL* mutations. One critical VHL target is hypoxia-inducible factor 1α, a transcription factor that regulates genes in response to hypoxia, including an angiogenic transcriptional program that contributes to the highly vascular tumors associated with VHL loss.
- Inactivating mutations of the VHL E3 ubiquitin ligase are the cause of VHL syndrome, which is associated with susceptibility to renal cell carcinoma, central nervous system hemangioblastomas, pheochromocytoma, pancreatic tumors, and other neoplasms.
- In other cases, E3s are overexpressed and act as dominant oncogenes. One example of this involves MDM2, a ubiquitin ligase that targets the p53 protein for degradation, and the abundance of which is increased in cancers by mechanisms such as gene amplification.[125]

Proteasome inhibitors, which block protein proteolysis by the proteasome, have emerged as important antineoplastic agents, particularly for the treatment of hematologic cancers.[126,127] Bortezomib, carfilzomib, and ixazomib are useful in the treatment of multiple myeloma and other hematologic malignancies. Other inhibitors of the proteasome or more specific proteasomal pathways are currently being studied in clinical trials. Given that general proteasome inhibitors affect a large number of proteins normally degraded by the proteasome, the mechanisms that account for the therapeutic index associated with these inhibitors remain unclear. In addition to general proteasome inhibitors, activators or inhibitors of specific components of the ubiquitin ligase pathway are of great clinical interest. For example, inhibitors of the SPOP ubiquitin ligase have been developed and show activity in kidney cancer models.[128]

The ubiquitin-proteasome system also plays a role in the actions of other chemotherapeutics. For example, thalidomide and related drugs cause the cereblon E3 ubiquitin ligase to abnormally degrade specific protein substrates, which may explain their efficacy in myelodysplastic syndromes with chromosome 5q deletions and in multiple myeloma.[129]

New therapeutics, known as proteolysis-targeting chimeras or selective degraders, are being designed to hijack the ubiquitin-proteasome system to selectively degrade a protein of interest. These small molecules operate with two active domains: one that binds a target protein with high affinity, and a second that engages an E3 ubiquitin ligase. In this manner, an oncogene or another desired therapeutic protein target can be selected for cancer therapy.

CONTROL OF CELLULAR DIFFERENTIATION AND CELL FATE

Most somatic cells exist in a terminally differentiated postmitotic state, which is established by complex transcriptional pathways. Master regulators of cellular differentiation and related processes are often involved in cancer.

Wnt/β-Catenin Pathway

An important example of this concept is the Wnt/β-catenin pathway, which has vital roles in development and cellular self-renewal. Indeed, abnormal Wnt signaling is implicated in many cancers.[130]

- Soluble Wnt proteins bind to membrane-bound receptors, and this prevents the ubiquitin-dependent degradation of β-catenin by the proteasome. β-Catenin then translocates to the nucleus, where it stimulates a transcriptional program in concert with the T-cell factor/lymphoid enhancer factor transcription factor.
- Regulation of this pathway is quite complex, and many proteins augment or restrain Wnt pathway activation.
- The best-characterized role of Wnt pathway activation in human cancer is in familial adenomatous polyposis, a hereditary colon cancer syndrome caused by deletion of the adenomatous polyposis coli (APC) tumor suppressor[131] (also described in Chapter 13).
- APC loss upregulates Wnt signaling by increasing β-catenin stability, leading to inappropriate transcription. Although first described in familial adenomatous polyposis, *APC* mutations are found in most sporadic colon cancers and are an early step in colorectal cancer progression.[132]
- Many other cancers also have aberrant Wnt signaling, including uterine cancers, brain cancers, and some leukemias.[14]

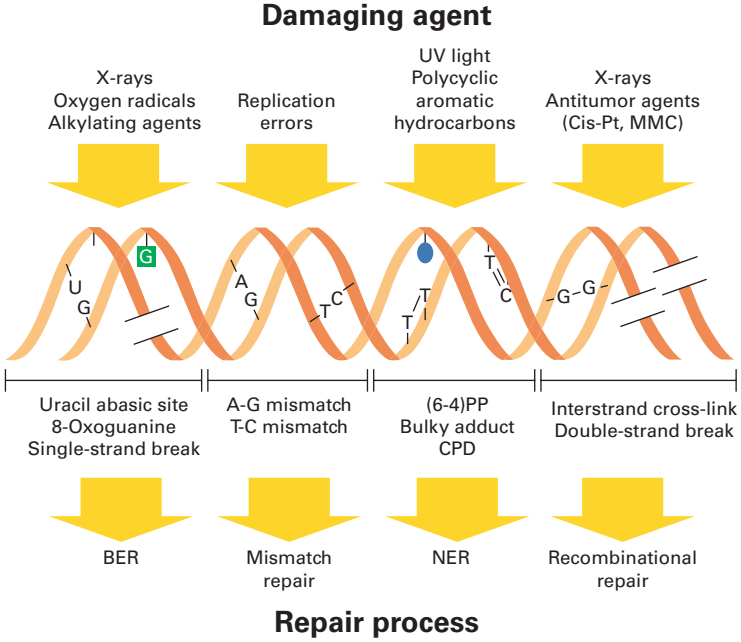
Other Pathways Regulating Cellular Differentiation

Many other proto-oncogenes affect the pathways that regulate differentiation.[133]

- Retinoic acid receptor α (RARα) is rearranged in several translocations found in acute promyelocytic leukemia, most commonly t(15;17), which produces a PML::RARα fusion protein. This fusion protein acts as a dominant-negative mutation that inhibits expression of RARα target genes and blocks differentiation.
  - The PML::RARα fusion is targeted by all-*trans* retinoic acid, which is used in conjunction with combination chemotherapy to induce remission in patients with acute promyelocytic leukemia. All-*trans* retinoic acid binds to the fusion protein and prevents it from bringing corepressors to RARα target genes, reversing the differentiation block and allowing promyelocytes to proceed down their normal differentiation pathway.[134]

- Core-binding factor is another transcription factor regulating hematopoietic differentiation that is involved in translocations found in acute leukemia. These translocations [inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB::MYH11*] produce dominant-negative proteins that inhibit core-binding factor target gene expression, which is thought to impair hematopoietic cell differentiation.[135]
- *NOTCH* genes encode transmembrane receptors that influence transcriptional programs involved in cell fate and differentiation and are frequently altered in human cancers.[136]
- NOTCH signaling is activated by ligand binding, which causes NOTCH proteins to be cleaved, forming intracellular domains that translocate to the nucleus and activate transcription.
  - NOTCH proteins play important roles in lymphoid differentiation and are likely drivers of hematologic cancers. *NOTCH1* was first described in a subset of patients with T-cell acute lymphocytic leukemia, and activating *NOTCH1* mutations occur in as many as 50% of patients with this disease.[137]
  - *NOTCH* may act as a tumor suppressor in some cancers, because 20% of squamous cell carcinomas show inactivating mutations in these genes. How *NOTCH* acts as an oncogene in some clinical situations and as a tumor suppressor in others remains poorly understood.[138]
  - Nirogacestat, a γ-secretase inhibitor that blocks the activation of NOTCH, is approved for the management of desmoid tumors.[139]
- The hedgehog signaling pathway is another example of a molecular process intricately involved in development and cell fate decisions that is hijacked by cancer cells to promote abnormal growth.
  - Hedgehog itself is an extracellular ligand that binds to and activates the Ptch1 cell-surface receptor, which, in turn, allows activation of the Smo cell-surface receptor. Smo sends intracellular signals that ultimately lead to the Gli transcription factor activating gene expression programs that drive cellular phenotypes.
  - Mutations or other alterations in hedgehog signaling components can be found in both hereditary and sporadic tumors and are especially important in basal cell skin cancers and medulloblastomas.
  - Specific inhibitors of components of this pathway, including the Smo inhibitors erismodegib, glasdegib, and vismodegib, are approved for the treatment of basal cell cancers and leukemias and are being tested in other disease states. Arsenic trioxide, which is approved for the treatment of acute promyelocytic leukemia, is thought to function in part because of the inhibition of Gli transcription factors.[140]

Figure 2-8 DNA Lesions and Repair Mechanisms



Common DNA-damaging agents (top), examples of lesions that can be introduced by these agents into the DNA double helix (middle), and the most frequently used repair mechanisms for such lesions (bottom). Distinct damaging sources can induce similar types of DNA lesions, and any one agent often induces more than one type of damage. The lesion spectra of different repair pathways may overlap.
Abbreviations: BER, base excision repair; CPD, cyclobutane pyrimidine dimer; MMC, mitomycin C; NER, nucleotide excision repair.

DNA REPAIR PATHWAYS

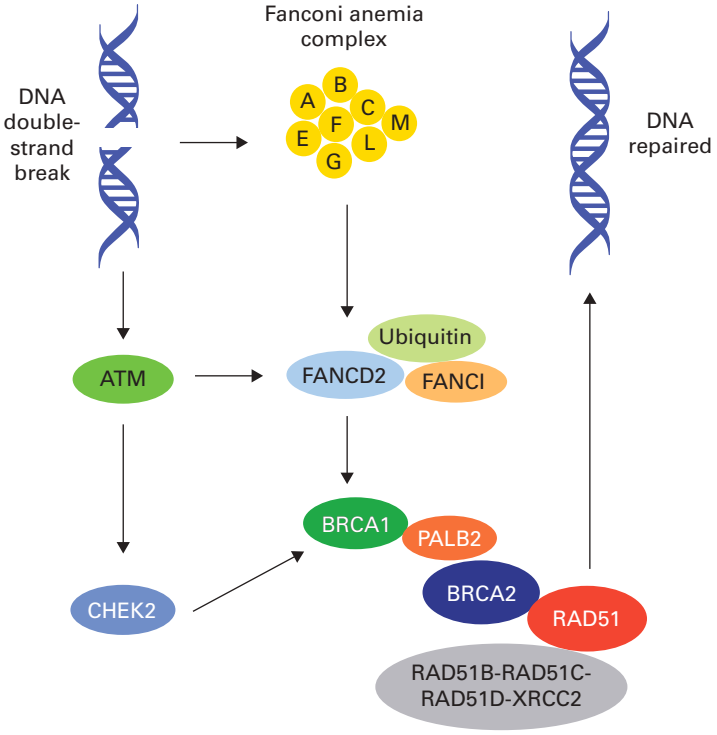
Mammalian cells use three major DNA repair pathways to maintain genomic integrity. The nucleotide excision-repair (NER) pathway recognizes and repairs UV light–induced nucleotide dimers and other DNA adducts. DNA recombination repair corrects double-strand DNA breaks induced by ionizing radiation and other agents. Finally, the DNA MMR pathways correct errors during DNA replication by removing the mismatched strand and enabling subsequent repair of the DNA. Mutations that disrupt these pathways cause genetic instability and are associated with inherited diseases characterized by sensitivity to DNA-damaging agents and by cancer predisposition (Fig. 2-8).

NER Pathways

NER pathways correct nucleotide lesions induced by UV light and adducts induced by chemical carcinogens, such as platinum substances.[141] There are two NER pathways: a global repair pathway and a transcription-coupled repair pathway that repairs DNA damage occurring during transcription. Germline mutations affecting these pathways give rise to sun-sensitive and developmental disorders, including xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy. Xeroderma pigmentosum is an autosomal-recessive disorder leading to neurodegeneration, sensitivity to UV light, abnormalities in skin pigmentation, and cancer predisposition. People with this disorder have a risk of skin cancer that is estimated to be 2,000 times higher than that of the general population. Eight genes have been associated with xeroderma pigmentosum; seven code for excision-repair proteins, and one is a DNA polymerase required for accurate replication of damaged DNA. Patients with NER deficiency are platinum resistant. By contrast, Cockayne syndrome is associated with two genes, *CSA* and *CSB*, which are involved in transcription-coupled DNA repair. Trichothiodystrophy is caused by a mutation of either *ERCC2/XPD* or *ERCC3/XPB*; both encode helicase subunits of the TFIIH transcription complex. Neither Cockayne syndrome nor trichothiodystrophy is associated with an increased cancer risk.

Base excision repair is a related process that can repair damaged DNA via a process that begins with excising the damaged base from the deoxyribose backbone and is suited to repairing a string of 1 to 10 nucleotides. *MUTYH* is an example of a DNA glycosylase that initiates this process, and germline mutations in this gene can predispose individuals to colorectal cancer.

Figure 2-9 Recombinational Repair of DNA Double-Strand Damage



DNA double-strand breaks recruit protein kinase ATM and also activate the Fanconi anemia core complex (FANCA/B/C/E/F/G/L/M) that monoubiquitinates the downstream targets FANCD2 and FANCI. ATM activates (phosphorylates) CHEK2 and FANCD2, and, in turn, CHEK2 phosphorylates BRCA1. Ubiquitinated FANCD2 complexes with BRCA1 and RAD51. The PALB2 protein then acts as a hub, bringing together BRCA1, BRCA2, and RAD51 at the site of a DNA double-strand break and also binds to RAD51C, a member of the RAD51 paralog complex RAD51B-RAD51C RAD51D-XRCC2 (BCDX2). The BCDX2 complex recruits RAD51 or stabilizes the damage sites. RAD51 plays a major role in homologous recombinational repair of DNA during double-strand break repair. In this process, an ATP-dependent DNA strand exchange takes place in which a single strand invades base-paired strands of homologous DNA molecules. RAD51 is involved in the search for homology and the strand-pairing stages of the process.

Homologous Recombination Pathway

Damage to DNA by radiation, chemicals (eg, chemotherapy), and other insults produces double-strand breaks, which are recognized and repaired by a coordinated response that involves proteins encoded by a wide range of tumor suppressor genes (Fig. 2-9). Germline mutations of some of these genes cause inherited syndromes with highly variable clinical manifestations. Ataxia telangiectasia is characterized by progressive cerebellar ataxia, telangiectasia, immunodeficiency, and increased tumorigenesis (most commonly hematopoietic neoplasms). The ataxia telangiectasia gene (*ATM*) encodes a large protein kinase with homology to PI3K. ATM is activated by serine phosphorylation in response to DNA breaks and phosphorylates a number of downstream substrates with critical roles in DNA repair and checkpoint pathways, including CHK2, TP53, BRCA1, and NBS1.[142] Cells derived from patients with ataxia telangiectasia exhibit increased DNA damage from radiation, as well as defects in normal cell-cycle responses to DNA damage, called checkpoints.

Fanconi anemia is an autosomal-recessive disease characterized by developmental abnormalities, bone marrow failure, and susceptibility to cancers, particularly AML, squamous cell cancer of the head and neck, gynecologic cancers, and esophageal cancer. Similar to ataxia telangiectasia, cells derived from patients with Fanconi anemia display aberrant responses to DNA-damaging agents. However, Fanconi anemia cells are not hypersensitive to ionizing radiation; rather, they are hypersensitive to DNA cross-linking by agents, such as diepoxybutane and mitomycin C. Classic studies defined many Fanconi anemia complementation groups, and 13 Fanconi anemia genes have now been cloned. Remarkably, many of these genes encode proteins that form a complex that catalyzes the monoubiquitination of two Fanconi anemia proteins, FANCD2 and FANCI.[139] Monoubiquitinated FANCD2 and FANCI become localized to nuclear repair foci after DNA damage, and these foci also contain FANCD1 (identical to the *BRCA2* breast cancer gene) and other proteins, including BRCA1 and NBS1. The intersection of the BRCA1 and FA pathways underscores the central importance of this DNA-damage sensing and repair mechanism in carcinogenesis.

The NBS1 protein is another component of nuclear repair foci implicated in a chromosome breakage syndrome. Nijmegen breakage syndrome is an autosomal-recessive disease characterized by microcephaly, immunodeficiency, and increased frequency of hematopoietic cancers that is caused by mutations in the *NBS1* gene. NBS1 forms a complex with MRE11 and RAD50, which binds to BRCA1 in nuclear repair foci. Deficiency of the NBS1 protein blocks the formation of the MRE11-NBS1-RAD50 complex, and this impairs the S-phase surveillance responses triggered by ATM. Accordingly, many of the symptoms of this disease are identical to the symptoms of ataxia telangiectasia.

Mutations in many components of the DNA-damage response (DDR) pathway can be found in both hereditary and sporadic cancers. Identification of these mutations is clinically relevant because they may predict sensitivity to PARP inhibitors and DNA-damaging agents, such as cisplatin. Ongoing studies are testing the efficacy of these agents in various tumor types with mutations in DDR components. Interestingly, tumors associated with germline DDR mutations may respond much more dramatically than those with somatic DDR mutations, suggesting that the timing of the mutation during tumor development is important.

DNA MISMATCH REPAIR

DNA MMR corrects errors that occur during DNA replication, which are primarily single-base mismatches or short insertions or deletions.[143] A complex of proteins binds to a DNA mismatch, identifies the DNA strand with a mismatch, and then excises and repairs the mismatch. Several of the MMR proteins are tumor suppressors involved in hereditary nonpolyposis colon cancer. People with hereditary nonpolyposis colon cancer/Lynch syndrome are at significantly increased risk of colon and uterine cancers, with increased risk of cancers in other organ sites as well.[144] The two most commonly mutated MMR genes in Lynch syndrome are *MSH2* and *MLH1. MSH2* is involved in the initial recognition of the mismatch, whereas *MLH1* helps determine which DNA strand contains the correct sequence. Mutations in other MMR genes are less commonly associated with hereditary nonpolyposis colon cancer and include *MSH6, PMS1*, and *PMS2*. Patients with hereditary nonpolyposis colon cancer inherit a nonfunctional MMR gene allele, and a subsequent loss of the remaining allele in a somatic cell ultimately gives rise to a tumor. Importantly, impaired MMR causes a hypermutable phenotype, as evidenced by MSI, which is readily detected in tumors by PCR-based assays that evaluate specific tumor DNA microsatellite fragments. Although MSI is the hallmark of hereditary nonpolyposis colon cancer, it is also found in a subset of sporadic colon cancers, but in these cases, *MLH1* is typically silenced by promoter hypermethylation rather than by gene mutation. Although dMMR proteins have been classically analyzed using IHC methods, NGS DNA analysis approaches can now be used to detect the presence of MSI in tumors, as described earlier.

The detection of dMMR/MSI in tumors is of high clinical relevance because it predicts a high probability of deep and prolonged responses to immune-modulating programmed cell death 1 (PD-1) inhibitors, including nivolumab and pembrolizumab.[39] High MSI (dMMR) was the first FDA-approved biomarker that was tissue agnostic and not based on the site of anatomic origin of the tumor. More recently, tumor mutation burden, which quantifies the number of mutations present in a specific cancer specimen and is likely a surrogate marker of defective MMR, also predicts the efficacy of immune-modulating agents.[145] Outside of dMMR, high tumor mutation burden can be driven by highly mutagenic oncogenic stimuli, such as chemical carcinogens, or by mutations in the proofreading domains of DNA polymerases α and ε, encoded by POLD1 and POLE, respectively.[49] Pembrolizumab is now FDA approved for solid tumors with high tumor mutation burden, as defined by at least 10 mutations per megabase.[145] It should be noted that although the FDA approval was tumor agnostic, the efficacy at this cut point was more prominent for some cancer types (eg, uterine and colorectal cancers) than others.

KEY POINTS

- Enzymes that promote protein degradation by the proteasome can function as tumor suppressors.
- Pharmacologic proteasome inhibitors are approved for the treatment of multiple myeloma and other hematologic cancers.
- Genes that regulate cellular differentiation are often mutated in hematologic cancers. Drugs that restore normal differentiation are important treatments for these diseases.
- DNA repair pathways contain many tumor suppressor genes that are mutated in both familial and sporadic cancers. Mutations that disable different elements of DNA repair pathways are associated with specific cancer syndromes.
- Inactivation of DNA-damage repair genes may predict response to PARP inhibitors and DNA-damaging agents.
- Inactivation of DNA MMR enzymes leading to MSI and high tumor mutation burden predicts response to PD-1 inhibitors.

CHECKPOINTS: CROSSROADS OF DNA REPAIR, CELL-CYCLE REGULATION, AND GENETIC INSTABILITY

The fidelity of the enzymes that replicate DNA and segregate chromosomes is largely responsible for the accurate propagation of genetic information. However, these enzymes have an intrinsic error rate, and the frequency of errors is increased by genotoxic insults. Normal cells continually monitor DNA replication and mitosis and stop the cell cycle if these do not occur correctly, allowing the damage to be repaired before proliferation resumes or apoptotic and/or senescent responses are initiated to block cell growth. The pathways that link cell-cycle progression to the accurate execution of prior cell-cycle events are called cell-cycle checkpoints.[146] (Note that this section refers to checkpoints as molecular processes that safeguard the genome from damage; such checkpoints are wholly distinct from the checkpoints present in the immune system that are targeted by immunotherapy.)

Mammalian cells have checkpoints that operate in each phase of the cell cycle and are intricately interwoven with the cell cycle and DNA repair machinery. The G1 and G2 checkpoints recognize DNA damage that occurs during these cell-cycle phases and initiate responses leading to either cell-cycle arrest or cell death. The S-phase checkpoint is also activated by DNA damage, as well as by inhibition of the proper function of the replication machinery (eg, by chemotherapeutics, such as hydroxyurea and cytarabine).

Checkpoint pathways are composed of sensors/mediators, signal transducers, and effectors. Sensors and mediators detect DNA damage and form protein complexes that accumulate in DNA repair foci. The DNA-damage signal is then transmitted by kinases, first ATM and ATR, and subsequently CHK1 and CHK2, which ultimately activate effectors, such as p53 and Cdc25. These regulate key processes, including cell-cycle progression, apoptosis, and DNA repair. Small-molecule inhibitors of many of these checkpoint kinases have been evaluated as anticancer therapeutics, although the activity to date has been modest at best. Importantly, checkpoint pathways, particularly p53 signaling, are disrupted in a large fraction of human cancers, where they are central drivers of genetic instability and tumor progression.

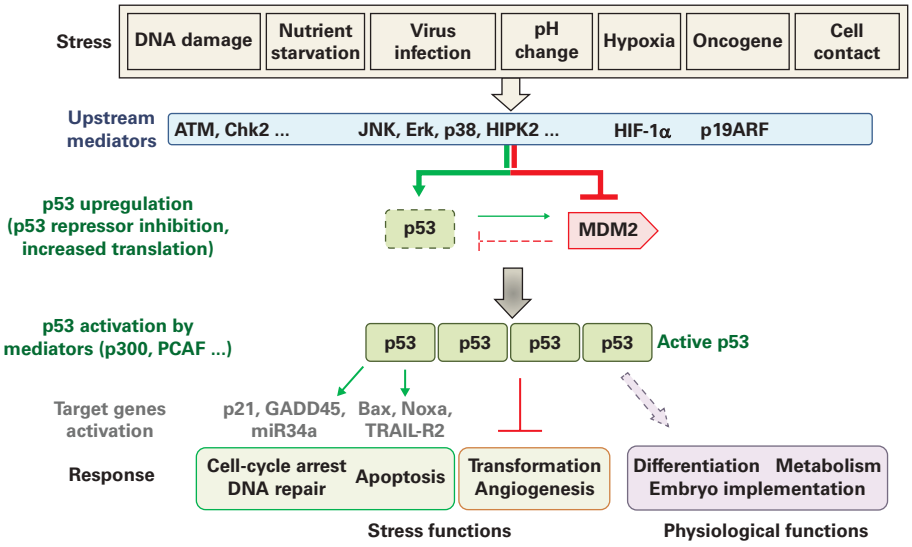
P53 PATHWAY

The p53 protein plays a central role in checkpoint pathways, and its cognate *TP53* gene is the most frequently mutated human tumor suppressor (Fig. 2-10).[147,148] Although *TP53* is mutated in up to half of all spontaneous cancers, its role as a tumor suppressor first came to light in studies of Li-Fraumeni syndrome, a rare autosomal disorder associated with the development of a wide variety of early-onset cancers, including soft tissue and bone sarcomas, as well as breast, brain, and colon cancers.

- The p53 protein is a transcription factor that is activated by many triggers, including DNA damage and replication stress.
- Activation of p53 can lead to cell-cycle arrest, apoptosis, or cellular senescence.
- Tumors most commonly inactivate *TP53* by a combination of loss of one gene copy coupled with mutation of the other copy, resulting in the expression of a protein with inactivating amino acid changes within critical functional domains.
- Another mechanism of suppression of p53 in tumors involves the MDM2 ubiquitin ligase.[125] *MDM2* gene expression is induced by p53, and the MDM2 protein functions in a negative feedback loop to downregulate p53 through ubiquitination.
- MDM2 is overexpressed in a wide spectrum of neoplasms, where it leads to decreased p53 abundance and function.
- Another gene that affects p53 degradation is the *ARF* tumor suppressor, which is frequently deleted in cancers.[149]
- ARF normally binds to MDM2, and this prevents MDM2 from ubiquitinating p53; however, when the *ARF* gene is deleted, MDM2 activity is unrestrained, causing p53 to be degraded.
- ARF expression is induced by oncogenes such as *MYC* and plays an important role in TP53 activation by oncogenic signaling. Thus, loss of ARF disables an important protective mechanism against oncogenic transformation.

There is enormous interest in developing cancer treatment strategies that target the p53 pathway, because studies in model systems have shown that restoration of p53 function has potent antitumor activity. Strategies that target the p53 pathway range from peptides that restore p53 protein function in cells with mutated p53 proteins to recombinant adenoviruses that selectively

Figure 2-10 The p53-MDM2-ARF Network



The activation of p53 classically occurs in response to many other cellular stresses that produce DNA damage, including oncogene-induced stress. Depending on the nature of the inducing signal, these DNA-damage responses activate a myriad of upstream mediators that lead to upregulation and activation of p53. This, in turn, results in activation of p53 target genes that serve to counteract the initiating cellular stress and protect the cell from further damage. When p53 is mutated or deleted, as it is in most cancers, these critical safeguards no longer function, and cellular stress continues unabated.
Uncovering the role of p53 splice variants in human malignancy: a clinical perspective by Surgent et al, taken from OncoTargets and Therapy © 2014 Surget et al. kill cells with *TP53* gene mutations. However, targeting remains a challenge because no clear targetable synthetic lethal vulnerability specific to TP53 has emerged since Wee1 inhibitors failed in clinical trials. It is now known that specific *TP53* mutations may have distinct functional activities. Specific mutations of *TP53* can elicit gain-of-function mutations.[150] This suggests that different therapeutic approaches might be required for each type of *TP53* mutation.

MITOTIC SPINDLE CHECKPOINT

The mitotic spindle assembly checkpoint ensures that chromosomes are equally segregated to daughter cells during mitosis.[151] It is the key safeguard against the gain or loss of whole chromosomes and other changes in chromosome structure, known collectively as chromosomal instability (CIN).

- During mitosis, chromosomes attach to the mitotic spindle through complex submicroscopic protein structures called kinetochores.
- In normal cells, the presence of unattached kinetochores signals that mitosis should not proceed to divide chromosomes toward the incipient daughter cells. This signal involves a conformational change of MAD2 into a closed form that binds Cdc20 and inactivates anaphase-promoting complex/cyclosome (APC/C; not to be confused with the adenomatous polyposis coli gene, known as *APC*).
- Kinetochores that are unattached to the mitotic spindle recruit MAD2 in the open conformation to bind MAD1. This interaction switches MAD2 to the closed form, which is released from the kinetochore as a soluble factor, instructing the cell to wait.
- A single unattached kinetochore is sufficient to maintain this wait signal, ensuring that the APC/C ubiquitin ligase remains in the off state until the cell is ready for accurate chromosome separation. Once all kinetochores are attached, the soluble signal from closed MAD2-Cdc20 is lost, and the APC/C activates to initiate the ubiquitination and turnover of cyclin B and securin, allowing cells to commit to chromosome segregation to new daughter cells.
- CIN is a common feature of cancer, more common than MSI.[152] Unlike in DNA-damage checkpoint genes, mutations in the genes controlling the mitotic checkpoint are rarely found in human cancers.

Perhaps the best-known case is in mosaic variegated aneuploidy, an extremely rare heritable condition characterized by CIN (variegated aneuploidy) and high cancer risk and caused by mutation of the kinetochore protein, BubR1.[153] The cause of CIN in

most tumors remains a mystery, given the dearth of mutations in kinetochore or mitotic regulatory proteins. These findings suggest that most CIN is caused indirectly by loss of other cell-cycle checkpoints or nongenetic changes, such as extra centrosomes that create error-prone cell divisions.[154] Furthermore, CIN is not simply present or absent in a tumor but can occur to various degrees in cancer, leading to distinct cancer behaviors. However, no standard or direct measures of CIN are available for routine use, and this feature, cell-by-cell variability of karyotypes in a tumor, is not measured by routine DNA sequencing, which averages the DNA levels across thousands of cells in a tumor.

KEY POINTS

- Checkpoints ensure the fidelity of cell division and protect against genomic instability.
- Checkpoint pathways are often dependent on normal tumor suppressor gene and DNA repair protein functions.
- Loss of checkpoint functions causes genomic instability and fosters the accumulation of multiple mutations in cancer cells.
- *TP53* is the most commonly mutated cancer gene, and it participates in diverse checkpoint responses. The p53 protein senses and responds to cellular stress by activating pathways that regulate processes such as cell-cycle progression and apoptosis.
- The mitotic checkpoint protects against chromosome loss, but this process is error-prone in many cancers, leading to CIN.

INFECTIOUS AGENTS AS DRIVERS OF CANCER

Infectious agents contribute to the pathogenesis of approximately 15% of all cancers worldwide, affecting more than 2 million people.[155] Examples of cancers that are associated with chronic viral infection are as follows:

- HPV: squamous cell carcinomas of the head and neck, cervix, penis, vulva, vagina, and anus
- Epstein-Barr virus: Burkitt and other types of lymphoma, nasopharyngeal carcinomas, and some stomach cancers
- Hepatitis B and C viruses: hepatocellular carcinoma
- HIV and Kaposi sarcoma–associated herpesvirus: Kaposi sarcoma
- HTLV-1: adult T-cell lymphoma
- Merkel cell polyomavirus: Merkel cell carcinoma

Extensive research has elucidated some of the molecular mechanisms infectious agents use to drive carcinogenesis. As noted, retroviruses can cause cancer through insertional mutagenesis. Other cancer-causing viruses express proteins that interfere with critical cancer pathways.

- HPV E6 protein promotes degradation of the tumor suppressor p53, affecting the DDR and DNA repair response, and HPV E7 promotes degradation of the cell-cycle inhibitor RB, driving cell growth, division, and proliferation.
- Whereas Epstein-Barr virus-associated lymphomas are characterized by a translocation involving the CMYC oncogene, Epstein-Barr virus also promotes B-cell survival and transformation via molecular mimicry, because Epstein-Barr virus gene products mimic activated cell-surface receptors and antiapoptotic proteins.
- Hepatitis B and C proteins promote the expression of genes associated with angiogenesis, enhanced cell motility, invasion, and metastasis.

In fact, many oncogenic viruses produce protein products that affect most of the hallmarks of cancer.[156] Given that virus-associated cancers frequently subvert normal cellular processes, the study of these cancers often yields insights into the biology of sporadic cancers. These insights include the identification of new oncogenes or tumor suppressor genes, as well as more complex aspects of tumor biology (eg, immune surveillance).

Although viruses are most commonly associated with cancer, other pathogens also contribute to carcinogenesis. Chronic infection with the intestinal bacteria *Helicobacter pylori* is associated with stomach cancers and low-grade lymphomas.[157] Similarly, hepatobiliary cancers, which are much more common in Southeast Asian populations, are in some cases associated with endemic infection with liver flukes.[158] Although less is known about the molecular mechanisms driving these cancers, chronic inflammation likely plays a major role.

Given the large number of human cancers associated with infections, there is much interest in preventing and/or treating the pathogens that increase cancer risk. Examples include the use of HPV vaccines to prevent squamous cell carcinoma and universal vaccination against the hepatitis B virus to decrease the incidence of hepatocellular cancers.[159] Elimination of *H. pylori* may prevent gastric cancer and often induces remission of gastric mucosa–associated lymphoid tissue lymphoma.[160,161] As more is learned about the molecular mechanisms driving infection-related cancers, targeted agents that specifically block the functions

of viral gene products will likely be developed. Finally, viral proteins expressed on the surface of pathogen-associated cancer cells represent attractive targets for various immunotherapeutics.

KEY POINTS

- Infection-associated cancers are common, affecting more than 2 million people per year worldwide, and most of these cancers result from chronic viral infections.
- Infectious agents frequently subvert molecular pathways related to the hallmarks of cancer, including cell-cycle checkpoints, proliferation, and apoptosis.
- The study of infection-associated cancers provides insights into the molecular basis of sporadic cancers.

EMERGING CONCEPTS IN TUMOR HETEROGENEITY AND EVOLUTION

Whereas initial studies from TCGA and other consortia were aimed at cataloging gene mutations and other changes in primary tumors from a wide range of organ/tissue types, later efforts included analyses of multiple biopsies from the same tumor, concurrent biopsies of primary and matched metastatic lesions (synchronous), and multiple biopsies over time (metachronous). Newer studies include single-cell NGS approaches. These data allow comprehensive studies of genetic heterogeneity within a single tumor, as well as the dynamic process of tumor evolution at various stages of the disease and its treatment.[15,162] It is now apparent that tumors may exhibit heterogeneous cell populations with distinct genetic changes at their earliest stages and that the idea of a linear progression of tumor evolution is overly simplistic.[15] In one seminal example, analysis of separate regions within a single primary renal cell carcinoma revealed marked genetic heterogeneity.[163] Heterogeneity has important implications for the selection of therapies based on the presence of targetable mutations in a single biopsy specimen, and it also informs our understanding of tumor evolution. For example, inactivation of the tumor suppressor *VHL* was the only genetic lesion present in all samples from a single renal cell carcinoma in the study by Gerlinger et al.[163] By contrast, other frequently mutated genes exhibited multiple and distinct mutations within different areas of the tumor. This suggests a model where the heterogeneous landscape of primary tumors serves as the substrate for subsequent tumor evolution, during which specific clones are enriched or lost as tumors grow, invade, and metastasize.

Molecular comparisons of metastatic lesions with their antecedent primary tumors reveal a similarly complex picture of tumor evolution, including the maintenance and/or enrichment of founder mutations, as well as new mutations unique to the metastatic lesions.[164,165] Indeed, discrete metastases can have markedly different genetic profiles. Together, these types of studies reveal complex models of tumor evolution, such as parallel evolution, where subclones within a single tumor may evolve independently of one another, and convergent evolution, where unique clonal populations develop molecularly distinct, but functionally equivalent, alterations in common cancer pathways. It should be noted that many studies of tumor evolution are based on exome or genome sequencing only; therefore, other molecular events such as copy-number variation, epigenetic effects, and proteomic changes are less understood. Finally, large-scale genetic changes, such as CIN or chromothripsis (extensive DNA rearrangements that cluster in specific genomic regions), can be seen in both primary and metastatic tumors. Whether these changes are causes or consequences of tumor evolution remains controversial, but there is much interest in targeting these processes in the clinic.[166,167]

Although understanding the heterogeneity and evolution of a patient's tumor could greatly affect therapeutic decisions, serial tumor sampling via invasive biopsy techniques is not readily feasible or favored by patients. However, leveraging improved technology for liquid biopsy, where a variety of circulating biomarkers can be isolated from routine blood draws, allows for easier sampling across the cancer continuum, from diagnosis to treatment to surveillance.[168] At diagnosis, liquid biopsies may simplify the identification of targetable mutations, especially when primary biopsy specimens are limited or uninformative. Commercially available genetic panels can be used to look for driver mutations in lung and other cancers using whole blood. Because liquid biopsies can monitor tumor evolution in real time, they can also serve as adjuncts to standard assessments of tumor response/progression after therapy has begun. For example, serial sampling of circulating tumor DNA from patients with *KRAS* wild-type colorectal cancer was used to investigate mechanisms of resistance to cetuximab.[169] This analysis showed evidence of *KRAS*-mutated subclones that were enriched after prolonged cetuximab therapy. Notably, cetuximab withdrawal led to resensitization of the tumor to this agent. Similarly, in lung cancer, blood can be used to look for secondary resistance mutations in driver genes, such as *EGFR* T790M, that arise after treatment with certain kinase inhibitors. The specific driver mutation can provide clues that influence drug choice in subsequent lines of therapy.

Finally, as the tools for monitoring become more sensitive, liquid biopsy may prove useful in other disease settings. Current studies are underway to explore the use of circulating biomarkers for early detection (tumor screening in asymptomatic individuals) and minimal residual disease (surveillance for recurrence after therapy). However, for now, these approaches remain investigational.

MODELS OF HUMAN CANCER

Genetic techniques developed over the last two decades now make it possible to create mouse models that recapitulate sporadic human cancers with increasing fidelity. The first generation of genetically engineered mouse models involved expressing oncogenes from transgenes (genes injected into oocytes) or developing knockout strains in which genes were inactivated by homologous recombination in mouse embryonic stem cells.[170] Hundreds of genes have been studied with these techniques, which have led to important advances in the understanding of gene functions in development and tumorigenesis. In fact, these methods are still in wide use today. However, these strategies affect gene expression early in development and, in the case of knockouts, affect every cell in an organism. These characteristics limit the ability to model human cancers, which sequentially acquire rare mutations in somatic cells.

Many cancer genes are lethal when disrupted in the mouse germline or lead to rapidly developing neoplasms in one tissue, precluding studies of slower-growing cancers. Various mouse genetic engineering strategies have been developed to circumvent these problems, for example, by restricting mutations to specific cell types or tissues or by temporally controlling gene mutation through the use of molecular switches. These approaches have led to mouse models that much more closely recapitulate human cancers.[171] Furthermore, the use of CRISPR/Cas9 gene editing systems to produce mouse strains with engineered oncogenic mutations is also revolutionizing the development of mouse cancer models, particularly by allowing the rapid development of mice with multiple mutations across different genes in a single step.[172]

Sophisticated xenografting methods, in which human cells are grown in murine hosts, are increasingly used for cancer biology research and may be useful tools to help guide treatment decisions in the future. Patient-derived xenografts (PDXs) are human tumor explants that are directly grown in immunocompetent mice, which is a more physiologic approach than establishing tumor cell lines in petri dishes. PDXs can be readily subjected to sequencing and screening approaches that seek to identify therapeutic vulnerabilities. Moreover, there is the potential to use PDX-bearing avatar mice to determine which chemotherapy drugs may be effective for the patient from whom the PDX was derived.[173] At present, widespread use of PDX models is hampered by high expense, high failure rates, and the prolonged time required to establish and propagate models. In addition, the investigation of novel immunotherapeutic approaches is hampered by the cross-species model of a human tumor in the background of the mouse immune system. To overcome this limitation, the development of mice with a humanized immune system is being used to further test immuno-oncology hypotheses in this model system.

Patient-derived organoids have recently been developed to characterize the biology and behavior of normal tissues and tumors.[174] Patient-derived organoids can be rapidly cultured directly from fresh tumor biopsies or surgical specimens in three-dimensional culture. This addresses some of the challenges of PDXs to allow broader use of real-time chemotherapy-sensitivity testing in the future. However, patient-derived organoids do not necessarily recapitulate immunologic responses because of their rapid growth and synthetic environment.

Although recent studies suggest that drug testing on patient-derived organoids can predict clinical treatment response, existing methods for making patient-derived organoids remain slow and costly. New approaches using novel emulsion microfluidics-based technology can create patient-derived micro-organospheres, a novel high-fidelity model of a patient's tumor generated in days, at low cost and with a high success rate. The technology generates thousands of microfluidics-based droplet organoids by mixing suspended cells from a small fraction of a biopsied tumor. Thousands of micro-organospheres can be generated quickly, tracked over weeks, and passaged indefinitely. A recent study highlighting this approach in patients with metastatic colorectal cancer used micro-organosphere technology and demonstrated that it could reliably assess tumor drug response in a timeframe that could be used for treatment decision-making.[175]

KEY POINTS

- NGS offers revealing, transformative, and comprehensive insights into cancer genomics.
- These technologies may enable personalized, targeted cancer therapy strategies based on specific mutations detected in a patient's tumor cells.
- Serial tumor biopsy reveals marked tumor heterogeneity and provides insights into tumor evolution that affect the selection of cancer therapies.
- Gene targeting and transgenic methods are used to create mouse models that mimic the genetic mutations found in human cancers. These models are invaluable for understanding the mechanisms underlying tumorigenesis and are used to determine the role of specific mutations in multistep tumorigenesis.
- Xenografting of patient tumor samples into mice is an additional aspect of personalized cancer medicine; it provides a potential platform to study tumor biology and treatment response in a timeframe that could allow therapeutic decisions to be based on results obtained with animal models.

HIGH-YIELD TAKEAWAYS

- Cancer develops through defined hallmarks, with oncogene activation, tumor suppressor loss, and inflammation driving tumor initiation, progression, and therapeutic targeting.
- NGS enables precision oncology by identifying actionable mutations and detecting inherited cancer risks, such as BRCA-related breast and ovarian cancers and Lynch syndrome–associated colorectal and endometrial cancers.
- Targeted therapies and immunotherapies (eg, HER2 inhibitors, immune checkpoint blockade) improve outcomes by exploiting oncogenic and immune vulnerabilities, though resistance mechanisms remain a major challenge.

Acknowledgments

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

MOLECULAR BIOLOGY 2

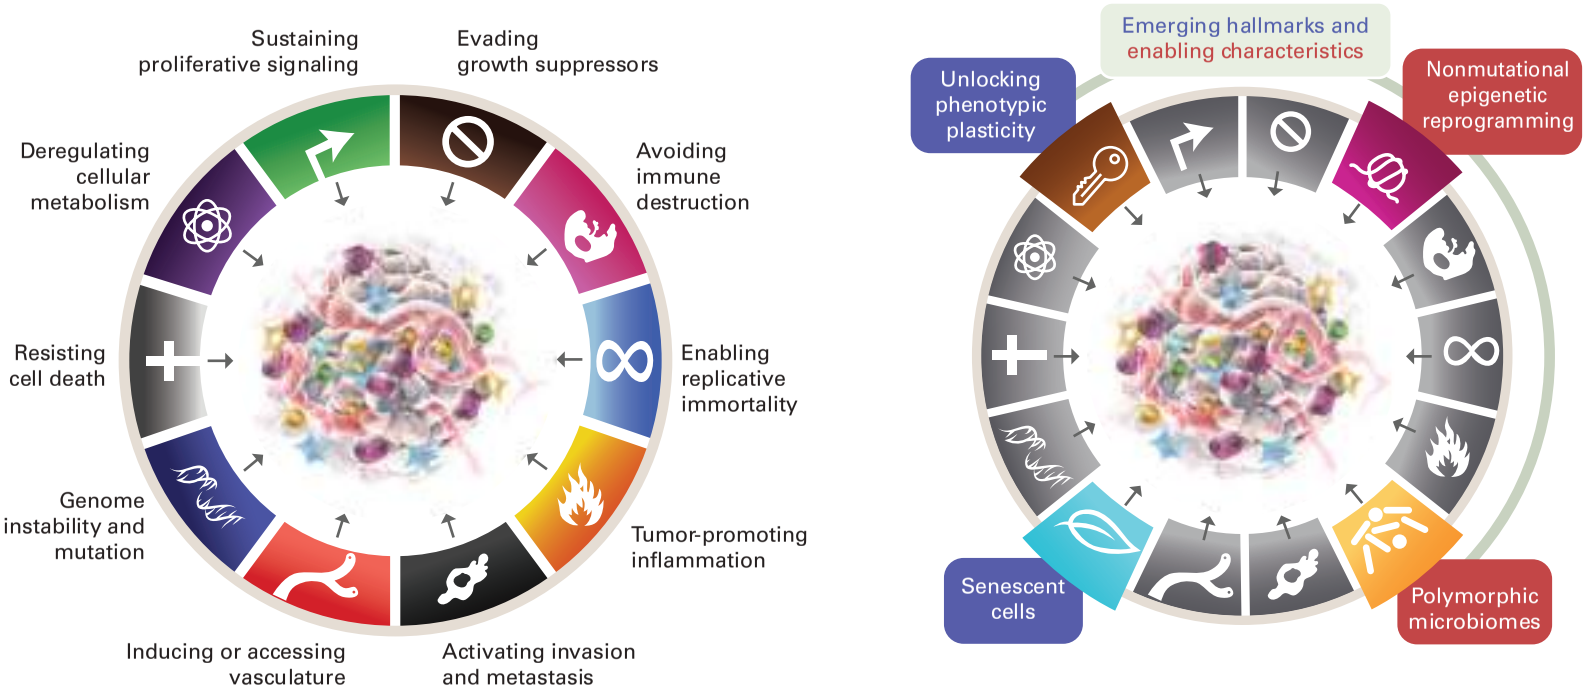
CHAPTER SUMMARY GUIDE

KEY POINTS

- Tumorigenesis is a multistep process that requires the gain of multiple mutations or characteristics that subvert safeguards preventing normal cells from transforming into cancer cells.
- All tumors share a number of hallmarks that contribute to their malignant phenotypes, but the specific molecular events that produce these phenotypes vary greatly among tumor types and individuals.
- Understanding of the hallmarks of cancer informs the development of targeted therapies.
- Genes are functional units of DNA that control the production of RNAs and proteins.
- Cells express only a subset of the genes contained within their genomes. Protein-coding genes are transcribed into mRNA in a process that is controlled by regulatory DNA elements (eg, enhancers and promoters).
- Noncoding RNAs, including miRNAs and long noncoding RNAs, are important regulators of gene expression and are often deregulated in human cancers.
- Gene expression is also regulated by epigenetic modifications of DNA and histones. Such chromatin modifications, which include methylation and acetylation, play a major role in determining the timing and extent of gene expression.
- Enzymes that catalyze epigenetic modifications are potential targets for cancer therapeutics.
- NGS methods use computational analysis of short nucleic acid sequence reads aligned with reference genome sequence information.
- NGS can define full mutational landscapes of individual tumor samples, including alterations in DNA sequence, as well as structural changes and epigenetic changes.
- Single-cell NGS provides insights into tumor heterogeneity and the complex cellular interactions within the tumor immune microenvironment.
- Analyses of mRNA by techniques such as reverse transcription PCR or RNA sequencing measure the expression of specific genes in tumor samples. This provides insights into cancer biology, as well as important diagnostic and prognostic information.
- Whole-genome genetic screens using small interfering RNA or CRISPR/Cas9 technologies can identify genes that promote or suppress cancer or mediate resistance to chemotherapy.
- Karyotyping reveals gross chromosomal structural anomalies in tumor cells, such as translocations and chromosomal deletions.
- FISH techniques detect structural alterations, such as translocations, deletions, fusions, and copy-number variations, directly inside cancer cells.
- Genome alterations identified by FISH are clinically relevant because they can predict sensitivity to molecularly targeted therapies and can be used to detect residual disease in hematologic cancers.
- Protein analyses reveal protein abundance, as well as functional modifications, such as phosphorylation and acetylation.
- Antibody-based protein detection techniques, such as Western blotting, ELISA, IHC, and flow cytometry, are used in a wide variety of clinical settings, including immunophenotyping for cancer diagnosis and classification, detection of minimal residual disease, and selection of therapy.
- Novel high-throughput protein analyses allow for large numbers of proteins to be analyzed in highly multiplexed fashions.
- MS-based proteomics allows for large-scale analyses of protein expression and modifications in tumor tissues.
- Proto-oncogenes are normal cellular genes that can be converted into oncogenes by mutations or epigenetic mechanisms, which alter their normal function or expression.
- Oncogenes encode proteins that are activated in tumors by mechanisms such as amplification, point mutation, and translocation. Oncogenes operate dominantly, and alteration of a single gene is sufficient to promote transformation.
- Tumor suppressor genes are inactivated in tumors by mechanisms such as deletion, point mutation, and gene silencing. Because they act in recessive fashion, the other copy of the gene must be deleted, typically by loss of heterozygosity.
- Mitogenic signaling pathways contain broadly acting proto-oncogenes, and their products are tyrosine kinases. Small-molecule kinase inhibitors and antibody-based therapeutics target many of these proteins.
- Genes that promote or inhibit the normal cell cycle are commonly mutated in cancer cells and are becoming important targets for cancer treatment.

- Many oncogenic mutations disrupt normal apoptotic responses. Inhibitors of proapoptotic proteins constitute another important new class of anticancer drugs.
- Enzymes that promote protein degradation by the proteasome can function as tumor suppressors.
- Pharmacologic proteasome inhibitors are approved for the treatment of multiple myeloma and other hematologic cancers.
- Genes that regulate cellular differentiation are often mutated in hematologic cancers. Drugs that restore normal differentiation are important treatments for these diseases.
- DNA repair pathways contain many tumor suppressor genes that are mutated in both familial and sporadic cancers. Mutations that disable different elements of DNA repair pathways are associated with specific cancer syndromes.
- Inactivation of DNA-damage repair genes may predict response to PARP inhibitors and DNA-damaging agents.
- Inactivation of DNA MMR enzymes leading to MSI and high tumor mutation burden predicts response to PD-1 inhibitors.
- Checkpoints ensure the fidelity of cell division and protect against genomic instability.
- Checkpoint pathways are often dependent on normal tumor suppressor gene and DNA repair protein functions.
- Loss of checkpoint functions causes genomic instability and fosters the accumulation of multiple mutations in cancer cells.
- *TP53* is the most commonly mutated cancer gene, and it participates in diverse checkpoint responses. The p53 protein senses and responds to cellular stress by activating pathways that regulate processes such as cell-cycle progression and apoptosis.
- The mitotic checkpoint protects against chromosome loss, but this process is error-prone in many cancers, leading to CIN.
- Infection-associated cancers are common, affecting more than 2 million people per year worldwide, and most of these cancers result from chronic viral infections.
- Infectious agents frequently subvert molecular pathways related to the hallmarks of cancer, including cell-cycle checkpoints, proliferation, and apoptosis.
- The study of infection-associated cancers provides insights into the molecular basis of sporadic cancers.
- NGS offers revealing, transformative, and comprehensive insights into cancer genomics.
- These technologies may enable personalized, targeted cancer therapy strategies based on specific mutations detected in a patient's tumor cells.
- Serial tumor biopsy reveals marked tumor heterogeneity and provides insights into tumor evolution that affect the selection of cancer therapies.
- Gene targeting and transgenic methods are used to create mouse models that mimic the genetic mutations found in human cancers. These models are invaluable for understanding the mechanisms underlying tumorigenesis and are used to determine the role of specific mutations in multistep tumorigenesis.
- Xenografting of patient tumor samples into mice is an additional aspect of personalized cancer medicine; it provides a potential platform to study tumor biology and treatment response in a timeframe that could allow therapeutic decisions to be based on results obtained with animal models.

Figure 2-1 Hallmarks of Cancer



The latest version of the hallmarks of cancer includes two emerging hallmarks and two enabling characteristics (right). These include unlocking phenotypic plasticity and senescent cells (emerging hallmarks) and non-mutational epigenetic reprogramming and polymorphic microbiomes (emerging enabling characteristics).

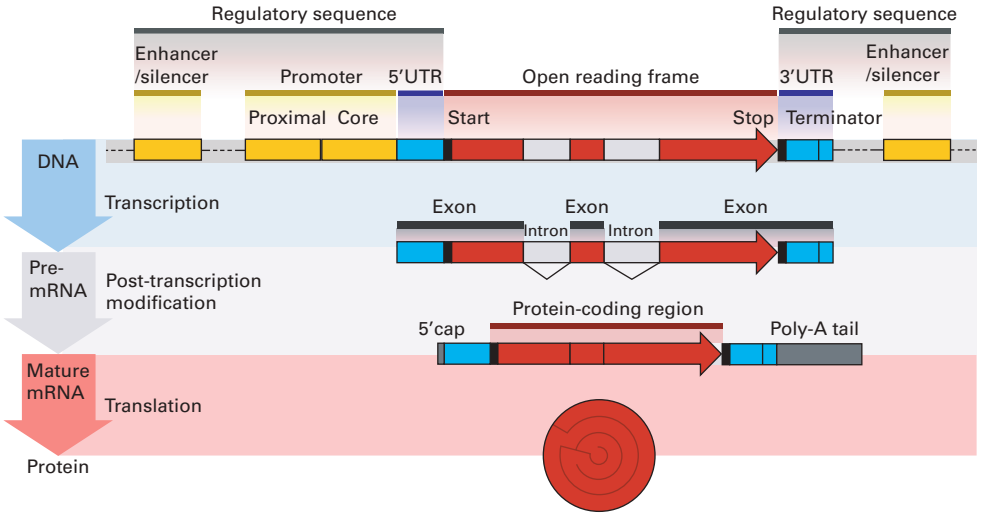
Figure 2-2 Schematic Diagram of an Idealized Gene



Schematic diagram of an idealized gene, including promoter elements, an enhancer, and the transcribed region of the gene. Regulatory sequences control when and where the protein-coding region is expressed. Promoter and enhancer regions regulate the transcription of the gene into a pre-mRNA, which is modified to add a 5′ cap and poly-A tail and remove introns. The mRNA 5′ and 3′ UTRs regulate translation of the final protein product.
Abbreviations: mRNA, messenger RNA; UTR, untranslated region.

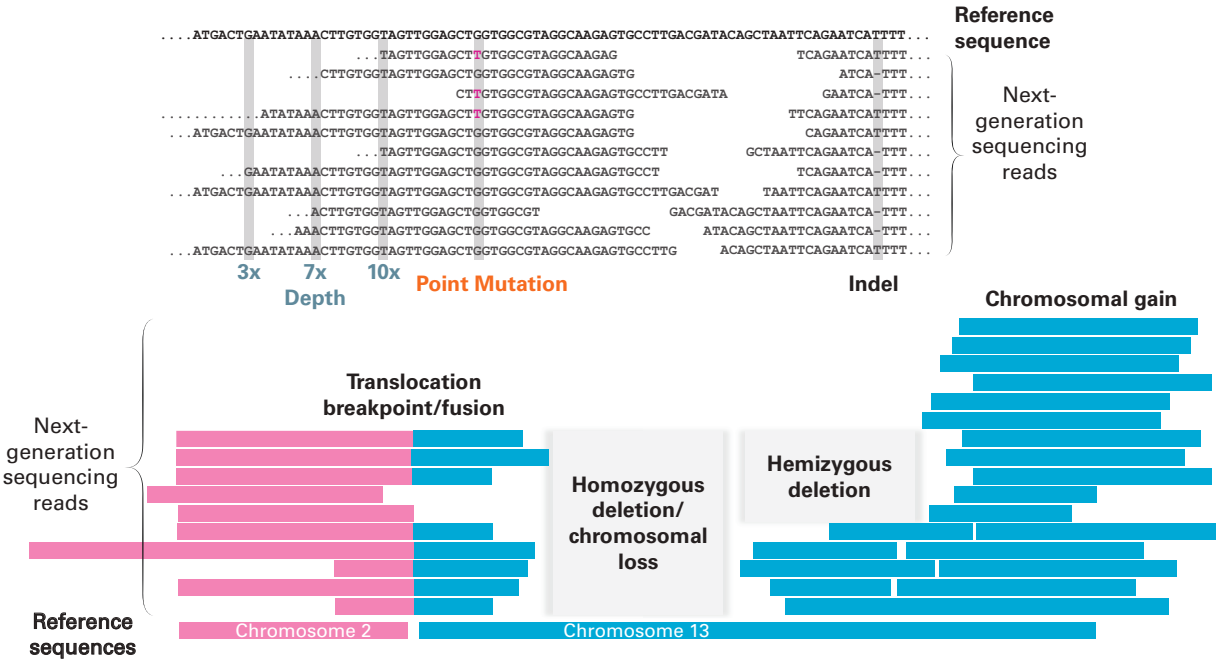
Figure 2-3 Types of Mutations Discovered by Next-Generation Genomic Sequencing



The upper diagram illustrates the alignment of different sequence reads created during NGS. Sequences are aligned to cover the reference genome. Sequencing depth describes the number of sequences produced, identified, and aligned around a specific region. The point mutation example shows the *KRAS* complementary DNA sequence as a reference and a c.34G > T mutation that results in the G12C variant of *KRAS*. Note that the mutation is not present in all reads of this analysis. Less common variants require a higher number of reads (ie, greater depth of sequencing). The small deletion (indel) has been inserted for illustration purposes only. The lower diagram presents a broader perspective of NGS results. It illustrates the translocation t(2;13) of *PAX3* on chromosome 2 with *FKHR* on chromosome 13, a translocation frequently found in alveolar rhabdomyosarcoma. Also shown are examples of a homozygous or hemizygous loss of chromosome 13, which occurs frequently in retinoblastoma, breast cancer, and prostate cancer, among others. In addition, chromosomal gain may occur in other settings, such as metastatic colorectal cancer.
Abbreviation: NGS, next-generation sequencing.

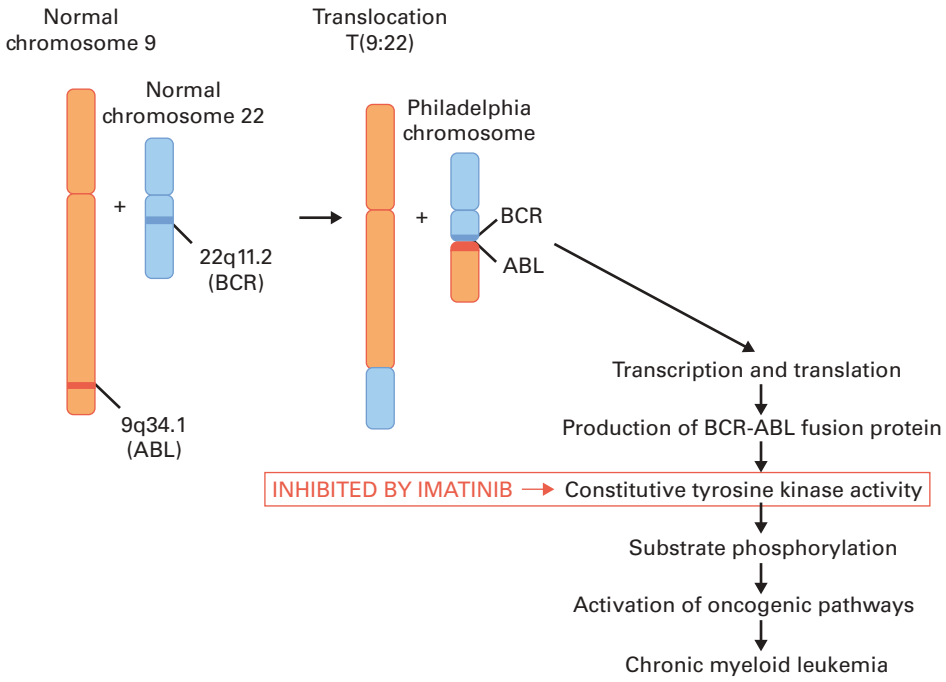
Figure 2-4 Translocation Leading to the Ph Chromosome and Role of BCR::ABL in the Pathogenesis of CML



The Ph chromosome is a foreshortened chromosome 22 resulting from an exchange between the long arms of chromosomes 9 and 22. This leads to the production of a BCR::ABL fusion protein that has constitutive kinase activity and promotes the development of CML. The tyrosine kinase inhibitor imatinib inhibits this constitutive kinase activity and can lead to long-term control of CML.

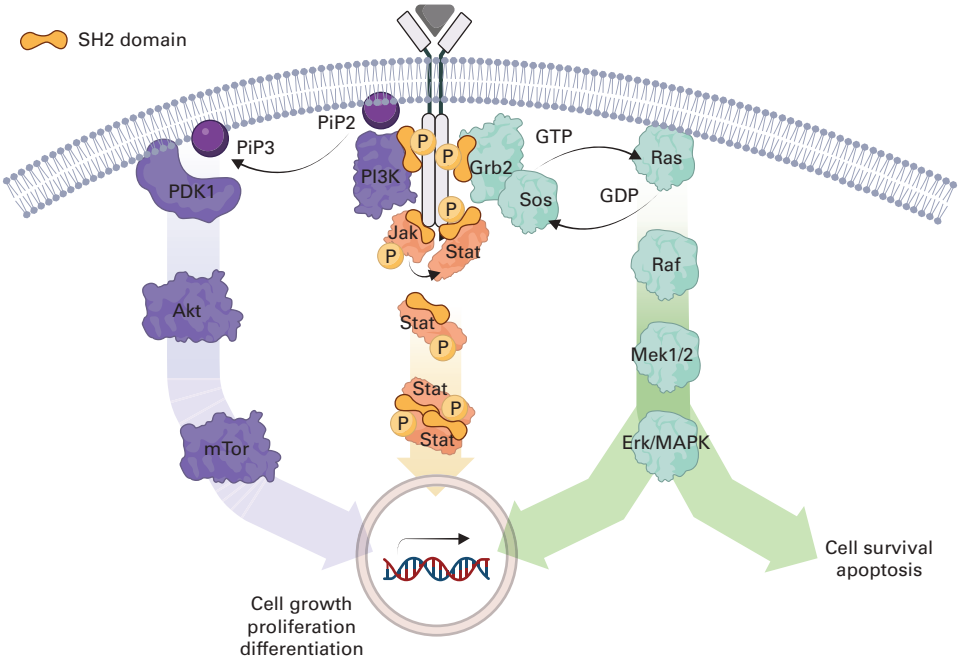
Figure 2-6 Mitogenic Signaling



This figure shows schematically the binding of an extracellular signal (dark gray triangle) to a transmembrane receptor (light gray structure transversing the cell membrane) that is being phosphorylated in the process, usually on tyrosine residues, yielding phosphotyrosines (Ps in yellow circles). Adapter molecules containing SH2 domains bind to the phosphotyrosines and recruit effector proteins in doing so. The examples in this figure (purple) are phosphoinositide 3-kinase (PI3K) and its downstream target phosphoinositide 3-kinase-dependent kinase (PDK1), which, in turn, activates protein kinase B (Akt). Akt activates the mammalian target of rapamycin (mTor), that is exerting promitogenic transcription, differentiation, or cell growth in the cell nucleus. Also, SH2 domain-containing molecules may recruit (orange pathway) Janus kinases (Jaks) and signal transducers and activators (Stats). Jaks phosphorylates Stats on tyrosine residues, amplifying the original signal from the transmembrane receptors. Stats themselves can shuttle into the nucleus and initiate or promote the described processes. The green route illustrates the amplification of the original phosphotyrosine signal via the growth factor-bound protein 2 (Grb2) and rat sarcoma protein (Ras) and its subsequent effectors. Activation of this route may lead to cell growth, proliferation, and differentiation, or cell survival and diminished apoptosis.

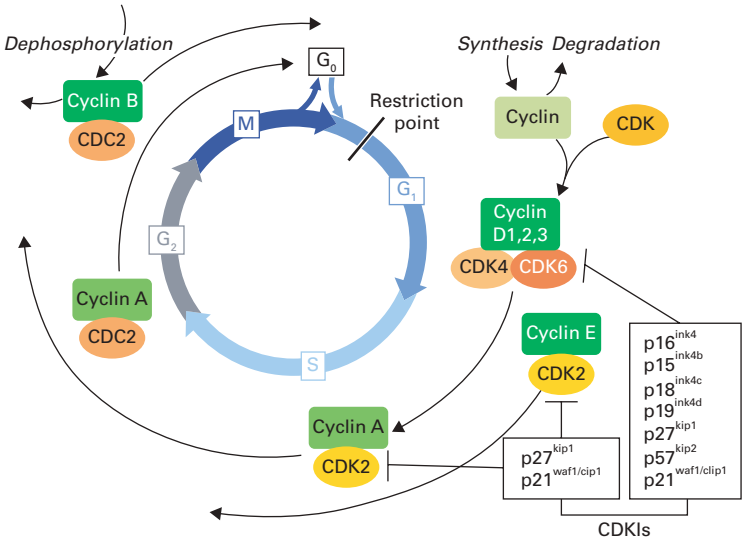
Figure 2-7 The Cell Cycle



The cell cycle is divided into four phases (G1, S, G2, and M). Progression through the cell cycle is promoted by CDKs, which are regulated positively by cyclins and negatively by CDK inhibitors. The restriction point is the point at which cells progress through the cell cycle independently of external stimuli.

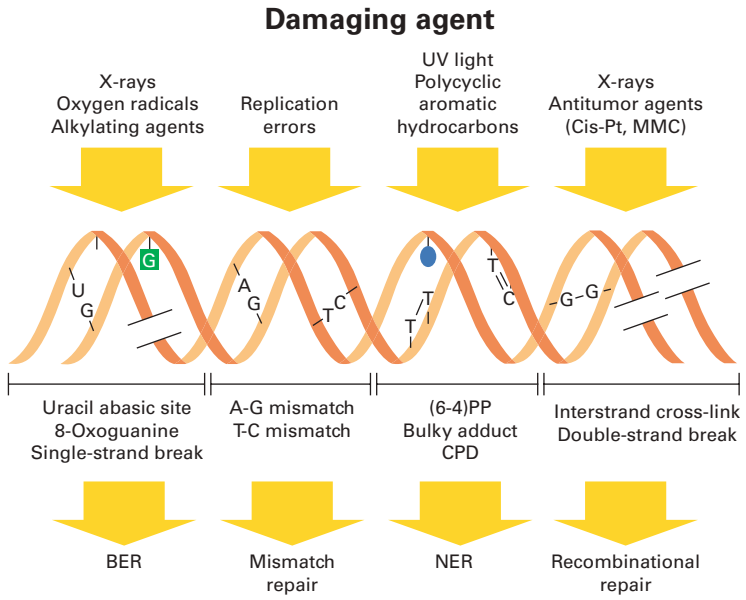
Figure 2-8 DNA Lesions and Repair Mechanisms



Common DNA-damaging agents (top), examples of lesions that can be introduced by these agents into the DNA double helix (middle), and the most frequently used repair mechanisms for such lesions (bottom). Distinct damaging sources can induce similar types of DNA lesions, and any one agent often induces more than one type of damage. The lesion spectra of different repair pathways may overlap.
Abbreviations: BER, base excision repair; CPD, cyclobutane pyrimidine dimer; MMC, mitomycin C; NER, nucleotide excision repair.

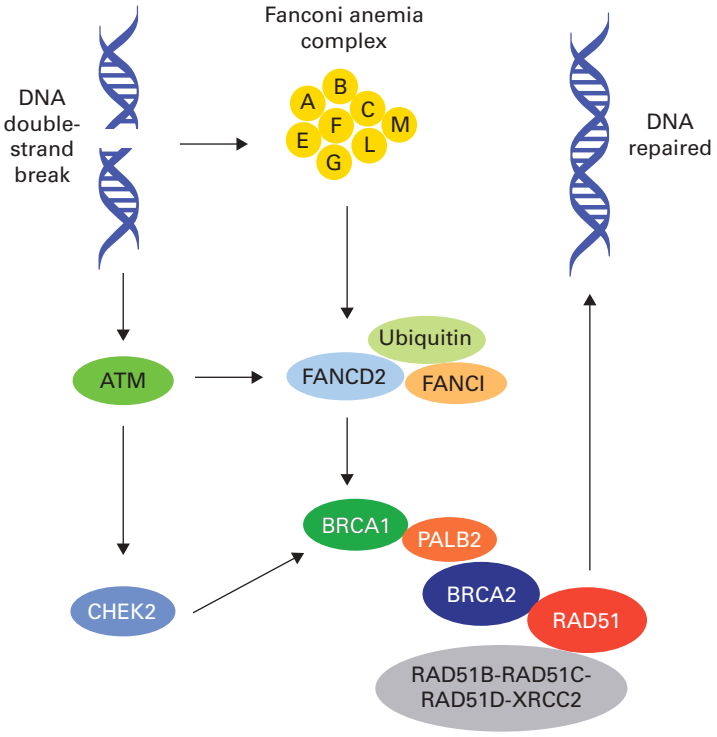
Figure 2-9 Recombinational Repair of DNA Double-Strand Damage



DNA double-strand breaks recruit protein kinase ATM and also activate the Fanconi anemia core complex (FANCA/B/C/E/F/G/L/M) that monoubiquitinates the downstream targets FANCD2 and FANCI. ATM activates (phosphorylates) CHEK2 and FANCD2, and, in turn, CHEK2 phosphorylates BRCA1. Ubiquitinated FANCD2 complexes with BRCA1 and RAD51. The PALB2 protein then acts as a hub, bringing together BRCA1, BRCA2, and RAD51 at the site of a DNA double-strand break and also binds to RAD51C, a member of the RAD51 paralog complex RAD51B-RAD51C RAD51D-XRCC2 (BCDX2). The BCDX2 complex recruits RAD51 or stabilizes the damage sites. RAD51 plays a major role in homologous recombinational repair of DNA during double-strand break repair. In this process, an ATP-dependent DNA strand exchange takes place in which a single strand invades base-paired strands of homologous DNA molecules. RAD51 is involved in the search for homology and the strand-pairing stages of the process.

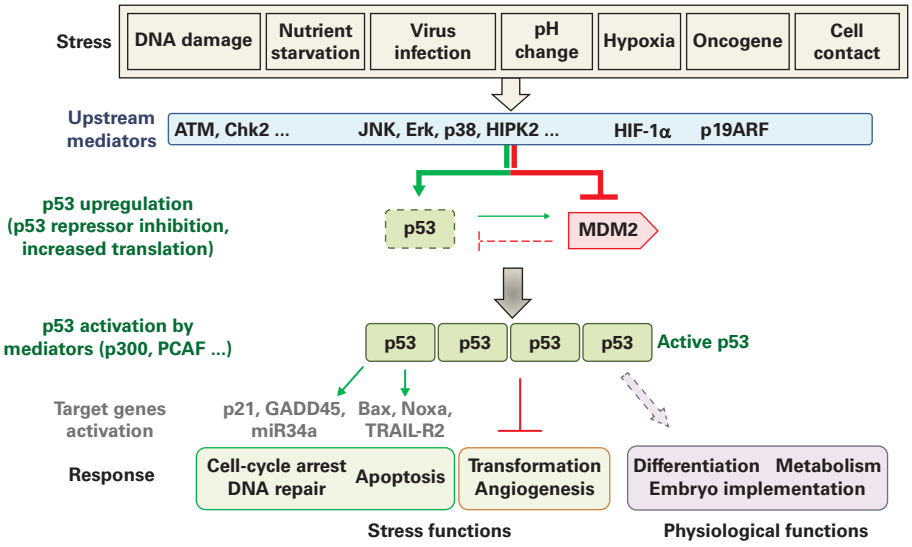
Figure 2-10 The p53-MDM2-ARF Network



The activation of p53 classically occurs in response to many other cellular stresses that produce DNA damage, including oncogene-induced stress. Depending on the nature of the inducing signal, these DNA-damage responses activate a myriad of upstream mediators that lead to upregulation and activation of p53. This, in turn, results in activation of p53 target genes that serve to counteract the initiating cellular stress and protect the cell from further damage. When p53 is mutated or deleted, as it is in most cancers, these critical safeguards no longer function, and cellular stress continues unabated.

CLINICAL PHARMACOLOGY 3

Suwicha Limvorasak, PharmD, and Paul S. Wissel, MD, FASCO

RECENT UPDATES

The US Food and Drug Administration (FDA) approved 49 oncologic drugs in 2024, including 18 novel drugs and 31 new indication expansion.[1] Notable approvals include 11 new drugs and an expanded indication for the first half of 2025. Key updates on recent approval include the following:

Small Molecules

- Avutometinib in combination with defactinib for the treatment of *KRAS*-mutated recurrent low-grade serous ovarian cancer, a first-in-class, RAF/MEK clamp that inhibits MEK kinase activity.
- Sotorasib in combination with panitumumab for the treatment of *KRAS* G12C-mutated metastatic colorectal cancer.[2]
- The second-generation, brain-penetrant, oral estrogen receptor antagonist, imlunestrant, was approved by the FDA for the treatment of estrogen receptor–positive, HER2 negative.
- Dordaviprone,[3] a protease activator, represents the first systemic therapy approved for recurrent H3 *K27M*-mutant diffuse midline glioma, a rare and aggressive brain tumor.

Biologics

- Datopotamab deruxtecan-dlnk, a TROP-2 direct antibody and topoisomerase inhibitor conjugate, for the treatment of locally advanced or metastatic epidermal growth factor receptor (EGFR)-mutated non–small cell lung cancer (NSCLC) patients who have received EGFR-directed therapy and platinum-based chemotherapy and for the treatment of unresectable or metastatic, hormone receptor–positive, HER2-negative breast cancer patients who have received prior endocrine-based therapy and chemotherapy.
- A next-generation ROS1 inhibitor, taletrectinib, for ROS1-positive NSCLC.
- Telisotuzumab vedotin, an antibody-drug conjugate with a monomethyl auristatin E cytotoxic payload for the treatment of NSCLC with high c-met protein expression defined as a strong (3+) membrane and/or cytoplasmic staining on at least ≥50% of tumor cells.
- Tafasitamab-cxix[4] for relapsed or refractory follicular lymphoma, a humanized monoclonal antibody that targets and binds to the CD19 protein on the surface of B-cells, including those found in B-cell lymphomas.[5]
- Penpulimab-kcqx,[4] an anti–PD-1 monoclonal antibody for recurrent or metastatic non–keratinizing nasopharyngeal carcinoma,[6] in combination with platinum-based chemotherapy or as monotherapy.[7]
- Zenocutuzumab-zbco, a monoclonal antibody that targets HER3 and blocks interaction with HER2, for the treatment of metastatic NSCL and metastatic pancreatic cancer harboring an *NRG1* gene fusion.[8]
- *ESR1*[2]-mutated advanced breast cancer progressed after at least one line of endocrine therapy.[9]
- Cell therapy obecabtagene autoleucel (a CD19-directed genetically modified autologous T cell immunotherapy) for adult patients with relapsed or refractory B-cell precursor acute lymphoblastic leukemia (ALL).[10,11]

Drug Label Updates

- A recent FDA safety announcement highlighted the important awareness to the product labeling of capecitabine and fluorouracil (5-FU). The change in product labeling elevates the clinical significance and consequences of dosing fluoropyrimidines to patients with DPD enzyme deficiency from warnings and precautions to a black box warning. Serious or fatal adverse reactions may occur in patients with certain homozygous or compound heterozygous DYPD variants that result in complete DPD deficiency. Test for genetic variants of DYPD prior to initiating treatment is advised unless immediate treatment is necessary.[12]

OVERVIEW

Cancer therapy has changed dramatically, with biomarker-driven targeted therapies, immunotherapy, antibody-drug conjugates, radioligand therapies, and bispecific targeted therapies representing major recent advances. While patients still benefit from traditional hormone therapy and cytotoxic chemotherapy in selected cancer types, they are often given in combination or sequentially with novel therapies. Several anticancer drugs exhibit a narrow therapeutic window, with a tight difference between a toxic dose and a therapeutic dose requiring a careful balance between the anticancer treatment benefit and the adverse effects on normal tissue. This chapter provides an overview of the relevant issues and considerations related to anticancer drug therapy.

PRINCIPLES OF HORMONAL THERAPY, CHEMOTHERAPY, TARGETED THERAPIES, ANTIBODY-DRUG CONJUGATES, AND IMMUNOTHERAPIES

HORMONAL THERAPY FOR CANCER

Hormonal therapies are mostly used to treat breast cancer and prostate cancer. They work by altering the production of hormones, blocking the hormone receptors (HRs) on cancer cells, or substituting chemically similar agents for the active hormones. Hormonal therapies are categorized based on their function and/or the type of hormone that is affected. Cyclin-dependent kinase (CDK) inhibitors are used in combination with hormonal therapies for the treatment of HR-positive, HER2-negative metastatic breast cancer.

Selective Estrogen Receptor Modulator (Tamoxifen)

- Mechanism of action: Selective estrogen receptor modulators (SERMs) such as tamoxifen bind to the estrogen receptor and thereby alter the action of estrogen. Their mechanism of action depends on the activation of different hormone-binding domains, which determine antagonist, agonist, or mixed-response therapeutic action. Tamoxifen has estrogen receptor antagonist activity in the breast and agonist activity in bone. It also manifests the agonist activity in the endometrium (uterus), which increases the risk of endometrial cancer.[13]
- Adverse effects/toxicities: SERM induces menopausal symptoms such as hot flashes, nausea, and vomiting. Additional toxicities include vaginal bleeding, bone pain, menstrual irregularities, headache, and depression. Rare toxicities include retinal toxicity and thromboembolic disorders, including pulmonary emboli. Concomitant warfarin therapy with tamoxifen may increase the risk of bleeding because of an interaction via the CYP2C9 enzyme.

Aromatase Inhibitors

- Mechanism of action: Aromatase inhibitors are a class of drugs that inhibit the enzyme aromatase, which converts circulating androgens to estrogens. Aromatase inhibitors are not effective in premenopausal patients with breast cancer in whom the ovaries are the main source of estrogen production. To overcome this liability, ovarian suppression or ablation has been used in combination with aromatase inhibitors in premenopausal women with breast cancer.
- There are two types of aromatase inhibitors: steroidal and nonsteroidal. Exemestane is a steroidal irreversible aromatase inhibitor, and anastrozole and letrozole are nonsteroidal reversible aromatase inhibitors.
- Adverse effects/toxicities: Aromatase inhibitors can cause hot flashes, vaginal dryness, musculoskeletal pain, and headache.
- Aromatase inhibitors have not been associated with an increased risk of endometrial cancer as seen with tamoxifen. However, they are known to increase the incidence of bone fractures and osteoporosis because of profound suppression of estrogen levels.[14] Bone mineral density assessment is recommended before starting an aromatase inhibitor and every 2 years thereafter.

Selective Estrogen Receptor Degrader (Fulvestrant, Elacestrant, and Imlunestrant)

- Mechanism of action: In contrast to SERMs, selective estrogen receptor degraders (SERDs) are antiestrogens designed to bind to the estrogen receptor and induce its destabilization and degradation, thereby inhibiting dimerization and abolishing the estrogen receptor signaling pathway. A common mechanism of endocrine therapy resistance is the acquisition of estrogen receptor 1 (*ESR1*) mutations.[15] The first-generation SERD fulvestrant is a pure estrogen receptor antagonist with no known agonistic activity, but it has modest activity against *ESR1*-mutant tumors. Efforts to develop second- and third-generation SERDs with superior bioavailability, pharmacokinetic properties, and potent antiestrogenic activity have led to the discovery of orally available SERDs such as elacestrant and imlunestrant. These new oral selective estrogen receptor degraders effectively target ESR1 mutations, which commonly confer resistance to endocrine therapy.
- Adverse effects/toxicities: As a class, the adverse effect profile of SERDs is generally comparable with that of aromatase inhibitors, given their systemic pure antiestrogenic activity.

Fulvestrant

- Mechanism of action: Fulvestrant is a steroidal analog of 17β-estradiol that competitively binds to the estrogen receptor in cancer cells, producing a nuclear complex that leads to a dose-related downregulation of estrogen receptors and inhibits cancer growth.
- It is effective in tamoxifen-resistant, estrogen receptor–positive breast cancer.

- Adverse effects/toxicities: Fulvestrant can cause hot flashes, increased liver enzymes (over 15% incidence), abdominal pain, constipation, diarrhea, and arthralgia.

Elacestrant and Imlunestrant

- Elacestrant and imlunestrant are the oral SERDs approved by the FDA for adults with estrogen receptor–positive, HER2-negative, *ESR1* mutation–positive advanced, or metastatic breast cancer with disease progression after at least one line of endocrine therapy.
- Mechanism of action: Elacestrant and imlunestrant inhibit 17β-estradiol–mediated cell proliferation at concentrations that result in estrogen receptor alpha degradation. In vitro and in vivo data suggested these agents exhibited antitumor activity in cancer models that are resistant to fulvestrant and CDK 4/6 inhibitors, as well as in models carrying *ESR1* mutations.
- Adverse effects/toxicities: Elacestrant and imlunestrant can cause hypercholesterolemia and hypertriglyceridemia, musculoskeletal pain, hot flashes, nausea, vomiting, and fatigue.

Antiandrogens

Prostate cancer depends on testosterone for its growth. Consequently, androgen receptor inhibition results in decreased proliferation of tumor cells and a reduction in tumor volume.

First-Generation Antiandrogens (Flutamide, Bicalutamide, and Nilutamide)

- Mechanism of action: First-generation non–steroidal antiandrogens competitively inhibit the binding of androgens (testosterone and dihydrotestosterone) to the androgen receptors and thereby inhibit tumor growth.
- Half-life: Bicalutamide and nilutamide have longer half-lives of 7 and 2 days, respectively, which allows for once-daily dosing compared with a 6- to 8-hour half-life for flutamide.
- Adverse effects/toxicities: Adverse effects observed with non–steroidal antiandrogens are considered a class effect associated with the blockade of the androgen receptor. These include gynecomastia, breast pain, hot flashes, decreased libido, hepatotoxicity, and gastrointestinal (GI) symptoms.
- To avoid tumor flare from the initial testosterone surge with a gonadotropin-releasing hormone analog, first-generation antiandrogens are usually started at least 1 week before giving the gonadotropin-releasing hormone agonist. This blocks the androgen receptor from binding to testosterone.

Second-Generation Antiandrogens (Enzalutamide, Apalutamide, and Darolutamide)

- Mechanism of action: These offer advantages to overcome disease resistance. They provide stronger binding affinity to the androgen receptors and prevent androgen receptor translocation, DNA binding, and receptor-mediated transcription.
- Adverse effects/toxicities: As a class effect, second-generation antiandrogens increase the risk of seizures because of off-target g-aminobutyric acid A inhibition. Enzalutamide has the highest risk of seizures compared with apalutamide and darolutamide, given the degree of central nervous system (CNS) penetration.

Luteinizing Hormone (Gonadotropin)–Releasing Hormone Analogs (Goserelin and Leuprolide) and Antagonist (Degarelix and Relugolix)

- Mechanism of action: Luteinizing hormone (gonadotropin)–releasing hormone (LHRH/GnRH) analogs bind to the LHRH/GnRH receptor on the hypothalamus, causing an initial surge in the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). With prolonged administration, LHRH/GnRH agonists desensitize the pituitary gland, downregulate the GnRH receptor, thereby decreasing the production of LH and FSH. Reduced LH and FSH results in suppression of the production of sex hormones.
- Degarelix and relugolix are unique antagonists that target and block gonadotropin-releasing HRs, leading to a rapid decrease in testosterone without a surge in secretion of LH and FSH. An advantage of using degarelix and relugolix is the avoidance of tumor flare (manifested as bone pain).
- Adverse effects/toxicities: These can cause hot flashes, weight gain, impotence, reduced libido, GI disturbances (constipation, nausea, and vomiting), gynecomastia, and peripheral edema. Long-term androgen deprivation therapy prolongs the QT interval and can increase the risk of cardiovascular disease, including myocardial infarction, hypertension, and stroke.

Abiraterone Acetate

- Mechanism of action: Abiraterone is a pregnenolone derivative that irreversibly inhibits 17α-hydroxylase/17,20-lyase, an enzyme that converts pregnenolone and progesterone into androgens, dehydroepiandrosterone, and androstenedione. These androgens are then converted into testosterone and dihydrotestosterone in peripheral tissues. Enzymes such as 17α-hydroxylase/17,20-lyase involved in steroid synthesis are often upregulated in hormone-refractory prostate cancer. Abiraterone lowers serum testosterone concentration to castrate levels without significantly affecting serum hydrocortisone levels.

- In addition, because of 17α-hydroxylase/17,20-lyase inhibition, abiraterone can cause increased mineralocorticoids as a result of compensatory upregulation of the hypothalamic-pituitary-adrenal axis. Consequently, this may result in hypertension, hypokalemia, and fluid retention. Concomitant administration with corticosteroids is vital and reduces the incidence and severity of these adverse events.
- Adverse effects/toxicities: These include cardiovascular issues (congestive heart failure and arrhythmias), adrenal insufficiency, adrenocortical insufficiency, and hepatotoxicity.

CYTOTOXIC CHEMOTHERAPY

Cytotoxic chemotherapy is commonly used for the treatment of a wide variety of cancers. While this is a heritage therapy introduced to the clinic decades ago, it remains the most frequently prescribed class of drugs. The goal is to inhibit cell proliferation and growth, thus avoiding cancer cell invasion and metastasis. The cytotoxic effect of chemotherapy is most significant during the S phase, as it interferes with DNA synthesis, entry into M phase, and mitosis. Three basic principles underlie the use of cytotoxic chemotherapy:

1. The fractional cell kill hypothesis, which states that a constant proportion of cells are killed per cycle;
2. A linear relationship between drugs administered and cell kill; and
3. The Goldie-Coldman hypothesis, which suggests that tumors acquire a spontaneous mutation that confers drug resistance.

These principles apply best to rapidly growing cancers, such as leukemias and lymphomas, and they at least partially explain why cytotoxic chemotherapy is most effective in rapidly growing cells. Based on these principles, cytotoxic chemotherapy is typically administered for multiple cycles at the highest tolerable dose, in combination with other agents with different mechanisms of action and non–overlapping adverse effects. They have a narrow therapeutic index, and adverse effects can be severe and sometimes fatal. These agents are potentially curative in some malignancies, such as testicular cancer.[16] However, clinical use of cytotoxic chemotherapy depends on the ability to balance the killing of cancer cells with minimizing toxicity to the normal cells.

Chemotherapy agents can be classified based on their effects on the cell cycle. Cell cycle–specific agents preferentially kill proliferating cells while non–cell cycle–specific agents kill both normal and cancer cells. Each of the transitions in the cell cycle requires activation of CDKs. Chemotherapy can be divided into several categories based on its mechanism of action (Fig. 3-1).

Figure 3-1 Cell Cycle and Site of Cytotoxic Agents

Alkylating Agents

- Mechanism of action: There are six classes of alkylating agents: (1) alkyl sulfonates (bendamustine and busulfan), (2) DNA methylating (procarbazine), (3) ethyleneimines (thiotepa), (4) nitrogen mustards (cyclophosphamide, ifosfamide, and melphalan), (5) nitrosoureas (carmustine), and (6) triazenes (dacarbazine and temozolomide). Their mechanism of action involves interfering with the DNA replication process, causing DNA cross-linking and preventing the strands of DNA from separating. They also inhibit cell division and replication by inhibiting the transcription of DNA to RNA, thereby stopping protein synthesis.
- Cyclophosphamide and ifosfamide are prodrugs that require cytochrome P450 metabolism to release active alkylating metabolites: phosphoramide mustard and acrolein. Mesna is usually administered with these agents to prevent acrolein-induced hemorrhagic cystitis.
- Adverse effects/toxicities: The primary dose-limiting toxicity is bone marrow suppression, with secondary limiting effects on the proliferating cells of the intestinal mucosa. The extent and onset of leukocyte, platelets, and red cell suppression vary among agents, with a nadir at 6 to 10 days and recovery in 14 to 21 days (post-dosing). Nausea and vomiting are frequent side effects of alkylating agents. The frequency and severity are dependent on the dose of the alkylating agent. Important delayed toxicities include cardiotoxicity, non–infectious pneumonitis, peripheral neuropathy, infertility, veno-occlusive disease, and secondary malignancies.
- The highly lipid-soluble alkylating agents can cross the blood-brain barrier and cause CNS toxicity, including seizures, altered mental status, cerebellar dysfunction, and cranial nerve palsies.
- The functionality of one alkylating agent, temozolomide, is limited in the presence of the DNA repair enzyme *O*-6-methylguanine-DNA methyltransferase (MGMT).

Platinum Analogs (Carboplatin, Cisplatin, and Oxaliplatin)

- Mechanism of action: Platinum analogs bind to the N7 position of guanine and adenine residues, leading to the formation of intrastrand or interstrand cross-links, thereby preventing the DNA strands from unwinding properly during replication. These cross-links trigger cellular signaling pathways that recognize DNA damage, leading to cell cycle arrest.
- Adverse effects/toxicities: Most common and significant side effects are bone marrow suppression, nausea and vomiting, diarrhea, nephrotoxicity, ototoxicity, hypersensitivity reactions, and electrolyte imbalances. To mitigate these toxicities, vigorous hydration and electrolyte supplementation are often administered before treatment with platinum analogs. With repeated administrations, hypersensitivity reactions become a significant problem with platinum analogs. Several strategies have been proposed, including switching to other platinum agents, skin testing,[17] desensitization,[18] step-up dosing, and prolonged duration of infusion.
- Because of structural differences from other platinum analogs, oxaliplatin can affect sensory neurons and cause peripheral neuropathy, which may be exacerbated by cold temperatures. The risk of developing neuropathy increases with cumulative doses of oxaliplatin.

Antimetabolites

- Mechanism of action: Antimetabolites interfere with DNA and RNA synthesis by competing for the binding sites on key enzymes for nucleotide synthesis and mimicking natural metabolites. Examples of antimetabolites are (1) purine analogs (cladribine, clofarabine, fludarabine, mercaptopurine, nelarabine, pentostatin, and thioguanine), (2) pyrimidine analogs (capecitabine and fluorouracil), (3) folate antagonists (methotrexate, pemetrexed, and pralatrexate), and (4) cytidine analogs (cytarabine and gemcitabine). Notably, fluorouracil is commonly coadministered with leucovorin; the L isomer enhances the effect of 5-fluorouracil (5-FU) by inhibition of thymidylate synthetase. The cytotoxic effects of antifolates are mediated by their respective polyglutamate metabolites, which are potent and directly inhibit enzyme dihydrofolate reductase, thymidylate synthase, and other key enzymes involved in purine biosynthesis.
- Adverse effects/toxicities: The main side effects are myelosuppression, mucositis, skin rash, hepatotoxicity, neurotoxicity, nephrotoxicity, and GI toxicity. Methotrexate-induced nephrotoxicity results from the intratubular precipitation of its metabolites in acidic urine. In addition, renal excretion is inhibited in the presence of other drugs such as probenecid, penicillin, cephalosporins, aspirin, and non–steroidal anti-inflammatory drugs. High-dose methotrexate can be fatal unless reversed by leucovorin initiated within 42 hours.

Topoisomerase Inhibitors

- Mechanism of action: There are two main types of topoisomerases: (1) topoisomerase I (TOP1) and (2) topoisomerase II (TOP2). TOP1 acts by untwisting the DNA duplex, thereby allowing DNA supercoiling relaxation. TOP1 inhibitors include the camptothecins (irinotecan and topotecan). TOP2 acts by allowing the passage of an intact DNA duplex through the DNA double-strand break generated by the enzymes, after which TOP2 relegates the broken duplex. In addition, intercalations between base pairs in the DNA are formed, causing additional DNA breaks. Examples of TOP2 inhibitors are anthracyclines (doxorubicin, daunorubicin, idarubicin, and mitoxantrone) and epipodophyllotoxins (etoposide and teniposide).

- Topoisomerase inhibitors have become an important payload class for antibody-drug conjugates (ADCs) in recent years. They can be effective against tumors resistant to traditional microtubule-targeting ADC payloads (eg, MMAE and DM1).
- Adverse effects/toxicities: The most common side effects are myelosuppression, GI toxicity, mucositis, alopecia, and cardiac toxicity. Rare but serious side effects include secondary malignancies such as myelodisplastic syndromes (MDS) and acute myeloid leukemia, particularly from alkylating agents and topoisomerase II inhibitors. All anthracyclines can cause cardiotoxicity, where the risk is increased with cumulative doses. Myocardial damage can occur with doxorubicin, with incidences from 1% to 20% for cumulative doses from 300 to 500 mg/m^2 when administered every 3 weeks.

PRESENTING CASE STUDY 1

A 65-year-old man with a 6-month history of early satiety and weight loss of 10% body weight (20 pounds) presents with gastric adenocarcinoma and extensive liver metastasis. The tumor is HER2 negative, microsatellite stable proficient, and has a combined positive score of 0. The patient tolerates first-line 5-fluorouracil, leucovorin, and oxaliplatin (FOLFOX) and achieves tumor shrinkage for 6 months. At the time of progression (10 months after first dose of FOLFOX), his Eastern Cooperative Oncology Group (ECOG) performance status is 1, and he requests continued treatment. Laboratory findings support full-dose therapy, notable for an absolute neutrophil count of 3,500 cells/μL, aspartate aminotransferase two times the upper reference limit, alkaline phosphate level 1.5 times the upper reference limit, and bilirubin level 1.1 times the upper reference limit. He tolerates 3 months of single-agent irinotecan with stable disease and returns to the clinic for the next course of treatment. Complete blood count shows no change in values, and he is moved directly to the chemotherapy administration area, which is busy, with subdued lighting. Full-dose irinotecan is administered. Later that afternoon, his bilirubin level is 3.5 times the upper reference limit. The patient is instructed by his oncologist to return to the clinic the next day for management of expected irinotecan toxicity. By the clinic room window, icteric sclera is noted.

If you had known that the patient's bilirubin level was high, how would you have approached dosage?

Metastatic gastric cancer in a patient with an ECOG performance status of 0 or 1 and acceptable organ function is an indication for standard first-line therapy. Given the patient's biomarker status, the oncologist selected FOLFOX as an appropriate first-line therapy. Median progression-free survival in this setting is about 6 months. The oncologist in this scenario selected irinotecan as a second-line therapy. Clinics routinely have rapid complete blood count testing available, which is used to evaluate patients' myelosuppressive therapy, while the chemistry panel (eg, serum bilirubin) typically requires more time to process. An icteric sclera can be identified when a bilirubin level is greater than 3.0 mg/L or approximately 2.5 times the upper reference limit.

How would you improve clinical workflow to ensure timely detection of irinotecan toxicity, considering the limitations of rapid laboratory tests and the importance of clinical observation?

Complete blood count with differential and chemistry panels should be routinely monitored before each irinotecan administration. Electrolyte levels should be corrected if outside of the reference range, particularly in the setting of severe or chronic diarrhea. In patients with a history of severe neutropenia, *UGT1A1* genotyping should be considered for the **28* and **6* alleles to determine *UGT1A1* metabolizer status before starting therapy with irinotecan or liposomal irinotecan. Dose reduction should be considered for patients known to be homozygous for the *UGT1A1*28* or **6* alleles.

The most common adverse event of irinotecan toxicity is diarrhea (early or late onset).[19] Early-onset diarrhea usually occurs within several hours of infusion and may be accompanied by cholinergic symptoms (eg, abdominal cramping, rhinitis, lacrimation, and salivation). The mean symptom duration is about 30 minutes and is usually well controlled by anticholinergic agents such as atropine. Late-onset diarrhea associated with irinotecan is usually unpredictable and noncumulative and can occur at any dose level. The pathophysiology of late diarrhea is multifactorial, involving dysmotility, secretory factors, and a direct toxicity of the intestinal mucosa. Late-onset diarrhea can be life-threatening and should be treated promptly with antidiarrhea agents (eg, loperamide). Patients with diarrhea should be monitored and given fluids and electrolytes as needed.[19] Antibiotic therapy can be instituted if patients develop ileus, fever, or severe neutropenia. There is no known antidote for irinotecan overdose.[19]

Clinical Pharmacology Pearl: While checking complete blood count with differential testing is routinely performed before giving myelosuppressive agents, tests that assess the drug's metabolic pathway can be overlooked at times. Dose adjustment is recommended in patients with elevated bilirubin from baseline values. Use is not recommended in patients with a bilirubin level higher than 2.0 mg/dL. See Tables 3-9 and 3-10 in the Hepatic Impairment section of this chapter for further guidance.[20]

UGT1A1 tests do not typically cover the **6* alteration in the first exon but measure **28*. The **6* alteration is most common in Asian populations. The allele frequency typically ranges from 10% to 30% and is rare in White and Black populations.[21]

Microtubule-Targeting Agents

- Mechanism of action: Agents targeting microtubules can be broadly classified as microtubule-stabilizing agents, such as taxanes (docetaxel, paclitaxel, cabazitaxel, and nab-paclitaxel) and epothilones (ixabepilone) or microtubule-destabilizing agents, such as vinca alkaloids (vincristine and vinblastine) according to the effects on tubulin polymerization. Stabilization or destabilization of microtubules disrupts cell mitosis, leading to cell cycle arrest. Other tubulin agents, such as eribulin, a synthetic analog of the marine macrolide halichondrin B, work by inhibiting tubulin polymerization.
- Adverse effects/toxicities: The common side effects are myelosuppression, alopecia, peripheral neuropathy, fatigue, nausea and vomiting, diarrhea, skin rash, and mucositis. Hypersensitivity reactions are commonly seen with taxanes because of the solvent used in formulation. All vinca alkaloids can be fatal if given intrathecally. These agents undergo biliary excretion and require dose adjustment for hepatic impairment. Neurotoxicity and syndrome of inappropriate antidiuretic hormone secretion (SIADH) are unique side effects of vinca alkaloids.

Epigenetic Modifying Agents

- Mechanism of action: Epigenetic modifying agents alter the epigenetic status of genes and influence gene expression without changing the underlying DNA sequence. They can be broadly classified into two main forms: (1) DNA methylation and (2) histone modifications. DNA methyltransferase inhibitors such as azacitidine and decitabine inhibit the enzymes responsible for adding methyl groups to DNA, leading to hypomethylation. Histone deacetylase inhibitors such as vorinostat, romidepsin, and panobinostat prevent the removal of acetyl groups from histones, thereby inducing cell apoptosis. Tazemetostat inhibits the zeste homolog 2 enzyme (EZH2) that adds the methyl groups to histone protein, a process called histone methylation.
- Adverse effects/toxicities: The common toxicities associated with these agents are bone marrow suppression, nausea and vomiting, diarrhea, and fatigue.

SMALL-MOLECULE TARGETED ANTICANCER DRUGS

- Mechanism of action: They exert their effect on specific "targeted receptors" that are involved in cancer growth, metastasis, and immortality. Most of them inhibit important cancer targets, such as serine, threonine, and tyrosine kinase inhibitors (TKIs); proteasome; and other proteins involved in DNA damage repair, cell cycle progression, and signal transduction pathways. For example, therapy that inhibits TKIs prevents TKIs from phosphorylating tyrosine residues on their substrates. They block activation of downstream signaling pathways that control cell growth in both cancer and normal cells.
- Inhibition of one gene of a pathway, either because of the presence of a mutation or by pharmacological intervention, may not result in cell death. However, simultaneous inhibition of two genes or pathways can result in cell death, a concept referred to as "synthetic lethality." Tumors with compromised ability to repair double-strand DNA breaks by homologous recombination, including those with defects in the *BRCA1* and *BRCA2* genes, are highly sensitive to inhibition of the base excision repair pathway by poly ADP ribose polymerase (PARP) inhibitors (see Table 3-1).
- Unlike larger monoclonal antibodies that frequently target extracellular receptors, small-molecule cancer drugs are much smaller in size, allowing them to translocate through plasma membranes and bind to intracellular receptors. They are typically oral and administered continuously because of their short lifespan compared with monoclonal antibodies.
- Metabolism typically occurs via the cytochrome P450 system. This creates an environment where drug-drug interactions occur.
- Food and other medications that alter gastric pH or gastric enzymes can increase or decrease absorption of oral anticancer agents, induce or inhibit metabolism, leading to changes in plasma concentrations, and compromise efficacy or increase adverse effects. In addition, certain small-molecule inhibitors can target multiple cell surface receptors and other intracellular proteins, leading to off-target toxicities.[22]

Table 3-1 **Targeted Therapies With Biomarker Selection: EGFR and MET Inhibitors**

	Sensitive Mutation/ Required Biomarkers	Food Effect	pH Dependent (Yes/No)	Drug Interactions	Use	Notes
EGFR inhibitors						
Erlotinib	Exon 19 deletions, exon 21 L858R	Empty stomach	Yes	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and grapefruit	Advanced NSCLC; first line or subsequent lines; *EGFR* mutant	Approved before the discovery of EGFR biomarker; has a maintenance indication in unselected patients
Gefitinib	Exon 19 deletions, exon 21 L858R	With or without food	Yes	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and grapefruit	Advanced NSCLC; first line or subsequent lines; *EGFR* mutant	Initially approved on phase 2 data in unselected populations; failed in phase 3 trial and was taken off the market
Afatinib	Exon 19 deletions, exon 21 L858R, S7681, L861Q, and G719X	Empty stomach	No	Not metabolized by CYP	Advanced NSCLC; first line or subsequent lines; *EGFR* mutant	Retains activity in erlotinib- or gefitinib-resistant patients; has a maintenance indication in unselected patients
Dacomitinib	Exon 19 deletions, exon 21 L858R	With or without food	Yes	Strong CYP2D6 inhibitor; inhibits the metabolism of drugs that are metabolized by CYP2D6	Advanced NSCLC; first line or subsequent lines; *EGFR* mutant	More effective than gefitinib, but also has more adverse effects
Osimertinib	Exon 19 deletions, exon 21 L858R, T790M	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and has the potential for QT prolongation	Adjuvant treatment of early-stage, locally advanced, and metastatic *EGFR*-mutated NSCLC	Improved PFS in first-line setting compared with gefitinib or erlotinib; preferred if CNS penetration is needed
Lazertinib	Exon 19 deletions, exon 21 L858R substitution	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors.	First-line treatment of locally advanced or metastatic NSCLC with exon 19 deletion or exon 21 L858R substitution	Use in combination with amivantamab. Prophylactic anticoagulation should be given for the first 4 months of treatment
Sunvozertinib	Exon 20 insertion	With food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Locally advanced or metastatic NSCLC with EGFR exon 20 insertion	Take with food to reduce GI toxicities
MET inhibitors						
Capmatinib	MET exon 14 skipping	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Metastatic NSCLC with MET exon 14–skipping mutation	
Tepotinib	MET exon 14 skipping	With food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Metastatic NSCLC with MET exon 14–skipping mutation	A clinical trial used a liquid biopsy for assignment

Abbreviations: CNS, central nervous system; CYP, cytochrome P450; EGFR, epidermal growth factor receptor; GI, gastrointestinal; NSCLC, non–small cell lung cancer; PFS, progression-free survival.

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

- Adverse effects/toxicities: Most "on-target" adverse effects are driven by excessive interruption of receptor signaling pathways. Kinase inhibitors that have higher affinities to certain receptors and are considered more specific to a target intracellular receptor may be more tolerable and have fewer side effects. Irreversible kinase inhibitors covalently bind to their target receptors or enzymes and, therefore, cannot be readily reversed. Compared to reversible kinase inhibitors, irreversible kinase inhibitors may exert more on- and off-target effects. However, most TKIs have off-target side effects related to the molecule's lack of specificity. Some later generations of targeted therapy can increase activity and reduce off-target toxicity, such as the first- and second-generation Bruton TKIs.[22]

Targeted therapies have been a mainstay treatment of a variety of cancers, particularly those with actionable mutations; unfortunately, the development of resistance and disease progression frequently occurs. A now common drug development strategy is to develop second- and third-generation agents that target the same pathway but have improved pharmacologic properties compared with the first-generation agents or are able to target known resistance mechanisms. An example is osimertinib, an epidermal growth factor receptor (EGFR) inhibitor that has additional activity in the presence of the known *EGFR* T790M resistance mutation.

Tables 3-1, 3-2, 3-3, 3-4, and 3-5 list small-molecule targeted therapies that require a biomarker for use, the associated biomarkers, and drug and food effects. Combinations of small-molecule targeted therapies, cytotoxic chemotherapy, and/or immunotherapy are currently being evaluated in clinical trials.

PRESENTING CASE STUDY 2

Four years ago, a 65-year-old woman with a history of hypertension and mild irritable bowel disease was diagnosed with chronic myelogenous leukemia (CML). After starting imatinib, she achieved a complete cytogenetic and molecular response, which continued until 3 months ago when imatinib resistance was noted. The hematologist selected nilotinib as her next therapy. Before initiating nilotinib, a 12-lead electrocardiogram (ECG) demonstrated a Fridericia-corrected QT interval (QTcF) of 420 milliseconds. After 1 week, she returned to the clinic for a scheduled follow-up. Repeat 12-lead ECG showed a QTcF of 460 milliseconds. Her blood pressure was within the upper reference limit on current antihypertensive medication. She reported grade 1 diarrhea and nausea, which she attributed to anxiety that the nilotinib may not achieve the complete response she experienced while on imatinib.

Over the ensuing week, the patient's diarrhea continued, and her nausea progressed with some vomiting. She sought help from a local urgent care center which prescribed ondansetron and metronidazole with advice to increase fluid intake and eat a banana, rice, applesauce, toast (BRAT) diet. Over the next 2 days, her symptoms improved, and ondansetron was continued to prevent nausea and vomiting.

Yesterday, she collapsed while working at an outpatient center. The rapid response team was called to perform resuscitation. The team was aware of the new CML therapy she was taking but not the addition of symptomatic care for nausea and vomiting. The team noted torsade de pointes. She was given a magnesium infusion to correct this serious cardiac arrhythmia. She was stabilized and moved to the cardiac care unit until the rate, rhythm, and intervals were within the reference range. Upon discharge, her electrolytes returned to within reference range, and ECG revealed sinus rhythm with a QTcF of 420 milliseconds. Her discharge summary revealed torsade de pointes secondary to hypokalemia and hypomagnesemia due to persistent diarrhea and vomiting.

How would this recently reported laboratory abnormality influence your decision to review the patient's current medications?

Nilotinib is a more potent, second-generation BCR-ABL tyrosine kinase inhibitor that demonstrates superior efficacy over imatinib in achieving deeper and more sustained molecular responses in CML. A higher incidence of cardiovascular events has been reported with nilotinib. The precautions for its use are well described in the black box warning, including QT prolongation and sudden death. Use should be avoided in patients with hypokalemia and hypomagnesemia while periodically monitoring the QTc interval. This patient showed an acceptable QTc interval after 1 week of nilotinib treatment and continued to take the medication. Over time, her gastrointestinal adverse events persisted, leading to an electrolyte imbalance. In addition, the two concomitant medications added for symptomatic control of nausea, vomiting, and diarrhea are known to elevate the risk of torsade de pontes. In this patient, those multiple risk factors led to a life-threatening cardiac event. Fortunately, the clinic staff reacted quickly and appropriately.[26,27]

When administering a therapy with a high potential for drug-drug interactions, careful assessment of risk for clinical sequelae and patient education is crucial. The oncologist had reviewed the risks with the patient and her family before starting therapy. Continuation of care, including informing the healthcare team when a new concurrent medication is used while on treatment, should be maintained via traditional communication methods (eg, phone call) or an automated alert system integrated with an electronic health record. While all signs and symptoms that comprise adverse events are important to report to a healthcare professional on the team, identifying the signs and symptoms that can lead to a serious adverse event needs to rise in priority through patient education and reminders. Using the black box warning of nilotinib (as well as the warning and precaution) can assist the health care practitioner in establishing priority.[26,27]

MONOCLONAL ANTIBODIES

- Mechanism of action: Monoclonal antibodies are therapeutic agents bioengineered to target specific antigens that are either unique to or overexpressed by tumor cells. The main direct mechanism of many monoclonal antibodies is to block growth factor receptor signaling; other mechanisms involve immune-mediated cell killing and payload delivery or have specific effects on the tumor vasculature and stroma.
- While the first monoclonals were murine based, over time, hybrid and humanized monoclonals have been developed. To understand the source, the stem will be different; ximab is chimeric, and zumab will be humanized, and umab is human. Therapies with less human structure may have more therapy-related side effects. For example, cetuximab and rituximab are chimeric human-mouse monoclonal antibodies, which can cause more infusion reactions compared with fully humanized antibodies such as bevacizumab, panitumumab, pertuzumab, and trastuzumab.

Examples of a few tumor antigens that have been successfully targeted using monoclonal antibodies are EGFR, vascular endothelial growth factor (VEGF), and erythroblastic oncogene B (ERBB2) receptor TKI or HER2, HGFR, insulin-like growth factor-1 receptor (IGF-1R), platelet-derived growth factor receptor (PDGFR), and cluster of differentiation CD20.

- For example, bevacizumab is an antibody directed toward soluble VEGF, the ligand for the VEGF receptor that drives angiogenesis.[28,29] Therefore, inhibition of VEGF by the monoclonal antibody bevacizumab decreases angiogenesis. Inhibiting VEGF is also the target for ziv-aflibercept (a recombinant fusion protein) by a different mechanism.
- The FGFR family consists of FGFR1, FGFR2, FGFR3, and FGFR4. Signaling through FGFR activates downstream signaling through the MAPK and PI3K/AKT pathways to regulate cell differentiation, proliferation, survival, and migration. Erdafitinib and pemigatinib are FDA-approved FGFR inhibitors for the treatment of urothelial carcinoma with *FGFR2* or *FGFR3* alteration and for the treatment of cholangiocarcinoma with *FGFR2* fusions or rearrangement, respectively.
- Daratumumab is among the therapies utilized for first-line treatment of multiple myeloma. It is an IgG1κ human monoclonal antibody that binds to CD38 and inhibits the growth of CD38-expressing tumor cells.
- Monoclonal antibodies often are large proteins that are resistant to degradation, which allows them to remain in circulation for longer periods compared with small-molecule targeted inhibitors. A longer half-life, however, also means a slower reversal of toxicity after treatment interruption or withdrawal.
- In addition, monoclonal antibodies often do not require dosage adjustments for liver or kidney dysfunction.

Targeted monoclonal antibodies tend to have fewer adverse effects compared with cytotoxic chemotherapy, but they have unique adverse effects, such as infusion reactions and dermatologic toxicities related to the antigens they target. For example, cetuximab, an antibody that acts on EGFR, which is found on normal skin cells and cancer cells, can consequently cause a serious skin rash in some patients. Antibodies to HER2, such as trastuzumab, have a black box warning for cardiotoxicity requiring cardiac monitoring.[30]

ANTIBODY-DRUG CONJUGATES

ADCs are a type of monoclonal antibody designed to increase therapeutic efficacy while minimizing the toxicity of anticancer agents. An ADC consists of three parts: an antibody drug that is highly specific with high binding affinity, long circulating half-life, and low immunogenicity[31]; a cytotoxic chemotherapy drug with stability, solubility, and amenability to conjugation; and a linker that connects the antibody to the cytotoxic chemotherapy.

Table 3-2 **Targeted Therapies With Biomarker Selection: ALK, ROS, and BRAF Inhibitors**

	Sensitive Mutation/ Required Biomarkers	Food Effect	pH Dependent (Yes/No)	Drug Interactions	Use	Notes
ALK and/or ROS1 inhibitors						
Crizotinib	*ALK* translocation	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and has the potential for QT prolongation	Advanced NSCLC; first line or subsequent lines; *ALK* or *ROS1* positive; unresectable, recurrent, or refractory inflammatory anaplastic lymphoma, *ALK* positive	More effective than chemotherapy, but less effective than alectinib; only ALK inhibitor with ROS1 indication
Ceritinib	*ALK* translocation	With food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and grapefruit	Advanced NSCLC; first line or subsequent lines; *ALK* positive	More effective than chemotherapy
Alectinib	*ALK* translocation	With food	No	Not metabolized by CYP	Advanced NSCLC; first line or subsequent lines; *ALK* positive	Improved PFS over crizotinib; preferred if CNS penetration is needed
Brigatinib	*ALK* translocation	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Advanced NSCLC; after failure of crizotinib; *ALK* positive	Improved PFS over crizotinib; blood pressure should be controlled before initiation
Lorlatinib	*ALK* translocation	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Advanced NSCLC; after crizotinib and one other drug; *ALK* positive	See reference[23]
Ensartinib[24]	*ALK* translocation	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors; Avoid P-gp inhibitor	Advanced NSCLC; ALK inhibitor naive; *ALK positive*	Monitor uric acid while on treatment
Repotrectinib	ROS1 rearrangement	With or without food	No	CYP3A4 inducer; interacts with CYP3A4 inducers and inhibitors	Advanced NSCLC; first line or subsequent lines; *ROS1* fusion positive	Inhibits both wild-type and G2032R-mutant *ROS1* fusions; may be better for patients with brain metastases[25]
Taletrectinib[4]	ROS1 rearrangement	Empty stomach	Yes	CYP3A4 inducer; interacts with CYP3A4 inducers and inhibitors	Advanced NSCLC; first line or subsequent lines; *ROS1* positive	Monitor uric acid and skeletal fractures while on treatment

	Sensitive Mutation/ Required Biomarkers	Food Effect	pH Dependent (Yes/No)	Drug Interactions	Use	Notes
BRAF inhibitors						
Dabrafenib	V600E, V600K	Empty stomach	No	CYP3A4 and CYP2CB substrate; interacts with CYP3A4 and CYP2C8 inducers and inhibitors	First line; adjuvant melanoma, metastatic melanoma, metastatic NSCLC, metastatic anaplastic thyroid, *BRAF* mutant; unresectable or metastatic solid tumors with *BRAF* V600E mutation	Improved PFS and OS over dacarbazine as a single agent; used in combination with the MEK inhibitor to prevent resistance
Vemurafenib	V600E, V600K	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	First-line, metastatic melanoma, Erdheim-Chester disease, *BRAF* mutant; refractory NSCLC with *BRAF* V600 mutation	Improved PFS over dacarbazine as the single agent; used in combination with the MEK inhibitor to prevent resistance
Encorafenib	V600E, V600K	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	First-line, metastatic melanoma, *BRAF* mutant; first-line, metastatic colon cancer, *BRAF* mutant	Only BRAF inhibitor indicated for colon cancer in combination with cetuximab; correct hypokalemia or hypomagnesemia before treatment initiation
Tovorafenib	*BRAF* fusion or rearrangement, V600E mutation	Empty stomach	Yes	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Relapsed or refractory low-grade glioma	Monitor uric acid, CPK level, and skeletal fractures while on treatment

Abbreviations: CYP, cytochrome P450; H2, H2 histamine antagonists (eg, famotidine); NSCLC, non–small cell lung cancer; OS, overall survival; PFS, progression-free survival; PPI, proton pump inhibitors (eg, omeprazole).

Table 3-3 **Targeted Therapies With Biomarker Selection: NTRK and PARP Inhibitors**

	Sensitive Mutation/ Required Biomarkers	Drug Interactions	Use	Notes
NTRK inhibitors				
Entrectinib	*NTRK, ROS1* fusions	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Metastatic NSCLC; *ROS1* rearrangement; solid tumor with known *NTRK* fusion	
Larotrectinib	*NTRK* fusion	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Solid tumor with known *NTRK* fusion	First small-molecule disease–agnostic approval
Repotrectinib	NTRK fusion	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Locally advanced or metastatic NSCLC with ROS1 positive; Solid tumors with *NTRK* gene fusion positive	
PARP inhibitors				
Olaparib	BRCA1/BRCA2	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Metastatic breast cancer, HER2 negative, germline *BRCA* mutated; ovarian cancer maintenance, *BRCA* mutant; metastatic prostate cancer with homologous recombination repair gene-mutated; pancreatic cancer with germline *BRCA* mutated; first-line maintenance	Because of the difference in dosing and bioavailability, do not substitute capsules for tablets
Rucaparib	BRCA1/BRCA2	Moderate CYP1A2 inhibitor; inhibits the metabolism of drugs that are metabolized by CYP1A2	*BRCA*-mutant recurrent ovarian cancer maintenance; metastatic prostate cancer castration resistant, *BRCA* mutated; locally advanced or metastatic pancreatic cancer, germline *BRCA2*-mutated maintenance therapy	Associated with a moderate or high emetic potential, antiemetics are recommended to prevent nausea and vomiting
Niraparib	Testing not required	Not metabolized by CYP	Recurrent ovarian cancer, maintenance therapy	Associated with a moderate or high emetic potential, antiemetics are recommended to prevent nausea and vomiting
Talazoparib	BRCA1/BRCA2	Not metabolized by CYP	Locally advanced or metastatic breast cancer, *BRCA* mutant	

Abbreviations: CYP, cytochrome P450; NSCLC, non–small cell lung cancer; PARP, poly ADP ribose polymerase.
All are not pH dependent. All can be provided with or without food.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 3-4 **Targeted Therapies With Biomarker Selection: FLT3 and IDH Inhibitors**				
	Sensitive Mutation/ Required Biomarkers	**Drug Interactions**	**Use**	**Notes**
FLT3 inhibitors				
Midostaurin	ITD, point mutations	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Newly diagnosed AML, *FLT3* mutation positive; in combination with chemotherapy during induction and consolidation therapy	First-in-class FLT3 inhibitor
Gilteritinib	ITD, point mutations	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Relapsed or refractory AML, *FLT3* mutant	
Quizartinib	ITD, point mutations	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Newly diagnosed AML, *FLT3* mutation positive; in combination with chemotherapy during induction and consolidation therapy	Second-generation FLT3 inhibitor
IDH1/IDH2 inhibitors				
Enasidenib	IDH2	No known drug interactions	Relapsed or refractory AML, *IDH2* mutant	First-in-class IDH2 inhibitor
Ivosidenib	IDH1	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Relapsed or refractory AML, *IDH1* mutant; newly diagnosed acute myeloid leukemia with *IDH1* mutation in combination with azacytidine; locally advanced or metastatic *IDH1*-mutated cholangiocarcinoma	First-in-class IDH1 inhibitor
Vorasidenib	IDH1 or IDH2	Interact with CYP2C8 inhibitors and inducers; sensitive CYP3A4 substrates	Astrocytoma or oligodendroglioma with a susceptible *IDH1* or *IDH2* mutation	May promote tumor growth in patients with NF1 tumors

Abbreviations: AML, acute myeloid leukemia; AUC, area under the curve; ITD, internal tandem duplication.
All are not pH dependent. Except for midostaurin, all can be provided with or without food; with ivosidenib, avoid high-fat meals (increases AUC by 25%).

Table 3-5 **Targeted Therapies With Biomarker Selection: Various Inhibitors**					
	Sensitive Mutation/ Required Biomarkers	**Food Effect**	**Drug Interactions**	**Use**	**Notes**
FGFR inhibitors					
Erdafitinib	*FGFR2, FGFR3* mutations and fusions	With or without food	CYP3A4 and CYP2C9 substrates; interacts with inducers and inhibitors of both enzymes	Locally advanced or metastatic urothelial carcinoma with *FGFR3* or *FGFR2* alterations	First-in-class FGFR inhibitor; better activity in *FGFR3* point mutations over *FGFR3* and *FGFR2* fusions
Futibatinib	*FGFR2* fusion or rearrangement	With or without food	CYP3A4, CYP2D6, and CYP2C9 substrates; interacts with inducers and inhibitors of both enzymes	Locally advanced or metastatic cholangiocarcinoma with *FGFR2* fusion or rearrangement	

	Sensitive Mutation/ Required Biomarkers	Food Effect	Drug Interactions	Use	Notes
Pemigatinib	*FGFR2* fusion	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Previously treated, locally advanced, or metastatic cholangiocarcinoma with *FGFR2* fusion; relapsed or refractory myeloid/ lymphoid neoplasms with *FGFR1* rearrangement	
RET inhibitors					
Selpercatinib	*RET* fusions or mutations	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	*RET* mutant and *RET* fusion–positive medullary thyroid cancer; locally advanced or metastatic *RET*-positive NSCLC; locally advanced or metastatic *RET* fusion–positive solid tumors	First-in-class RET inhibitor; optimize blood pressure before treatment initiation
Pralsetinib	*RET* fusions	Empty stomach	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	*RET* mutant and *RET* fusion–positive medullary thyroid cancer; metastatic NSCLC with *RET* fusion	Do not administer for at least 2 weeks after major surgery and until after adequate wound healing has occurred
PI3K inhibitors					
Alpelisib	*PIK3CA* mutations	With food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors; CYP2C9 inducer; avoid sensitive substrates such as warfarin	Postmenopausal women and men with HR-positive, HER2-negative, *PIK3CA* mutated with advanced or metastatic breast cancer	Approved in combination with fulvestrant; first-in-class PIK3CA inhibitor; optimize blood glucose before treatment initiation
Inavolisib	*PIK3CA* mutations	With or without food	BCRP/ABCG2 and P-gp/ABCB1 substrate	Endocrine-resistant, *PIK3CA*-mutated, HR-positive, HER2-negative locally advanced or metastatic breast cancer	Reduce the dose for moderate renal impairment
AKT inhibitors					
Capivasertib	*PIK3CA, AKT1*, and *PTEN* alterations	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	HR-positive, HER2-negative, locally advanced, or metastatic breast cancer with genetic alterations in one or more of these genes: *PIK3CA, AKT1*, and *PTEN*	Improved PFS with benefits observed in the overall population and among patients with AKT pathway-altered tumors

	Sensitive Mutation/ Required Biomarkers	Food Effect	Drug Interactions	Use	Notes
PDGFRA inhibitors					
Avapritinib	*PDGFRA* exon 18 mutation	Empty stomach	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Unresectable or metastatic GIST with *PDGFRA* exon 18 mutation	First-in-class PDGFRA inhibitor; associated with a moderate or high emetic potential risk; antiemetics may be recommended to prevent nausea and vomiting
EZH2 inhibitors					
Tazemetostat	*EZH2* gain-of-function mutations, *SMARCA* loss-of-function mutations	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Adults and children age 16 or older with metastatic or locally advanced epithelioid sarcoma, relapsed or refractory follicular lymphoma salvage therapy, or those with *EZH2* mutation	First-in-class EZH2 inhibitor
MEK inhibitors					
Trametinib	*BRAF* V600E, V600K	Empty stomach	None	First-line, adjuvant melanoma, metastatic melanoma, metastatic NSCLC, metastatic anaplastic thyroid cancer, *BRAF* mutant; low-grade recurrent serous ovarian cancer; solid tumors, unresectable or metastatic with *BRAF* V600E mutation	Only approved in combination with dabrafenib
Cobimetinib	*BRAF* V600E, V600K	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	First-line, metastatic melanoma, *BRAF* mutant; treatment of histiocytic neoplasms	Only approved in combination with vemurafenib; causes severe photosensitivity
Binimetinib	*BRAF* V600E, V600K	With or without food	None	First-line, metastatic melanoma, *BRAF* mutant	Only approved in combination with encorafenib; LVEF >50% required
Selumetinib	MEK1, MEK2	Empty stomach	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Children aged 2 years or older with NF1 and plexiform neurofibromas	
Mirdametinib	MEK1, MEK2	With or without food	None	Children aged 2 years or older with NF1 and plexiform neuroblastomas	

	Sensitive Mutation/ Required Biomarkers	Food Effect	Drug Interactions	Use	Notes
RAS inhibitors					
Sotorasib	*KRAS* G12C		Caution with CYP3A4 inducers and inhibitors, PgP substrates and acid-reducing agents	*KRAS* G12C mutated locally advanced or metastatic NSCLC	>20% diarrhea, hepatotoxicity, cough, and musculoskeletal pain
Adagrasib	*KRAS* G12C	With or without food	Caution with CYO3a4 inducers, inhibitors, substrates, CYP2c9, cyp 2d6, P-gp substrates, drugs that prolong QTc	*KRAS* G12C mutated locally advanced NSCLC and CRC	Diarrhea, QTc prolongation, hepatotoxicity, and ILD/pneumonitis

Abbreviations: CRC, colorectal cancer; GIST, gastrointestinal stromal tumor; HR, hormone receptor; ILD, interstitial lung disease; LVEF, left ventricular ejection fraction; NF1, neurofibromatosis type 1; NSCLC, non–small cell lung cancer; ORR, overall response rate; PFS, progression-free survival; P-gp, P-glycoprotein.
All are not pH dependent.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

- Mechanism of action: An ADC works by binding to the receptor differentially found on cancer cells. The cancer cells will engulf the ADC, and cytotoxic chemotherapy is released to cause cancer cell destruction with relative sparing of normal cells. How cytotoxic chemotherapy is released inside the cancer cells depends on the design of the linker: cleavable or noncleavable.
- Noncleavable linkers enhance stability in plasma to prevent premature cytotoxic chemotherapy cleavage and decrease the potential for off-target toxicity. They depend on mature lysosomes for linker degradation and cytotoxic agent release,[32] such as ado-trastuzumab emtansine.
- Cleavable linkers, conversely, rely on physiologic conditions such as pH, glutathione concentrations, and proteases to cleave the cytotoxic agent from the linker.[33] ADCs with cleavable linkers may be advantageous in some settings in which there is heterogeneity in target expression because not all tumor cells uniformly express the ADC antigen target, and surrounding cell killing occurs with local release of chemotherapy, known as the "bystander effect."
- Adverse effects/toxicities: Possible adverse effects seen with ADCs are often caused by the release of cytotoxic payload into the bloodstream before reaching the cancer cell. These can include peripheral neuropathy, hepatotoxicity, visual changes, mucositis, and hematologic effects.
- Infusion reactions can also occur with ADCs, with typical onset occurring during the infusion and 24 to 48 hours after infusion. Reactions may range from pyrexia, dyspnea, rigors, and hypotension to anaphylaxis. Selecting appropriate premedications is essential for specific ADCs and often includes antihistamine and acetaminophen with or without corticosteroids.

IMMUNOTHERAPY

Immunotherapy is defined as a therapeutic approach that targets or manipulates the immune system and ultimately seeks to harness the host's adaptive and innate immune responses to eliminate cancer cells.[34]

- Mechanism of action: Immunotherapy induces the patient's immune response and results in the development of specific immune effectors (ie, antibodies and T cells).
- Cytotoxic T-cell lymphocyte antigen-4 (CTLA-4) was the first T-cell checkpoint to be identified. CTLA-4 is a downregulator of T-cell activation pathways. Ipilimumab is a recombinant human immunoglobulin G1 monoclonal antibody that binds to CTLA-4 and consequently blocks its effect, leading to enhanced T-cell activation and proliferation.
- The CTLA-4 inhibitor, along with programmed cell death protein 1 (PD-1) and programmed death ligand 1 (PD-L1) inhibitors, is an example of active immunotherapy. They do not target cancer cells but work by reactivating or promoting antitumor immunity.[35] CTLA-4 is a negative regulator of T-cell activity. Ipilimumab is a monoclonal antibody that binds to CTLA-4 and blocks the interaction of CTLA-4 with its ligands, CD80/CD86. Blockade of CTLA-4 has been shown to augment T-cell activation and proliferation.
- PD-L1 expressed on some cancer cells binds to PD-1 on T cells, resulting in T-cell deactivation. The PD-1 and PD-L1 inhibitors block this receptor-ligand signaling pathway, overcome immune escape mechanisms, and enhance T-cell response,

leading to T-cell activation and proliferation.[36] Therefore, PD-1 and PD-L1 inhibitors rely on the host immune system for anticancer effects. Overall, this class of therapy is effective, particularly in tumors that display a positive tumor proportion score (TPS), a high combined positive score (CPS), or a high tumor mutational burden (TMB). TPS is defined as the number of PD-L1–positive tumor cells as a % of the total number of viable tumor cells; CPS is defined as the number of positive tumor cells, lymphocytes, and macrophages as a % of the total number of viable tumor cells. A high CPS generally refers to a score of 1% or higher. TMB is the number of mutations found in the DNA of cancer cells. A TMB of 10 mutations per megabase or greater is considered TMB high.

- Lymphocyte activation gene 3 (*LAG3*), which is expressed by B cells, T cells, NK cells, and tumor-infiltrating lymphocytes (TILs), is used to regulate immune checkpoint pathways. *LAG3*-blocking antibodies restore the effector function of exhausted T cells and increase their ability to attack tumor cells.
- Adverse effects/toxicities: Immune-mediated toxicities may involve any organ but commonly involve the GI (colitis), hepatic, endocrine, and pulmonary systems. Toxicologic events may occur with different onsets, with some developing within days, whereas others may have delayed onsets in months or years during treatment and after discontinuation.

PD-L1 expression is a commonly used clinical biomarker of checkpoint inhibitor response, and some FDA-approved indications are based on the level of biomarker positivity, although many indications do not require biomarker positivity, and patients without these biomarkers can respond to checkpoint inhibitor therapy.

PD-1–targeting immune checkpoint inhibitors have demonstrated durable clinical responses in patients with microsatellite instability-high (MSI high)/mismatch repair–deficient tumors, leading to the FDA approval of the checkpoint inhibitor, pembrolizumab, for this indication.

TMB is another commonly used biomarker. In June 2020, the FDA approved the anti–PD-1 therapy pembrolizumab for treating patients with advanced and refractory cancers with a high TMB. Several other biomarkers (ie, TILs, immune signatures) are actively being investigated.[37,38] PD-1 pathway inhibitors may be combined with CTLA-4 inhibitors for the treatment of melanoma and renal cell carcinoma and with cytotoxic chemotherapy for some solid tumors; however, they are also commonly used as single agents. More recently, they have been used in combination with a LAG3 inhibitor for the treatment of unresectable or metastatic melanoma.

Adoptive cell therapy, such as TILs, gene-modified T cells expressing novel T-cell receptors, chimeric antigen receptors, or bispecific T-cell engager antibodies, is another strategy to modify the host immune system to recognize tumor cells, thereby enhancing cytotoxic T-cell activity. Immune-mediated toxicities include cytokine release syndrome (CRS), immune effector cell-associated neurotoxicity syndrome (ICANS), and infusion-related reactions (see "Cellular Therapies" chapter for more information).

BISPECIFIC T-CELL ENGAGERS

- Mechanism of action: Bispecific T-cell engager binds to two different antigens simultaneously, with one arm binding to a tumor-associated antigen and the other arm binding to an immune cell receptor, commonly CD3 on T cells. This dual binding brings a T cell into close contact with a tumor cell, forming an immunological synapse. Examples of FDA-approved bispecific T-cell engagers are elranatamab, linvoseltamab, and teclistamab, which bind to the B-cell maturing antigen on myeloma cells and the CD3 receptor on the patient's T cell.
- Adverse effects/toxicities: Among the therapy-related adverse events are the black box warning of CRS and ICANS. Infusion reactions usually occur early during the initial step-up dosing and particularly during the first infusion. The incidence and severity of these reactions often decrease with subsequent infusions. Target organ effects may also occur given target dual blockers by bispecific T-cell engagers.
- Delta-like ligand 3 (DLL3), a notch ligand that is highly expressed on fast-growing tumor cells such as small cell lung cancer (SCLC) and neuroendocrine tumors, has become an emerging target for bispecific T-cell engagers. Examples of DLL3/CD3 bispecific T-cell engagers that are approved by the FDA are tarlatamab and tislelizumab-isgr for the treatment of extensive stage SCLC.

KEY POINTS

- Hormonal therapies are most commonly used to treat breast cancer and prostate cancer. They work by altering the production of hormones, blocking the activity of particular HRs in the body, or substituting chemically similar agents for the active hormones.
- Cytotoxic chemotherapy remains an important component of many cancer therapy regimens in the neoadjuvant, adjuvant, and metastatic settings for solid tumors and for hematologic malignancies.
- Small-molecule targeted receptor inhibitors offer distinct advantages as therapeutics. Most can be administered orally.
- Monoclonal antibodies are therapeutic agents bioengineered to target specific extracellular receptors or cell surface antigens that are either unique to or overexpressed by tumor cells.
- ADCs are anticancer agents that consist of an antibody, a cytotoxic payload, and a linker that work to enhance the therapeutic effect while minimizing toxicity to normal cells.

- Immune checkpoint inhibitor immunotherapy results in durable clinical benefit in some patients and is associated with a unique spectrum of adverse effects known as immune-related adverse effects, which include dermatologic, GI, hepatic, endocrine, and other less common inflammatory effects.
- CRS and ICANS are common with cellular therapy and can be managed by interleukin-6 (IL-6) inhibitors and corticosteroids. Patients are usually hospitalized for proper monitoring and management of these adverse effects.

BIOMARKERS FOR DRUG SELECTION OF TARGETED THERAPIES

Cancer is associated with an accumulation of mutations. Most mutations are neutral (passenger mutations), but a few driver mutations give cancer cells a selective advantage. Targeting these mutations with small molecules is an effective treatment strategy, and the mutation itself is a predictive biomarker.

Novel therapies emerge with new targets such as talquetamab, a bispecific GPRC5-CD3T cell engager, or capivasertib, the first-in-class AKT inhibitor. New drugs are typically more potent and can overcome mutational resistance or limitations seen with first-generation agents, such as better CNS penetration or different adverse effects or drug interaction profiles. Variability in pharmacologic properties is used to guide drug selection. In addition, resistance often develops in targeted small molecules after therapy. For example, EGFR inhibitors bind in the TKI domain of EGFR, and when a mutation occurs in the binding pocket, the drug can no longer bind, and resistance develops. Mutations such as the T790M mutation in EGFR exon 20 prevent binding of first- and second-generation TKIs to the ATP-binding site of EGFR.[39] The next-generation EGFR inhibitor osimertinib is FDA approved for the treatment of metastatic EGFR T790M-positive non–small cell lung cancer (NSCLC).[40] Earlier generations of ROS1 (ROS proto-oncogene 1) TKIs that are approved for treatment of *ROS1* fusion–positive NSCLC may lead to the development of resistance and have limited intracranial activity. Repotrectinib is a next-generation ROS1 TKI with activity against *ROS1* fusion–positive cancers, including resistance mutations such as ROS1 G2032R. First- and second-generation BTK inhibitors have been available for the treatment of chronic lymphocytic leukemia or small lymphocytic lymphoma. They all share common resistance mechanisms, predominantly through mutations in BTK at C481, affecting the binding ability of the drugs, or by mutations in the downstream target PLCG2. Pirtobrutinib is the first non–covalent reversible BTK inhibitor approved by the FDA this year for the treatment of adult patients with relapsed or refractory mantle cell lymphoma after two previous lines of systemic therapies, and it inhibits both wild-type and C481-mutant BTK.

Biomarker testing is continually evolving to be incorporated into clinical decisions. Recently, ASCO convened an expert panel to update the biomarkers to guide systemic therapy for metastatic breast cancer guidelines.[41] The panel recommended that tests for *PIK3CA* mutations should be performed to determine eligibility for alpelisib or inavolisib, and testing for the *BRAF* V600 mutation should be performed before initiating treatment with vemurafenib, encorafenib, or dabrafenib.

PHARMACOKINETICS

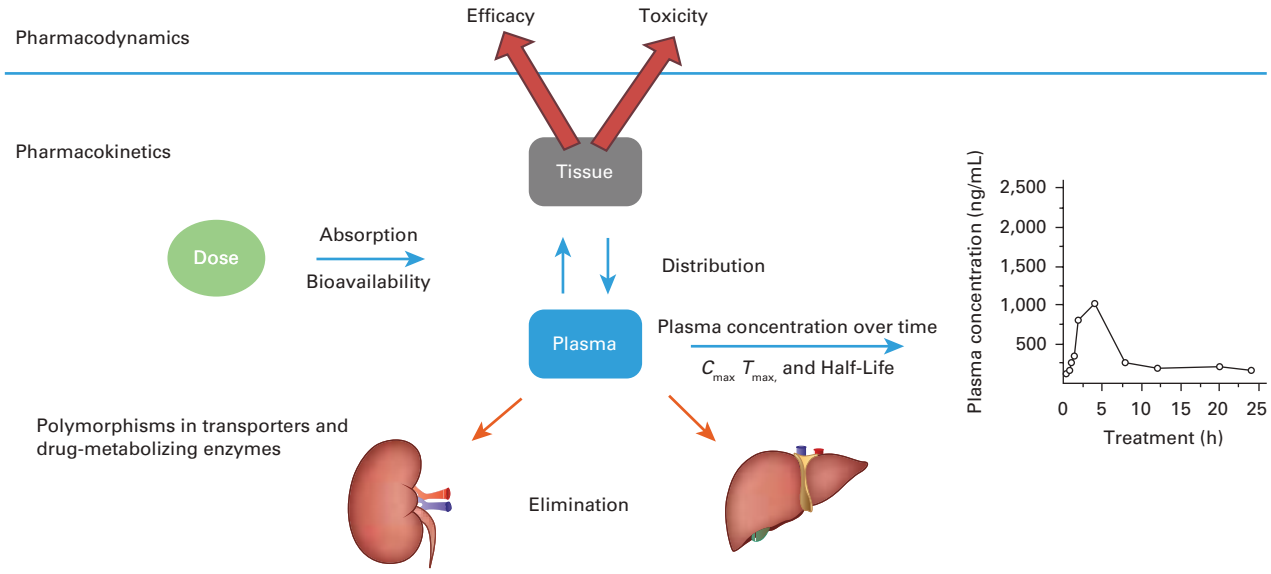
Pharmacokinetics, used to describe dose-concentration relationships, is the mathematical relationship describing the time course of absorption, distribution, metabolism, and excretion (ADME) of drugs and metabolites in the body,[33,42,43] and is often described as "what the body does to the drug" (see Table 3-6 and Fig. 3-2).

Table 3-6 Basic Pharmacokinetics Definitions

Parameter Abbreviation	Definition	Equation	Use/Association
C_{max}	Maximal drug concentration	Visual extrapolation	Can be associated with acute adverse effects
T_{max}	Time at which the maximum drug concentration is achieved	Visual extrapolation	Time that acute adverse effects occur
$t_{1/2}$	Time required for the plasma concentration to decrease by half, or half-life	$T_{1/2}$ 0.698 × Vd/clearance	Determines how long a drug is measurable in the plasma in the body
AUC	Area under the curve	Dose/clearance	Measure of systemic drug exposure
Vd	Volume of distribution	Dose/concentration at time 0 (extrapolated)	Where the drug goes in the body
Cl	Clearance	Dose/AUC	How fast the drug is eliminated

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 3-2 Overview of Pharmacokinetics, Pharmacodynamics, and Pharmacogenetics



Abbreviations: C_{max}, maximum concentration; T_{max}, time at which maximum concentration is achieved.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

The biologic, physiologic, and physicochemical factors that influence the transfer processes of drugs in the body also influence the rate and extent of ADME of those drugs in the body. Typically, pharmacokinetic parameters are determined by measuring drug concentrations in plasma or other relevant distribution sites. The ADME properties of a drug determine the amount of drug exposure in the body, including the target site.

The starting point for introducing any drug into the body is its administration. Common routes of administration include oral, intravenous, intramuscular, subcutaneous, and intrathecal. The proportion of the drug that reaches the systemic circulation after administration is the pharmacokinetic parameter bioavailability (abbreviated as "F" in applicable equations and some texts).

Historically, almost all anticancer agents were administered intravenously, and the bioavailability of intravenously administered agents is defined as 100%, simplifying pharmacokinetic modeling for these agents. However, small-molecule targeted agents are typically administered orally, making bioavailability an important consideration. Adequate exposure can be achieved with oral administration of small-molecule agents.

Factors that influence oral bioavailability include route of administration, absorption factors, and metabolism factors.

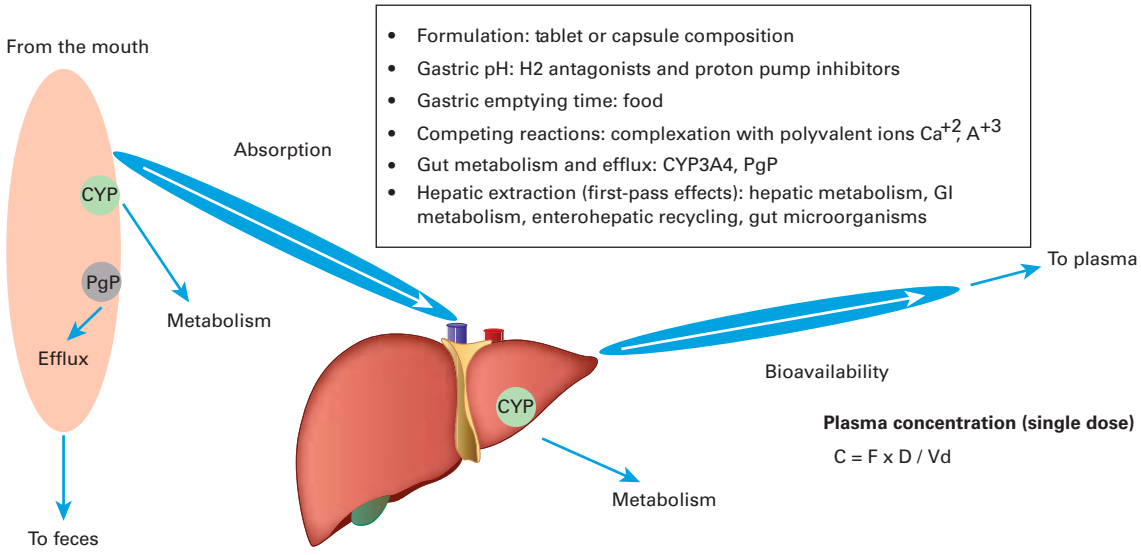
- Absorption is often pH dependent and is discussed in the Drug Interactions section of this chapter. In addition, the fraction of drug lost during the process of absorption, or the first-pass effect, also reduces drug bioavailability (Fig. 3-3).[44]

The purpose of pharmacokinetics in clinical drug development is to assess relationships between plasma concentrations and clinical outcomes of interest, typically efficacy and adverse effects. Many important pharmacokinetic parameters can be estimated by visual inspection of the plasma versus time concentration curve.

- The maximum concentration (C_{max}) is the highest observed concentration. The time when C_{max} occurs is the T_{max}.
- C_{max} is useful clinically for predicting acute toxicity, including infusion reactions and electrocardiogram (ECG) changes. T_{max} is useful in predicting when these toxicities are likely to occur.
- Measured concentration and time data are used to determine pharmacokinetic parameters, which may be primary or secondary.

Primary pharmacokinetic parameters depend on the physiology of the body and the physiochemical properties of the drug, and they include clearance, volume of distribution, and bioavailability.

Figure 3-3 Factors Influencing Oral Absorption



Abbreviations: A, aluminum; C, concentration; Ca, calcium; CYP, cytochrome P450; D, dose; F, bioavailability; H2, histamine 2; k, elimination rate constant; PgP, P-glycoprotein; Vd, volume of distribution.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

- Clearance is the amount of drug eliminated per unit of time.
  - It informs the dose and schedule of drug administration.
  - It is assumed to be constant and is the process by which a drug is removed from the body either as an unchanged drug through renal elimination or by metabolism and subsequent elimination through the urine or feces.
  - It is a proportionality factor that relates the concentration of a drug measured in the body to the rate of elimination and is a function of renal or hepatic activity.
- Volume of distribution is a proportionality constant that relates the amount of drug in the body to the concentration of the drug that was measured.
  - The larger the volume of distribution, the more likely the drug will be found in the tissues of the body, typically at the sites of action.
  - Drugs with a volume of distribution of no more than 3 L are considered confined to the plasma. If the volume of distribution is greater than 50 L, the drug is considered to be distributed to all tissues in the body, especially the fatty tissue. Conceptually, the volume of distribution describes the location of the drug in the body.
- Bioavailability is the proportion of a drug that enters the systemic circulation. Half-life and area under the curve (AUC) are secondary pharmacokinetic parameters because they can be calculated from primary parameters (if those are known). They can also be determined from the concentration versus time curve.
- The AUC represents the total drug exposure over time and can be used to predict response and chronic adverse effects. The AUC depends on the drug amount that enters the systemic circulation (ie, dose and bioavailability) and on the system's ability to eliminate the drug (ie, clearance).
- The half-life is the time required for the concentration to decrease by half and is primarily determined by clearance.
- Drugs and biologics are considered to be eliminated after five half-lives have elapsed. Notably, small molecules generally have shorter half-lives (5-FU is 8-20 minutes and paclitaxel 13-52 hours), while biologics generally have much longer half-lives (trastuzumab 2-13 days).
- The half-life is used clinically to determine dosing frequency and washout periods in clinical trials or when starting new medications.
- For example, erlotinib has a half-life of approximately 36 hours, so in a patient whose disease is progressing on erlotinib therapy and who is switching to osimertinib therapy, typically 1 week of not taking erlotinib should be allowed (180 hours or approximately 7 days) to prevent the development of additive adverse effects.
- Any significant dysfunction of the primary organ responsible for drug excretion, prolonged drug clearance, and third fluid spacing may necessitate dose reduction or schedule alteration.

KEY POINTS

- C_{max}, which occurs at T_{max}, can predict acute toxicity, such as ECG changes, infusion reactions, and acute blood pressure elevations.
- The AUC best reflects systemic exposure and can predict response for some antineoplastics.
- Pharmacokinetic assessments are important in determining drug-drug interactions and making recommendations on the dose and schedule of anticancer agents.
- Half-life guides the frequency of administration and determines washout periods in clinical trials. Dosing in clinical trials often considers the half-life of targeted therapies. For example, patients are often not eligible for initiating dosing of a study agent in a clinical trial until five half-lives of the targeted therapy have elapsed.

PHARMACODYNAMICS

Pharmacodynamics is often summarized as the study of "what a drug does to the body."[45,46] Most anticancer drugs are developed to interact with a biological structure (eg, receptor, enzyme, and transporter) and that interaction leads to a pharmacodynamic effect or an anticancer effect, although off-target effects also occur that can result in adverse effects. Predicting pharmacodynamic effects is critical to drug development. In some cases, such as the carboplatin AUC that predicts thrombocytopenia, plasma pharmacokinetics predict pharmacodynamic effects. However, assessing anticancer activity in solid tumors is challenging. The difficulty arises from an incomplete understanding of a drug's mechanism of action and from difficulties in measuring drug activity at its target or in the cancer cell. For example, to measure the activity of a TKI, a relevant pharmacodynamic study would be to measure TKI activity by assessing the phosphorylation of key substrates in the cancer cells before and after treatment with the drug. Technical and clinical issues make this type of study difficult because repeated tumor biopsies and real-time enzyme assays would be required. Enhancing the ability to assess pharmacodynamic markers in peripheral blood or surrogate tissue is an active area of clinical investigation.

In the absence of a measurable pharmacodynamic biomarker, the coupling of pharmacodynamic mathematical models with plasma pharmacokinetic data is an effective strategy for the study of exposure to response and clinical trial simulations. New strategies include the development of physiologic models that recognize that blood flow to the cancer varies from plasma blood flow. In addition to pharmacokinetic and pharmacodynamic data, these models incorporate physiologic properties (eg, blood flow and organ volume) and drug properties (eg, partition across organs). Incorporation of a predictive preclinical pharmacokinetic/pharmacodynamic model in preclinical studies and early-stage clinical trials can inform the drug development process and reduce the failure rate in later-stage clinical trials.

PHARMACOGENETICS

Pharmacogenetics is the study of variability in drug response due to heredity. In this context, there are germline polymorphisms (occurring in all host cells) in drug-metabolizing pathways or drug targets that are inherited and can affect individual responses to drugs in terms of therapeutic and adverse effects. Notably, with the exception of uridine diphosphate glucuronosyltransferase 1A (UGT1A), which is associated with Gilbert's syndrome, polymorphisms do not typically cause medical conditions. Much of this genetic variation is in the form of single-nucleotide polymorphisms (SNPs). SNPs are defined as variants with population frequencies of at least 1% that can alter the amino acid sequence of the encoded protein or alter RNA splicing, leading to altered kinetics and catalysis of the protein. The concordance between genotype and phenotype is not complete. Many individuals who experience adverse effects will not have an SNP in a known drug-metabolizing pathway for a given anticancer agent. Likewise, not all SNPs are functional. To aid in the use and interpretation of pharmacogenetic results, all drugs with biomarker information (ie, protein targets, germlines, and tumor mutations) in their product labeling are listed on the FDA website,[47] and evidence-based clinical practice guidelines for using pharmacogenetic information are available from the Clinical Pharmacogenetics Implementation Consortium (https://cpicpgx.org/).[48] The consortium's practice guidelines also include polymorphism frequency by ethnicity.

Examples below highlight some notable drugs with pharmacogenetic associations that may indicate an impact on a drug's safety or a patient's response (see Table 3-7).

5-FLUOROURACIL AND CAPECITABINE

- Metabolism: Dihydropyrimidine dehydrogenase (DPD; encoded by *DPYD*) catalyzes the first and rate-limiting step in the conversion of 5-FU to dihydrofluorouracil.

Some polymorphisms result in reduced activity of DPD, which subsequently results in reduced clearance and increased half-life of 5-FU, and they are associated with adverse effects, including severe myelosuppression, neurotoxicity, and GI toxicity.

Capecitabine, a prodrug of 5-FU, is converted to 5-FU and metabolized by DPD. Therefore, toxic effects are similar in patients with decreased or non–functioning *DPYD* variants.

Table 3-7 **Drugs Commonly Used in Oncology That Have Pharmacogenetic Implications**

Drug	Gene	Variant Genotype	Consequence of Variant Genotype	Recommendation	Strength of Recommendation*
Capecitabine/ fluorouracil	DPYD	IM	Increased toxicity	IM: Reduce starting dose	Strong
		PM		PM: Avoid if possible, or reduce dose by 75%	
Irinotecan, liposomal irinotecan	UGT1A1	PM	Increased toxicity	Select alternative therapy if possible	Moderate
Mercaptopurine	TPMT, NUDT15	IM	Increased toxicity	IM: Reduce dose by 50%	Strong
		PM		PM: Reduce dose 10-fold	
Tamoxifen	CYP2D6	PM	Decreased efficacy	Select an alternative agent not metabolized by CYP2D6 (eg, aromatase inhibitor if postmenopausal)	Weak

Abbreviations: IM, intermediate metabolizer; PM, poor metabolizer.
*Clinical Pharmacogenetics Implementation Consortium evidence level, except for irinotecan, for which the recommendations are the authors' opinion.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Multiple meta-analyses have demonstrated the relationship between these genetic polymorphisms and adverse effects; guidelines recommend dose reductions for patients who do not metabolize these drugs well, and alternative dosing strategies have been proposed.[49] DPYD variants should be routinely assessed before initiation of 5-FU or capecitabine based therapy.

ASCO guidelines on DPYD testing align with the FDA labeling updates to test patients for genetic variants of DPYD prior to initiating treatment unless immediate treatment is necessary. Other oncology guidelines for DYPD testing may differ among various organizations considering insurance coverage determination and testing turnaround times. Molecular analysis of patients with DPD deficiency has identified over 128 mutations and polymorphisms in the DPYD gene that may result in partial or total loss of DPD activity. A complete DPD deficiency generally refers to variants on DYPD*2A, DPYD*13 and DPYD HapB3, patients with certain homozygous or compound heterozygous of these variants should avoid treatment with 5-FU or capecitabine based therapy. For patients with partial DPD deficiency or DYPD intermediate metabolizer, doses should be individualized or reduced with closer monitoring for severe diarrhea, mucositis and pancytopenia. While testing for a patient's level of DPD activity is widely available, the turn-around time for availability of the test result can be several days. Reducing the turn-around time has been identified as an important component in delivering safer therapy in a clinically relevant time period.[50]

IRINOTECAN AND LIPOSOMAL IRINOTECAN

- Metabolism: Irinotecan, a prodrug, is metabolized in vivo to 7-ethyl-10-hydroxycamptothecin (SN-38), which is a potent inhibitor of topoisomerase 1. 7-Ethyl-10-hydroxycamptothecin is inactivated by glucuronidation to form the glucuronide conjugate 7-ethyl-10-hydroxycamptothecin G (SN-38G) in a reaction catalyzed by the polymorphic hepatic enzyme UGT1A1.[51]
- A dinucleotide repeat polymorphism in the TATA box in the promoter for *UGT1A1* results in reduced hepatic *UGT1A1* expression and is considered the most common cause of Gilbert syndrome (mild unconjugated hyperbilirubinemia).[52]
- Patients homozygous for the *UGT1A1*28* polymorphism have substantially lower 7-ethyl-10-hydroxycamptothecin glucuronidation rates and substantially higher rates of grade 4 or 5 neutropenia and severe diarrhea when treated with irinotecan than those who do not carry this genetic variant.[53]
- Despite an FDA label change recommending dose reduction for patients who metabolize this drug poorly, the irinotecan dose is infrequently adjusted clinically for this polymorphism.

THIOPURINES (MERCAPTOPURINE AND 6-THIOGUANINE)

Mercaptopurine and 6-thioguanine are purine antimetabolites used clinically to treat pediatric and adult leukemias.

- Metabolism: Thiopurines are metabolized, in part, by *S*-methylation and catalyzed by the enzyme thiopurine *S*-methyltransferase (TPMT).
- Individuals with reduced activity experience substantially increased adverse effects when receiving mercaptopurine.

- TPMT activity, measured either by a phenotypic enzyme test or by sequencing for polymorphisms with subsequent dose reductions in patients with intermediate and poor metabolism of the drugs, is routinely performed in clinical practice.[54-58]
- Polymorphisms in nucleoside diphosphatase (*NUDT15*), which catalyzes the conversion of cytotoxic thioguanine triphosphate metabolites to the less toxic thioguanine monophosphate, are associated with thiopurine adverse effects and have been reported more recently, and assessment is moving into clinical practice.[59]
- Patients with TPMT or NUDT15 deficiency are at increased risk for severe toxicity at conventional mercaptopurine doses and generally require dose reductions.

TAMOXIFEN

- Metabolism: Tamoxifen is a prodrug activated by CYP2D6 to its active metabolite endoxifen.
- Patients with little or no CYP2D6 activity may have a poor response to tamoxifen because of inadequate conversion to the active drug.
- This relationship is controversial, with conflicting literature reported. The majority of the literature discusses the adjuvant treatment of estrogen receptor–positive breast cancer, wherein patients with little or no CYP2D6 activity have an increased risk of recurrence; however, there are insufficient data at this time to suggest that this affects survival.[60]
- Current guidelines recommend selecting an alternative therapy in patients who have little or no CYP2D6 activity, which is a reasonable strategy because aromatase inhibitors are preferred for use by postmenopausal women, and therapeutic alternatives are available for premenopausal women (eg, ovarian suppression and aromatase inhibitors with or without additional targeted therapies). CYP2D6 activity levels can be determined using a test to identify a patient's CYP2D6 genotype from genomic DNA extracted from a whole-blood sample. Similar to the data on patients with little or no CYP2D6 activity, the literature is also conflicting regarding concurrent use of CYP2D6 inhibitors and tamoxifen, which is the pharmacologic equivalent of the poor metabolism genotype.

Initially, a prospective study reported that plasma endoxifen concentrations were substantially lower in patients receiving concurrent tamoxifen and strong inhibitors of CYP2D6, whereas weak inhibitors had little effect.[61] However, a recently reported population cohort study that included more than 14,000 women concurrently receiving tamoxifen and selective serotonin reuptake inhibitors (SSRIs) showed no increased risk of death among women receiving SSRIs that were weak inhibitors of CYP2D6 compared with those taking strong inhibitors of CYP2D6, although follow-up was short, at less than 2 years.[62] Given the availability of SSRIs such as venlafaxine that are weak CYP2D6 inhibitors, avoiding the use of strong CYP2D6 inhibitors such as fluoxetine and paroxetine concurrently with tamoxifen seems prudent.

The two most common therapeutic strategies for patients with variant genotypes are dose reduction or use of an alternative agent. However, with the exception of the thioguanines, pharmacogenetic testing is rarely performed in clinical practice for a variety of reasons, including lack of clinical trial evidence supporting appropriate dose reduction, lack of insurance coverage for testing, lack of alternative therapeutic options, physician preference for dose adjustments after toxicity, and the inability to get test results returned in time to affect chemotherapy dosing or drug selection. A recent trend in increased direct-to-consumer pharmacogenetic testing may actually encourage the use of pharmacogenetic information in clinical practice.[63-65]

DRUG INTERACTIONS

Drug interactions are typically pharmacokinetic and result from one drug or effect, when used concomitantly, causing a change in the plasma concentrations of another drug by affecting the drug's absorption (eg, food and pH), metabolism, or elimination. The risk of an adverse event due to drug interactions is higher when multiple medications, particularly those that are metabolized by cytochrome P450 enzymes, are prescribed concomitantly. Examples of common CYP enzymes involved in drug metabolism include CYP3A4, CYP2D6, CYP2C8, CYP2C9, CYP1A2, and CYP2D19.[66,67]

ABSORPTION

The proportion of the drug that reaches the systemic circulation after administration is the pharmacokinetic parameter bioavailability, which is calculated as drug exposure attained relative to that attained with intravenous administration of the same drug. Changes in absorption often affect bioavailability.

Factors that affect drug absorption and bioavailability are as follows:

- Food and pH effects can interfere with drug absorption and are major considerations when developing oral drugs. The FDA typically requires a food effect study for all new agents.
- Food (in particular, food with a high-fat content) may increase, decrease, or not affect drug bioavailability, depending on the drug, which is measured by differences in the pharmacokinetic parameters (ie, C_{max} and AUC ratios) between the fed and fasted states.

- An example of this food effect is the concomitant use of abiraterone acetate with food, in which increased drug exposure after abiraterone administration occurred in a fed state compared with the fasted state. This food effect is more pronounced with a high-fat meal than a low-fat meal. Consequently, prescribing information recommended that the standard dose (1,000 mg once per day) of abiraterone is to be taken on an empty stomach, with no food consumed for at least 2 hours before and for at least 1 hour after dosing, to minimize variability in drug exposure.

pH effects such as acid suppression therapy, including antacids, histamine H2 antagonists, and proton pump inhibitors, lower gastric pH and can influence absorption of concurrently administered medications, especially those with pH-dependent solubility.[68]

Antacids work by binding to and neutralizing stomach acid, resulting in a rapid onset and short duration of effect (approximately 2 hours).

- Histamine H2 receptor antagonists reversibly compete with histamine at the H2 receptors to reduce gastric acid secretion, with effects lasting approximately 12 hours after the dose.
- Proton pump inhibitors irreversibly bind to the proton pump that secretes gastric acid, resulting in at least 24 hours of gastric acid suppression. All therapies can increase gastric pH to greater than 6. In addition, polyvalent cations found in antacids can bind to some drugs, forming insoluble chelates that limit drug absorption.[69]

If a drug has reduced solubility above a pH of 6, drug interaction studies are typically required by the FDA and are of designs similar to those described for food effects. The results of drug interaction studies also inform the product label: If the AUC or C_{max} ratio falls outside the 90% CI, a significant drug interaction between acid-lowering therapies is determined. Of note, pH-dependent absorption is not always a class effect. For example, bosutinib, dasatinib, and nilotinib have pH-dependent absorption, with reduced absorption at a lower pH; however, imatinib has pH-independent absorption.[70]

METABOLISM

The majority of metabolism occurs in the liver and, to a lesser extent, in the GI tract for orally absorbed drugs. Drugs may be inducers, inhibitors, or substrates of a drug-metabolizing enzyme. A complete list of substrates, inhibitors, and inducers of the CYP enzymes can be found on the FDA website,[71] although CYP3A4 is most commonly involved in drug interactions involving oral targeted therapies. Observed changes arising from metabolic drug-drug interactions can be substantial (an order of magnitude or more decrease or increase in the plasma concentrations of a drug or metabolite) and can include formation of toxic and/or active metabolites or increased exposure to a toxic parent compound. These large changes in exposure can alter the safety and efficacy profile of a drug and/or its active metabolites in important ways. For many newer medications, dose adjustments are included in the product labeling. For example, erlotinib is metabolized primarily by CYP3A4, and the prescribing information recommends that dose decreases of erlotinib should be considered if it is concurrently administered with strong CYP3A inhibitors.

The magnitude of CYP-mediated drug interactions can be assessed by changes in pharmacokinetics following administration of perpetrators using the FDA classifications of strong, moderate, or weak as below:

- Strong inducer: a drug that decreases the AUC of substrates by ≥80%
- Moderate inducer: a drug that decreases the AUC of substrates by 50% to <80%
- Weak inducer: a drug that decreases the AUC of substrates by <50%
- Strong inhibitor: a drug that increases the AUC of substrates by >5-fold or >80% decrease in clearance
- Moderate inhibitor: a drug that increases the AUC of substrates by 2 to <5-fold or 50% to 80% decrease in clearance
- Weak inhibitor: a drug that increases the AUC of substrates by 1.25 to <2-fold or 20% to 50% decrease in clearance

TRANSPORT-MEDIATED INTERACTIONS

Some chemotherapy drugs are substrate for influx transporters, like organic anion transporting polypeptides (OATPs), BCRP, and P-glycoprotein (P-gp). The transporters can modulate intratumoral levels of chemotherapy and, in some settings, cause ineffective concentrations of active chemotherapy.

- P-gp: P-gp is a transmembrane ATP-binding cassette (ABC) transporter that is involved in chemotherapy resistance by actively pumping a wide range of chemotherapeutic agents out of cancer cells. By reducing tumor concentrations, chemotherapy activity can become ineffective. P-gp substrates include doxorubicin, daunorubicin, vincristine, vinblastine, etoposide, paclitaxel, and docetaxel.
- Breast cancer resistance protein (BCRP, also known as ABCG2): BCRP is also among the ABC proteins. Substrates of this efflux protein transporter include topotecan, mitoxantrone, and methotrexate.
- OATPs *OAT1B1* and OATP1B3: These influx transport proteins facilitate a wide variety of drugs into liver cells. Substrates include irinotecan/SN38, paclitaxel, methotrexate, doxorubicin, and some TKIs.

KEY POINTS

- Drug interactions with oral cancer therapies, particularly TKIs, are common and may be clinically important.
- Drug interactions affecting gastric absorption are usually related to food or pH effects. These can be managed by avoiding concurrent administration of pH-lowering agents.
- Food effects can be managed by counseling patients on when to take their medication (ie, with or without food). Some drugs may require administration with a low-fat meal.
- Drug interactions related to metabolism or elimination can be managed by avoiding concurrent administration, if possible, or by adjusting doses.
- Grapefruit, grapefruit juice, Seville oranges, and star fruit are CYP3A4 inhibitors. Patients should be instructed to avoid consuming these products while taking cancer therapies that are metabolized via CYP3A4.
- Patients with TPMT or NUDT15 deficiency are at increased risk for severe toxicity at conventional mercaptopurine doses and generally require dose reductions.
- DPD is an enzyme encoded by the DPYD gene and promotes the first step of the fluorouracil degradation pathway. This pathway helps convert majority of drug to its inactive metabolites. Patients with partially or complete DPD deficiency cannot adequately degrade fluoropyrimidines, are at increased risk of severe, potentially fatal toxicity. Test for DPD deficiency before starting 5-FU or capecitabine therapy should be performed. Avoid use in patients with complete DPD deficiency and reduce dose in those with partial DPD deficiency.[50]

ANTIDOTES FOR CHEMOTHERAPY OVERDOSES

GLUCARPIDASE FOR INTRAVENOUS AND INTRATHECAL METHOTREXATE OVERDOSE

Glucarpidase is a rescue agent approved by the FDA for use in patients with delayed methotrexate excretion. The medication is a recombinant bacterial enzyme that cleaves methotrexate into inactive metabolites. It has a rapid onset of action, with greater than 97% reduction in methotrexate concentration within 15 minutes of intravenous administration, and is able to maintain a reduced methotrexate concentration for up to 8 days. Because glucarpidase can falsely elevate methotrexate immunoassay measurements for approximately 48 hours after administration, a chromatographic method should be used during this time.

Consensus guidelines suggest that optimal glucarpidase administration is within 48 to 60 hours from the start of high-dose methotrexate, usually defined as intravenous doses of at least 500 mg/m^2 given over 2 to 36 hours.[72] A repeat glucarpidase dose within 48 hours of the first dose is not recommended because it would have less efficacy. Leucovorin calcium is a substrate for glucarpidase and may compete with methotrexate for binding sites. It should be administered at least 2 hours before or 2 hours after a glucarpidase dose and should be continued for the first 48 hours after glucarpidase administration.

Overdoses of intrathecal methotrexate can occur when methotrexate doses meant for systemic administration are given intrathecally. Data from a limited number of patients studied suggest that glucarpidase may also be beneficial for overdoses of intrathecal methotrexate.[73] Adverse reactions related to glucarpidase include nausea and vomiting, hypotension, paresthesia, hot flashes, and headache.

URIDINE TRIACETATE FOR 5-FLUOROURACIL OR CAPECITABINE OVERDOSE OR EARLY-ONSET TOXICITY

Uridine triacetate is indicated for emergency treatment of 5-FU or capecitabine overdose (regardless of the presence of symptoms) or early onset of severe toxicities, including acute cardiomyopathy, altered mental status, mucositis, severe nausea and diarrhea, and neutropenia. Potential errors leading to overdose or severe toxicities can be related to 5-FU chemotherapy pump malfunctions or misprogramming and accidental ingestion of capecitabine tablets. In addition, genetic enzyme variants, such as those with homozygous or heterozygous DPD mutations, can lead to an increased risk for acute early-onset toxicity.[74] FDA recently approved changes in safety labeling for FU in patients with DPD deficiency and has recommended *DPYD* testing as part of a boxed warning. Dose reduction is recommended in patients carrying deleterious germline variants.

Uridine works by competing with fluorouridine triphosphate, a 5-FU metabolite, which can be incorporated into the RNA of hematopoietic cells and GI cells to reduce 5-FU toxicity in normal cells.[75] Adult dosing consists of uridine triacetate 10 g orally every 6 hours for 20 doses beginning as soon as possible and within 96 hours after the end of 5-FU or capecitabine administration; pediatric patients received 6.2 g/m^2 (maximum of 10 g) orally every 6 hours.

SODIUM THIOSULFATE TO REDUCE THE RISK OF OTOTOXICITY ASSOCIATED WITH CISPLATIN

Sodium thiosulfate is indicated to reduce the risk of cisplatin-induced ototoxicity in pediatric patients 1 month or older with localized solid tumors. It is reserved for patients receiving cisplatin infusion of less than or equal to a 6-hour duration. For a duration greater than 6 hours, irreversible ototoxicity may have already occurred, and therefore, sodium thiosulfate may not be efficacious.

The most common adverse reactions associated with sodium thiosulfate are vomiting, nausea, hypernatremia, hypokalemia, and decreased hemoglobin. Before each dose of sodium thiosulfate, antiemetic therapy should be given, and the sodium level should be measured to ensure that it is within normal limits.

The recommended sodium thiosulfate dose is based on surface area according to actual body weight. It is administered as an intravenous infusion over 15 minutes after cisplatin infusions of 1 to 6 hours duration.

METHYLENE BLUE FOR IFOSFAMIDE-INDUCED ENCEPHALOPATHY

Methylene blue currently does not have FDA approval for use in ifosfamide-induced encephalopathy; adverse reactions include confusion, ataxia, weakness, seizures, somnolence, and hallucinations. Onset may be 2 to 48 hours after commencing treatment. When reversible, symptoms usually resolve within 1 to 3 days. However, available data from case reports indicate that methylene blue is an option to reverse ifosfamide neurotoxicity. It inhibits monoamine oxidase, thereby preventing the generation of the neurotoxic chloroacetaldehyde metabolite. Methylene blue can be given orally or intravenously, with an initial dose of 50 mg in adults or every 4 to 8 hours until symptoms resolve. It should be used with caution in patients with glucose-6-phosphate dehydrogenase deficiency because it may result in hemolysis and anemia.

KEY POINTS

- One avenue to combat toxicities and prevent permanent sequelae is to administer antidotes if a chemotherapy overdose occurs.
- Uridine triacetate is indicated for emergency treatment of 5-FU or capecitabine overdose.
- Glucarpidase is a rescue agent approved by the FDA for use in patients with delayed methotrexate excretion.
- Methylene blue is an option for use in patients with ifosfamide-induced encephalopathy. It should be used with caution in patients with glucose-6-phosphate deficiency.

SPECIAL POPULATIONS

RENAL IMPAIRMENT

Most drugs are cleared by elimination of an unchanged drug by the kidney and/or by metabolism in the liver. For a drug eliminated primarily through renal excretory mechanisms, impaired renal function may alter its pharmacokinetics and pharmacodynamics.[76] An accurate assessment of renal function is critical to dosing chemotherapy, and both the NCCN and the International Society of Geriatric Oncology recommend assessment of renal function before initiating chemotherapy, although there is currently no consensus on the best method. Creatinine clearance (CrCl) can be measured directly with a 24-hour urine collection, although this is often impractical in terms of time, cost, and convenience. There are also several equations to calculate CrCl. The Cockcroft-Gault equation[77] is commonly used; however, guidance from the FDA for assessing clinical trial eligibility based on renal function now suggests that any "contemporary, widely accepted, and clinically applicable equation" is usually sufficient.[78] "Renal clearance of a drug is proportional to the individual's GFR (expressed as mL/minute). Hence, when providing a recommended dosage in adult patients with renal impairment, use the eGFR as mL/minute." Refer to local prescribing information for current recommendations on dose adjustments for renal impairment. See Table 3-8 for dose adjustment for patients with renal dysfunction. Although the most common type of change arising from renal impairment is a decrease in renal excretion or possibly renal metabolism of a drug or its metabolites, renal impairment has also been associated with other changes, such as those in absorption, hepatic metabolism, plasma protein binding, and drug distribution.[76] These changes may be more important in patients with severely impaired renal function and have been observed even when the renal route is not the primary route of elimination of a drug.

Table 3-8 **Dosing Guidelines of Selected Anticancer Agents for Patients With Renal Dysfunction**

Agent	Dose Adjustment in Renal Dysfunction
Bleomycin	CrCl 40-50 mL/min, 70% of the full dose
	CrCl 30-40 mL/min, 60% of the full dose
	CrCl 20-30 mL/min, 55% of the full dose
	CrCl 10-20 mL/min, 45% of the full dose
	CrCl 5-10 mL/min, 40% of the full dose
Capecitabine	CrCl 30-50 mL/min, 75% of the full dose
	CrCl <30 mL/min, omit

Agent	Dose Adjustment in Renal Dysfunction
Carboplatin	Dose based on GFR, using the Calvert formula: Dose (mg) = target AUC × (GFR + 25). AUC = 5–7 Hemodialysis: Carboplatin dose (mg) = Target AUC × 25, administer on a non–dialysis day; hemodialysis should occur between 12 and 24 hours after carboplatin dose
Carmustine	CrCl 45-60 mL/min, 80% of the full dose
	CrCl 30-45 mL/min, 75% of the full dose
	CrCl <30 mL/min, 70% of the full dose
Cisplatin	CrCl 46-60 mL/min, 50% of the full dose
	CrCl 31-45 mL/min, 25% of the full dose
	CrCl <30 mL/min, omit
Cladribine	CrCl 10-50 mL/min, 75% of the full dose
	CrCl <10 mL/min, 50% of the full dose
Cyclophosphamide	CrCl 10-20 mL/min, 75% of the full dose
	CrCl <10 mL/min, 50% of the full dose
Cytarabine	High and intermediate dose (1 g/m^2 or more per dose)
	CrCl 30-59 mL/min: 50% of the full dose
	CrCl <30 mL/min: use is not recommended, consider an alternative agent
Dacarbazine	CrCl 30-60 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 50% of the full dose
	CrCl <10 mL/min, omit
Daunorubicin	Scr >3 mg/dL, 50% of the full dose
	CrCl 30-50 mL/min, 75% of the full dose
	CrCl <30 mL/min, 50% of the full dose
Etoposide	CrCl 15 to 50 mL/min, 75% of the full dose
	CrCl <15 mL/min, 50% of the full dose
Fludarabine	CrCl 30-70 mL/min, 50% of the full dose
	CrCl <30 mL/min, omit
Hydroxyurea	CrCl 45-60 mL/min, 80% of the full dose
	CrCl 30-45 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 50% of the full dose
	CrCl <10 mL/min, 20% of the full dose
Ifosfamide	CrCl 46-60 mL/min, 80% of the full dose
	CrCl 31-45 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 70% of the full dose
	CrCl <10 mL/min, omit
Lenalidomide (use for MDS/myelofibrosis osteosclerosis)	CrCl 30-60 mL/min, 5 mg once every 24 hours
	CrCl <30 mL/min (not requiring dialysis), 5 mg once every 48 hours
	CrCl <30 mL/min (requiring dialysis), 5 mg 3 × per week after each dialysis
Lenalidomide (use for multiple myeloma)	CrCl 30-60 mL/min, 10 mg once every 24 hours
	CrCl <30 mL/min (not requiring dialysis), 15 mg once every 48 hours
	CrCl <30 mL/min (requiring dialysis), 5 mg once per day; dose after dialysis on dialysis days
Lomustine	CrCl 45-60 mL/min, 75% of the full dose
	CrCl 30-45 mL/min, 70% of the full dose
	CrCl <30 mL/min, omit
Melphalan	CrCl 45-60 mL/min, 85% of the full dose
	CrCl 30-45 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 70% of the full dose

Agent	Dose Adjustment in Renal Dysfunction
	CrCl <10 mL/min, 50% of the full dose; for high dose (>1 g/m^2), consider TDM
	CrCl <10 mL/min, omit
Methotrexate	CrCl <30 mL/min, avoid use
	CrCl <10 mL/min, omit
Oxaliplatin	CrCl <30 mL/min, omit
Pemetrexed	CrCl <45 mL/min, omit
Pentostatin	CrCl 45-60 mL/min, 70% of the full dose
	CrCl 30-45 mL/min, 60% of the full dose
	CrCl <30 mL/min, consider using alternative drugs, if possible
Topotecan	CrCl 30-60 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 50% of the full dose
	CrCl <10 mL/min, omit

Abbreviations: AUC, area under the curve; CrCl, creatinine clearance; GFR, glomerular filtration rate; MDS, myelodisplastic syndromes; TDM, therapeutic dose monitoring.

HEPATIC IMPAIRMENT

The liver is involved in the clearance of many drugs through a variety of oxidative and conjugative metabolic pathways and/or through biliary excretion of unchanged drug or metabolites.[79] Alterations of these excretory and metabolic activities by hepatic impairment can lead to drug accumulation or, less often, failure to form an active metabolite.[80] The level of hepatic impairment (drug-induced liver injury [DILI]) is typically defined more by the level of total bilirubin rather than transaminase levels. Greater levels of liver damage are associated with serious adverse events and death. Values of liver dysfunction as an alarm to consider the discontinuation were initially defined by gastroenterologist Hyman Zimmerman, who proposed what is now known as Hy's law.

Briefly, Hy's law cases have the following three components: (1) The drug causes hepatocellular injury, generally shown by a higher incidence of threefold or greater elevations above the upper limit normal (ULN) of alanine transaminase (ALT) or aspartate transaminase (AST) than the (nonhepatotoxic) control drug or placebo. (2) Among trial subjects showing such aminotransferase (AT) elevations, often with ATs much greater than 3 × ULN, one or more also show elevation of serum TBL to more than 2 × ULN, without initial findings of cholestasis (elevated serum alkaline phosphatase [ALP]). (3) No other reason can be found to explain the combination of increased AT and TBL, such as viral hepatitis A, B, or C; preexisting or acute liver disease; or another drug capable of causing the observed injury.[80]

Hepatic disease can alter the absorption and the disposition of drugs (pharmacokinetics) as well as their efficacy and safety (pharmacodynamics). Refer to local prescribing information for current recommendations on dose adjustments for hepatic impairment (see Tables 3-9 and 3-10).

Table 3-9 Dosing Guidelines of Selected Anticancer Agents for Patients With Hepatic Dysfunction

Agent	Dose Adjustment in Hepatic Dysfunction
Cabazitaxel	Mild impairment (total bilirubin >1-1.5× ULN or AST $ 1.5× ULN, dose at 20 mg/m^2)
	Moderate impairment (total bilirubin >1.5-3× ULN and any AST), dose at 15 mg/m^2
	Total bilirubin >3× ULN, omit
Docetaxel	Transaminase >1.5× ULN and ALP >2.5× ULN, the recommended dose is 75 mg/m^2
	Total bilirubin >ULN and/or transaminase >3.5× ULN, associated with ALP >6× ULN, should not be used unless strictly indicated
Doxorubicin (liposomal)	Total bilirubin 1.2-3.0 mg/dL or AST 60-180 units/L, 50% of the full dose
	Total bilirubin >3.0 mg/dL or AST >180 units/L, 25% of the full dose
	Total bilirubin >5.0 mg/dL, omit
Fluorouracil	Total bilirubin >5.0 mg/dL, omit
Gemcitabine	Increased AST: no need for dose adjustment; increased total bilirubin: reduce dose by 20% (ie, from 1,000 to 800 mg/m^2) and increase if tolerated

Agent	Dose Adjustment in Hepatic Dysfunction
Irinotecan	Increased transaminase <3× ULN if no liver metastasis OR <5× ULN if liver metastasis are present. Total bilirubin >2 dosing should not be administered
Ixabepilone (monotherapy)	Total bilirubin <1.5× ULN and AST <10× ULN and AST:ALT ratio <10× ULN, reduce the dose to 32 mg/m^2
	Total bilirubin 1.5-3× ULN and transaminase <10× ULN, dose at 20 mg/m^2; may escalate dose up to 30 mg/m^2 maximum in subsequent cycles if tolerated
Ixabepilone (in combination with capecitabine)	Total bilirubin >ULN or transaminase >2.5× ULN, omit
Mitoxantrone	Total bilirubin 1.5-3.0 mg/dL, 50% of the full dose
	Total bilirubin >3.0 mg/dL, 25% of the full dose
Paclitaxel (3-hour infusion and first course of therapy)	Transaminase <10× ULN and total bilirubin 1.26-2× ULN, recommended dose = 135 mg/m^2
	Transaminase <10× ULN and total bilirubin 2.01-5× ULN, recommended dose = 90 mg/m^2
	Transaminase 10× ULN or total bilirubin >5× ULN dosing is not recommended
Paclitaxel (24-hour infusion and first course of therapy)	Transaminase 2-10× ULN and total bilirubin <1.5 mg/dL, dose 5× at 100 mg/m^2
	Transaminase <10× ULN and total bilirubin 1.6-7.5 mg/dL, dose 5× at 50 mg/m^2
	Transaminase 10× ULN or total bilirubin >7.5 mg/dL, omit
Sorafenib	Total bilirubin 1.5× ULN: 400 mg twice per day
	Total bilirubin 1.5-3× ULN: 200 mg twice per day
	Total bilirubin >3× ULN: omit
Vinblastine	Total bilirubin 1.5-3.0 mg/dL or AST 60-180 units/L, 50% of the full dose
	Total bilirubin >3.1 mg/dL or AST >180 IU/L, omit
Vincristine	Total bilirubin 1.5-3.0 mg/dL or AST 60-180 units/L, 50% of the full dose
	Total bilirubin >3.1 mg/dL or AST >180 units/L, omit
Vinorelbine	Total bilirubin 2.1-3× ULN: 50% of dose
	Total bilirubin >3× ULN: 25% of dose

Abbreviations: ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; ULN, upper limit of normal.
Reproduced under Creative Commons license. Source: Hendrayana T, Wilmer A, Kurth V, et al. Anticancer dose adjustment for patients with renal and hepatic dysfunction: from scientific evidence to clinical application. *Sci Pharm*. 2017;85:8. doi:10.3390/scipharm85010008

Table 3-10 Dosing Guidelines for Selected Anticancer Agents for Patients With Renal and Hepatic Dysfunction

	Dose Adjustment	
Agent	**In Renal Function**	**In Hepatic Dysfunction**
Bendamustine	Renal impairment: CrCl <40 mL/min, omit	Moderate (transaminase 2.5-10× ULN and total bilirubin 1.5-3× ULN) or severe (total bilirubin >3× ULN), omit
Cyclophosphamide	CrCl <10 mL/min, 50% of the full dose	Total bilirubin >3.1-5.0 mg/dL or AST >180 IU/L, 75% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Daunorubicin	Serum creatinine >3 mg/dL, 50% of the full dose	Total bilirubin 1.5-3.0 mg/dL or AST 60-180 IU/L, 75% of the full dose
		Total bilirubin >3.1-5.0 mg/dL or AST >180 IU/L, 50% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Doxorubicin	CrCl <10 mL/min, 75% of the full dose	Total bilirubin 1.5-3.0 mg/dL or AST 60-180 IU/L, 50% of the full dose
		Total bilirubin >3.1-5.0 mg/dL or AST >180 IU/L, 25% of the full dose
		Total bilirubin >5.0 mg/dL, omit

Agent	Dose Adjustment	
	In Renal Function	**In Hepatic Dysfunction**
Epirubicin	Serum creatinine >5 mg/dL, lower doses should be considered	Total bilirubin 1.2-3.0 mg/dL or AST 2-4× ULN, 50% of the full dose
		Total bilirubin >3.0 mg/dL or AST >4× ULN, 25% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Erlotinib	CrCl <10 mL/min, omit	Total bilirubin 1-7 mg/dL or AST 2-3× ULN, 50% of the full dose
		Total bilirubin >7.0 mg/dL, omit
Etoposide	CrCl >15-50 mL/min, 75% of the full dose	Total bilirubin 1.5-3 mg/dL or AST 60-180 units, 50% of the full dose
	CrCl <15 mL/min, omit	Total bilirubin 2-3 mg/dL or AST >180 units, omit
Hydroxyurea/ hydroxycarbamide	CrCl 10-60 mL/min, 75% of the full dose	Total bilirubin 1.5-5.0 mg/dL or AST 60-180 units/L, 50% of the full dose
	CrCl <10 mL/min, 50% of the full dose	Total bilirubin >5.0 mg/dL or AST >180 units/L, omit
Idarubicin	Serum creatinine 2–2.5 mg/dL, dose reduction recommended	Total bilirubin 2.5-5.0 mg/dL, 50% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Imatinib	CrCl 40-59 mL/min, doses >600 mg are not recommended	Initial dose: severe hepatic impairment
	CrCl 20-39 mL/min, 50% of the full dose; dose can be increased up to a maximum of 400 mg	Initial dose: 75% of the full dose
	CrCl <20 mL/min, use with caution (in two patients with severe renal impairment, doses of 100 mg/d were tolerated)	Hepatic toxicity during treatment: transaminases >5× ULN or total bilirubin >3× ULN; omit
		Restart at reduced doses (reduce from 400 to 300 mg, from 600 to 400 mg, or from 800 to 600 mg) when transaminases <2.5× ULN and total bilirubin <1.5× ULN
Methotrexate	For low dose (<1 g/m^2), CrCl 30-60 mL/min, 50% of the full dose	Total bilirubin 3.1-5.0 mg/dL or AST >180 units, 75% of the full dose
	CrCl <30 mL/min, omit	Total bilirubin >5.0 mg/dL, omit
	For high dose (>1 g/m^2), consider TDM	Total bilirubin >5.0 mg/dL, omit
Mitomycin C	CrCl 30-60 mL/min, 75% of the full dose	Total bilirubin 1.5-3.0 mg/dL, 50% of the full dose
	CrCl 10-30 mL/min, 50% of the full dose	Total bilirubin >3.0 mg/dL or transaminase >3× ULN, 25% of the full dose
	CrCl <10 mL/min, omit	

Abbreviations: AST, aspartate transaminase; CrCl, creatinine clearance; TDM, therapeutic dose monitoring; ULN, upper limit of normal.

OLDER ADULT PATIENTS

Usually, there are no significant differences in pharmacokinetics for cytotoxic agents on the basis of age alone.[81,82] Although a number of age-related changes in drug ADME can contribute to differences in treatment tolerance between older and younger patients, these changes are influenced by many other factors, and age alone is a poor predictor of drug tolerability. With the exception of conditioning regimens used for stem cell transplantations, no empirical dose reductions are recommended that are based solely on age. For patients with cancer who are older than 65 years, the 2018 ASCO Guideline recommends that a geriatric assessment be performed. Using a geriatric assessment tool to evaluate patients besides their chronological age may provide a complementary evaluation of an adult's fitness for cancer therapy.[83]

An important potential issue in older adult patients is renal clearance. Over a life span, renal mass decreases by approximately 25% to 30%, and renal blood flow decreases by 1% per year after the age of 50 years.[84] The decline in glomerular filtration rate with age is estimated at 0.75 mL/min per year after age 40 years; however, approximately one-third of patients have no change in CrCl, with age. Because of the physiologic decline in renal function with age, chemotherapy agents primarily excreted renally must be dosed with caution in older patients, although routine dose reductions are not recommended.

Recently, tools that predict chemotherapy toxicity have been developed to determine severe chemotherapy toxicity in older adults. Extermann et al.[85] developed the Chemotherapy Risk Assessment Scale for High-Age Patients to predict grade 3 or greater nonhematologic toxicity and grade 4 or greater hematologic toxicity. Therefore, incorporating geriatric assessment domains would allow clinicians to better identify at-risk older adult patients who are vulnerable to morbidity and/or mortality from cancer therapies.

OBESITY

The ratio of adipose tissue to lean body mass is altered in obesity and can affect the volume of distribution of lipid-soluble medications. Lipid-soluble medications can accumulate in adipose tissue, which serves essentially as a depot, thus prolonging the duration of drug effect and increasing the total amount of drug in the body.

The weight used for dosing is another important concern. Typically, chemotherapy dosing is based on body surface area (BSA), which is commonly calculated with the Mosteller or Dubois method and is based on actual height and weight. Because of toxicity concerns, clinicians sometimes use either ideal body weight or adjusted ideal body weight, or cap the BSA at 2.0 m^2 rather than use the actual body weight to calculate BSA. Observational studies have shown that no more than 40% of obese patients are dosed lower than their actual body weight.[86-88] Treating patients with less than full weight-based dosing of chemotherapy is thought to contribute to the higher mortality rate observed in obese patients. ASCO convened an expert panel to evaluate the literature about obesity and dosing. The panel concluded that there was no evidence that actual weight dosing in obese patients resulted in more adverse effects, and the panel recommended that full weight-based chemotherapy doses be used, although high-dose conditioning regimens are exceptions.[89]

KEY POINTS

- Empirical dose reductions are recommended for some drugs in patients with underlying hepatic and/or renal dysfunction.
- With the exception of conditioning regimens used for stem cell transplants, no empirical dose reductions are recommended that are based solely on age.
- Selecting the appropriate initial dose for a patient can be based upon patients' comorbidity, age, and fragility, concurrent medications known to inhibit or induce drug metabolism, and/or known genetic polymorphism. Recommended starting dose can be varied depending on the countries where the drug or treatment is authorized and their regulatory policies.
- Dose modification during treatment is common and determined based on the patient's tolerability.
- Actual body weight and actual BSA should be used for dosing obese patients with drugs that use weight-based dosing.[90-93]

DOSE SELECTION

INITIAL DOSE SELECTION FOR A GIVEN PATIENT

Selecting the initial dose for a patient is part of the art and science of being an oncologist. While the frequency of incorrect dose modifications as part of standard of care is low, the percentage of oncologists who modify dose in a manner different from guidelines is substantial (ref). Publications have described that the decision process, particularly for patients with metastatic disease, involves the considerations of the patient's age, ability to tolerate the therapy-related side effects, trade-offs between safety and efficacy, and discussion with the patient. In addition to these clinician-based assessments, it is important to have the knowledge of the approved dose supported by the dosing instructions from the original study (peer-reviewed publication) that determined safety and efficacy in that patient population, as well as publication based on the larger clinical database from the pivotal study that has been reviewed by the FDA, EMEA, and other agencies in granting approval for clinical use when making the decision on the initial dose and dose modification. For example, the published clinical evidence that demonstrated superior efficacy of a PDL-1 inhibitor to etoposide and platinum and gained approval for clinical use included a Kaplan-Meier curve for survival and a safety table, all totaled with 16 rows of safety results. The publication does not include advice on dose modification. To gain agency approval, the entire clinical database is submitted for agency review, and agency investigators inspect the records at sites that contributed to the safety and efficacy results for primary source verification. From this evaluation, the advice on starting dose and specific toxicity-based dose modifications is generated and published. That publication included several pages of important safety information as well as toxicity-based dose modification schemas. When selecting an initial dose for an individual patient, this information should also be reviewed and considered.

TOXICITY-BASED DOSE MODIFICATION

For subsequent cycles, the patient's tolerability of the previous cycle is reviewed, and the decision is made to select the dose for the next cycle. Clinical experience in the evaluation of the patient's history of the previous cycle's signs and symptoms, review of laboratory results, and physical exam is integrated into this decision. Awareness and review of the agencies' dose modification schema (or the schema used in the pivotal trial's protocol) are important considerations in selecting the initial dose and subsequent modifications. The schema can include a defined toxicity (on its own) that requires no dose modification, a toxicity that advises dose modification, a toxicity that advises dose discontinuation, as well as treatment for the defined toxicity.

Tables 3-11 and 3-12 are hypothetical examples of a dose modification schema that would advise dose modification based on tolerability reported in the previous cycle. Such tables are specific to the agent used and the patient setting in which the therapy is administered. The tables direct the investigator to make modifications when such a graded event occurs. For oncology agents used in clinical practice as standard of care, the guidance issued by the respective countries' regulatory agencies are excellent sources of this information.

Table 3-11 Example of Dose Modification Schema for Hematologic Toxicity

Event ANC	Postponement of Cycle	Dose Reduction
ANC >1.5 × 10^9/L	No cycle postponement.	No dose reduction
ANC 1.0-1.5 × 10^9/L	Postpone treatment until ANC is >ANC 1.5 × 10^9/L. Resume cycle with GCSF.	No dose reduction
ANC 0.5-1 × 10^9/L	Postpone treatment until ANC is >ANC 1.5 × 10^9/L. Resume cycle with GCSF.	Reduce dose by 15%
ANC <0.5 × 10^9/L	Postpone treatment until ANC is ANC 1.0-1.5 × 10^9/L. Resume cycle with GCSF. If no recovery to ANC >1.5 × 10^9/L by day 29, stop treatment.	Reduce dose by 25%

Abbreviations: ANC, absolute neutrophil count; GCSF, granulocyte-colony stimulating factor.

Table 3-12 Example of Dose Modification Schema for Hepatic Toxicity

Event	Dose Modification Algorithm
ALT <3.0× URL	Continue study treatment at the current dose
ALT 3-5× URL without bilirubin elevation	Interrupt study treatment, monitor subject closely, perform liver panel at least weekly until ALT returns to grade 1. If there is no recovery in 6 weeks, permanently discontinue therapy. If ALT recovers to <3× ULN within 6 weeks, readminister at reduced dose and monitor ALT weekly
ALT >5× URL without bilirubin elevation	If no recovery to grade 1 in 2 weeks, permanently discontinue. If recovery in 2 weeks, readminister at a reduced dose and monitor ALT weekly. If ALT elevations recur >3× ULN, permanently discontinue therapy
ALT >3× URL and bilirubin elevation	Permanently discontinue therapy. Initiate a potential Hy's law evaluation for drug-induced liver injury immediately. Consider a hepatology consultation

Abbreviations: ALT, alanine aminotransferase; ULN, upper limit of normal; URL, upper reference limit.

PROJECT OPTIMUS AND THE ONCOLOGY DOSING TOOLKIT

Historically, drug development for cytotoxic agents focused almost exclusively on identifying the maximum tolerated dose (MTD), often with less emphasis on determining the optimal dose for a given population. While this approach established clinical benefits, it frequently failed to identify regimens that provided the highest clinical activity with the lowest toxicity.

To address this, the FDA launched Project Optimus, a multidisciplinary effort to reform dose-finding paradigms in oncology. As a central part of this initiative, the FDA developed the Oncology Dosing Toolkit to provide developers with a practical framework for implementing these new optimization standards.[94]

TOOLKIT'S ROLE IN DOSE SELECTION

The Oncology Dosing Toolkit is designed to support decision-making throughout the development lifecycle. It provides the methodology to address three critical overarching questions central to the Project Optimus mission:

1. **Dose Escalation:** Which dosages will be evaluated during the initial dose-escalation phase?
2. **Dose Investigation:** Which dosages will be chosen for further investigation (eg, in a randomized dosage evaluation)?
3. **Registration:** What dosages will be selected for the final registration trial(s)?

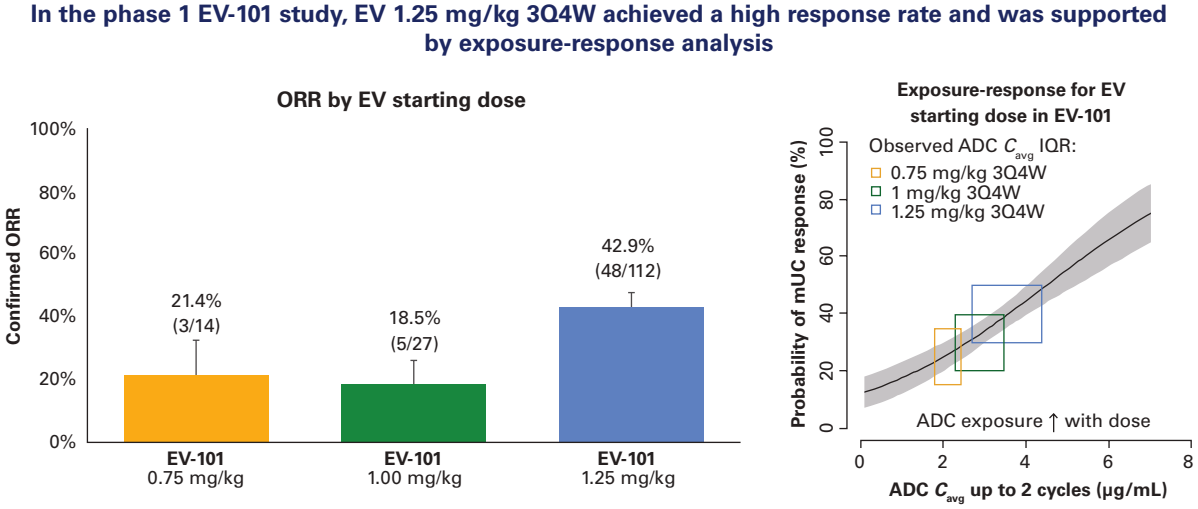
By utilizing the toolkit early, investigators gain access to FDA guidance on key design issues, including translational evidence, pharmacokinetic characteristics, safety/efficacy data, and modeling and simulation approaches.

CASE STUDY: ENFORTUMAB VEDOTIN (EV-101)

A practical application of these optimization principles was presented at the 2024 ASCO Annual Meeting regarding enfortumab vedotin (EV). The evidence supporting the current clinical dose was determined across multiple cohorts, ensuring a sufficient patient population to confirm a favorable benefit-risk profile, a hallmark of the Project Optimus approach.

Figure 3-4 illustrates the dose-response relationship, showing a rise in overall response rate correlated with increasing dose. The insert curve shows a predictable increase in systemic exposure, providing assurance that dose modifications will result in expected changes in adverse events. Figure 3-5 further confirms this via the dose-toxicity relationship.

Figure 3-4 EV-101 Clinical Dose Selection by Dose Response and Exposure Response



Abbreviations: 2L+, second and later lines; 3Q4W, days 1, 8, and 15 of a 28-day cycle; ADC, antibody-drug conjugate; C_{avg}, time-averaged exposure up to two cycles; EV, enfortumab vedotin; mUC, metastatic urothelial carcinoma; ORR, objective response rate.
Error bar = one standard deviation. Analysis populations for both dose-response and exposure-response were based on actual treatment arms.
Adapted from Petrylak DP, Chia YL, Yu EY, et al. Impact of exposure on outcomes with enfortumab vedotin in patients with locally advanced or metastatic urothelial cancer. Presented at: Annual Meeting of the American Society of Clinical Oncology; May 29, 2024; Chicago, IL.

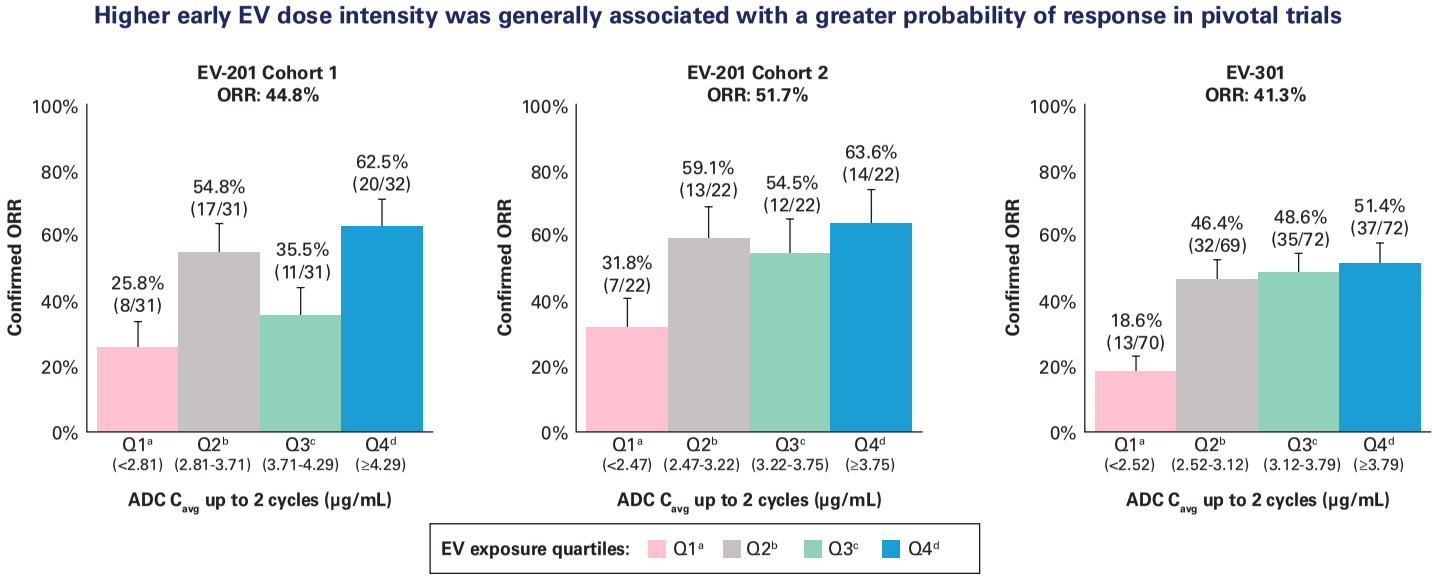
According to FDA reviewers, the proposed regimen of 1.25 mg/kg (up to 125 mg) was selected based on a superior benefit/risk ratio observed in study EV-101. While the 1.25 mg/kg dose was associated with greater tumor response, it also required more frequent dose reductions (32%) compared to lower dose levels (0% at 0.75 mg/kg; 10% at 1 mg/kg). Weight-based dosing for EV was ultimately supported by population pharmacokinetic modeling and simulation analyses, consistent with the toolkit's emphasis on exposure-response data.

EVOLUTIONARY SHIFT IN METHODOLOGY

The landscape of dose optimization has evolved significantly since the launch of Project Optimus in 2021. Industry practice has shifted from the traditional "3+3" design toward Bayesian methods. Data from one high-volume phase I center of excellence indicate that the use of Bayesian methods increased from 48% in 2021 to 75% in 2024. This evolution toward improved precision in MTD determination and dose-level toxicity is expected to deliver clinical regimens with enhanced therapeutic benefit and manageable toxicity profiles.

Figure 3-5 EV-101 Clinical Dose Selection Confirmation and Exposure Response



Abbreviations: ADC, antibody-drug conjugate; C_{avg}, time-averaged exposure up to two cycles; EV, enfortumab vedotin; mUC, metastatic urothelial carcinoma; ORR, objective response rate; Q, quartile.

All data presented are from a post hoc, explanatory analysis. Error bar = one standard deviation.

Average ADC exposures were divided into four quartiles: [a]Q1 represents the EV exposures between 0% and 25%; [b]Q2: 25% to 50%; [c]Q3: 50% to 75%; [d]Q4: 75% to 100% (the highest EV exposure quartile).

DRUG DEVELOPMENT: NOVEL CLINICAL TRIAL DESIGN AND SPECIAL POPULATIONS

Clinical trials are critical to the development of new anticancer therapies, and an understanding of novel clinical trial designs for targeted therapies is critical.

NOVEL TRIAL DESIGNS

With molecular characterization of cancers becoming routine in clinical practice, treating tumors according to molecular characteristics rather than histologic classification is becoming more widespread, requiring new study designs. Common designs include umbrella and basket trials. In umbrella trials, multiple mutations in a single tumor type are targeted by different drugs. An example is a current National Cancer Institute (NCI) Clinical Trials Network study in second-line squamous cell cancer of the lung in which mutations in *MET, PI3K, CDK4/6*, and others are targeted by different agents.[47,94] Basket trials use targeting of a specific molecular aberration, regardless of the tissue of origin. An example of a basket trial is the National Cancer Institute Molecular Analysis for Therapy Choice trial (NCI-MATCH), which has now led to the newer trial, ComboMATCH. Novel trial designs and criteria for assessment of tumor response are being used to evaluate immunotherapies and agents targeting the tumor microenvironment. A form of basket trial is the use of expansion cohorts, each recruiting a defined tumor type, after the completion of the rising-dose phase I stage of a first-time-in-human study.

KEY POINTS

- With the emergence of molecularly targeted agents, novel study designs such as umbrella and basket trials have been introduced.
- Dose optimization strategies during drug development are essential to ensure maximum efficacy while minimizing toxicity.[95]

HIGH-YIELD TAKEAWAYS

- Coadministered supportive care drugs, like antifungal azoles and some HIV and antiseizure medicines, can inhibit or induce CYP3A4, thereby altering the clearance and effect of existing anticancer therapy.
- Patients with DPD deficiency receiving 5-FU can experience enhanced myelosuppression, which can be fatal. Patients with the *UGT1A1*28* homozygous genotype receiving irinotecan can experience enhanced myelosuppression and diarrhea.
- EFGR-directed therapy, particularly TKIs, can cause interstitial lung disease (shortness of breath and dry cough) and usually requires permanent discontinuation of therapy.

Acknowledgments

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

CLINICAL PHARMACOLOGY 3

CHAPTER SUMMARY GUIDE

KEY POINTS

- Hormonal therapies are most commonly used to treat breast cancer and prostate cancer. They work by altering the production of hormones, blocking the activity of particular HRs in the body, or substituting chemically similar agents for the active hormones.
- Cytotoxic chemotherapy remains an important component of many cancer therapy regimens in the neoadjuvant, adjuvant, and metastatic settings for solid tumors and for hematologic malignancies.
- Small-molecule targeted receptor inhibitors offer distinct advantages as therapeutics. Most can be administered orally.
- Monoclonal antibodies are therapeutic agents bioengineered to target specific extracellular receptors or cell surface antigens that are either unique to or overexpressed by tumor cells.
- ADCs are anticancer agents that consist of an antibody, a cytotoxic payload, and a linker that work to enhance the therapeutic effect while minimizing toxicity to normal cells.
- Immune checkpoint inhibitor immunotherapy results in durable clinical benefit in some patients and is associated with a unique spectrum of adverse effects known as immune-related adverse effects, which include dermatologic, GI, hepatic, endocrine, and other less common inflammatory effects.
- CRS and ICANS are common with cellular therapy and can be managed by interleukin-6 (IL-6) inhibitors and corticosteroids. Patients are usually hospitalized for proper monitoring and management of these adverse effects.
- C_{max}, which occurs at T_{max}, can predict acute toxicity, such as ECG changes, infusion reactions, and acute blood pressure elevations.
- The AUC best reflects systemic exposure and can predict response for some antineoplastics.
- Pharmacokinetic assessments are important in determining drug-drug interactions and making recommendations on the dose and schedule of anticancer agents.
- Half-life guides the frequency of administration and determines washout periods in clinical trials. Dosing in clinical trials often considers the half-life of targeted therapies. For example, patients are often not eligible for initiating dosing of a study agent in a clinical trial until five half-lives of the targeted therapy have elapsed.
- Drug interactions with oral cancer therapies, particularly TKIs, are common and may be clinically important.
- Drug interactions affecting gastric absorption are usually related to food or pH effects. These can be managed by avoiding concurrent administration of pH-lowering agents.
- Food effects can be managed by counseling patients on when to take their medication (ie, with or without food). Some drugs may require administration with a low-fat meal.
- Drug interactions related to metabolism or elimination can be managed by avoiding concurrent administration, if possible, or by adjusting doses.
- Grapefruit, grapefruit juice, Seville oranges, and star fruit are CYP3A4 inhibitors. Patients should be instructed to avoid consuming these products while taking cancer therapies that are metabolized via CYP3A4.
- Patients with TPMT or NUDT15 deficiency are at increased risk for severe toxicity at conventional mercaptopurine doses and generally require dose reductions.
- DPD is an enzyme encoded by the DPYD gene and promotes the first step of the fluorouracil degradation pathway. This pathway helps convert majority of drug to its inactive metabolites. Patients with partially or complete DPD deficiency cannot adequately degrade fluoropyrimidines, are at increased risk of severe, potentially fatal toxicity. Test for DPD deficiency before starting 5-FU or capecitabine therapy should be performed. Avoid use in patients with complete DPD deficiency and reduce dose in those with partial DPD deficiency.[50]
- One avenue to combat toxicities and prevent permanent sequelae is to administer antidotes if a chemotherapy overdose occurs.
- Uridine triacetate is indicated for emergency treatment of 5-FU or capecitabine overdose.
- Glucarpidase is a rescue agent approved by the FDA for use in patients with delayed methotrexate excretion.
- Methylene blue is an option for use in patients with ifosfamide-induced encephalopathy. It should be used with caution in patients with glucose-6-phosphate deficiency.
- Empirical dose reductions are recommended for some drugs in patients with underlying hepatic and/or renal dysfunction.

- With the exception of conditioning regimens used for stem cell transplants, no empirical dose reductions are recommended that are based solely on age.
- Selecting the appropriate initial dose for a patient can be based upon patients' comorbidity, age, and fragility, concurrent medications known to inhibit or induce drug metabolism, and/or known genetic polymorphism. Recommended starting dose can be varied depending on the countries where the drug or treatment is authorized and their regulatory policies.
- Dose modification during treatment is common and determined based on the patient's tolerability.
- Actual body weight and actual BSA should be used for dosing obese patients with drugs that use weight-based dosing.[90-93]
- With the emergence of molecularly targeted agents, novel study designs such as umbrella and basket trials have been introduced.
- Dose optimization strategies during drug development are essential to ensure maximum efficacy while minimizing toxicity.[95]

Table 3-1 **Targeted Therapies With Biomarker Selection: EGFR and MET Inhibitors**

	Sensitive Mutation/ Required Biomarkers	Food Effect	pH Dependent (Yes/No)	Drug Interactions	Use	Notes
EGFR inhibitors						
Erlotinib	Exon 19 deletions, exon 21 L858R	Empty stomach	Yes	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and grapefruit	Advanced NSCLC; first line or subsequent lines; *EGFR* mutant	Approved before the discovery of EGFR biomarker; has a maintenance indication in unselected patients
Gefitinib	Exon 19 deletions, exon 21 L858R	With or without food	Yes	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and grapefruit	Advanced NSCLC; first line or subsequent lines; *EGFR* mutant	Initially approved on phase 2 data in unselected populations; failed in phase 3 trial and was taken off the market
Afatinib	Exon 19 deletions, exon 21 L858R, S7681, L861Q, and G719X	Empty stomach	No	Not metabolized by CYP	Advanced NSCLC; first line or subsequent lines; *EGFR* mutant	Retains activity in erlotinib- or gefitinib-resistant patients; has a maintenance indication in unselected patients
Dacomitinib	Exon 19 deletions, exon 21 L858R	With or without food	Yes	Strong CYP2D6 inhibitor; inhibits the metabolism of drugs that are metabolized by CYP2D6	Advanced NSCLC; first line or subsequent lines; *EGFR* mutant	More effective than gefitinib, but also has more adverse effects
Osimertinib	Exon 19 deletions, exon 21 L858R, T790M	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and has the potential for QT prolongation	Adjuvant treatment of early-stage, locally advanced, and metastatic *EGFR*-mutated NSCLC	Improved PFS in first-line setting compared with gefitinib or erlotinib; preferred if CNS penetration is needed
Lazertinib	Exon 19 deletions, exon 21 L858R substitution	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors.	First-line treatment of locally advanced or metastatic NSCLC with exon 19 deletion or exon 21 L858R substitution	Use in combination with amivantamab. Prophylactic anticoagulation should be given for the first 4 months of treatment
Sunvozertinib	Exon 20 insertion	With food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Locally advanced or metastatic NSCLC with EGFR exon 20 insertion	Take with food to reduce GI toxicities
MET inhibitors						
Capmatinib	MET exon 14 skipping	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Metastatic NSCLC with MET exon 14–skipping mutation	
Tepotinib	MET exon 14 skipping	With food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Metastatic NSCLC with MET exon 14–skipping mutation	A clinical trial used a liquid biopsy for assignment

Abbreviations: CNS, central nervous system; CYP, cytochrome P450; EGFR, epidermal growth factor receptor; GI, gastrointestinal; NSCLC, non–small cell lung cancer; PFS, progression-free survival.

Table 3-2 **Targeted Therapies With Biomarker Selection: ALK, ROS, and BRAF Inhibitors**

	Sensitive Mutation/ Required Biomarkers	Food Effect	pH Dependent (Yes/No)	Drug Interactions	Use	Notes
ALK and/or ROS1 inhibitors						
Crizotinib	*ALK* translocation	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and has the potential for QT prolongation	Advanced NSCLC; first line or subsequent lines; *ALK* or *ROS1* positive; unresectable, recurrent, or refractory inflammatory anaplastic lymphoma, *ALK* positive	More effective than chemotherapy, but less effective than alectinib; only ALK inhibitor with ROS1 indication
Ceritinib	*ALK* translocation	With food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors and grapefruit	Advanced NSCLC; first line or subsequent lines; *ALK* positive	More effective than chemotherapy
Alectinib	*ALK* translocation	With food	No	Not metabolized by CYP	Advanced NSCLC; first line or subsequent lines; *ALK* positive	Improved PFS over crizotinib; preferred if CNS penetration is needed
Brigatinib	*ALK* translocation	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Advanced NSCLC; after failure of crizotinib; *ALK* positive	Improved PFS over crizotinib; blood pressure should be controlled before initiation
Lorlatinib	*ALK* translocation	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Advanced NSCLC; after crizotinib and one other drug; *ALK* positive	See reference[23]
Ensartinib[24]	*ALK* translocation	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors; Avoid P-gp inhibitor	Advanced NSCLC; ALK inhibitor naive; *ALK positive*	Monitor uric acid while on treatment
Repotrectinib	ROS1 rearrangement	With or without food	No	CYP3A4 inducer; interacts with CYP3A4 inducers and inhibitors	Advanced NSCLC; first line or subsequent lines; *ROS1* fusion positive	Inhibits both wild-type and G2032R-mutant *ROS1* fusions; may be better for patients with brain metastases[25]
Taletrectinib[4]	ROS1 rearrangement	Empty stomach	Yes	CYP3A4 inducer; interacts with CYP3A4 inducers and inhibitors	Advanced NSCLC; first line or subsequent lines; *ROS1* positive	Monitor uric acid and skeletal fractures while on treatment

	Sensitive Mutation/ Required Biomarkers	Food Effect	pH Dependent (Yes/No)	Drug Interactions	Use	Notes
BRAF inhibitors						
Dabrafenib	V600E, V600K	Empty stomach	No	CYP3A4 and CYP2CB substrate; interacts with CYP3A4 and CYP2C8 inducers and inhibitors	First line; adjuvant melanoma, metastatic melanoma, metastatic NSCLC, metastatic anaplastic thyroid, *BRAF* mutant; unresectable or metastatic solid tumors with *BRAF* V600E mutation	Improved PFS and OS over dacarbazine as a single agent; used in combination with the MEK inhibitor to prevent resistance
Vemurafenib	V600E, V600K	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	First-line, metastatic melanoma, Erdheim-Chester disease, *BRAF* mutant; refractory NSCLC with *BRAF* V600 mutation	Improved PFS over dacarbazine as the single agent; used in combination with the MEK inhibitor to prevent resistance
Encorafenib	V600E, V600K	With or without food	No	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	First-line, metastatic melanoma, *BRAF* mutant; first-line, metastatic colon cancer, *BRAF* mutant	Only BRAF inhibitor indicated for colon cancer in combination with cetuximab; correct hypokalemia or hypomagnesemia before treatment initiation
Tovorafenib	*BRAF* fusion or rearrangement, V600E mutation	Empty stomach	Yes	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Relapsed or refractory low-grade glioma	Monitor uric acid, CPK level, and skeletal fractures while on treatment

Abbreviations: CYP, cytochrome P450; H2, H2 histamine antagonists (eg, famotidine); NSCLC, non–small cell lung cancer; OS, overall survival; PFS, progression-free survival; PPI, proton pump inhibitors (eg, omeprazole).

Table 3-3 **Targeted Therapies With Biomarker Selection: NTRK and PARP Inhibitors**

	Sensitive Mutation/ Required Biomarkers	Drug Interactions	Use	Notes
NTRK inhibitors				
Entrectinib	*NTRK, ROS1* fusions	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Metastatic NSCLC; *ROS1* rearrangement; solid tumor with known *NTRK* fusion	
Larotrectinib	*NTRK* fusion	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Solid tumor with known *NTRK* fusion	First small-molecule disease–agnostic approval
Repotrectinib	NTRK fusion	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Locally advanced or metastatic NSCLC with ROS1 positive; Solid tumors with *NTRK* gene fusion positive	
PARP inhibitors				
Olaparib	BRCA1/BRCA2	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Metastatic breast cancer, HER2 negative, germline *BRCA* mutated; ovarian cancer maintenance, *BRCA* mutant; metastatic prostate cancer with homologous recombination repair gene-mutated; pancreatic cancer with germline *BRCA* mutated; first-line maintenance	Because of the difference in dosing and bioavailability, do not substitute capsules for tablets
Rucaparib	BRCA1/BRCA2	Moderate CYP1A2 inhibitor; inhibits the metabolism of drugs that are metabolized by CYP1A2	*BRCA*-mutant recurrent ovarian cancer maintenance; metastatic prostate cancer castration resistant, *BRCA* mutated; locally advanced or metastatic pancreatic cancer, germline *BRCA2*-mutated maintenance therapy	Associated with a moderate or high emetic potential, antiemetics are recommended to prevent nausea and vomiting
Niraparib	Testing not required	Not metabolized by CYP	Recurrent ovarian cancer, maintenance therapy	Associated with a moderate or high emetic potential, antiemetics are recommended to prevent nausea and vomiting
Talazoparib	BRCA1/BRCA2	Not metabolized by CYP	Locally advanced or metastatic breast cancer, *BRCA* mutant	

Abbreviations: CYP, cytochrome P450; NSCLC, non–small cell lung cancer; PARP, poly ADP ribose polymerase.
All are not pH dependent. All can be provided with or without food.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 3-4 **Targeted Therapies With Biomarker Selection: FLT3 and IDH Inhibitors**

	Sensitive Mutation/ Required Biomarkers	Drug Interactions	Use	Notes
FLT3 inhibitors				
Midostaurin	ITD, point mutations	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Newly diagnosed AML, *FLT3* mutation positive; in combination with chemotherapy during induction and consolidation therapy	First-in-class FLT3 inhibitor
Gilteritinib	ITD, point mutations	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Relapsed or refractory AML, *FLT3* mutant	
Quizartinib	ITD, point mutations	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Newly diagnosed AML, *FLT3* mutation positive; in combination with chemotherapy during induction and consolidation therapy	Second-generation FLT3 inhibitor
IDH1/IDH2 inhibitors				
Enasidenib	IDH2	No known drug interactions	Relapsed or refractory AML, *IDH2* mutant	First-in-class IDH2 inhibitor
Ivosidenib	IDH1	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Relapsed or refractory AML, *IDH1* mutant; newly diagnosed acute myeloid leukemia with *IDH1* mutation in combination with azacytidine; locally advanced or metastatic *IDH1*-mutated cholangiocarcinoma	First-in-class IDH1 inhibitor
Vorasidenib	IDH1 or IDH2	Interact with CYP2C8 inhibitors and inducers; sensitive CYP3A4 substrates	Astrocytoma or oligodendroglioma with a susceptible *IDH1* or *IDH2* mutation	May promote tumor growth in patients with NF1 tumors

Abbreviations: AML, acute myeloid leukemia; AUC, area under the curve; ITD, internal tandem duplication.
All are not pH dependent. Except for midostaurin, all can be provided with or without food; with ivosidenib, avoid high-fat meals (increases AUC by 25%).
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 3-5 **Targeted Therapies With Biomarker Selection: Various Inhibitors**

	Sensitive Mutation/ Required Biomarkers	Food Effect	Drug Interactions	Use	Notes
FGFR inhibitors					
Erdafitinib	*FGFR2, FGFR3* mutations and fusions	With or without food	CYP3A4 and CYP2C9 substrates; interacts with inducers and inhibitors of both enzymes	Locally advanced or metastatic urothelial carcinoma with *FGFR3* or *FGFR2* alterations	First-in-class FGFR inhibitor; better activity in *FGFR3* point mutations over *FGFR3* and *FGFR2* fusions
Futibatinib	*FGFR2* fusion or rearrangement	With or without food	CYP3A4, CYP2D6, and CYP2C9 substrates; interacts with inducers and inhibitors of both enzymes	Locally advanced or metastatic cholangiocarcinoma with *FGFR2* fusion or rearrangement	
Pemigatinib	*FGFR2* fusion	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Previously treated, locally advanced, or metastatic cholangiocarcinoma with *FGFR2* fusion; relapsed or refractory myeloid/ lymphoid neoplasms with *FGFR1* rearrangement	
RET inhibitors					
Selpercatinib	*RET* fusions or mutations	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	*RET* mutant and *RET* fusion–positive medullary thyroid cancer; locally advanced or metastatic *RET*-positive NSCLC; locally advanced or metastatic *RET* fusion–positive solid tumors	First-in-class RET inhibitor; optimize blood pressure before treatment initiation
Pralsetinib	*RET* fusions	Empty stomach	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	*RET* mutant and *RET* fusion–positive medullary thyroid cancer; metastatic NSCLC with *RET* fusion	Do not administer for at least 2 weeks after major surgery and until after adequate wound healing has occurred
PI3K inhibitors					
Alpelisib	*PIK3CA* mutations	With food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors; CYP2C9 inducer; avoid sensitive substrates such as warfarin	Postmenopausal women and men with HR-positive, HER2-negative, *PIK3CA* mutated with advanced or metastatic breast cancer	Approved in combination with fulvestrant; first-in-class PIK3CA inhibitor; optimize blood glucose before treatment initiation

	Sensitive Mutation/ Required Biomarkers	Food Effect	Drug Interactions	Use	Notes
Inavolisib	*PIK3CA* mutations	With or without food	BCRP/ABCG2 and P-gp/ABCB1 substrate	Endocrine-resistant, *PIK3CA*-mutated, HR-positive, HER2-negative locally advanced or metastatic breast cancer	Reduce the dose for moderate renal impairment
AKT inhibitors					
Capivasertib	*PIK3CA, AKT1*, and *PTEN* alterations	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	HR-positive, HER2-negative, locally advanced, or metastatic breast cancer with genetic alterations in one or more of these genes: *PIK3CA, AKT1*, and *PTEN*	Improved PFS with benefits observed in the overall population and among patients with AKT pathway-altered tumors
PDGFRA inhibitors					
Avapritinib	*PDGFRA* exon 18 mutation	Empty stomach	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Unresectable or metastatic GIST with *PDGFRA* exon 18 mutation	First-in-class PDGFRA inhibitor; associated with a moderate or high emetic potential risk; antiemetics may be recommended to prevent nausea and vomiting
EZH2 inhibitors					
Tazemetostat	*EZH2* gain-of-function mutations, *SMARCA* loss-of-function mutations	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Adults and children age 16 or older with metastatic or locally advanced epithelioid sarcoma, relapsed or refractory follicular lymphoma salvage therapy, or those with *EZH2* mutation	First-in-class EZH2 inhibitor
MEK inhibitors					
Trametinib	*BRAF* V600E, V600K	Empty stomach	None	First-line, adjuvant melanoma, metastatic melanoma, metastatic NSCLC, metastatic anaplastic thyroid cancer, *BRAF* mutant; low-grade recurrent serous ovarian cancer; solid tumors, unresectable or metastatic with *BRAF* V600E mutation	Only approved in combination with dabrafenib

	Sensitive Mutation/ Required Biomarkers	Food Effect	Drug Interactions	Use	Notes
Cobimetinib	*BRAF* V600E, V600K	With or without food	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	First-line, metastatic melanoma, *BRAF* mutant; treatment of histiocytic neoplasms	Only approved in combination with vemurafenib; causes severe photosensitivity
Binimetinib	*BRAF* V600E, V600K	With or without food	None	First-line, metastatic melanoma, *BRAF* mutant	Only approved in combination with encorafenib; LVEF >50% required
Selumetinib	MEK1, MEK2	Empty stomach	CYP3A4 substrate; interacts with CYP3A4 inducers and inhibitors	Children aged 2 years or older with NF1 and plexiform neurofibromas	
Mirdametinib	MEK1, MEK2	With or without food	None	Children aged 2 years or older with NF1 and plexiform neuroblastomas	
RAS inhibitors					
Sotorasib	*KRAS* G12C		Caution with CYP3A4 inducers and inhibitors, PgP substrates and acid-reducing agents	*KRAS* G12C mutated locally advanced or metastatic NSCLC	>20% diarrhea, hepatotoxicity, cough, and musculoskeletal pain
Adagrasib	*KRAS* G12C	With or without food	Caution with CYO3a4 inducers, inhibitors, substrates, CYP2c9, cyp 2d6, P-gp substrates, drugs that prolong QTc	*KRAS* G12C mutated locally advanced NSCLC and CRC	Diarrhea, QTc prolongation, hepatotoxicity, and ILD/pneumonitis

Abbreviations: CRC, colorectal cancer; GIST, gastrointestinal stromal tumor; HR, hormone receptor; ILD, interstitial lung disease; LVEF, left ventricular ejection fraction; NF1, neurofibromatosis type 1; NSCLC, non–small cell lung cancer; ORR, overall response rate; PFS, progression-free survival; P-gp, P-glycoprotein.
All are not pH dependent.

Table 3-6 **Basic Pharmacokinetics Definitions**

Parameter Abbreviation	Definition	Equation	Use/Association
C_{max}	Maximal drug concentration	Visual extrapolation	Can be associated with acute adverse effects
T_{max}	Time at which the maximum drug concentration is achieved	Visual extrapolation	Time that acute adverse effects occur
$t_{1/2}$	Time required for the plasma concentration to decrease by half, or half-life	$T_{1/2}$ 0.698 × Vd/clearance	Determines how long a drug is measurable in the plasma in the body
AUC	Area under the curve	Dose/clearance	Measure of systemic drug exposure
Vd	Volume of distribution	Dose/concentration at time 0 (extrapolated)	Where the drug goes in the body
Cl	Clearance	Dose/AUC	How fast the drug is eliminated

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 3-7 **Drugs Commonly Used in Oncology That Have Pharmacogenetic Implications**

Drug	Gene	Variant Genotype	Consequence of Variant Genotype	Recommendation	Strength of Recommendation*
Capecitabine/ fluorouracil	DPYD	IM	Increased toxicity	IM: Reduce starting dose	Strong
		PM		PM: Avoid if possible, or reduce dose by 75%	
Irinotecan, liposomal irinotecan	UGT1A1	PM	Increased toxicity	Select alternative therapy if possible	Moderate
Mercaptopurine	TPMT, NUDT15	IM	Increased toxicity	IM: Reduce dose by 50%	Strong
		PM		PM: Reduce dose 10-fold	
Tamoxifen	CYP2D6	PM	Decreased efficacy	Select an alternative agent not metabolized by CYP2D6 (eg, aromatase inhibitor if postmenopausal)	Weak

Abbreviations: IM, intermediate metabolizer; PM, poor metabolizer.
*Clinical Pharmacogenetics Implementation Consortium evidence level, except for irinotecan, for which the recommendations are the authors' opinion.

Table 3-8 **Dosing Guidelines of Selected Anticancer Agents for Patients With Renal Dysfunction**	
Agent	**Dose Adjustment in Renal Dysfunction**
Bleomycin	CrCl 40-50 mL/min, 70% of the full dose
	CrCl 30-40 mL/min, 60% of the full dose
	CrCl 20-30 mL/min, 55% of the full dose
	CrCl 10-20 mL/min, 45% of the full dose
	CrCl 5-10 mL/min, 40% of the full dose
Capecitabine	CrCl 30-50 mL/min, 75% of the full dose
	CrCl <30 mL/min, omit
Carboplatin	Dose based on GFR, using the Calvert formula: Dose (mg) = target AUC × (GFR + 25). AUC = 5–7 Hemodialysis: Carboplatin dose (mg) = Target AUC × 25, administer on a non–dialysis day; hemodialysis should occur between 12 and 24 hours after carboplatin dose
Carmustine	CrCl 45-60 mL/min, 80% of the full dose
	CrCl 30-45 mL/min, 75% of the full dose
	CrCl <30 mL/min, 70% of the full dose
Cisplatin	CrCl 46-60 mL/min, 50% of the full dose
	CrCl 31-45 mL/min, 25% of the full dose
	CrCl <30 mL/min, omit
Cladribine	CrCl 10-50 mL/min, 75% of the full dose
	CrCl <10 mL/min, 50% of the full dose
Cyclophosphamide	CrCl 10-20 mL/min, 75% of the full dose
	CrCl <10 mL/min, 50% of the full dose
Cytarabine	High and intermediate dose (1 g/m^2 or more per dose)
	CrCl 30-59 mL/min: 50% of the full dose
	CrCl <30 mL/min: use is not recommended, consider an alternative agent
Dacarbazine	CrCl 30-60 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 50% of the full dose
	CrCl <10 mL/min, omit
Daunorubicin	Scr >3 mg/dL, 50% of the full dose
	CrCl 30-50 mL/min, 75% of the full dose
	CrCl <30 mL/min, 50% of the full dose
Etoposide	CrCl 15 to 50 mL/min, 75% of the full dose
	CrCl <15 mL/min, 50% of the full dose
Fludarabine	CrCl 30-70 mL/min, 50% of the full dose
	CrCl <30 mL/min, omit
Hydroxyurea	CrCl 45-60 mL/min, 80% of the full dose
	CrCl 30-45 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 50% of the full dose
	CrCl <10 mL/min, 20% of the full dose
Ifosfamide	CrCl 46-60 mL/min, 80% of the full dose
	CrCl 31-45 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 70% of the full dose
	CrCl <10 mL/min, omit
Lenalidomide (use for MDS/myelofibrosis osteosclerosis)	CrCl 30-60 mL/min, 5 mg once every 24 hours
	CrCl <30 mL/min (not requiring dialysis), 5 mg once every 48 hours
	CrCl <30 mL/min (requiring dialysis), 5 mg 3 × per week after each dialysis

Agent	Dose Adjustment in Renal Dysfunction
Lenalidomide (use for multiple myeloma)	CrCl 30-60 mL/min, 10 mg once every 24 hours
	CrCl <30 mL/min (not requiring dialysis), 15 mg once every 48 hours
	CrCl <30 mL/min (requiring dialysis), 5 mg once per day; dose after dialysis on dialysis days
Lomustine	CrCl 45-60 mL/min, 75% of the full dose
	CrCl 30-45 mL/min, 70% of the full dose
	CrCl <30 mL/min, omit
Melphalan	CrCl 45-60 mL/min, 85% of the full dose
	CrCl 30-45 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 70% of the full dose
	CrCl <10 mL/min, 50% of the full dose; for high dose (>1 g/m^2), consider TDM
	CrCl <10 mL/min, omit
Methotrexate	CrCl <30 mL/min, avoid use
	CrCl <10 mL/min, omit
Oxaliplatin	CrCl <30 mL/min, omit
Pemetrexed	CrCl <45 mL/min, omit
Pentostatin	CrCl 45-60 mL/min, 70% of the full dose
	CrCl 30-45 mL/min, 60% of the full dose
	CrCl <30 mL/min, consider using alternative drugs, if possible
Topotecan	CrCl 30-60 mL/min, 75% of the full dose
	CrCl 10-30 mL/min, 50% of the full dose
	CrCl <10 mL/min, omit

Abbreviations: AUC, area under the curve; CrCl, creatinine clearance; GFR, glomerular filtration rate; MDS, myelodisplastic syndromes; TDM, therapeutic dose monitoring.

Reproduced under Creative Commons license. Source: Hendrayana T, Wilmer A, Kurth V, Schmidt-Wolf IG, Jaehde U. Anticancer dose adjustment for patients with renal and hepatic dysfunction: from scientific evidence to clinical application. *Sci Pharm*. 2017;85:8. doi:10.3390/scipharm85010008

Table 3-9 **Dosing Guidelines of Selected Anticancer Agents for Patients With Hepatic Dysfunction**	
Agent	**Dose Adjustment in Hepatic Dysfunction**
Cabazitaxel	Mild impairment (total bilirubin >1-1.5× ULN or AST $ 1.5× ULN, dose at 20 mg/m^2)
	Moderate impairment (total bilirubin >1.5-3× ULN and any AST), dose at 15 mg/m^2
	Total bilirubin >3× ULN, omit
Docetaxel	Transaminase >1.5× ULN and ALP >2.5× ULN, the recommended dose is 75 mg/m^2
	Total bilirubin >ULN and/or transaminase >3.5× ULN, associated with ALP >6× ULN, should not be used unless strictly indicated
Doxorubicin (liposomal)	Total bilirubin 1.2-3.0 mg/dL or AST 60-180 units/L, 50% of the full dose
	Total bilirubin >3.0 mg/dL or AST >180 units/L, 25% of the full dose
	Total bilirubin >5.0 mg/dL, omit
Fluorouracil	Total bilirubin >5.0 mg/dL, omit
Gemcitabine	Increased AST: no need for dose adjustment; increased total bilirubin: reduce dose by 20% (ie, from 1,000 to 800 mg/m^2) and increase if tolerated
Irinotecan	Increased transaminase <3× ULN if no liver metastasis OR <5× ULN if liver metastasis are present. Total bilirubin >2 dosing should not be administered
Ixabepilone (monotherapy)	Total bilirubin <1.5× ULN and AST <10× ULN and AST:ALT ratio <10× ULN, reduce the dose to 32 mg/m^2
	Total bilirubin 1.5-3× ULN and transaminase <10× ULN, dose at 20 mg/m^2; may escalate dose up to 30 mg/m^2 maximum in subsequent cycles if tolerated
Ixabepilone (in combination with capecitabine)	Total bilirubin >ULN or transaminase >2.5× ULN, omit
Mitoxantrone	Total bilirubin 1.5-3.0 mg/dL, 50% of the full dose
	Total bilirubin >3.0 mg/dL, 25% of the full dose
Paclitaxel (3-hour infusion and first course of therapy)	Transaminase <10× ULN and total bilirubin 1.26-2× ULN, recommended dose = 135 mg/m^2
	Transaminase <10× ULN and total bilirubin 2.01-5× ULN, recommended dose = 90 mg/m^2
	Transaminase 10× ULN or total bilirubin >5× ULN dosing is not recommended
Paclitaxel (24-hour infusion and first course of therapy)	Transaminase 2-10× ULN and total bilirubin <1.5 mg/dL, dose 5× at 100 mg/m^2
	Transaminase <10× ULN and total bilirubin 1.6-7.5 mg/dL, dose 5× at 50 mg/m^2
	Transaminase 10× ULN or total bilirubin >7.5 mg/dL, omit
Sorafenib	Total bilirubin 1.5× ULN: 400 mg twice per day
	Total bilirubin 1.5-3× ULN: 200 mg twice per day
	Total bilirubin >3× ULN: omit
Vinblastine	Total bilirubin 1.5-3.0 mg/dL or AST 60-180 units/L, 50% of the full dose
	Total bilirubin >3.1 mg/dL or AST >180 IU/L, omit
Vincristine	Total bilirubin 1.5-3.0 mg/dL or AST 60-180 units/L, 50% of the full dose
	Total bilirubin >3.1 mg/dL or AST >180 units/L, omit
Vinorelbine	Total bilirubin 2.1-3× ULN: 50% of dose
	Total bilirubin >3× ULN: 25% of dose

Abbreviations: ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; ULN, upper limit of normal.
Reproduced under Creative Commons license. Source: Hendrayana T, Wilmer A, Kurth V, et al. Anticancer dose adjustment for patients with renal and hepatic dysfunction: from scientific evidence to clinical application. *Sci Pharm*. 2017;85:8. doi:10.3390/scipharm85010008

Table 3-10 **Dosing Guidelines for Selected Anticancer Agents for Patients With Renal and Hepatic Dysfunction**

Agent	Dose Adjustment	
	In Renal Function	**In Hepatic Dysfunction**
Bendamustine	Renal impairment: CrCl <40 mL/min, omit	Moderate (transaminase 2.5-10× ULN and total bilirubin 1.5-3× ULN) or severe (total bilirubin >3× ULN), omit
Cyclophosphamide	CrCl <10 mL/min, 50% of the full dose	Total bilirubin >3.1-5.0 mg/dL or AST >180 IU/L, 75% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Daunorubicin	Serum creatinine >3 mg/dL, 50% of the full dose	Total bilirubin 1.5-3.0 mg/dL or AST 60-180 IU/L, 75% of the full dose
		Total bilirubin >3.1-5.0 mg/dL or AST >180 IU/L, 50% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Doxorubicin	CrCl <10 mL/min, 75% of the full dose	Total bilirubin 1.5-3.0 mg/dL or AST 60-180 IU/L, 50% of the full dose
		Total bilirubin >3.1-5.0 mg/dL or AST >180 IU/L, 25% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Epirubicin	Serum creatinine >5 mg/dL, lower doses should be considered	Total bilirubin 1.2-3.0 mg/dL or AST 2-4× ULN, 50% of the full dose
		Total bilirubin >3.0 mg/dL or AST >4× ULN, 25% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Erlotinib	CrCl <10 mL/min, omit	Total bilirubin 1-7 mg/dL or AST 2-3× ULN, 50% of the full dose
		Total bilirubin >7.0 mg/dL, omit
Etoposide	CrCl >15-50 mL/min, 75% of the full dose	Total bilirubin 1.5-3 mg/dL or AST 60-180 units, 50% of the full dose
	CrCl <15 mL/min, omit	Total bilirubin 2-3 mg/dL or AST >180 units, omit
Hydroxyurea/ hydroxycarbamide	CrCl 10-60 mL/min, 75% of the full dose	Total bilirubin 1.5-5.0 mg/dL or AST 60-180 units/L, 50% of the full dose
	CrCl <10 mL/min, 50% of the full dose	Total bilirubin >5.0 mg/dL or AST >180 units/L, omit
Idarubicin	Serum creatinine 2–2.5 mg/dL, dose reduction recommended	Total bilirubin 2.5-5.0 mg/dL, 50% of the full dose
		Total bilirubin >5.0 mg/dL, omit
Imatinib	CrCl 40-59 mL/min, doses >600 mg are not recommended	Initial dose: severe hepatic impairment
	CrCl 20-39 mL/min, 50% of the full dose; dose can be increased up to a maximum of 400 mg	Initial dose: 75% of the full dose
	CrCl <20 mL/min, use with caution (in two patients with severe renal impairment, doses of 100 mg/d were tolerated)	Hepatic toxicity during treatment: transaminases >5× ULN or total bilirubin >3× ULN; omit
		Restart at reduced doses (reduce from 400 to 300 mg, from 600 to 400 mg, or from 800 to 600 mg) when transaminases <2.5× ULN and total bilirubin <1.5× ULN

Agent	Dose Adjustment	
	In Renal Function	**In Hepatic Dysfunction**
Methotrexate	For low dose (<1 g/m^2), CrCl 30-60 mL/min, 50% of the full dose	Total bilirubin 3.1-5.0 mg/dL or AST >180 units, 75% of the full dose
	CrCl <30 mL/min, omit	Total bilirubin >5.0 mg/dL, omit
	For high dose (>1 g/m^2), consider TDM	Total bilirubin >5.0 mg/dL, omit
Mitomycin C	CrCl 30-60 mL/min, 75% of the full dose	Total bilirubin 1.5-3.0 mg/dL, 50% of the full dose
	CrCl 10-30 mL/min, 50% of the full dose	Total bilirubin >3.0 mg/dL or transaminase >3× ULN, 25% of the full dose
	CrCl <10 mL/min, omit	

Abbreviations: AST, aspartate transaminase; CrCl, creatinine clearance; TDM, therapeutic dose monitoring; ULN, upper limit of normal.
Reproduced under Creative Commons license. Source: Hendrayana T, Wilmer A, Kurth V, et al. Anticancer dose adjustment for patients with renal and hepatic dysfunction: from scientific evidence to clinical application. *Sci Pharm*. 2017;85:8. doi:10.3390/scipharm85010008

Table 3-11 **Example of Dose Modification Schema for Hematologic Toxicity**		
Event ANC	**Postponement of Cycle**	**Dose Reduction**
ANC >1.5 × 10^9/L	No cycle postponement.	No dose reduction
ANC 1.0-1.5 × 10^9/L	Postpone treatment until ANC is >ANC 1.5 × 10^9/L. Resume cycle with GCSF.	No dose reduction
ANC 0.5-1 × 10^9/L	Postpone treatment until ANC is >ANC 1.5 × 10^9/L. Resume cycle with GCSF.	Reduce dose by 15%
ANC <0.5 × 10^9/L	Postpone treatment until ANC is ANC 1.0-1.5 × 10^9/L. Resume cycle with GCSF. If no recovery to ANC >1.5 × 10^9/L by day 29, stop treatment.	Reduce dose by 25%

Abbreviations: ANC, absolute neutrophil count; GCSF, granulocyte-colony stimulating factor.

Table 3-12 **Example of Dose Modification Schema for Hepatic Toxicity**	
Event	**Dose Modification Algorithm**
ALT <3.0× URL	Continue study treatment at the current dose
ALT 3-5× URL without bilirubin elevation	Interrupt study treatment, monitor subject closely, perform liver panel at least weekly until ALT returns to grade 1. If there is no recovery in 6 weeks, permanently discontinue therapy. If ALT recovers to <3× ULN within 6 weeks, readminister at reduced dose and monitor ALT weekly
ALT >5× URL without bilirubin elevation	If no recovery to grade 1 in 2 weeks, permanently discontinue. If recovery in 2 weeks, readminister at a reduced dose and monitor ALT weekly. If ALT elevations recur >3× ULN, permanently discontinue therapy
ALT >3× URL and bilirubin elevation	Permanently discontinue therapy. Initiate a potential Hy's law evaluation for drug-induced liver injury immediately. Consider a hepatology consultation

Abbreviations: ALT, alanine aminotransferase; ULN, upper limit of normal; URL, upper reference limit.

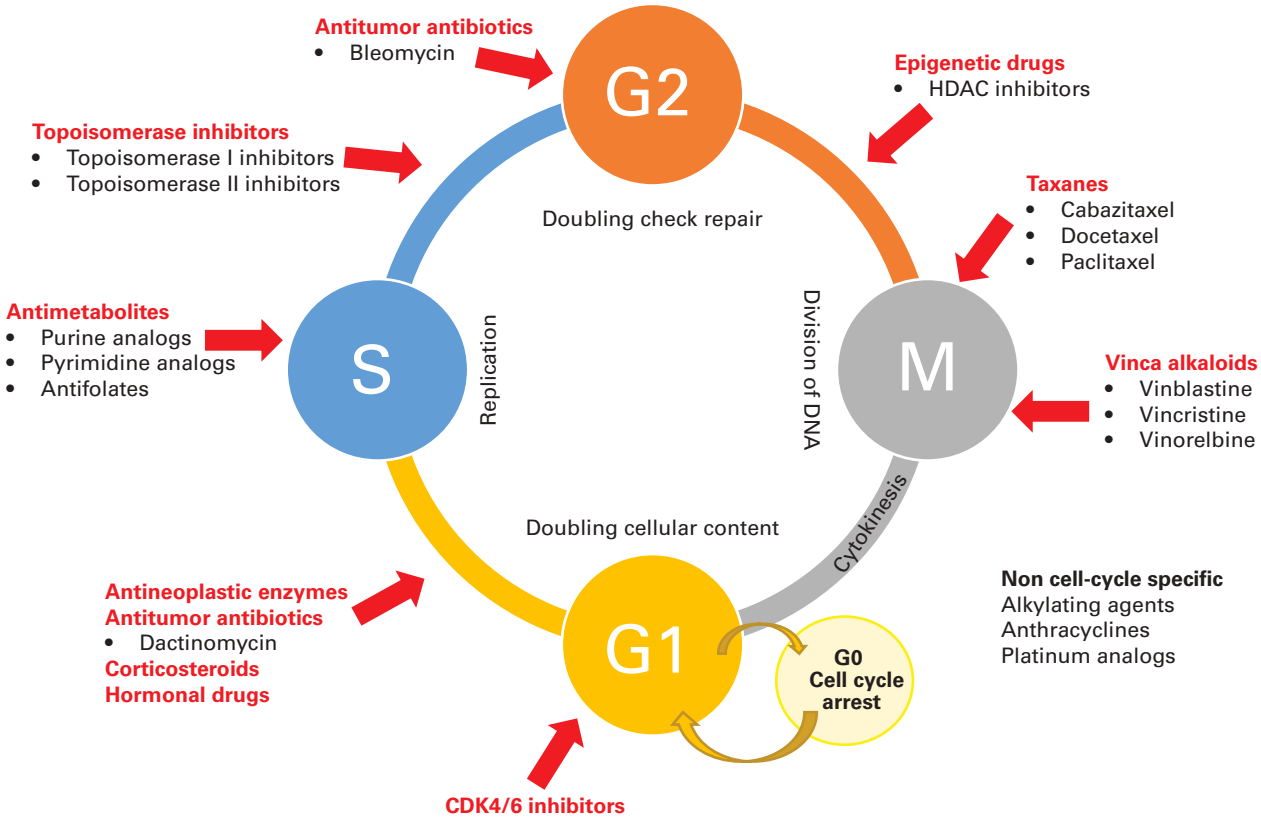
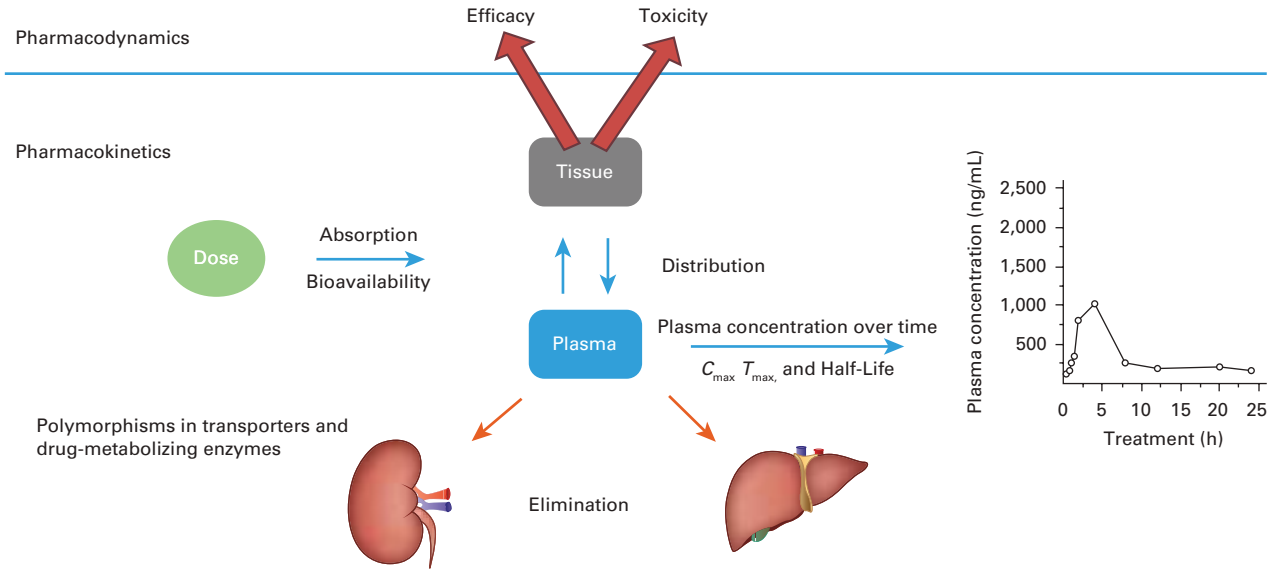
Figure 3-1 Cell Cycle and Site of Cytotoxic Agents



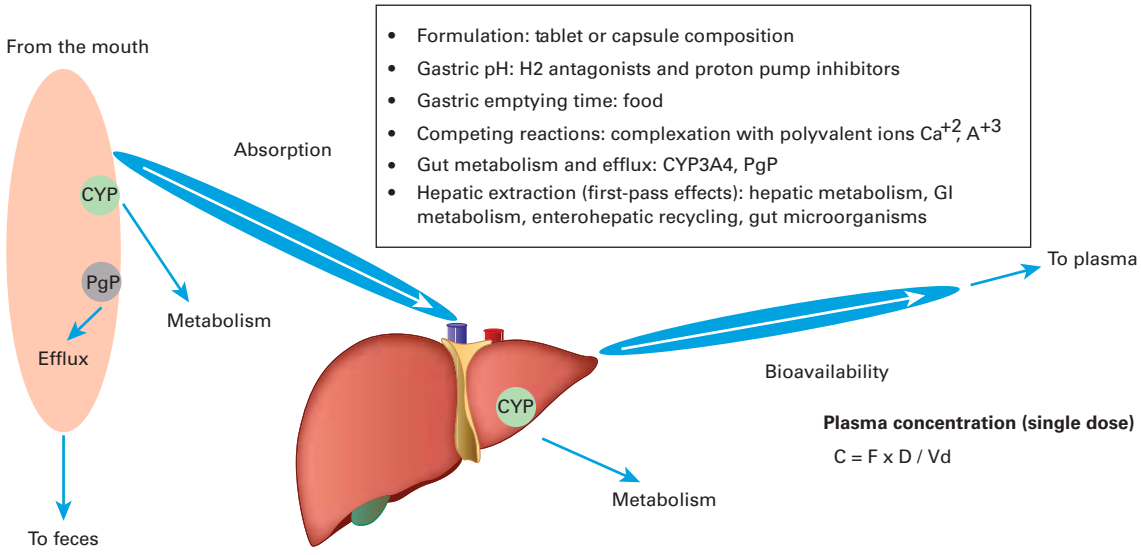
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 3-2 Overview of Pharmacokinetics, Pharmacodynamics, and Pharmacogenetics



Abbreviations: C_{max}, maximum concentration; T_{max}, time at which maximum concentration is achieved.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

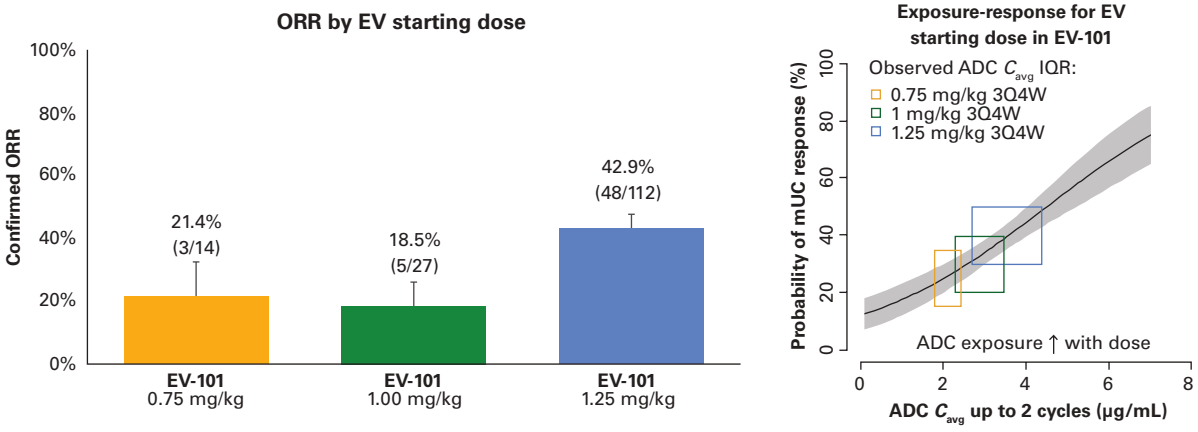
Figure 3-3 Factors Influencing Oral Absorption



Abbreviations: A, aluminum; C, concentration; Ca, calcium; CYP, cytochrome P450; D, dose; F, bioavailability; H2, histamine 2; k, elimination rate constant; PgP, P-glycoprotein; Vd, volume of distribution.

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 3-4 EV-101 Clinical Dose Selection by Dose Response and Exposure Response



Abbreviations: 2L+, second and later lines; 3Q4W, days 1, 8, and 15 of a 28-day cycle; ADC, antibody-drug conjugate; C_{avg}, time-averaged exposure up to two cycles; EV, enfortumab vedotin; mUC, metastatic urothelial carcinoma; ORR, objective response rate.
Error bar = one standard deviation. Analysis populations for both dose-response and exposure-response were based on actual treatment arms.
Adapted from Petrylak DP, Chia YL, Yu EY, et al. Impact of exposure on outcomes with enfortumab vedotin in patients with locally advanced or metastatic urothelial cancer. Presented at: Annual Meeting of the American Society of Clinical Oncology; May 29, 2024; Chicago, IL.

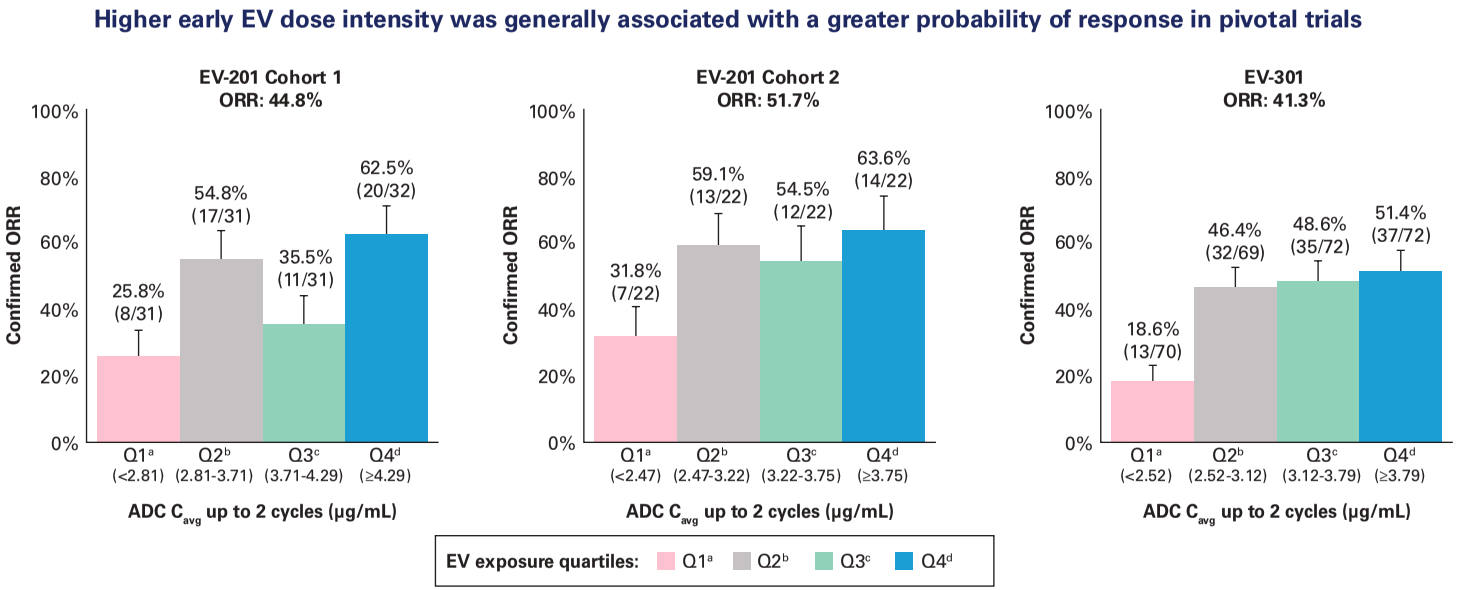
Figure 3-5 EV-101 Clinical Dose Selection Confirmation and Exposure Response



Abbreviations: ADC, antibody-drug conjugate; C_{avg}, time-averaged exposure up to two cycles; EV, enfortumab vedotin; mUC, metastatic urothelial carcinoma; ORR, objective response rate; Q, quartile.

All data presented are from a post hoc, explanatory analysis. Error bar = one standard deviation.

Average ADC exposures were divided into four quartiles: [a]Q1 represents the EV exposures between 0% and 25%; [b]Q2: 25% to 50%; [c]Q3: 50% to 75%; [d]Q4: 75% to 100% (the highest EV exposure quartile).

Adapted from Petrylak DP, Chia YL, Yu EY, et al. Impact of exposure on outcomes with enfortumab vedotin in patients with locally advanced or metastatic urothelial cancer. Presented at: Annual Meeting of the American Society of Clinical Oncology; May 29, 2024; Chicago, IL. doi:10.1200/jco.2024.42.16_suppl.4503

PRINCIPLES OF IMMUNO-ONCOLOGY AND BIOLOGIC THERAPY

4

Christos Fountzilas, MD, and Ulka Vaishampayan, MD

OVERVIEW

Knowledge of immuno-oncology and biologic therapies has become essential for the practicing oncologist, given the wide clinical application. Since the introduction of interferon (IFN) more than 25 years ago, progress in biologic therapy for cancer has been rapid. The introduction of immune checkpoint inhibitors has had a major effect on the management of many malignancies and paved the way for the development of single-agent and combinatorial approaches addressing immune mechanisms. Cellular therapy has produced remarkable results in patients with refractory hematologic malignancies and is now under evaluation for solid tumors. This chapter focuses on the basic principles of immune and biologic therapy, including immunology, pharmacology, and toxicology in cancer therapeutics. A more detailed review of the clinical application of specific agents is provided in tumor-specific chapters.

IMMUNE SURVEILLANCE AND IMMUNOEDITING

The immune system protects against microbial pathogens while maintaining tolerance to self.[1,2] In addition, the immune system continually recognizes and removes malignant cells that arise throughout an individual's lifetime (immune surveillance) through antigen-specific (adaptive immunity) and antigen-nonspecific (innate immunity) mechanisms. Patients with suppressed immune systems (such as organ transplant recipients) are unable to adequately perform this immune surveillance and are at increased risk for developing malignancy. Further evidence of the role of immune surveillance in cancer control is provided by the reports of spontaneous regression of cancer, as well as cancer responses to withdrawal of immunosuppression. An activated immune system is a positive prognostic factor in multiple cancers.

Brisk infiltration in tumor specimens by subpopulations of lymphocytes, especially $CD8^+$ T cells, is an independent positive prognostic factor in melanoma, ovarian, and lung cancer.[3-5] Likewise, the natural occurrence of a humoral immune response to a tumor-associated antigen is associated with a favorable clinical outcome in cancers such as breast cancer.[6] Most importantly, pharmacologic modulation of the immune response with cytokines and various types of antibodies has produced objective tumor responses in patients.

Animal models have demonstrated the existence of immunoediting, in which activation of immune mechanisms initially destroys tumor cells (elimination phase). Over time, tumor cells may escape the immune pressure and enter a dormancy state where the immune system can still control the net growth of the cancer (equilibrium phase). Finally, secondary to tumor- and/or host-specific changes, cancer cells escape immune surveillance. The tumor then grows progressively, leading to the establishment of clinically apparent disease (escape phase).[7-9]

MEDIATORS OF IMMUNE SURVEILLANCE AND THE TUMOR MICROENVIRONMENT

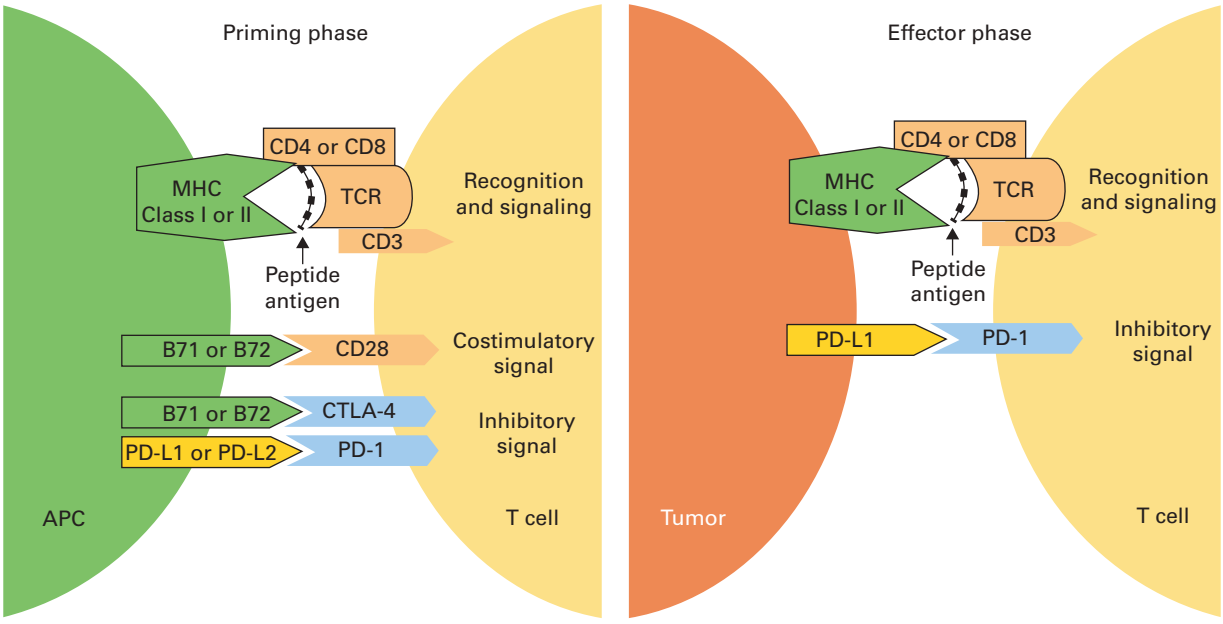
A diverse set of immune cell populations and secreted factors (cytokines, chemokines, growth factors) mediates immune surveillance. Their effect, depending on the context and other host- and tumor-related factors, may be either antitumor or tumor-promoting factors. For example, mutations involving pathways that are part of the immune activation cascade, such as disruptive mutations or, conversely, amplifications of JAK1 or JAK2 (implicated in IFN-dependent signaling), and activation of the WNT/β-catenin pathway can influence antitumor immune responses.[10] Tumors can vary in how they interact with the immune system. They may be spontaneously immune-infiltrated, ignored, not yet detected by the immune system, actively suppressed, or can form a defensive barrier from the immune system by activating tumor-intrinsic gene expression profiles. Tumors not only can escape immune response but also can exploit the immune response to promote their growth, invasion, and metastasis. Local tumor growth within the stroma is promoted by angiogenesis, mediated by interleukin (IL)-1, IL-8, and

the vascular endothelial growth factor (VEGF), which can be secreted by a variety of different immune cells. In addition to angiogenic factors, macrophages produce matrix metalloproteinases (MMPs) that degrade the extracellular matrix, facilitating cell invasion and metastasis. Many tumor cells express chemokine receptors and respond to chemokines in vitro. These chemokines can serve as tissue-specific attractants, promoting tumor cell migration or metastasis. Transforming growth factor-β (TGF-β), tumor necrosis factor (TNF)-α, and IL-6 can directly promote the growth of some tumors while suppressing the growth of others.

T CELLS AND IMMUNE CHECKPOINTS

T cells play a central role in adaptive immune responses as both effectors and regulators. The signaling complex of T cells includes the T-cell receptor (TCR), the accessory molecules (CD4 or CD8), and the CD3 signal transduction module.[11] The TCR only binds to peptide fragments of antigens that are noncovalently complexed with major histocompatibility complex (MHC) molecules, which are integral membrane glycoproteins (Fig. 4-1). There are two types of MHC molecules. Class I MHC molecules (eg, human leukocyte antigen-A [HLA-A], HLA-B, HLA-C) are expressed on most cell types and serve as the antigen-presenting molecules recognized by $CD8^+$ T cells (mainly cytotoxic T-cell lymphocytes [CTLs]). Class II MHC molecules (eg, HLA-DR, HLA-DP, HLA-DQ) are recognized by $CD4^+$ T cells (mainly helper T cells [Th]) and are present primarily on antigen-presenting cells (APCs) but can also be present on other cells, including tumor cells. Polymorphisms within MHC molecules determine whether a peptide fragment will complex with the MHC molecule and, therefore, whether a T cell from an individual will respond to a specific epitope of an antigen (MHC restriction). Effective surveillance requires that the tumor antigens are recognized by the immune system with high affinity against specific HLAs. Examples of tumor antigens/therapeutic targets of interest are described in Table 4-1. A high tumor mutation burden (TMB) increases the likelihood that some of these mutations will give rise to neoantigens—abnormal peptides displayed on the tumor cell surface by MHC molecules that the immune system can recognize as "non-self."[12,13] When a tumor expresses many neoantigens, it becomes more visible to the immune system, particularly to cytotoxic $CD8^+$ T cells capable of recognizing and attacking these antigen-bearing cells. This heightened immunogenicity helps explain why tumors with a high TMB, such as mismatch repair–deficient (dMMR) tumors,[14] are more likely to respond to immune checkpoint inhibitors (ICIs).

Figure 4-1 Regulation of T-Cell Priming and Effector Function



During the priming phase of T-cell activation, antigens are presented to T cells through the TCR as peptide fragments within MHC molecules on APCs. The primary costimulatory signal is delivered through the CD28 receptor on the T cell after engagement of its ligands B7-1 or B7-2 on the APC. Fully effective engagement also depends on interactions among several other molecules, such as adhesion molecules (not shown). Failure of the costimulatory B7/CD28 complex to be engaged results in either a nonactivated T cell or anergy. Engagement of CTLA-4 on the T cell by the same B7-1or B7-2 ligands results in inhibition of the response. Similarly, engagement of the PD-1 receptor with one of its two ligands, PD-L1 or PD-L2, on APCs also results in inhibition of the response. PD-L1 is also expressed by tumors. During the effector phase, engagement of PD-1 on the activated T cell by PD-L1 on the tumor results in inhibition of T-cell function.

Abbreviations: APC, antigen-presenting cell; CTLA-4, CTL antigen 4; MHC, major histocompatibility complex; TCR, T-cell receptor.

Table 4-1 **Clinical Applications of Immunotherapy and Biologic Therapy**

Biologic Agent	Examples of Agents and Common Indications	Mechanism of Action	Significant Adverse Effects
Cytokines	Interleukin-2 (melanoma, renal cell carcinoma)[15-20]	T- and NK-cell activation/ stimulation	Fever, chills, hypotension, capillary leak syndrome
	Interferon-α (hairy cell leukemia)[21]	Upregulation of MHC type I, NK-cell stimulation, antiproliferative, and antiangiogenesis	Fever, chills, myalgia, fatigue, depression, liver dysfunction, and myelotoxicity
	Filgrastim/pegfilgrastim (prevention of neutropenic fever)	Induction of the production and release of neutrophils from the bone marrow enhances their functional capacity in the periphery	Bone pain, local skin reactions
Unconjugated monoclonal antibodies[22]	Bevacizumab* (colorectal cancer) Ramucirumab** (colorectal and gastric/gastroesophageal cancer) [23,24]	Anti-VEGF/VEGFR	Hypertension, proteinuria, wound healing complications, thromboembolic events, bleeding, and reversible posterior leukoencephalopathy[25]
	Cetuximab (RASwt and $KRAS^{G12C}$ colorectal cancer in combination with adagrasib; head and neck cancer)[26-29] Panitumumab (RASwt and $KRAS^{G12C}$ colorectal cancer in combination with sotorasib)[27,30-32]	Anti-EGFR, CMC, ADCC	Acneiform rash, infusion-related reaction, hypomagnesemia
	Zolbetuximab (gastric and gastroesophageal cancer)[33,34]	Anti-Claudin 18.2, ADCC, CMC	Nausea, vomiting, anorexia
	Rituximab (B-cell NHL)[35] Ofatumumab*** (CLL)[36] Obinutuzumab**** (CLL, follicular lymphoma)[37-39]	Anti-CD20, CMC, ADCC	Infusion-related reaction, hypogammaglobulinemia, progressive multifocal leukoencephalopathy,[40] and HBV reactivation[41,42]
	Tafasitamab***** (follicular lymphoma, diffuse large B-cell lymphoma)	Anti-CD19, ADCC, ADCP	Neutropenia, fever, infection, and diarrhea
	Daratumumab# (myeloma)[43-45]	Anti-CD38, CMC, ADCC	Infusion-related reaction, fatigue, nausea, fever, and respiratory symptoms
	Elotuzumab# (myeloma)[46]	Anti-SLAMF7, ADCC	Infusion-related reaction, infections, hepatotoxicity, and secondary primary malignancies
	Trastuzumab^ (breast, colorectal, gastric cancer, endometrial cancer)[47-50] Pertuzumab^^ (breast cancer)[51,52]	Anti-HER2, CMC, ADCC	Cardiotoxicity and hypersensitivity reactions

Biologic Agent	Examples of Agents and Common Indications	Mechanism of Action	Significant Adverse Effects
Immune checkpoint inhibitors	Pembrolizumab (melanoma, renal, lung cancer, MSI-H cancers, esophageal cancer, and biliary cancer)[47,53-60] Nivolumab (melanoma, renal, lung cancer, hepatocellular carcinoma, MSI-H colorectal cancer, and esophageal cancer)[55,61-68] Penpulimab (nasopharyngeal carcinoma)[69] Retifanlimab (anal cancer)[70] Toripalimab (nasopharyngeal)[71]	Anti-PD-1	Fatigue, pruritus, rash, diarrhea, and arthralgia; immune-related toxicities can be seen at any organ system Most common: (1) thyroid dysfunction, (2) adrenal insufficiency, (3) pneumonitis, (4) colitis, (5) dermatitis, and (6) arthritis Less common: (1) nephritis, (2) hepatitis, (3) hypophysitis, (4) encephalitis, (5) neuritis, (6) myositis, (7) uveitis, and (8) mucositis
	Durvalumab (hepatocellular carcinoma, lung, biliary cancer, and bladder)[72-76] Atezolizumab (hepatocellular carcinoma)[77] Avelumab (bladder cancer)[78] Cosibelimab (cutaneous squamous cell carcinoma)	Anti-PD-L1	
	Ipilimumab (lung cancer, melanoma, renal cell carcinoma, hepatocellular carcinoma, and MSI-H colorectal cancer)[61-66] Tremelimumab (hepatocellular carcinoma)[72]	Anti-CTLA-4, ADCC[79]	
	Relatlimab (melanoma)[80]	Anti-LAG-3	

Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; ADCP, antibody-dependent cell-mediated phagocytosis; CLL, chronic lymphocytic leukemia; CMC, cell-mediated cytotoxicity; CTLA-4, CTL antigen 4; EGFR, epidermal growth factor receptor; Fc, fraction-crystallizable; HBV, hepatitis B virus; HER2, human epidermal receptor 2; LAG-3, lymphocyte activation gene 3; MHC, major histocompatibility complex; MSI-H, microsatellite instability-high; NHL, non-Hodgkin lymphoma; NK, natural killer; VEGF, vascular endothelial growth factor.
*Bevacizumab targets VEGF-A.
**Ramucirumab targets VEGFR-2.
***Ofatumumab binds to both the small and the large loops of the CD20 molecule on B cells. Its location is closer to the membrane, which, in theory, allows for more effective complement deposition and subsequent B-cell killing. Preclinical data have suggested improved CMC and ADCC compared with rituximab.
****Obinutuzumab is a humanized anti-CD20 monoclonal antibody that has been glycoengineered to reduce core fucosylation, conferring enhanced affinity for the human FcγRIIIa receptor on effector cells and, hence, enhanced ADCC. As a type 2 monoclonal antibody, obinutuzumab has a lower capacity to relocalize CD20 into lipid rafts upon binding, compared with the type 1 antibodies rituximab and ofatumumab, and is less potent in inducing CMC. It is, however, more potent in mediating cell adhesion and direct cell death. Obinutuzumab and rituximab bind adjacent and partially overlapping epitopes on CD20 but acquire different orientations upon binding, which most likely contributes to the different biologic characteristics of type 1 and 2 antibodies.
*****Tafasitamab is a humanized engineered anti-CD19 monoclonal antibody, which incorporates S239D and I332E mutations into the Fc region of humanized anti-CD19 immunoglobulin G, enhancing its affinity for FcγRIIIa and subsequently ADCC and increased ADCP.
#Use of monoclonal antibodies in myeloma can interfere with the usual assays used to monitor M-protein.
^Trastuzumab targets the HER2 extracellular domain epitope IV.[81]
^^Pertuzumab targets the HER2 extracellular domain near the junction of domains I, II, and III.[82]

T-cell activation requires not only the presentation of an antigen within the context of an MHC molecule and stimulation through the CD3 module but also costimulatory signals (Fig. 4-1). Activation, in turn, is regulated by coinhibitory signals, which are essential in limiting the magnitude of the immune response (and potential autoimmunity) (Fig. 4-1). The CD28 family of receptors includes the stimulatory receptor CD28 and the inhibitory receptors CTL antigen 4 (CTLA-4; also called CD152) and

PD-1. Receptors of the CD28 family interact with the B7 family of ligands, which include B7-1 (also called CD80), B7-2 (also called CD86), and PD-L1 (also called B7-1H) and PD-L2 (also called B7-DC). Several other receptor-ligand engagements can act as modulators of the immune response, collectively known as immune checkpoints, including those mediated by the following costimulatory and coinhibitory molecules (Table 4-2). PD-1–expressing T cells can secrete IFN-β upon initial T-cell activation, and this, in turn, upregulates PD-L1 on tumor cells, conferring on the tumor and T-cell interaction a dependence on this ligand-receptor association that can be therapeutically targeted by antibodies.

Table 4-2 Positive and Negative Immune Checkpoints

Costimulatory Receptors	Coinhibitory Receptors
CD28	CTLA-4 (CD152)
4-1BB (CD137)	PD-1 (CD279)
CD27	BTLA (CD272)
CD40L (CD154)	LAG-3 (CD223)
OX40 (CD134)	TIM-3 (CD366)
ICOS, (CD278)	PD-1H (VISTA)
GITR (TNFRSF18)	CD160
	CD244 (NK-cell receptor 2B4)
	TIGIT (CD)

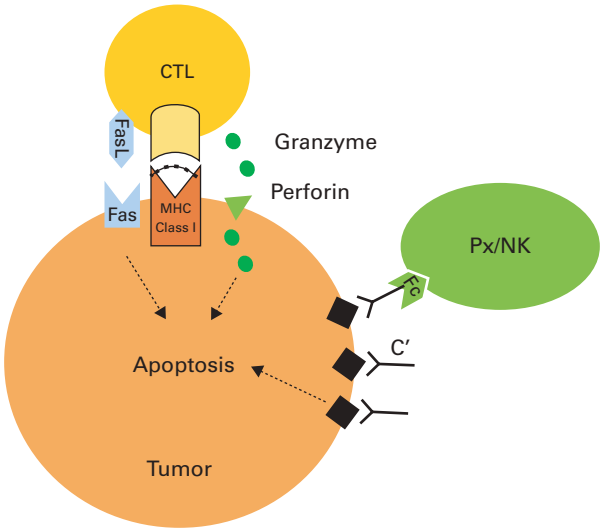
Abbreviations: BTLA, B- and T-cell attenuator; GITR, glucocorticoid-induced tumor necrosis factor (TNF) receptor-related protein; ICOS, inducible T-cell costimulatory; LAG-3, lymphocyte activation gene 3; NK, natural killer; TIGIT, T-cell immunoreceptor with immunoglobulin and ITIM domains; TIM-3, T-cell immunoglobulin and mucin-domain containing 3; VISTA, V-domain immunoglobulin suppressor of T-cell activation.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Once a T cell has been activated and differentiates into a cytotoxic T cell, the predominant mechanism of CTL cytotoxicity is granule exocytosis and the release of perforin and granzymes. The second mechanism is mediated by the death activator Fas ligand, which is expressed on the cell surface of CTLs (Fig. 4-2). Both mechanisms cause cells to undergo apoptosis. When CTL cells are appropriately activated, they produce cytokines, such as IFN-γ and IL-2, among others, that also can directly mediate or enhance antitumor effects.[83] CTLs can move to another cell and, by reorienting their granules to another region of contact, destroy it. In this manner, CTLs can kill many tumor cells, resulting in a robust and specific serial killing response that is considered to play a central role in immune-mediated tumor rejection (Fig. 4-2).

Helper $CD4^+$ T-cell lymphocytes (Th) secrete cytokines that regulate all immune cells. They are essential in generating CTLs, regulating B-cell antibody production, and activating phagocytes. Depending on the context of the antigen encounter and its uptake and the activation status of the APCs, several types of responses can be promoted, including a cellular immune response mediated by CTLs and macrophages, referred to as a Th-cell type 1 (Th1) response, or a humoral response mediated by an antibody, referred to as a Th2 response. Predominant cytokines produced in a Th1-associated response are IFN-γ and IL-2. Predominant cytokines produced in a Th2-associated response are IL-4, IL-5, and IL-13. Th cells are required in an antitumor response largely to help naive $CD8^+$ T cells, leading to their differentiation and activation into tumor-specific CTLs and the development of antigen-specific memory. Cytokines produced by Th cells may also mediate antitumor effects by activating macrophages and NK cells. Other types of responses include inflammatory Th17 responses (named for the IL-17 family of cytokines produced) and regulatory responses. Few T-cell responses are purely Th1 or Th2; often, a complex mix of cytokines is produced, but the Th1/Th2 axis provides a useful framework, with Th1 responses generally considered as antitumor and Th2/Th17 as tumor promoting.[84]

Regulatory T (Treg) cells are subsets of T cells capable of antigen-specific and antigen-nonspecific cell recognition.[85] In healthy individuals, Treg cells maintain tolerance by suppressing the expansion of effector cells directed against self-antigens. Treg cells that express CD4, CD25, low levels of CD127 (IL-7 receptor), and forkhead box P3 (FOXP3; a forkhead family transcriptional regulator) play a central role in maintaining immune self-tolerance. The mechanism of suppression of self-reactive lymphocytes is not yet clear, but it does involve direct cell-to-cell contact or the production of IL-10 or TGF-β. Given that tumors express antigens that are normal self-constituents, $CD4^+CD25^+FOXP3^+$ Treg cells engaged in the maintenance of self-tolerance may impede tumor-reactive T cells. In cancer, the prognostic significance of both circulating and intratumoral Treg cells may be context- and time-dependent and affected by the tumor type, the other cells in the tumor microenvironment, and soluble molecules that vary with treatment. In most cancers, data show that an abundance of intratumoral Treg cells confers a poorer prognosis; however, for some cancers, such as colorectal and esophageal cancers, they seem to be associated with a better prognosis.[86]

Figure 4-2 Mechanisms of Cell Killing by CTLs and Antibodies



After attaching to the MHC-peptide complex, CTLs discharge cytoplasmic granules containing perforin and granzymes by exocytosis. Perforin molecules insert themselves into the plasma membrane of target cells, which enables granzymes to enter the cell. Granzymes are serine proteases that, once inside the cell, activate caspases that cause the cells to undergo apoptosis. When CTLs bind to their target, they also upregulate Fas ligand on their surface, which binds with the Fas receptor on the surface of the target cell, leading to its death (also by apoptosis). Antibodies recognize an antigen in its native conformation. After binding, when a complement-reactive site on the antibody is present, a cascade of reactions can be set into motion, including the activation of many molecules of the complement system, which, in turn, activate increasing amounts of a series of enzymes that ultimately result in complement-dependent cytotoxicity. A product of the complement cascade also strongly activates phagocytosis by macrophages and neutrophils. These phagocytes, as well as natural killer (NK) cells, bind their Fc receptor (CD16) to the antibody and destroy the ADCC. Antibody-recognizing cell surface molecules that regulate cell signaling or growth can directly elicit apoptosis. Antibody binding can also block receptor-ligand binding and natural downstream signaling.
Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; C′, complement; CTL, cytotoxic T-cell lymphocyte; Fc, fraction-crystallizable.

NK CELLS

NK cells comprise less than 10% of circulating lymphocytes. They are part of the innate non-antigen-specific response to pathogens and transformed cells. Although their cytotoxic mechanisms are similar to those of CTLs, NK cells do not require recognition of MHC molecules (non-MHC-restricted lysis). In fact, class I MHC molecules send a negative regulatory signal through receptors on the NK cells (killer inhibitory receptors) that inhibit NK-cell lytic function. Conversely, loss of class I MHC molecules on tumor cells may result in NK-cell killing of cells that could otherwise escape T-cell recognition. Under normal homeostatic conditions, multiple families of NK-cell receptors that inhibit their activation exert the predominant effects, whereas inflammation and infection, as well as malignancy, may lead to activation through a number of other activating receptors that recognize soluble and cell membrane ligands on tumors and infected cells. In addition, in contrast to CTLs, NK cells express fraction-crystallizable (Fc) receptors (CD16) and, therefore, can mediate antibody-dependent cellular cytotoxicity (ADCC). When activated, NK cells also produce IFN-γ. Although NK cells do not require activation for lytic activity, the stimulation of NK cells with IFNs and IL-2 markedly enhances their antitumor activity. In contrast to CTLs, which can kill multiple cells, evidence shows that NK cells must rearm themselves by exposure to IL-2 before they are effective against new targets.[87]

DENDRITIC CELLS

Dendritic cells (DCs) are a widely distributed heterogeneous population of APCs. DCs function at the intersection of innate and adaptive immune responses. Upon stimulation and activation provided by microbes (through toll-like receptors), cytokines, and/or T-cell signals (eg, CD40 ligand), DCs undergo additional maturation and migrate to secondary lymphoid tissues, where they present antigens to T cells. The nature of the immune response elicited depends on a variety of factors, including the mode and duration of activation and the cytokine milieu. Two distinct DC lineages have been described in humans. Myeloid DCs express the receptor for granulocyte-macrophage colony-stimulating factor (GM-CSF) and other myeloid markers. Plasmacytoid DCs lack myeloid cell markers and express the receptor for IL-3 (CD123). Myeloid DCs reside in tissues and are the most efficient APCs, particularly with regard to the primary activation of naive T cells, and they stimulate tumor-reactive CTLs, which include IL-12-dependent mechanisms. Plasmacytoid DCs reside in peripheral blood, and, after encountering a virus, they secrete large amounts of IFN-γ. The role of plasmacytoid DCs in antitumor immunity is under investigation.

MACROPHAGES

Macrophages mediate a variety of functions and play a central role in both innate and adaptive immunity. Macrophages are specialized phagocytes that function through the enzymatic generation of reactive oxygen and nitrogen species and by proteolytic digestion. Phagocytosis is mediated through surface receptors for complement and other opsonins. Macrophages can act as APCs, express Fc receptors (CD16) for antibodies mediating ADCC, and secrete VEGF. Distinct activation states of macrophages have been described; M1 macrophages (antitumor) produce high levels of inducible nitric oxide synthase, IL-12, and TNF, whereas M2 macrophages (tumor promoting) produce arginase, IL-10, TGF-β, and prostaglandin E_2. Whereas M2 macrophages are associated with a decrease in survival for patients with cancer, M1 macrophages have been associated with improved survival.[3] Like the Th1/Th2 paradigm, M1/M2 is a useful framework but does not account for the enormous heterogeneity in myeloid cells. In tumor tissues, tumor-associated macrophages (TAMs) are a subtype of macrophages that are often associated with poor outcomes.[88] The tumor immune adaptation, difficulty in selectively targeting M2, and inherent plasticity of these cells make targeting them challenging.

MYELOID-DERIVED SUPPRESSOR CELLS

Myeloid-derived suppressor cells (MDSCs), present in tumors and lymphoid organs, can inhibit T-cell functions and play a role in tumor-associated immune suppression. They have been described in patients with many types of solid tumors.[86,89,90] Human MDSCs are more poorly defined than those in murine models but include $CD14^+$ myeloid cells, $CD15^+$ polymorphonuclear leukocyte cells, and reduced HLA-DR. MDSCs express the common myeloid markers CD33 and CD11b. The precise nature of this regulatory cell population depends on the tumor and tumor-derived factors of the host. In patients with cancer, an increased number of MDSCs seems to correlate with poor outcomes in multiple settings.[91,92] This highly plastic population suppresses T-cell functions through different molecular pathways, mostly involving arginase metabolism products, inducible nitric oxide synthase, reactive oxygen species, and/or production of soluble inhibitory factors such as TGF-β, IL-10, prostaglandin E_2, and nitric oxide.

KEY POINTS

- Cells of the antigen-nonspecific innate and antigen-specific adaptive immune systems contribute to antitumor immunity.
- Immune responses are highly regulated to maintain tolerance to self and limit immune-mediated damage to normal tissues.
- This continuous interaction between tumor cells and immune cells is characterized as immune surveillance and immunoediting. Immune surveillance has three phases: elimination, equilibrium, and escape.
- Immune cells can have both antitumor and tumor-promoting effects.
- The interaction between tumor and immune cells is bidirectional.
- Tumors can subvert the immune response by stimulating the production of immune cell factors that promote angiogenesis, invasion, and metastasis.
- Immune cell cytokines may also function as tumor growth factors.
- T cells recognize antigens presented to their TCRs as peptide fragments within MHC molecules (MHC restriction). T-cell activation requires stimulation not only through the TCR but also through immune costimulatory receptors.
- Interactions with coinhibitory receptors on T cells, referred to as immune checkpoints, suppress unwanted and harmful self-directed immune activities as well as antitumor immune responses.
- Recognition of tumor cells by the immune system can be influenced by a variety of factors, including the tumor's intrinsic antigenic potential (eg, mutational burden and neoantigen signature, strength of immunogenicity of tumor antigens), pre-existing host immune condition, and products of genomic aberrations that affect pathways driving the immune response.
- Th cells promote Th1-associated immune responses (antitumor) through the production of cytokines, such as IFN-γ and IL-2, and promote Th2-associated immune responses (tumor promoting) through the production of cytokines, such as IL-4 and IL-5.
- CTLs and NK cells kill tumors by apoptosis through granule exocytosis and Fas-mediated mechanisms.
- DCs are the most efficient APCs.
- Several lymphoid and myeloid cell populations suppress immune responses, including TAMs, Tregs, and MDSCs.

MECHANISMS OF IMMUNE ESCAPE

There are several mechanisms tumors can use to escape immune surveillance. Tumors can be highly heterogeneous; the repertoire of tumor antigens on the cells of one tumor may be variable, often within the same patient, and can evolve over time. Tumors can also escape the immune system by modifying factors on both the T-cell and tumor side of the equation. On the T-cell side, downregulation of class I MHC molecules and other components of the antigen-presentation process can occur frequently.

Downregulation of the CD3 ζ-chain of the TCR complex and impairment of function have been shown in T cells isolated from patients with cancer.[93] On the tumor side, tumor expression of PD-L1 and PD-L2 is considered a significant mediator of immune evasion. The expression of Fas ligand by some tumor cells may help to maintain a state of immune privilege by inducing apoptosis of Fas-sensitive T and NK effector cells (ie, the Fas counterattack). There is also evidence that a tumor's expression of antiapoptotic molecules, which prevent perforin- or death receptor–dependent cytotoxicity, can result in escape, despite expression of the target antigen. In addition, tumor-associated factors, such as underglycosylated tumor-associated mucins, have been shown to reduce the binding of antibodies to tumor cell surfaces.

A high degree of immunologic tolerance naturally exists, limiting the generation of potent immune effectors. This can be exploited by tumors where Treg cells engaged in the maintenance of self-tolerance may impede tumor-reactive T cells. The Th-cell response may also be skewed toward a Th2 phenotype that leads to impaired Th1 responses.[94] The balance between CTL- and NK-attracting (ie, CCL5, CXCL9, CXCL10) versus MSDC- and Treg cell–attracting (ie, CCL2, CCL22, CXCL8, CXCL12) chemokines can drive the capacity for mounting an adequate antitumor immune response. Tumor cells and the surrounding stroma may release a number of suppressive cytokines and other soluble factors, such as prostaglandin E_2, inhibiting antitumor immunity.[95] Cancer-associated factors inhibit the production and stimulatory capacity of DCs.[96] TGF-β is produced by host as well as tumor cells. TGF-β can inhibit the differentiation of T cells into CTLs and Th cells and promote the generation of Treg cells. By producing cytokines (eg, GM-CSF), cancers can promote the infiltration of M2-polarized macrophages and MDSCs that can inhibit T-cell function.

KEY POINTS

- Although immune checkpoints are necessary to prevent unchecked autoimmunity, tumors can co-opt these mechanisms to escape immune-mediated elimination.
- Cancer evasion of the immune system results not only from immunosuppressive factors secreted by or expressed on the tumor but also from the ability of the tumor to modulate antigen expression and be endowed with or later develop mechanisms of resistance to immune effectors.
- The recognition of evasion mechanisms involved in tumor immune escape can be exploited therapeutically.

BIOLOGIC AGENTS

Biologic agents can exert their antineoplastic effect through either immune or nonimmune pathways. The immune response can be activated through (1) the increase in the activity and or numbers of immune effector cells and (2) the modification of tumor cells so that they are more susceptible to immune effector cells. Some agents, such as the anti-epidermal growth factor receptor (anti-EGFR) and human epidermal receptor 2 (HER2) antibodies, can have both immune- and nonimmune-mediated antitumor effects. Some biologics are administered not to promote direct antitumor responses but, rather, to ameliorate the adverse events of therapy, including immune-related adverse events (irAEs), or mitigate the risk of complications as supportive approaches. These include growth factors used in the setting of chemotherapy-related myelotoxicity, suppressive immune modulators used in the context of irAEs (eg, infliximab, tocilizumab, vedolizumab), and monoclonal antibodies used to palliate tumor-related complications (eg, denosumab).

The pharmacokinetics of biologic agents are quite variable. Elimination half-lives for most cytokines are measured in minutes to hours and, for most antibodies, in days to weeks. Infused cells can persist for months.

Clinically available biologic agents can be broadly categorized into the following:

- Cytokines
- Monoclonal antibodies
- Antibody-drug conjugates (ADCs)
- Bispecific antibodies
- Cellular therapies
- Vaccines
- Viral oncolytic therapies

A detailed description of each agent in clinical use today is beyond the scope of this chapter. Table 4-1 summarizes some of the most commonly used agents, their mechanism of action, and adverse events.

CYTOKINES

Cytokines are a diverse group of small proteins released by immune and nonimmune cells distributed throughout the body. Cytokines play integral roles in innate and adaptive immunity as effector and regulatory molecules and play a role in a variety of other biological

processes. Cytokines, which are active physiologically at low concentrations, generally act locally (autocrine or paracrine), but also at a distance (endocrine). They are characterized by pleiotropy (one cytokine, multiple effects), redundancy (multiple cytokines, one effect), and synergy (the sum of the responses together is greater than the sum of the individual responses). There is also a contextual aspect to cytokines where their effects can depend on the overall milieu in which they are found.

THERAPEUTIC MONOCLONAL ANTIBODIES AND ADCS

Most of the approved antibodies in oncology are either IgG1 or IgG2 monoclonal antibodies, engaging Fc receptors on NK cells and macrophages and mediating successful complement cell-mediated cytotoxicity (CMC) and ADCC, or blocking IgG4 monoclonal antibodies, designed to block downstream signaling but not able to mediate CMC or ADCC.

Therapeutic monoclonal antibodies come in the following three forms:

- Chimeric (ie, murine variable chain fused to a human constant chain, termed ximab, and 65%-90% human)
- Humanized (ie, murine hypervariable or complementarity-determining regions grafted to human Ig, termed zumab, and 95% human)
- Fully human (termed umab).

Triggering of tumor antigen-specific cellular immunity by monoclonal antibody, in conjunction with immune escape mechanisms used by tumor cells, may contribute to differential clinical responses to monoclonal antibody–based immunotherapy.[79] The antigenic heterogeneity of most tumors presents challenges, as does the small fraction of administered antibodies that bind to tumors because of the occasional inability of antibodies to penetrate large tumor masses. Furthermore, binding of antibodies to antigens in circulation can also limit delivery to the tumor. In addition, therapeutic antibodies can elicit immune responses with the formation of antidrug antibodies, a phenomenon that has potential implications for antitumor activity for some agents.[97,98] Although now rare, because of the use of prophylaxis with premedications and broader incorporation of fully human antibodies, immune responses to artificial humanized antibodies can still be problematic, causing hypersensitivity reactions or neutralization of the antibody. Whether they target tumor cell membrane determinants, factors involved in tumor progression such as angiogenesis, or immune checkpoints, monoclonal antibodies are mainstays of cancer therapy.

Monoclonal antibodies have been used to deliver toxins, cytotoxic drugs, or radiation to malignant cells (as opposed to activating host antitumor mechanisms).[99] These agents—ADCs,[100-109] antibody-toxin conjugates,[110] or radiopharmaceutical conjugates[111-113]—can promote antitumor immunity by aiding tumor cell killing with the toxic cargo in a specific way through the specificity of the antibody-targeting aspect. The tumor antigen release can lead to antigen uptake by endogenous APCs when present in the tumor microenvironment. In addition, ADCs can have a bystander effect—tumor cell death in the vicinity of the target tumor cells after intracellular or extracellular release of the payload—that can potentiate the antitumor effect.[114] Pulmonary toxicity is an uncommon yet very serious adverse event of commonly used ADCs.[115,116]

ADCs combine a monoclonal antibody with a payload of a cytotoxic drug. The antigen is usually a receptor or protein on the cell surface that is solely or dominantly expressed on cancer cells—such as HER2 or TROP-2. The antibody and payload are connected by a chemical bond called a linker, which dissolves when the antibody binds the antigen and releases the payload into the cell. This enables targeted drug delivery. While ADCs primarily exert their cytotoxic effect on the cancer cells, they can also affect other cells that express the targeted antigen, and the release of the cytotoxic payload can induce similar toxicities as seen with that class of agents when administered directly, such as peripheral neuropathy for antimicrotubule agents or nausea, diarrhea, and myelosuppression for topoisomerase-1 inhibitors.[117,118]

KEY POINTS

- Cytokines are cell-to-cell signal mediators designed to act locally, but are detectable systemically, and can enhance the activity of antitumor immune effector cells.
- Monoclonal antibodies can mediate antitumor activity through immune mechanisms and nonimmune mechanisms (eg, direct induction of apoptosis, interference with target signaling).
- Because of infusion reactions, premedication is required for treatment with many monoclonal antibodies.
- Unique and often severe organ toxicity related to the molecule being targeted can be seen.
- Pulmonary toxicity is an uncommon but very serious adverse event from some ADCs.

IMMUNE CHECKPOINT INHIBITORS

ICIs (mainly anti-PD-1/PD-L1 and anti-CTLA-4 monoclonal antibodies) as monotherapy and in combinations have successfully been used in multiple solid tumors, including but not limited to melanoma,[61] renal cell carcinoma,[62] non–small cell lung cancer (NSCLC),[63] hepatocellular carcinoma,[64,72] and microsatellite instability-high (MSI-H) or dMMR colorectal cancer.[65] Furthermore,

combinations of anti-PD-1 and anti-LAG-3 (lymphocyte activation gene 3) monoclonal antibodies are effective as initial treatment of advanced melanoma.[80] Importantly, ICI use has been expanded in earlier-stage disease as adjuvant[53,54,66] or neoadjuvant[119] therapy. In addition, combinatorial approaches, including ICIs and distinct classes of antineoplastic drugs, have been investigated in randomized trials and incorporated into clinical practice. Anti-PD-1/PD-L1 monoclonal antibodies in combination with chemotherapy[55,56,67,68,73-75] and small-molecule inhibitors[57,58,120] or other monoclonal antibodies[77] and ADCs[121] are some examples that have become available for clinical use in specific scenarios.[59,60,71,75]

ICIs can cause irAEs that are similar to autoimmune diseases, including the following:

- Dermatologic: rash and inflammatory dermatitis
- Gastrointestinal: colitis and hepatitis
- Renal: nephritis
- Nervous system: peripheral neuropathy and encephalitis
- Endocrine: hypophysitis leading to adrenal insufficiency and hyper/hypothyroidism
- Musculoskeletal: inflammatory arthritis
- Hematologic: hemolytic anemia
- Lung: pneumonitis

Rarely, irAEs can include autoimmune conditions such as rheumatoid arthritis, type 1 diabetes, aplastic anemia, autoimmune hemolytic anemia, autoimmune neutropenia, hemophagocytic lymphohistiocytosis, and immune thrombocytopenic purpura.

The type of ICI and the patient's cancer type can affect the frequency and type of irAEs. For example, patients with melanoma are more likely to experience skin and gastrointestinal irAEs, while patients with NSCLC are more likely to experience pulmonary irAEs.[122] In most cases, irAEs can be treated with temporary immunosuppression using glucocorticoids, tumor necrosis factor-alpha antagonists, or mycophenolate mofetil. Infliximab is not advisable in patients with liver dysfunction. In severe cases, such as myocarditis, severe pneumonitis, colitis, or encephalitis, it is necessary to permanently discontinue the use of ICIs. IrAEs can impact multiple organs and require a multidisciplinary team of experts for treatment. They are unpredictable in timing, can affect one or multiple systems, and if clinically significant, will require immunosuppression, usually with steroids. Some of the irAEs can lead to permanent irreversible conditions.[122-126]

In general, ICI combinations (especially anti-PD-1/PD-L1 combined with anti-CTLA-4) are associated with a significant increase in the incidence of irAEs compared with either agent alone, requiring experience and close communication among the treating clinician, the patient, and other members of the healthcare team. Identification of predictors that will allow patients to be selected for single or combined therapy is awaited. Lower or priming doses of anti-CTLA-4 and alternative dosing schedules may also be appropriate toxicity-mitigation strategies.[72] Guidelines that encompass a thorough review of irAEs and detailed management recommendations have been published and are useful tools for the mitigation of risks associated with these agents.[123-126]

NUANCES OF RESPONSE ASSESSMENT WITH IMMUNOTHERAPY

The unique mechanisms of action of ICIs targeting CTLA-4, PD-1, and PD-L1 make the assessment of response by conventional criteria difficult, and atypical patterns of response have been documented. Although immune-related response criteria have been proposed, the applicability and, more importantly, interpretation in clinical practice remain challenging.[127] Patients may infrequently have atypical patterns of response. Pseudoprogression describes a phenomenon where infiltration of the tumor microenvironment by immune cells presents radiographically as initial apparent worsening of the disease (ie, initial enlargement of existing lesions and/or appearance of new lesions) that is followed by subsequent response. With the limitation of inconsistency in the definition of this phenomenon, the incidence is <10% and does not appear to differ depending on tumor type.[128] In addition, delayed responses after initial radiographic progression, although rare, can occur. As such, treatment beyond the first documented radiographic progression may be acceptable in select situations, particularly in the setting of clinical stability or symptomatic improvement. Occasionally, radiographic responses can take longer to become apparent compared with those with cytotoxic or targeted therapy. Continued disease regression and disease control can be seen after immunotherapy is completed. Furthermore, some patients who do not meet criteria for objective response can have prolonged periods of stable disease that are clinically relevant.

Patients with organ transplants and autoimmune conditions are at increased risk of toxicity from immunotherapy. The incidence of graft rejection is 36% and varies depending on the transplant type (decreased risk of rejection in non-kidney transplant), ICI–based strategy (decreased risk with anti-CTLA4 monotherapy and concomitant use of chemotherapy), type of immunosuppression (decreased risk with steroids and mTOR inhibitors), and use of ICI before the transplant with long washout time (>60 days).[129-131] The cancer-related outcomes are worse in patients with melanoma and other solid tumors compared to squamous skin cancer.[130] In HIV patients, treatment with ICIs was noted to be safe in a retrospective analysis from the Cancer Therapy Using Checkpoint Inhibitors in People Living With HIV-International (CATCH-IT) Consortium.[132] In this study, 30% of the patients had

CD4 counts <200 cells/μL, and 94% had viral load <400 copies/mL. The adverse event rate was no different than that seen in non-HIV patients. The efficacy and long-term outcomes of ICIs in this patient population were also similar to those of non-HIV patients. In a smaller prospective observational study, the incidence of grade 3 or higher irAEs was increased in patients diagnosed with HIV for more than 17 years, with CD4 counts <200 cells/μL, positive cytomegalovirus serology, or history of cancer surgery (39179255). In a prospective phase 1 trial, 32 patients with HIV-associated Kaposi sarcoma were treated with pembrolizumab, the overall response rate was 62% in all patients and 87% in patients without prior systemic treatment.[133] There was no difference in response based on CD4 cell count. On the contrary, in a phase 1 study of nivolumab in HIV patients with Kaposi sarcoma and other solid tumors, objective responses were only observed in patients with CD4 counts ≥200 cells/μL.[134] If possible, patients with HIV should be treated with antiviral therapy before starting therapy. Autoimmune diseases are relative contraindications. The decision to treat with ICI therapy can be made based on the severity of the condition and the extent of immunosuppression needed within the process of shared decision-making.[135] The risk of flare of the underlying autoimmune disease and new irAE is 41% and 33%, respectively, with at least moderate severity in 7% and 12%, respectively.[136] The overall management of these patients should be personalized, and the treating oncologist must be in close communication with the patient's rheumatologist for the appropriate preventive measures and treatment strategy should a flare occur.

KEY POINTS

- Immune checkpoint blockade with antibodies against CTLA-4, PD-1, PD-L1, and LAG-3 is an effective method for reversing cancer immunosuppression and promoting immune responses against several cancer types.
- Checkpoint inhibition is associated with a unique spectrum of adverse events called irAEs, which can occur unpredictably and have the potential to affect any organ system.
- The combination of ICIs (anti-PD-1 in combination with anti-CTLA-4 agents or LAG-3) may result in improved response rates and disease control at a cost of greater toxicity. However, increased incidence of long-term remission is reported in some malignancies such as metastatic melanoma.
- ICIs can be safely combined with other therapeutics, including chemotherapy, ADCs, and small-molecule inhibitors, and lead to increased response in several cancer types.
- ICIs can be safely administered in patients with HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) with careful monitoring. Antiviral therapy should be initiated before treatment if possible.
- Treatment with ICIs in patients with underlying autoimmune disease can lead to disease flare. Treatment with ICIs can be considered in these patients after shared decision-making and after the autoimmune disease is optimized while minimizing immunosuppressive medication exposure.

BISPECIFIC ANTIBODY THERAPY

A bispecific antibody is a synthetic protein composed of fragments of two different monoclonal antibodies and consequently binds to two different types of antigens. Bispecific monoclonal antibodies have been developed to simultaneously bind to two or more targets on the same cell surface or to an immune effector cell and a tumor cell to destroy the tumor cell.[137]

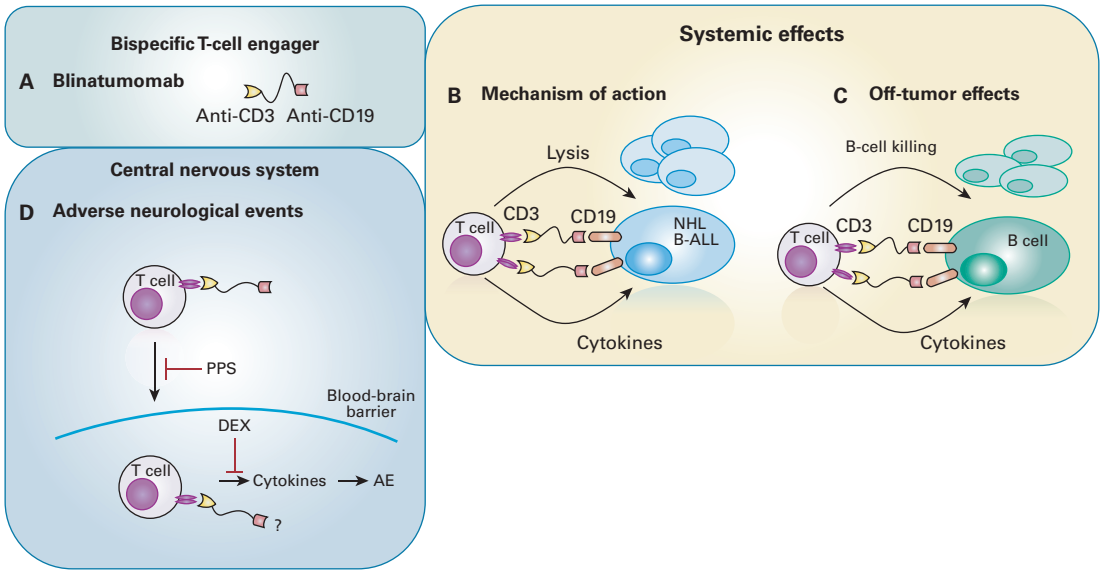
Blinatumomab was the first FDA-approved bispecific antibody that simultaneously targets CD3 (T-cell specific) and CD19 (B-cell specific). Blinatumomab belongs to a class of constructed antibodies known as bispecific T-cell engagers (Fig. 4-3). Blinatumomab brings a $CD3^+$ cytotoxic T cell into proximity with the CD-19-expressing malignant B cells. Once they are bound, the T cells rapidly activate and induce perforin-mediated death to the targeted tumor cells. Blinatumomab is approved by the FDA for the treatment of Philadelphia chromosome–negative relapsed or refractory B-lineage acute lymphocytic leukemia (ALL) in adult patients on the basis of the results from the phase 3 TOWER study.[138] It is also approved in adult and pediatric patients in first or second complete remission with detectable minimal residual disease.[139]

Glofitamab is a novel CD3/CD20 targeting bispecific T-cell engager approved with adults with refractory diffuse large B-cell lymphoma.[140] Bispecific T-cell engagers targeting the B-cell maturation antigen (BCMA) or GPRC5D are also approved for patients with refractory multiple myeloma.[141,142] Linvoseltamab-gcp is a bispecific BCMA-directed CD3 T-cell engager for adults with relapsed or refractory multiple myeloma who have received at least four prior lines of therapy, including a proteasome inhibitor (PI), an immunomodulatory agent (IMiD), and an anti-CD38 monoclonal antibody.

Tebentafusp-tebn is a bispecific T-cell engager approved for metastatic uveal melanoma that targets the glycoprotein 100 (gp100) peptide presented by HLA-A02:01 on uveal melanoma cells and CD3 on T cells, thereby redirecting T cells to lyse tumor cells.[143] Tarlatamab is a bispecific T-cell engager targeting DLL3 and CD3, and it is approved for use in previously treated small-cell lung cancer.[144]

The toxicities of bispecific T-cell engagers are related to activation of the immune system as well as other on-target effects. Notable examples of the former are the cytokine release syndrome (CRS) and the immune effector cell–associated neurotoxicity syndrome (ICANS).[145] The CRS is marked by symptoms that mimic a systemic inflammatory response syndrome, ranging from mild constitutional symptoms to life-threatening hypotension, hypoxia, fever, and multiorgan dysfunction. The CRS is largely attributed to the secretion of cytokines and chemokines by T cells, monocytes or macrophages, and DCs, including IL-1, IL-2, and

Figure 4-3 Bispecific T-Cell Engagers as Treatment of B-Cell Lymphoma



Activity of the bispecific T-cell engager blinatumomab (A). This bispecific T-cell engager protein can connect a T cell and (B) a CD191 tumor cell or (C) a CD191 B cell by simultaneously binding CD3 and CD19. When both single-chain variable fragments bind to their target antigens, T-cell activation is triggered, which leads to the release of cytotoxic granules and cytokines (eg, IFN). Lysis of the tumor cell or B cell involves membrane perforation followed by programmed cell death induced by granzymes. Bispecific T-cell engagers trigger serial killing by activated T cells. (D) Approaches to limit adverse neurologic events caused by blinatumomab treatment include the blocking of activated T-cell migration into the CNS through PPS treatment or the reduction of cytokine activity through the use of corticosteroids, such as DEX. Which cells blinatumomab may recognize in the CNS (eg, tumor cells) is unknown, but the adverse effects resolve when treatment is discontinued.
Abbreviations: AE, adverse event; B-ALL, B-cell acute lymphoblastic leukemia; CNS, central nervous system; DEX, dexamethasone; NHL, non-Hodgkin lymphoma; PPS, pentosan polysulfate.

IL-6. Patients with bulky disease and comorbidities are at increased risk of CRS development. Based on underlying mechanisms, anti-IL-6 receptor agents (eg, tocilizumab, siltuximab) represent the cornerstones in the management of severe CRS. ICANS has a less understood pathogenesis and may be characterized by confusion, ataxia, aphasia, seizures, and cerebral edema or increased intracranial pressure.[146] Anti-IL-6 agents and corticosteroids are also effective tools in reversing ICANS. Tebentafusp-tebn can cause skin toxicity (dry skin, rash) as a result of targeting of gp100-positive melanocytes. These adverse events decrease in frequency and severity after the initial doses of tebentafusp-tebn.

Amivantamab, an EGFR and mesenchymal-epithelial transition factor (MET) bispecific antibody, is approved for patients with exon 20 insertion–positive NSCLC as monotherapy after progression during or in combination with platinum-based chemotherapy.[147,148] It is also approved in combination with lazertinib as first-line treatment for patients with locally advanced or metastatic NSCLC with EGFR exon 19 deletions or exon 21 L858R substitution mutations.[149] Amivantamab leads to tumor regression by simultaneous inhibition of the EGFR and MET pathways as well as ADCC.[150] The most common adverse reactions to amivantamab monotherapy are rash, infusion-related reactions, paronychia, musculoskeletal pain, dyspnea, nausea, fatigue, edema, stomatitis, cough, constipation, and vomiting.[147] The addition of amivantamab to chemotherapy increases skin toxicities (paronychia, rash), diarrhea, infusion-related reactions, and neutropenia.[148] Note that the dosing recommendations of amivantamab are different when used as monotherapy versus in combination with platinum-based chemotherapy.

KEY POINTS

- Bispecific T-cell engagers have been developed to simultaneously bind a tumor cell to an immune effector cell, leading to tumor cell lysis.
- Amivantamab is a bispecific antibody that simultaneously targets and downregulates both the EGFR and MET pathways, leading to cell death.

CELLULAR THERAPY

Adoptive cell therapy refers to the infusion of immune cells that have been expanded or engineered ex vivo. A variety of immune effector cells have been explored for adoptive cellular therapy and tested in clinical trials. Early efforts examined the infusion of

lymphokine-activated killer cells, which had little activity and required coadministration of high-dose IL-2 to maintain it. Initial studies of patients with advanced melanoma and renal cell carcinoma demonstrated antitumor activity. Comparable results, however, were subsequently seen with high-dose IL-2 alone. Methods of generating antitumor CTLs by culturing peripheral blood, lymph nodes, or tumor-infiltrating lymphocytes (TILs) with cytokines and tumor antigens ex vivo have also been evaluated clinically over the last 2 to 3 decades. Response rates of 50% or higher among selected patients with metastatic melanoma accompanied by long progression-free survival were observed with the infusion of TILs in nonrandomized studies, which served as important proof of principle for the antitumor potency and durable responses possible with this approach.[151] Treatment with TILs is superior to ipilimumab in regard to progression-free survival in patients with advanced melanoma with prior anti-PD-1 therapy in a randomized phase 3 clinical trial.[152]

CHIMERIC ANTIGEN RECEPTOR AND TCR-MODIFIED T CELLS

Chimeric antigen receptors (CARs) are composed of an extracellular immunoglobulin-derived antigen recognition domain, a transmembrane domain, and an intracellular T-cell signal domain that includes a CD3 complex–derived chain and costimulation signaling domains (eg, CD28, 4-1BB). CARs redirect T-cell specificity toward antibody-recognized surface antigens and are not MHC restricted. CAR T cells targeting CD19 have demonstrated significant activity in refractory B-cell malignancies.[153,154] Similarly, CAR T cells targeting BCMA are approved for the treatment of relapsed or refractory myeloma.[155,156] The results from first-generation CAR T cells in solid tumors are not as encouraging, with the exception of the GD2-targeting CAR T cell for neuroblastoma.[157] TCR-modified T cells have demonstrated activity in the treatment of solid tumors (including melanoma and sarcomas) as well as hematologic malignancies (eg, acute myeloid leukemia),[158] but are structurally dependent on HLA type and antigen expression on the MHC molecules of the target cell.[159,160]

Adoptive transfer of expanded and activated effector cells is not limited to engineered T cells. NK cells are also being tested, particularly allogeneic NK cells that are engineered for high effector function.[161,162] Adoptive cellular therapy with ex vivo expanded autologous TILs is approved for patients with refractory melanoma.[163,164] Sipuleucel-T is an autologous cellular immunotherapy derived from peripheral blood mononuclear cells that are cultured ex vivo with PA2024, a fusion protein consisting of prostatic acid phosphatase and GM-CSF. It is approved for the treatment of asymptomatic or minimally symptomatic metastatic castration-resistant prostate cancer.[164,165] The approach is designed for the GM-CSF portion of the fusion molecule to activate blood monocytes and APCs to present prostatic acid phosphatase as a tumor antigen.[164,165] Because the clinical benefit is very modest, current investigations are testing sipuleucel-T as neoadjuvant therapy[166] or in combinations.[167]

The toxicities of adoptive T-cell therapies can be severe and include B-cell aplasia (for B-cell-targeting T-cell therapies), CRS, and ICANS. The cytokine secretion in CRS can be due to tumor target recognition and response or off-target/off-tumor responses, which can be due to nontumor expression of the target antigen or to unexpected mimicry of the target by a highly related gene.[168] Anti-IL-6 agents and corticosteroids represent the cornerstones in the management of CRS occurring after CAR T-cell therapy. ICANS has a less understood pathogenesis and may be characterized by confusion, ataxia, aphasia, seizures, and cerebral edema or increased intracranial pressure.[146]

DONOR LYMPHOCYTE INFUSION

Cells infused in allogeneic hematopoietic stem cell transplantation represent an effective adoptive cellular therapy in clinical use. An allogeneic graft-versus-leukemia effect, which is a restricted form of graft-versus-host disease, has been suggested by the increased relapse rate for recipients of T-cell–depleted allografts, higher relapse rates after either syngeneic or autologous transplantation, and lower frequency of relapse for patients who develop graft-versus-host disease. Given these clinical observations, donor leukocyte infusion was tested among patients whose hematologic malignancies relapsed after allogeneic transplantation. Numerous reports have documented the success of donor leukocyte infusion for patients with chronic myeloid leukemia; the majority of these patients achieved durable complete molecular remission.[169] Acute myeloid leukemia has only modest response rates, and ALL rarely responds. Donor leukocyte infusion can also eradicate Epstein-Barr virus–associated post-transplantation lymphoproliferative disease after allogeneic transplantation. More recent studies have identified potential target antigens among patients responding to donor leukocyte infusion. The major drawback of donor leukocyte infusion is graft-versus-host disease, which is a major cause of transplantation-related mortality, and methods of promoting the graft-versus-leukemia effect over graft-versus-host disease are under active investigation. New investigational approaches aimed at improving the efficacy of donor leukocyte infusion include priming of donor lymphocytes to recipient tumor antigens ex vivo and infusions of alloreactive NK cells.

KEY POINTS

- Many cells of the immune system generated and/or modified ex vivo can be administered to an individual to induce an antitumor immune response.
- The use of reprogrammed CAR- and TCR-modified T cells has produced robust results in hematologic malignancies; nevertheless, the applicability of these approaches remains restricted to specialized centers, and toxicities can be limiting.

- Toxicities resulting from CAR T-cell therapies include CRS and ICANS and may require directed approaches that include the use of anti-IL-6 and anti-IL-6 receptor agents.
- Autologous cell immunotherapies and donor leukocyte infusion after allogeneic hematopoietic stem cell transplantation are examples of cellular therapies in clinical use and under active investigation.

ONCOLYTIC VIRUSES

Oncolytic viruses are emerging as important agents in cancer treatment.[170] They offer the attractive therapeutic combination of tumor-specific virus infection and replication (leading to tumor cell lysis) together with immune stimulation from the viral pathogen signals, thereby acting as potential in situ tumor vaccines. Talimogene laherparepvec (T-VEC) is a genetically engineered attenuated herpes simplex virus. It is approved for cutaneous melanoma with dermal/cutaneous mets amenable to intratumoral injection. T-VEC invades cancerous and healthy cells but can only replicate in cancer cells, where it secretes GM-CSF in the process. T-VEC kills tumor cells by direct oncolysis. In addition, the virus-produced GM-CSF recruits and activates dendritic cells, which process and present these antigens to T cells, thereby promoting a tumor-specific adaptive immune response. T-VEC is approved for the treatment of melanoma.[171] Most adverse events included constitutional symptoms and injection site reactions.[172]

KEY POINTS

- Oncolytic viruses are wild-type or genetically modified viruses that can selectively kill tumor cells via cell lysis (direct antitumor effect) or via the activation of antitumor immune responses.
- The efficacy of oncolytic viruses as single agents is limited.

PRESENTING CASE STUDY

A 70-year-old man presents to the clinic with hematuria. Cystoscopy reveals a bladder mass, and biopsy confirms high-grade urothelial cancer. CT scan shows multiple enlarged abdominal and pelvic lymph nodes and liver metastases. Liver biopsy indicates metastatic cancer consistent with urothelial primary. The patient's Eastern Cooperative Oncology Group performance status is 1; he is experiencing mild fatigue and weakness but is otherwise healthy and active. His creatinine clearance is 80 mL/min, and his hypertension is well controlled on current medication. He has no history of diabetes or coronary arterial disease.

The patient begins treatment with a combination of enfortumab vedotin, a nectin-4-targeted antibody-drug conjugate, and pembrolizumab, a PD-1 immune checkpoint inhibitor. He tolerates the first two cycles well, and CT demonstrates evidence of tumor response. After the third cycle, the patient is hospitalized for severe weakness and dizziness. His blood pressure is 80/50 mm Hg with tachycardia, and a rash with scattered ill-defined scaly erythematous papules on his chest, arms, and thighs is identified on physical examination. Laboratory values are as follows: sodium, 128 mEq/L; potassium, 5.6 mEq/L; creatinine, 5.8 mg/dL; and glucose, 722 mg/dL. Aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and bilirubin levels are within the upper reference limit. He has a leukocyte count of 5,800/μL, hemoglobin level of 10.2 g/dL, and platelet count of 165,000/μL. The patient's differentials are within the upper reference limit.

After initiating enfortumab vedotin and pembrolizumab for this patient, what key clinical factors and potential risks, specifically regarding overlapping toxicities, would you consider? How would you plan for early detection and management?

This case exemplifies the overlapping toxicities of enfortumab vedotin (hyperglycemia and rash) and pembrolizumab (immune skin toxicity, immune nephritis, and type 1 diabetes mellitus induced by immunotherapy). Renal dysfunction can be related to dehydration and hyperglycemia or could be an immune-related adverse event of nephritis.

The patient's hyperglycemia should be treated with insulin and hydration; however, if the renal dysfunction and/or rash presentation is related to pembrolizumab, then intervention with steroids is required. It is not possible in the initial presentation stages to clearly separate the cause of the toxicities. As a result, it is important to consider steroid therapy such as prednisone at a minimum dose of 1 to 2 mg/kg despite the patient's hyperglycemia and taper gradually as the condition reverses.

The patient responds well to the steroids and supportive care, and his rash improves. His glucose level returns to normal, and he is monitored on insulin therapy.

Rechallenge Decision

If a patient is in remission, ongoing observation and surveillance for cancer progression may be considered. If repeat therapy is initiated, it is advisable to start with a reduced enfortumab vedotin dose for one cycle and evaluate the patient's tolerability. If the patient tolerates treatment well, therapy can be continued, and pembrolizumab resumption can be reconsidered at a later date with precautions for close monitoring of renal function and for skin rash.

HIGH-YIELD TAKEAWAYS

- The main types of biologic anticancer therapies are as follows: cytokines, antibodies, viral oncolytic, immune checkpoint therapies, ADCs, bispecific T-cell engagers/T-cell engagers, and cellular therapies.
- Immunotherapy is rapidly becoming the backbone of cancer therapy and has the potential to induce long-term remissions.
- Immune checkpoint therapies have been proven to be safe to use in HIV, HBV, and HCV patients with careful monitoring. Antiretroviral therapy should be continued in HIV patients.
- Immune checkpoint therapies have adverse effects that can occur anytime during therapy and can impact any system within the body. These side effects can be severe and life-threatening, so immunosuppressive therapy should be used to reverse the toxicities.
- CAR T-cell therapies have demonstrated efficacy and are indicated in hematologic malignancies.
- MSI-H or dMMR status is a predictive biomarker for benefit from ICIs in all cancer types.

PRINCIPLES OF IMMUNO-ONCOLOGY AND BIOLOGIC THERAPY

4

CHAPTER SUMMARY GUIDE

KEY POINTS

- Cells of the antigen-nonspecific innate and antigen-specific adaptive immune systems contribute to antitumor immunity.
- Immune responses are highly regulated to maintain tolerance to self and limit immune-mediated damage to normal tissues.
- This continuous interaction between tumor cells and immune cells is characterized as immune surveillance and immunoediting. Immune surveillance has three phases: elimination, equilibrium, and escape.
- Immune cells can have both antitumor and tumor-promoting effects.
- The interaction between tumor and immune cells is bidirectional.
- Tumors can subvert the immune response by stimulating the production of immune cell factors that promote angiogenesis, invasion, and metastasis.
- Immune cell cytokines may also function as tumor growth factors.
- T cells recognize antigens presented to their TCRs as peptide fragments within MHC molecules (MHC restriction). T-cell activation requires stimulation not only through the TCR but also through immune costimulatory receptors.
- Interactions with coinhibitory receptors on T cells, referred to as immune checkpoints, suppress unwanted and harmful self-directed immune activities as well as antitumor immune responses.
- Recognition of tumor cells by the immune system can be influenced by a variety of factors, including the tumor's intrinsic antigenic potential (eg, mutational burden and neoantigen signature, strength of immunogenicity of tumor antigens), pre-existing host immune condition, and products of genomic aberrations that affect pathways driving the immune response.
- Th cells promote Th1-associated immune responses (antitumor) through the production of cytokines, such as IFN-γ and IL-2, and promote Th2-associated immune responses (tumor promoting) through the production of cytokines, such as IL-4 and IL-5.
- CTLs and NK cells kill tumors by apoptosis through granule exocytosis and Fas-mediated mechanisms.
- DCs are the most efficient APCs.
- Several lymphoid and myeloid cell populations suppress immune responses, including TAMs, Tregs, and MDSCs.
- Although immune checkpoints are necessary to prevent unchecked autoimmunity, tumors can co-opt these mechanisms to escape immune-mediated elimination.
- Cancer evasion of the immune system results not only from immunosuppressive factors secreted by or expressed on the tumor but also from the ability of the tumor to modulate antigen expression and be endowed with or later develop mechanisms of resistance to immune effectors.
- The recognition of evasion mechanisms involved in tumor immune escape can be exploited therapeutically.
- Cytokines are cell-to-cell signal mediators designed to act locally, but are detectable systemically, and can enhance the activity of antitumor immune effector cells.
- Monoclonal antibodies can mediate antitumor activity through immune mechanisms and nonimmune mechanisms (eg, direct induction of apoptosis, interference with target signaling).
- Because of infusion reactions, premedication is required for treatment with many monoclonal antibodies.
- Unique and often severe organ toxicity related to the molecule being targeted can be seen.
- Pulmonary toxicity is an uncommon but very serious adverse event from some ADCs.
- Immune checkpoint blockade with antibodies against CTLA-4, PD-1, PD-L1, and LAG-3 is an effective method for reversing cancer immunosuppression and promoting immune responses against several cancer types.

- Checkpoint inhibition is associated with a unique spectrum of adverse events called irAEs, which can occur unpredictably and have the potential to affect any organ system.
- The combination of ICIs (anti-PD-1 in combination with anti-CTLA-4 agents or LAG-3) may result in improved response rates and disease control at a cost of greater toxicity. However, increased incidence of long-term remission is reported in some malignancies such as metastatic melanoma.
- ICIs can be safely combined with other therapeutics, including chemotherapy, ADCs, and small-molecule inhibitors, and lead to increased response in several cancer types.
- ICIs can be safely administered in patients with HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) with careful monitoring. Antiviral therapy should be initiated before treatment if possible.
- Treatment with ICIs in patients with underlying autoimmune disease can lead to disease flare. Treatment with ICIs can be considered in these patients after shared decision-making and after the autoimmune disease is optimized while minimizing immunosuppressive medication exposure.
- Bispecific T-cell engagers have been developed to simultaneously bind a tumor cell to an immune effector cell, leading to tumor cell lysis.
- Amivantamab is a bispecific antibody that simultaneously targets and downregulates both the EGFR and MET pathways, leading to cell death.
- Many cells of the immune system generated and/or modified ex vivo can be administered to an individual to induce an antitumor immune response.
- The use of reprogrammed CAR- and TCR-modified T cells has produced robust results in hematologic malignancies; nevertheless, the applicability of these approaches remains restricted to specialized centers, and toxicities can be limiting.
- Toxicities resulting from CAR T-cell therapies include CRS and ICANS and may require directed approaches that include the use of anti-IL-6 and anti-IL-6 receptor agents.
- Autologous cell immunotherapies and donor leukocyte infusion after allogeneic hematopoietic stem cell transplantation are examples of cellular therapies in clinical use and under active investigation.
- Oncolytic viruses are wild-type or genetically modified viruses that can selectively kill tumor cells via cell lysis (direct antitumor effect) or via the activation of antitumor immune responses.
- The efficacy of oncolytic viruses as single agents is limited.

Table 4-1 **Clinical Applications of Immunotherapy and Biologic Therapy**

Biologic Agent	Examples of Agents and Common Indications	Mechanism of Action	Significant Adverse Effects
Cytokines	Interleukin-2 (melanoma, renal cell carcinoma)[15-20]	T- and NK-cell activation/ stimulation	Fever, chills, hypotension, capillary leak syndrome
	Interferon-α (hairy cell leukemia)[21]	Upregulation of MHC type I, NK-cell stimulation, antiproliferative, and antiangiogenesis	Fever, chills, myalgia, fatigue, depression, liver dysfunction, and myelotoxicity
	Filgrastim/pegfilgrastim (prevention of neutropenic fever)	Induction of the production and release of neutrophils from the bone marrow enhances their functional capacity in the periphery	Bone pain, local skin reactions
Unconjugated monoclonal antibodies[22]	Bevacizumab* (colorectal cancer) Ramucirumab** (colorectal and gastric/ gastroesophageal cancer) [23,24]	Anti-VEGF/VEGFR	Hypertension, proteinuria, wound healing complications, thromboembolic events, bleeding, and reversible posterior leukoencephalopathy[25]
	Cetuximab (RASwt and $KRAS^{G12C}$ colorectal cancer in combination with adagrasib; head and neck cancer)[26-29] Panitumumab (RASwt and $KRAS^{G12C}$ colorectal cancer in combination with sotorasib)[27,30-32]	Anti-EGFR, CMC, ADCC	Acneiform rash, infusion-related reaction, hypomagnesemia
	Zolbetuximab (gastric and gastroesophageal cancer)[33,34]	Anti-Claudin 18.2, ADCC, CMC	Nausea, vomiting, anorexia
	Rituximab (B-cell NHL)[35] Ofatumumab*** (CLL)[36] Obinutuzumab**** (CLL, follicular lymphoma)[37-39]	Anti-CD20, CMC, ADCC	Infusion-related reaction, hypogammaglobulinemia, progressive multifocal leukoencephalopathy,[40] and HBV reactivation[41,42]
	Tafasitamab***** (follicular lymphoma, diffuse large B-cell lymphoma)	Anti-CD19, ADCC, ADCP	Neutropenia, fever, infection, and diarrhea
	Daratumumab# (myeloma)[43-45]	Anti-CD38, CMC, ADCC	Infusion-related reaction, fatigue, nausea, fever, and respiratory symptoms
	Elotuzumab# (myeloma)[46]	Anti-SLAMF7, ADCC	Infusion-related reaction, infections, hepatotoxicity, and secondary primary malignancies
	Trastuzumab^ (breast, colorectal, gastric cancer, endometrial cancer)[47-50] Pertuzumab^^ (breast cancer)[51,52]	Anti-HER2, CMC, ADCC	Cardiotoxicity and hypersensitivity reactions

Biologic Agent	Examples of Agents and Common Indications	Mechanism of Action	Significant Adverse Effects
Immune checkpoint inhibitors	Pembrolizumab (melanoma, renal, lung cancer, MSI-H cancers, esophageal cancer, and biliary cancer)[47,53-60] Nivolumab (melanoma, renal, lung cancer, hepatocellular carcinoma, MSI-H colorectal cancer, and esophageal cancer)[55,61-68] Penpulimab (nasopharyngeal carcinoma)[69] Retifanlimab (anal cancer)[70] Toripalimab (nasopharyngeal)[71]	Anti-PD-1	Fatigue, pruritus, rash, diarrhea, and arthralgia; immune-related toxicities can be seen at any organ system Most common: (1) thyroid dysfunction, (2) adrenal insufficiency, (3) pneumonitis, (4) colitis, (5) dermatitis, and (6) arthritis Less common: (1) nephritis, (2) hepatitis, (3) hypophysitis, (4) encephalitis, (5) neuritis, (6) myositis, (7) uveitis, and (8) mucositis
	Durvalumab (hepatocellular carcinoma, lung, biliary cancer, and bladder)[72-76] Atezolizumab (hepatocellular carcinoma)[77] Avelumab (bladder cancer)[78] Cosibelimab (cutaneous squamous cell carcinoma)	Anti-PD-L1	
	Ipilimumab (lung cancer, melanoma, renal cell carcinoma, hepatocellular carcinoma, and MSI-H colorectal cancer)[61-66] Tremelimumab (hepatocellular carcinoma)[72]	Anti-CTLA-4, ADCC[79]	
	Relatlimab (melanoma)[80]	Anti-LAG-3	

Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; ADCP, antibody-dependent cell-mediated phagocytosis; CLL, chronic lymphocytic leukemia; CMC, cell-mediated cytotoxicity; CTLA-4, CTL antigen 4; EGFR, epidermal growth factor receptor; Fc, fraction-crystallizable; HBV, hepatitis B virus; HER2, human epidermal receptor 2; LAG-3, lymphocyte activation gene 3; MHC, major histocompatibility complex; MSI-H, microsatellite instability-high; NHL, non-Hodgkin lymphoma; NK, natural killer; VEGF, vascular endothelial growth factor.

*Bevacizumab targets VEGF-A.

**Bamucirumab targets VEGFR-2.

***Ofatumumab binds to both the small and the large loops of the CD20 molecule on B cells. Its location is closer to the membrane, which, in theory, allows for more effective complement deposition and subsequent B-cell killing. Preclinical data have suggested improved CMC and ADCC compared with rituximab.

****Obinutuzumab is a humanized anti-CD20 monoclonal antibody that has been glycoengineered to reduce core fucosylation, conferring enhanced affinity for the human FcγRIIIa receptor on effector cells and, hence, enhanced ADCC. As a type 2 monoclonal antibody, obinutuzumab has a lower capacity to relocalize CD20 into lipid rafts upon binding, compared with the type 1 antibodies rituximab and ofatumumab, and is less potent in inducing CMC. It is, however, more potent in mediating cell adhesion and direct cell death. Obinutuzumab and rituximab bind adjacent and partially overlapping epitopes on CD20 but acquire different orientations upon binding, which most likely contributes to the different biologic characteristics of type 1 and 2 antibodies.

*****Tafasitamab is a humanized engineered anti-CD19 monoclonal antibody, which incorporates S239D and I332E mutations into the Fc region of humanized anti-CD19 immunoglobulin G, enhancing its affinity for FcγRIIIa and subsequently ADCC and increased ADCP.

#Use of monoclonal antibodies in myeloma can interfere with the usual assays used to monitor M-protein.

^Trastuzumab targets the HER2 extracellular domain epitope IV.[81]

^^Pertuzumab targets the HER2 extracellular domain near the junction of domains I, II, and III.[82]

Table 4-2 **Positive and Negative Immune Checkpoints**	
Costimulatory Receptors	**Coinhibitory Receptors**
CD28	CTLA-4 (CD152)
4-1BB (CD137)	PD-1 (CD279)
CD27	BTLA (CD272)
CD40L (CD154)	LAG-3 (CD223)
OX40 (CD134)	TIM-3 (CD366)
ICOS, (CD278)	PD-1H (VISTA)
GITR (TNFRSF18)	CD160
	CD244 (NK-cell receptor 2B4)
	TIGIT (CD)

Abbreviations: BTLA, B- and T-cell attenuator; GITR, glucocorticoid-induced tumor necrosis factor (TNF) receptor-related protein; ICOS, inducible T-cell costimulatory; LAG-3, lymphocyte activation gene 3; NK, natural killer; TIGIT, T-cell immunoreceptor with immunoglobulin and ITIM domains; TIM-3, T-cell immunoglobulin and mucin-domain containing 3; VISTA, V-domain immunoglobulin suppressor of T-cell activation.

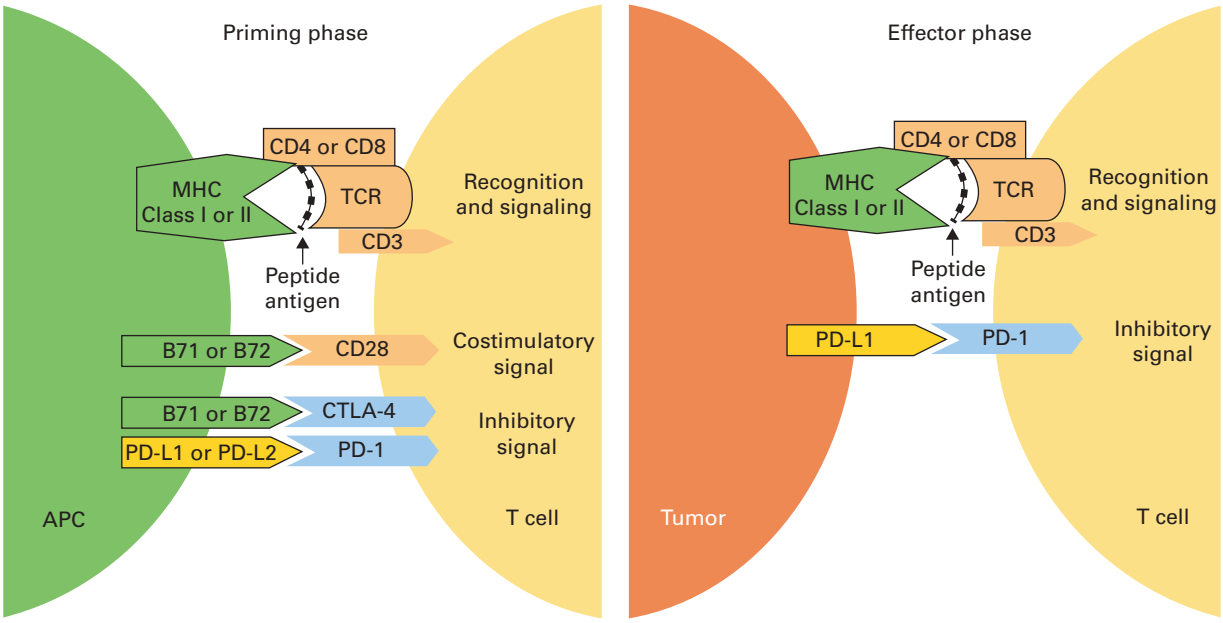
Figure 4-1 Regulation of T-Cell Priming and Effector Function



During the priming phase of T-cell activation, antigens are presented to T cells through the TCR as peptide fragments within MHC molecules on APCs. The primary costimulatory signal is delivered through the CD28 receptor on the T cell after engagement of its ligands B7-1 or B7-2 on the APC. Fully effective engagement also depends on interactions among several other molecules, such as adhesion molecules (not shown). Failure of the costimulatory B7/CD28 complex to be engaged results in either a nonactivated T cell or anergy. Engagement of CTLA-4 on the T cell by the same B7-1or B7-2 ligands results in inhibition of the response. Similarly, engagement of the PD-1 receptor with one of its two ligands, PD-L1 or PD-L2, on APCs also results in inhibition of the response. PD-L1 is also expressed by tumors. During the effector phase, engagement of PD-1 on the activated T cell by PD-L1 on the tumor results in inhibition of T-cell function.

Abbreviations: APC, antigen-presenting cell; CTLA-4, CTL antigen 4; MHC, major histocompatibility complex; TCR, T-cell receptor.

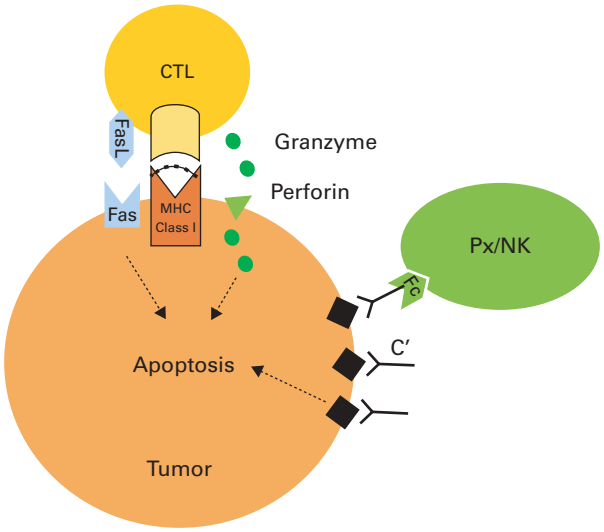
Figure 4-2 Mechanisms of Cell Killing by CTLs and Antibodies



After attaching to the MHC-peptide complex, CTLs discharge cytoplasmic granules containing perforin and granzymes by exocytosis. Perforin molecules insert themselves into the plasma membrane of target cells, which enables granzymes to enter the cell. Granzymes are serine proteases that, once inside the cell, activate caspases that cause the cells to undergo apoptosis. When CTLs bind to their target, they also upregulate Fas ligand on their surface, which binds with the Fas receptor on the surface of the target cell, leading to its death (also by apoptosis). Antibodies recognize an antigen in its native conformation. After binding, when a complement-reactive site on the antibody is present, a cascade of reactions can be set into motion, including the activation of many molecules of the complement system, which, in turn, activate increasing amounts of a series of enzymes that ultimately result in complement-dependent cytotoxicity. A product of the complement cascade also strongly activates phagocytosis by macrophages and neutrophils. These phagocytes, as well as natural killer (NK) cells, bind their Fc receptor (CD16) to the antibody and destroy the ADCC. Antibody-recognizing cell surface molecules that regulate cell signaling or growth can directly elicit apoptosis. Antibody binding can also block receptor-ligand binding and natural downstream signaling.
Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; C′, complement; CTL, cytotoxic T-cell lymphocyte; Fc, fraction-crystallizable.

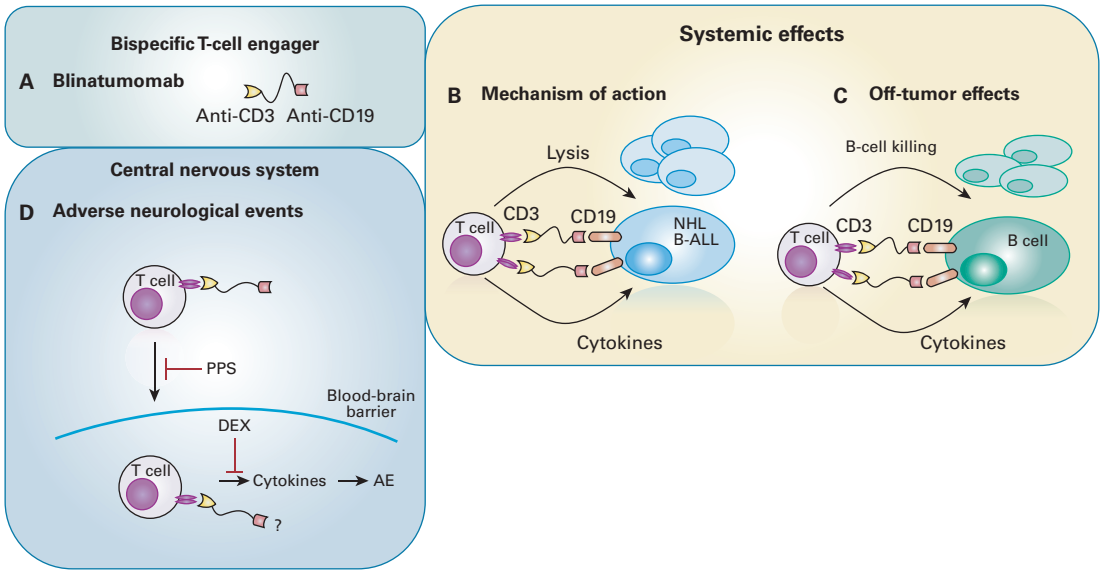
Figure 4-3 Bispecific T-Cell Engagers as Treatment of B-Cell Lymphoma



Activity of the bispecific T-cell engager blinatumomab (A). This bispecific T-cell engager protein can connect a T cell and (B) a CD191 tumor cell or (C) a CD191 B cell by simultaneously binding CD3 and CD19. When both single-chain variable fragments bind to their target antigens, T-cell activation is triggered, which leads to the release of cytotoxic granules and cytokines (eg, IFN). Lysis of the tumor cell or B cell involves membrane perforation followed by programmed cell death induced by granzymes. Bispecific T-cell engagers trigger serial killing by activated T cells. (D) Approaches to limit adverse neurologic events caused by blinatumomab treatment include the blocking of activated T-cell migration into the CNS through PPS treatment or the reduction of cytokine activity through the use of corticosteroids, such as DEX. Which cells blinatumomab may recognize in the CNS (eg, tumor cells) is unknown, but the adverse effects resolve when treatment is discontinued.

Abbreviations: AE, adverse event; B-ALL, B-cell acute lymphoblastic leukemia; CNS, central nervous system; DEX, dexamethasone; NHL, non-Hodgkin lymphoma; PPS, pentosan polysulfate.

CLINICAL TRIALS AND BIOSTATISTICS

5

Chen Hu, PhD, and Masha Kocherginsky, PhD

OVERVIEW

Clinical trials are the foundation for the development of novel drugs, interventions, and devices for the treatment, diagnosis, and prevention of diseases in humans. The primary objective of a study is the principal clinical research question framed as a scientific hypothesis to be investigated and tested using prospective clinical data. The study outcome is defined by the measured variables (eg, change in tumor burden per Response Evaluation Criteria in Solid Tumors [RECIST] 1.1 criteria) collected during the study. The endpoint is computed from the measured outcome. The primary endpoint should be clinically relevant, objectively measurable, and interpretable; sensitive to the effects of an intervention; and central to the sample size calculation required to detect a clinically meaningful effect size. For example, a study might be undertaken to assess the efficacy of a particular drug in a specific cancer type (objective), using tumor measurements (outcome) to estimate tumor response (endpoint).

The objectives, outcome measures, and endpoints of a particular clinical trial will be dictated by the type of clinical trial under consideration. To ensure confidence at the conclusion of a study, the effect of the study intervention must be measured with minimal bias and reasonable variation. Essential in achieving this goal are many fundamental clinical trial design features and biostatistical approaches described and discussed in this chapter.

Development of the clinical trial design is an iterative collaboration between the clinical investigators and the trial statistician. This process includes determinations regarding the selection of appropriate endpoints, control comparators, use of randomization, power analysis and sample size calculation, and feasibility and evaluation of various possible trial design options. Both clinical and statistical input are critical during trial design to ensure that research questions are well formulated and can be answered by the clinical trial.

STUDY OBJECTIVES

The primary objective of a clinical study is the principal clinical research question. A well-defined study question allows for specific hypothesis testing that can be quantified. Secondary research questions, often included in many studies, do not generally dictate statistical design considerations. When multiple outcomes are considered of primary importance, for example, progression-free survival (PFS) and overall survival (OS) in cancer, coprimary endpoints can also be used.

HYPOTHESIS TESTING

Hypothesis testing is used to determine whether there is evidence from the sample data to conclude that the underlying populations differ. For example, a researcher might be interested in knowing whether the survival distribution of patients treated with two distinct treatments differs. If there is evidence from the sample data that the difference in survival distribution between the groups is not 0 (on a log scale), it might be concluded that one treatment is better than the other. Hypothesis testing evaluates the amount of evidence in a sample and determines whether there is a statistically significant difference between groups, considering measures such as median survival or OS distribution, often summarized by the hazard ratio (HR). Many aspects of clinical trial design are framed in terms of hypothesis testing (Table 5-1).

Table 5-1 **Hypothesis Test Decisions and Error Types**

		Truth Based on Population (Universe)	
		Null Hypothesis Is True	**Null Hypothesis Is False**
Decision based on sample (data)	Reject the null hypothesis	Type I error	Correct decision (power)
	Do not reject the null hypothesis	Correct decision	Type II error

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

A statistical hypothesis test involves three components:

1. Formulation of the null and alternative hypotheses
2. Collection and analysis of data from a sample
3. Decision to either reject or not reject the null hypothesis (the phrase "do not reject" instead of the term "accept" is deliberate)

The null hypothesis (H0) is not the same as a scientific hypothesis and is often framed as the hypothesis of no difference in the parameter of interest.

The alternative hypothesis often reflects the scientific question and can be either a two-tailed (all possible values of the parameter of interest are considered except the null) or a one-sided alternative (the parameter of interest will vary from the null in only one direction). For example, in a trial of a new therapy, the scientific belief or hypothesis is likely that the new therapy will be more efficacious than the currently used standard therapy. However, the null hypothesis would be that the new therapy has the same efficacy as the standard therapy. In the clinical trial setting, the desired scientific outcome is usually to reject the null hypothesis. The amount of evidence against the null hypothesis is determined from the observed sample data. It is done this way because the null hypothesis is specific, so we can quantify the level of evidence with the *P* value, as described later. In contrast, the scientific hypothesis is not specific, meaning that it merely states that the new therapy is more efficacious than the standard therapy; it does not state how efficacious the new therapy is. Given the vagueness, it is not possible to quantify the evidence that supports this hypothesis. Therefore, we determine the evidence against the null hypothesis rather than the evidence for the alternative (ie, the scientific) hypothesis.

Two types of errors are possible when testing a hypothesis (Table 5-1). Type I error occurs when the null hypothesis (no difference between groups) is true but is rejected. The type I error rate, α, is the probability of making this type of error and arriving at a false-positive conclusion that the treatment groups are different when in reality they are not. On the other hand, a type II error occurs when the null hypothesis is not rejected when in fact it is not true (treatment groups are different). The type II error rate, β, is the probability of arriving at a false-negative conclusion that the treatment groups are not different when they actually do.

- Type I error rate (α): probability of rejecting the null hypothesis when the null hypothesis is true
- Type II error rate (β): probability of not rejecting the null hypothesis when this hypothesis is not true

What is more commonly of interest is the probability of correctly rejecting the null hypothesis when the alternative hypothesis is true, which is called power ($1 - \beta$).

Hypothesis tests require the calculation of a test statistic using sample data corresponding to one or more different groups (eg, different treatments). The computation of a test statistic and the associated *P* value differs by the type of trial endpoint, and the analysis is often performed using statistical software. Parametric tests are derived using a specific assumption about the distribution of the data within the population (eg, normal, binomial, exponential), whereas nonparametric tests make fewer assumptions. Although the latter feature is desirable, a nonparametric test will generally have less statistical power than a parametric test that is correctly matched to a specific distribution. These considerations usually become less important with the increasing sample size (eg, n ≥ 30 per group is widely used as the threshold). For large samples, the choice between a parametric or nonparametric test is less critical; for smaller ones, it is recommended that the investigator consult with a biostatistician about the most appropriate test (Tables 5-2 and 5-3).

Table 5-2 Choosing a Statistical Analysis Approach

Endpoint Type	One Predictor	Multiple Predictors or a Single Continuous Predictor
Binary (yes vs no)	χ^2 test or Fisher exact test	Logistic regression
Time to event	Log-rank test	Cox proportional hazards regression
Continuous	*t* test or Wilcoxon test	Linear regression
Paired/correlated data	Continuous: paired *t* test or signed rank test; binary: McNemar test	Mixed models or generalized mixed models
Categorical or ordinal	χ^2 test or Fisher exact test	Multinomial regression or proportional odds regression
Count data	Poisson or negative binomial regression	Poisson or negative binomial regression

Table 5-3 **Description of Common Statistical Tests**

Outcome	Setting	Test	Definition and Description
Continuous	Comparing means	Two-sample *t* test	Used to compare means between two groups for a quantitative variable; normal distribution and equal variance in each group are assumed; an unequal variance *t* test can be used if unequal variances are expected in the two groups; generally robust to small sample size and nonnormal distributions, but sensitive to outlying values, which inflate estimates of variability
		Paired *t* test	Used to compare paired quantitative data; for example, a paired *t* test can be used to determine whether there is a nonzero change in a quantitative characteristic measured before and after treatment in each patient; same sensitivity to outlying values as the two-sample *t* test
Continuous	Comparing medians or distributions	Wilcoxon rank sum (Mann-Whitney)	Nonparametric alternative to the two-sample *t* test; less sensitive to outlying values than the two-sample *t* test, although can be somewhat more conservative compared with *t* test (eg, if the data are normally distributed)
		Wilcoxon signed rank	Nonparametric alternative to the paired *t* test; less sensitive to outlying values than the paired *t* test, although somewhat more conservative
Binary	Comparing proportions	χ^2	Used to compare proportions between two or more groups; fairly robust to small sample sizes, unless there is an imbalance between groups
		Fisher exact	Used to compare proportions with small sample sizes; a commonly used rule of thumb is to use the Fisher exact test if <5 observations are expected in any of the cells of a contingency table; this test may be somewhat more conservative compared with the χ^2 test
		McNemar	Used to compare paired proportions; for example, a binary characteristic assessed before and after treatment in each patient; it is based only on the discordant pairs (where outcome is different) and is not used to assess concordance
Time to event	Comparing survival distribution	Log rank	Used to compare survival distributions between two or more groups; also, the Kaplan-Meier approach is used to estimate the survival distribution (curve)

OUTCOME MEASURES

The primary outcome is the measure that the clinical trial design team considers the most efficient or important for answering the scientific hypothesis. The primary outcome is determined at the planning stage of the trial and forms the basis for computing the sample size. The primary outcome needs to be defined a priori on the basis of assumptions or empirical evidence. A single primary outcome is typically designated to protect against the risk of an inflated false-positive error arising from the application of statistical tests to a large number of trial outcomes (endpoints) and/or the selection of the most favorable findings.

As an example, an investigator plans to evaluate a new therapy in patients with a particular malignancy. The investigator decides the new therapy will be administered to patients, and tumor measurements, toxicity, biomarkers, and patient-reported outcomes will be collected. All of these are outcome measures or dependent variables. The investigator decides that the tumor measurements are the primary outcome measure, keeping the other variables as secondary or exploratory outcomes. Using changes in tumor burden measurements, the investigator could consider estimating the objective response rate (ORR) as a result of the intervention or estimating PFS. On the basis of the selection of the ORR or PFS, the sample size will likely differ, and one of

these results will be the primary determinant of whether the study is considered a success or failure. The remaining assessments are hierarchically less important and are designated secondary or exploratory outcomes.

In cancer studies, OS is generally the primary outcome of interest, but in cancers with better prognosis or earlier lines of treatment it may take a long time to observe and can be influenced by subsequent therapies. As a result, intermediate endpoints such as best overall tumor response or PFS are often used because they can be assessed earlier and are believed to correlate with clinical benefit and OS although in many disease settings these associations may be weak or absent.

Formally, a surrogate endpoint is defined as a substitute for a direct measure of the primary endpoint of interest (ie, OS) and is expected to predict clinical benefit but does not measure it directly. To formally establish endpoint surrogacy, rigorous statistical validation is required, which often involves demonstrating a high correlation between the surrogate endpoint and OS at the individual level, as well as a high concordance between the treatment effect of the surrogate endpoint and that of OS across multiple randomized clinical trials.

STUDY ENDPOINTS

In clinical trials, the study endpoint can be measured objectively to determine whether the intervention being studied is beneficial. Endpoints can be continuous, binary, ordinal, categorical, or time to event. As in the example discussed in the preceding section, tumor measurements before and after therapy are the outcome measures, and on the basis of changes in those measures, the study endpoint could be the ORR or PFS. Other common examples of endpoints are OS and improvements in quality of life and relief of symptoms.

A majority of medical interventions have safety risks. Therefore, a study endpoint should be clinically meaningful, such as improved survival, or a benefit that is detectable to the patient, such as an improvement in symptoms, functional capacity, or disease prevention.

Before study initiation, the selected study endpoint should accurately assess the hypothesis being tested, be clinically meaningful, and not be subject to bias. Although OS is the gold standard for efficacy in oncology trials, it has limitations; for example, in good-prognosis settings, follow-up time may be too long to observe enough events (deaths), and it may also be confounded by subsequent therapies. A key component of the study design process is the commitment to collect high-quality data in accordance with objective standards to aid with analysis and future applications. One such tool to harmonize data quality across clinical research is the National Cancer Institute Common Data Elements effort. Adoption of these constraints aims to improve quality and reproducibility across disparate sources of clinical research through standard semantic and syntactic representations of any and all produced research data.

SAMPLE SIZE AND POWER CALCULATIONS

Sample size estimation and power analysis for a clinical trial generally require formulation and preliminary data for the following:

1. Set up statistical hypotheses for the primary outcome
2. Choose power and type I error rate
3. Select effect size
4. Determine variability of the outcome measure

- During clinical trial design, clinical research questions are formulated in terms of statistical hypotheses based on the selected primary endpoint. For example, in a randomized trial comparing an experimental treatment versus control with the primary outcome of tumor response (a binary endpoint), the null hypothesis would be that response rates are equal for the two treatments, and the alternative hypothesis would be that the two treatments are different (two-sided hypothesis test) or that the experimental treatment is better than the control (one-sided hypothesis test). The specified magnitude of the difference in response rates between treatments is called the effect size.
- Power is the probability of correctly rejecting the null hypothesis when it is not true. Stated differently, it is the probability of finding a statistically significant difference between groups when it exists. This probability should be sufficiently high, and in clinical trials, it is usually set at 80% or 90%. At the same time, the trial must maintain a sufficiently low probability of type I error rate α (making a false-positive conclusion), which is often set at $\alpha = 0.05$ in phase 3 trials. Higher power or a lower α level requires a larger sample size. If the alternative hypothesis is one sided, then the sample size is smaller compared with that necessary for a two-sided test when other parameters remain the same. Whether to use a one- or two-sided hypothesis test depends on the particular study setting and must be prespecified during study design. The approach of setting the type I error rate for one-sided tests at half the conventional type I error for two-sided tests is preferable in regulatory settings.[1] For instance, using a one-sided α of 0.025 instead of a two-sided α of 0.05 in a superiority trial can reduce the required sample size while preserving regulatory control of type I errors. Some journals may require planned two-sided tests when reporting efficacy results, especially secondary endpoints, for consistency across literature.

- Generally, the effect size is the smallest effect that would be considered clinically or biologically of interest; it is the minimum difference that is considered to be of clinical significance.[2] Depending on the type of primary endpoint in the study, the effect size may be expressed as a difference in proportions, a difference in means, or an HR. For continuous outcomes, standardized effect size $\delta = (\mu_1 - \mu_2)/\sigma$, which expresses the difference in means μ relative to the standard deviation σ, can be used as a convenient summary to be compared across outcomes measured on different scales. However, the use of the standardized effect size alone for power calculations is insufficient, and a clinically meaningful difference on the actual scale used to measure the outcome must be considered. The effect size magnitude has a large impact on the sample size; the smaller the effect size, the larger the sample size must be to detect it.
- Variability of the outcome measure resulting from sampling and measurement error is of primary importance. Higher variability indicates that the outcome cannot be measured precisely, and a larger sample size is necessary to make robust conclusions about group differences, whereas required sample size decreases with decreasing variability. During trial design, assumptions about variability of an outcome are often based on preliminary data from published studies or investigators' estimates from their own research.

The reader is referred to the freeware for sample size computation for simple one- and two-arm designs.[3] Commercial statistical software is also available for sample size calculations for a broader range of study designs.

Details of the clinical trial design and power calculations, including rationale for the selection of the effect size and justification of the underlying assumptions about variability, are included in the clinical trial protocol with sufficient details so that they can be reproduced by another statistician.

Care should be taken in making a distinction between clinical significance and statistical significance (Fig. 5-1). It is possible to have a statistically significant result that is not clinically significant. For example, a large clinical trial of early-stage disease could show a median improvement of 1 month in OS between two treatment arms that is statistically significant ($P = .001$). In this case, the result is statistically significant at the .05 level but has little clinical importance, with a median difference in OS of only 1 month. In contrast, it is also possible to have a clinically meaningful difference, for example, a survival difference of 6 months, that is not statistically significant ($P = .15$). This latter case may occur when studies are underpowered because of a sample size that is too small, and a larger study is required to quantify this difference with higher confidence.

Figure 5-1 Relationship Between Estimates and Confidence Intervals (CIs) and Their Statistical and Clinical Significance

Sample size is sensitive to the effect size. In most cases, halving the effect size results in an approximately four-fold increase in the sample size requirement, with all other factors unchanged. Conversely, doubling the effect size leads to an approximately 75% reduction in the required sample size. Therefore, it is critically important to carefully consider the effect size that is clinically meaningful for a study.

One method to calculate the approximate clinical significance of a trial result is to generate a net benefit value. Net benefit assists with determining whether a treatment or test would do more harm than good. Net benefit puts benefits and harms on the same scale. In the diagnostic setting, the trade-off is between diagnosing patients with disease versus ordering unnecessary additional testing for those who are healthy. In the therapeutic setting, the variables may be treatment response minus toxicity

or OS minus quality of life. During the trial design process, an exchange rate, a clinical judgment of the relative value of benefits and harms associated with the study intervention, can be formulated. Typical considerations in the model might be the number of patients who need to be treated for a patient to derive benefit. A range of acceptable net benefit values can be obtained from a decision curve. For additional resources related to this topic and worksheets to calculate the net benefit, refer to the ASCO Value Framework[4] and European Society of Medical Oncology (ESMO) Magnitude of Clinical Benefit Scale (https://www.esmo.org/guidelines/esmo-mcbs).

STATISTICAL ANALYSIS PLAN

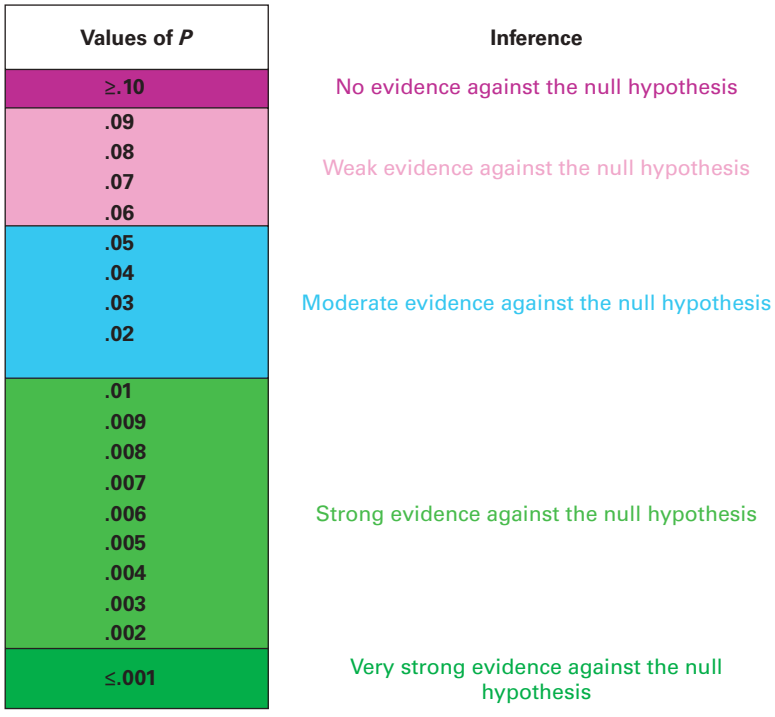
A statistical analysis plan (SAP) must be included in the clinical trial protocol and is an a priori description of the principal features of the eventual statistical analysis methods[1] that will be used to analyze trial data. An additional SAP document containing additional technical and statistical details may also be written after the protocol has been finalized but before the trial commences and is often used as a key regulatory document. The SAP is expected to provide sufficient details such that another statistician will be able to implement all planned analyses. It has been recommended that while developing the formal SAP, a minimum of 55 items be included, and these are divided into 6 major sections[5]:

1. Title and trial registration (11 items and subitems)
2. Introduction (2 items)
3. Study methods (9 items and subitems)
4. Statistical principles (8 items and subitems)
5. Trial population (8 items and subitems)
6. Analysis (17 items and subitems)

P VALUES

One of the most commonly used values in the statistical analysis of medical data, and possibly the most often misunderstood, is the *P* value (Fig. 5-2). The *P* value is calculated from the sample data, and it measures the strength of the evidence against the null hypothesis. Essentially, the *P* value is the probability that a result different from (or more different than) the one observed could be produced by chance alone, assuming that the null hypothesis is true. That is, it calculates the probability of obtaining the observed data, or data more in favor of the alternative hypothesis, if the null hypothesis is true. If the *P* value is small (close to 0), the sample data are not likely to be observed if the null hypothesis is true. This is evidence

Figure 5-2 Relationship Between *P*-Value Ranges and the Strength of Statistical Evidence Against the Null Hypothesis



Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

against the null hypothesis and suggests the data are due to a systematic effect. More concretely, it was recently reported that in a trial for men with high-risk localized prostate cancer, the 4-year OS rate was 89% for androgen suppression plus radiation treatment (two-treatment arm) compared with 93% for androgen suppression plus radiation treatment plus docetaxel (three-treatment arm), with an HR of 0.69 and a one-sided *P* value of .034.[6] Here, the null hypothesis is not explicitly stated, as is often the case. However, for a one-sided test, it is implied that the null hypothesis is that the three-treatment arm is equal to or worse than the two-treatment arm with respect to OS. In this case, the alternative hypothesis is that the three-treatment arm would see better results than the two-treatment arm because it has one additional treatment. This is a one-sided alternative hypothesis that will have a one-sided *P* value. Statisticians determine whether there is evidence against the null hypothesis as defined for the one-sided comparison. If there is evidence against the null hypothesis, they then reject the null hypothesis in favor of the alternative hypothesis. Typically, as in this example, a level of significance of .05 is used to determine if there is sufficient evidence to reject the null hypothesis. The *P* value is then calculated by assuming that there is no difference between the treatment arms (which would be an HR of 1) and determining how likely it would have been to observe an HR of 0.69 (the value computed from the trial data) or even lower. In this case, an HR of less than 1 favors the three-treatment arm. Because the *P* value is .034, meaning that if the HR were 1, the chance of observing an HR of ≤0.69 would be .034. Because this is lower than the level of significance (eg, $P = .034$ is lower than the level of significance of .05), the conclusion is that the three-treatment arm has better OS than the two-treatment arm.

What constitutes a small *P* value? This is set by stating a level of significance at the time the study is designed, which is called the level of significance or the significance level. In clinical research, $P < .05$ is commonly used to indicate statistical significance, meaning it is sufficient evidence against the null hypothesis. This number is arbitrary but often used in phase 3 trials. However, other significance levels are used in clinical research. For example, phase 2 trials often use a .10 significance level, because if the result is found to be statistically significant, it will be followed by a more stringent phase 3 trial to confirm its efficacy. Studies designed to determine associations of genomic/genetic measures with outcome often use a significance level that is substantially lower than .05 to minimize the overall false-positive rate. In the formal hypothesis-testing paradigm, it is equivalent to rejecting the null hypothesis when the type I error rate is set at 5%. There are a couple of common misinterpretations of the *P* value:

- Misinterpretation: The *P* value is the probability that the null hypothesis is true. Explanation: Because the *P* value is calculated by assuming that the null hypothesis is true, it cannot be a statement of the probability that the null hypothesis is true.
- Misinterpretation: When the *P* value is large or not statistically significant, this means that there is no difference. Explanation: When a result is not statistically significant, it means only that chance is one possible explanation for the observed data, if the null hypothesis is true. It does not mean that it has been established or proven that the null hypothesis is true. That is, absence of evidence against the null hypothesis is not evidence proving the null hypothesis.

What does a large *P* value mean? In the absence of any other information and assuming that the data arise from a properly designed study, the safest and most accurate interpretation is that there is insufficient evidence that the null hypothesis is false (Fig. 5-2). The reality is that the *P* value, whether small or large, actually carries little information. It conveys no information about the direction or magnitude of an effect, no information about the uncertainty in the estimated effect, and no information about the clinical significance of the effect. Even a small *P* value is no guarantee that an effect has clinical significance. In studies with a large sample size, even a modest departure from the null hypothesis can be associated with a high degree of statistical significance, but the departure from the null hypothesis may have little practical meaning. For example, it is possible to obtain $P < .0001$ with an observed difference in median survival between two treatments of only 1 month (which is statistically significant but not clinically meaningful) if the sample sizes are sufficiently large.

Recent articles in the statistical literature have recommended that investigators concentrate on reporting and interpreting uncertainty measures, such as the confidence interval (CI), rather than focusing on *P* values.[7] The CI represents a range that is likely to contain the true population value (Fig. 5-1). An interval with a 95% CI will be expected to contain the true value of the effect 95% of the time and miss it 5% of the time. Note that for any particular CI, it is unknown whether it contains the true value. The *P* value is only a statement about whether an observed result, or one more extreme, is due to chance, assuming that the null hypothesis is true. A CI for an HR crossing 1 implies that there is no difference between the treatments.

There is a relationship between significance levels and CIs. For example, if the null hypothesis is testing that there are no differences in survival time between two treatments, it can be written as an HR of 1. If the *P* value for the tests of the hypothesis is greater than the level of significance (eg, two-sided .05), then the 95% CI will contain 1 (value under the null hypothesis). Similarly, if a 95% CI for an HR does not contain 1, the implication is that the result is statistically significant at the .05-level of significance (ie, there is evidence of a difference in survival). The fallacy of thinking the null hypothesis value is the true value when the *P* value is greater than .05 is readily apparent, because the null value is only one among a range of possible values that could reasonably have produced the observed data.

CHOOSING A STATISTICAL ANALYSIS APPROACH

Choosing the type of statistical analysis to use involves the following key questions (Tables 5-2 and 5-3):

- What type of outcome measure is being used (eg, continuous, binary, time to event)?
- How many independent (explanatory) variables are being considered?
- Are any observations correlated (eg, pre- and posttreatment measurements, replicate or longitudinal assessments)?

Once these have been established, an appropriate statistical analysis method, or methods, can be determined using Table 5-2. For example, if at the start of a study, body mass index (a continuous measure) is being compared between patients with and without a certain genetic mutation (one explanatory variable that has two groups), we would use a two-sample *t* test or the Wilcoxon rank sum test because the two groups (with and without mutation) include different patients and there are no correlated observations. Similarly, if we want to compare response rates (binary outcome) between patients with or without the mutation, we would use a χ^2 or Fisher exact test, and when comparing OS (time-to-event outcome), we would use the log-rank test. If, however, we wanted to compare response rate or OS between patients with and without mutation, adjusting for their age, sex, and smoking history (multiple explanatory variables), we would use the logistic and Cox regression models, respectively. The statistical tests and regression models described here are the most commonly used methods. A variety of other more comprehensive statistical methods have been developed for more complex situations; for example, quantile regression models may be more appropriate for outcomes with skewed distributions where the median, rather than the mean, of the outcome may be of interest. Additional considerations when selecting the statistical analysis approach can be found in the article by Kim et al.[8]

KEY POINTS

- The primary objective of a clinical study is the principal clinical research question or the hypothesis to be tested.
- The primary outcome measure is the variable that will be measured during the clinical trial and on which the study endpoint will be based.
- Study endpoints are clinically meaningful results obtained after the study intervention.
- A false positive (type I error) is when the null hypothesis is true and incorrectly rejected; it is designated as α.
- A false negative (type II error) is when the null hypothesis is false and incorrectly not rejected; it is designated as β.
- Statistical contributions to the clinical trial design are essential, and trial design development is a collaboration between clinical investigators and the statistician.
- The American Statistical Association's six principles of statistical significance and *P* values are as follows[9]:

  1. *P* values can indicate how incompatible the data are with a specified statistical model.
  2. *P* values do not measure the probability that the studied hypothesis is true or the probability that the data were produced by random chance alone.
  3. Scientific conclusions and business or policy decisions should not be based only on whether a *P* value passes a specific threshold.
  4. Proper inference requires full reporting and transparency.
  5. A *P* value, or statistical significance, does not measure the size of an effect or the importance of a result.
  6. By itself, a *P* value does not provide a good measure of evidence regarding a model or hypothesis.

CLINICAL TRIAL DESIGN

Clinical trials play a fundamental role in progress on cancer research and in the development of novel interventions, prevention, and detection devices.[10] The traditional paradigm has classified clinical trials according to the general phases of drug development based on cytotoxic drugs. Although this classification does not account for all clinical trials relevant to oncology, it is a useful starting point for describing the key elements of trial design, which necessarily vary according to the objectives of the trial.

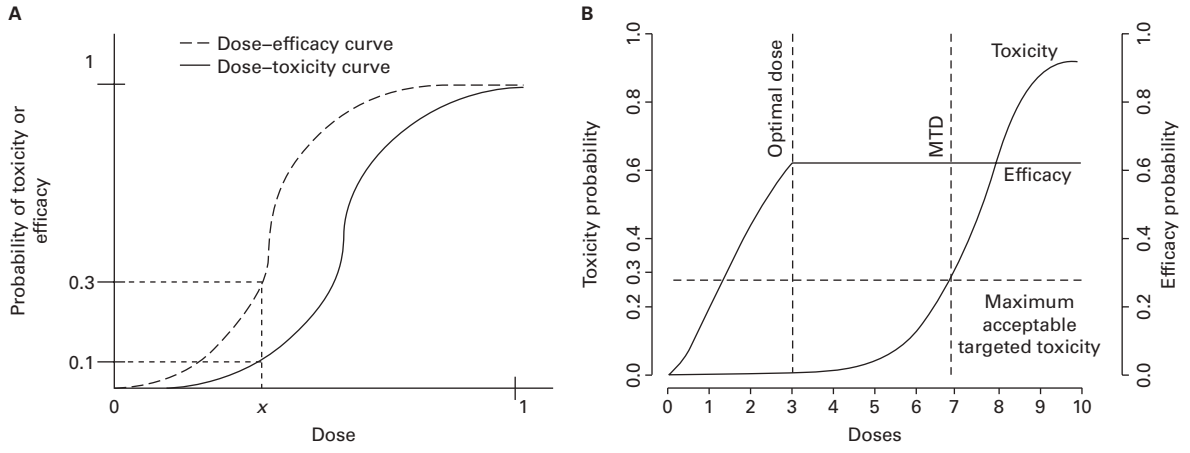
Phase 1 trials are often the first use of a drug or a drug combination in humans and focus on toxicity, with the goal of determining a dose that would have acceptable toxicity if the drug were effective. Phase 2 trials are designed to provide a preliminary indication of whether a therapy has anticancer effects. The result is considered preliminary because the study may be uncontrolled, use a surrogate endpoint (eg, tumor response instead of survival), or be too small to rule out false-positive findings. A phase 3 trial is typically a randomized controlled trial (RCT) that is sufficiently large to distinguish chance effects from true treatment effects. The definitive distinction between trial phases has become less precise in the era of precision medicine, and other trial classifications have been commonly used, including phase 1/2, 1b, 2/3, or 4. There is no recognized governing body for trial nomenclature, and trial sponsors are free to attach whatever labels they wish to a particular study. Sometimes, the label selected is motivated by regulatory or insurance considerations. For example, the US Food and Drug Administration (FDA) mandates definitions of trial phases for studies that it regulates, and insurers may decline coverage for patients participating in certain phase trials.

The considerations for power and type I error vary across phases. In phase 1 trials, which primarily focus on safety and dose finding, there is typically no formal consideration of statistical power or type I error because the sample size is small and not hypothesis driven. Phase 2 trials aim to assess preliminary efficacy and often prioritize high statistical power to detect potential signals of efficacy although they may tolerate a higher type I error rate to avoid prematurely discarding promising treatments. In contrast, phase 3 trials, designed to confirm efficacy and safety in a larger sample, require reasonably high statistical power (eg, 80% to 90%) to ensure reliable and generalizable results and strict control of type I error (commonly set at two-sided $\alpha = 0.05$) to maintain credibility and minimize false-positive findings.

PHASE 1 TRIALS

The goal of the initial phase of testing a new anticancer strategy in humans is finding a dose or schedule that yields an acceptable level of toxicity. What is deemed acceptable depends on the disease in question. In diseases such as cancer that have significant morbidity and mortality rates, the acceptable level of toxicity may be relatively high. It is often the case with cytotoxic drugs that drug toxicity is a measure of its potential efficacy, meaning that greater efficacy is expected with higher doses (Fig. 5-3A). However, higher doses mean more toxicity, and the goal is to find the highest dose with an acceptable level of toxicity. With newer targeted therapy or immunotherapy, the presumed relationship of toxicity and efficacy may differ, where higher doses of a targeted therapy or immunotherapy may yield undesirable off-target effects, and the design of appropriate phase 1 trials for these agents can be challenging (Fig. 5-3B). The major objective of a phase 1 trial is to find an acceptable drug dose to be used in subsequent phase 2 and higher trials, which is often referred to as the recommended phase 2 dose (RP2D). Phase 1 dose-finding trials are not designed to test drug efficacy although drug efficacy outcomes can often be assessed using, for example, disease-specific expansion cohorts in phase 1b trials, and the findings can be used to inform subsequent drug development and prioritization.

Figure 5-3 Dose-Response and Dose-Toxicity Relationships for Cytotoxic Versus Molecular Targeted Treatments



(A) Typical dose-toxicity and dose-efficacy curves for cytotoxic agents. This example illustrates that at dose *x*, the probability of efficacy is 30% and the probability of toxicity is 10%; hence, the therapeutic index of the drug at dose *x* is 10% divided by 30% = 1/3. (B) Illustration of dose-toxicity and dose-efficacy relationship for molecularly targeted agents.
Abbreviation: MTD, maximum tolerated dose.

STUDY OBJECTIVES AND PATIENT POPULATION

Traditionally, the objective of a phase 1 trial is to determine the maximum dose of an agent, either alone or in combination with other therapies (including radiation therapy), that yields an acceptable level of adverse events when administered on a specific schedule and by a specific route. This dose is referred to as the maximum tolerated dose (MTD) and is often selected as the RP2D for cytotoxic therapies. Phase 1 trials are necessarily small for ethical reasons because it is not expected that many patients enrolled in these trials will obtain benefit, particularly at lower doses. Typically, patients enrolled in phase 1 trials have received multiple lines of therapy, and there are no additional standard treatment options available. The patient population is generally heterogeneous with respect to the type of cancer but at times may be restricted to patients with specific cancers or tumor molecular profiles, depending on the agent being tested and its mechanism of action.

STUDY OUTCOME MEASURES

The outcome measures evaluated in phase 1 studies are toxicities related to the study intervention. The most common standard for rating the severity of adverse events is the National Cancer Institute Common Terminology Criteria for Adverse Events list, which provides specific objective criteria for grading a wide range of adverse events on a numeric scale: 0 (none), 1 (mild), 2 (moderate), 3 (severe), 4 (life threatening), and 5 (fatal). Beyond the severity of an adverse event, it is important to document the onset, resolution, and relatedness of the adverse event (eg, whether the adverse event is related to the study therapy, a concomitant medication, or underlying disease condition). Phase 1 study participants are generally evaluated at discrete regular intervals of a short cadence to capture the time course of adverse events.

STUDY ENDPOINTS

At the conclusion of a phase 1 clinical trial, the primary goal is to estimate a dose that can be taken forward into later phase studies. Most dose-escalation designs aim to identify the MTD, which is the highest dose associated with an acceptable risk of dose-limiting toxicity (DLT). The RP2D is usually determined after the MTD is identified and often reflects additional information beyond acute toxicity. These considerations may include data from dose expansion cohorts, cumulative or delayed toxicities, pharmacokinetic and pharmacodynamic findings, and preliminary evidence of activity.

Although the MTD is the most common primary endpoint in traditional cytotoxic trials, the RP2D may differ from the MTD when longer term tolerability or biological activity suggests a lower or occasionally higher dose is more appropriate. Some contemporary dose-finding designs, particularly those used with molecularly targeted agents or immunotherapies, may aim to identify an optimal biological dose (OBD). An OBD focuses on achieving adequate target engagement or biological activity with acceptable toxicity, especially in settings where the MTD is not reached or is not clinically informative.

The adverse event criteria are used to determine the MTD on the basis of the severity of the experienced adverse events. Adverse events of severity or duration such that further exploration of higher doses is unacceptable because of toxicity are said to be DLTs. A dose below the level where DLTs are experienced generally defines the MTD. Phase 1b trials may also include one or more dose-expansion cohorts, usually at the MTD, for additional safety evaluation before a phase 2 trial is initiated, as well as for preliminary activity evaluation, for example, in different types of cancer. Other factors may be considered that may result in the RP2D being lower than the MTD. For example, for molecularly targeted agents, efficacy may increase initially but then plateau, whereas toxicity may be low in this dose range and the MTD may not be reached (Fig. 5-3B). For such agents, the goal is to find the optimal , which is the lowest safe dose at which the highest efficacy is achieved.

One of the most important criteria in a phase 1 trial is the definition of a DLT. Although most phase 1 trials have a similar definition for what constitutes a DLT, the definition can be tailored to reflect adverse events expected on the basis of the mechanism of action of the agent. Most definitions of DLTs exclude grade 1 or 2 adverse events and possibly some grade 3 toxicities, if these are expected and manageable (eg, neutropenia, nausea/vomiting). A typical definition of a DLT might be a grade 3 or worse nonhematological adverse event or a grade 4 or worse hematological adverse event that is attributable to the agent being tested. This is the starting definition of a DLT for most trials, and the study team may make modifications on the basis of expected manageable adverse events, yielding, for example, any grade 3 or worse nonhematological adverse event other than diarrhea or a grade 4 or worse hematological adverse event that is attributable to the tested agent. Assigning attribution to the adverse event is also important, and DLT definition usually includes only the adverse events attributed to treatment rather than the underlying disease.

It is also important to specify the DLT assessment window, during which adverse events will be evaluated for dose-escalation decisions. Duration of the DLT evaluation window is often driven by the pharmacokinetics and the mechanism of action of the agent. For cytotoxic therapies, this is typically a relatively short time, often just the first treatment cycle (eg, 28 days), and reflects only acute adverse events. For novel anticancer therapies, including immunotherapy, as well as for radiation therapy, delayed-onset toxicities are common, and the DLT assessment window must be long enough to capture a majority of treatment-related toxicities. Adverse events that occur after the DLT assessment period are typically not used for dose-escalation decisions as part of trial design but may affect the selection of the RP2D or how the agent is used in subsequent phase 2 trials.

Trials should also define who is considered evaluable for toxicity.[11] For example, patients who discontinue treatment before completion of the DLT assessment period without having a DLT may be considered non-evaluable for toxicity. Modern phase 1 dose-escalation statistical designs, including the Bayesian optimal interval (BOIN), which is described later in this chapter, can accommodate situations when some patients at a particular dose level are non-evaluable by providing decision rules for each possible sample size at that dose level. Non-evaluable patients may also be replaced during dose escalation, which would also need to be prespecified in the protocol.

DOSE RANGE SELECTION

Phase 1 trials prespecify the starting dose of the treatment being evaluated for the first cohort of patients as well as a sequence of doses to be tested in subsequent cohorts. If the agent in question has not yet been assessed in humans, the initial dose is typically derived from animal experiments. If the agent has been used in humans but with a different route of administration, on a

different schedule, or in combination with different treatments (including as a monotherapy) than currently being tested, the starting dose is selected on the basis of all available human experience with the treatment. For trials that are testing the agent for the first time in humans, a common starting dose ranges from one-tenth to one-third of the mouse lethal dose for 10% of mice. Subsequent dose levels are determined by increasing the preceding dose by decreasing fractions, for example, 100%, 67%, 50%, 40%, and 33%. This sequence and those with slight variations are called modified Fibonacci dose levels. Starting dose levels for agents that are likely to be well tolerated, such as biological agents, may be determined by log (ie, 10-fold) or half-log increases of the preceding dose.

DESIGN OPTIONS

Many considerations go into determining an appropriate phase 1 dose-escalation design, and as with other clinical studies, it is important for clinical investigators to work closely with statisticians to refine the trial objectives and ensure that an appropriate design is chosen. The dose-escalation rules in phase 1 must address how patients should be allocated to doses, and at the end of the trial, the design should provide the RP2D. Additional key design questions[11] include whether the MTD or biologically optimal dose should be selected for further study; how many agents are escalated in combination treatments; acceptable toxicity (DLT) rate, DLT definition, and assessment window; dose-escalation cohort size and the expected sample size; which doses should be evaluated; and trial operating characteristics. These components of phase 1 design are often overlooked but must be addressed in collaboration with the statistician.

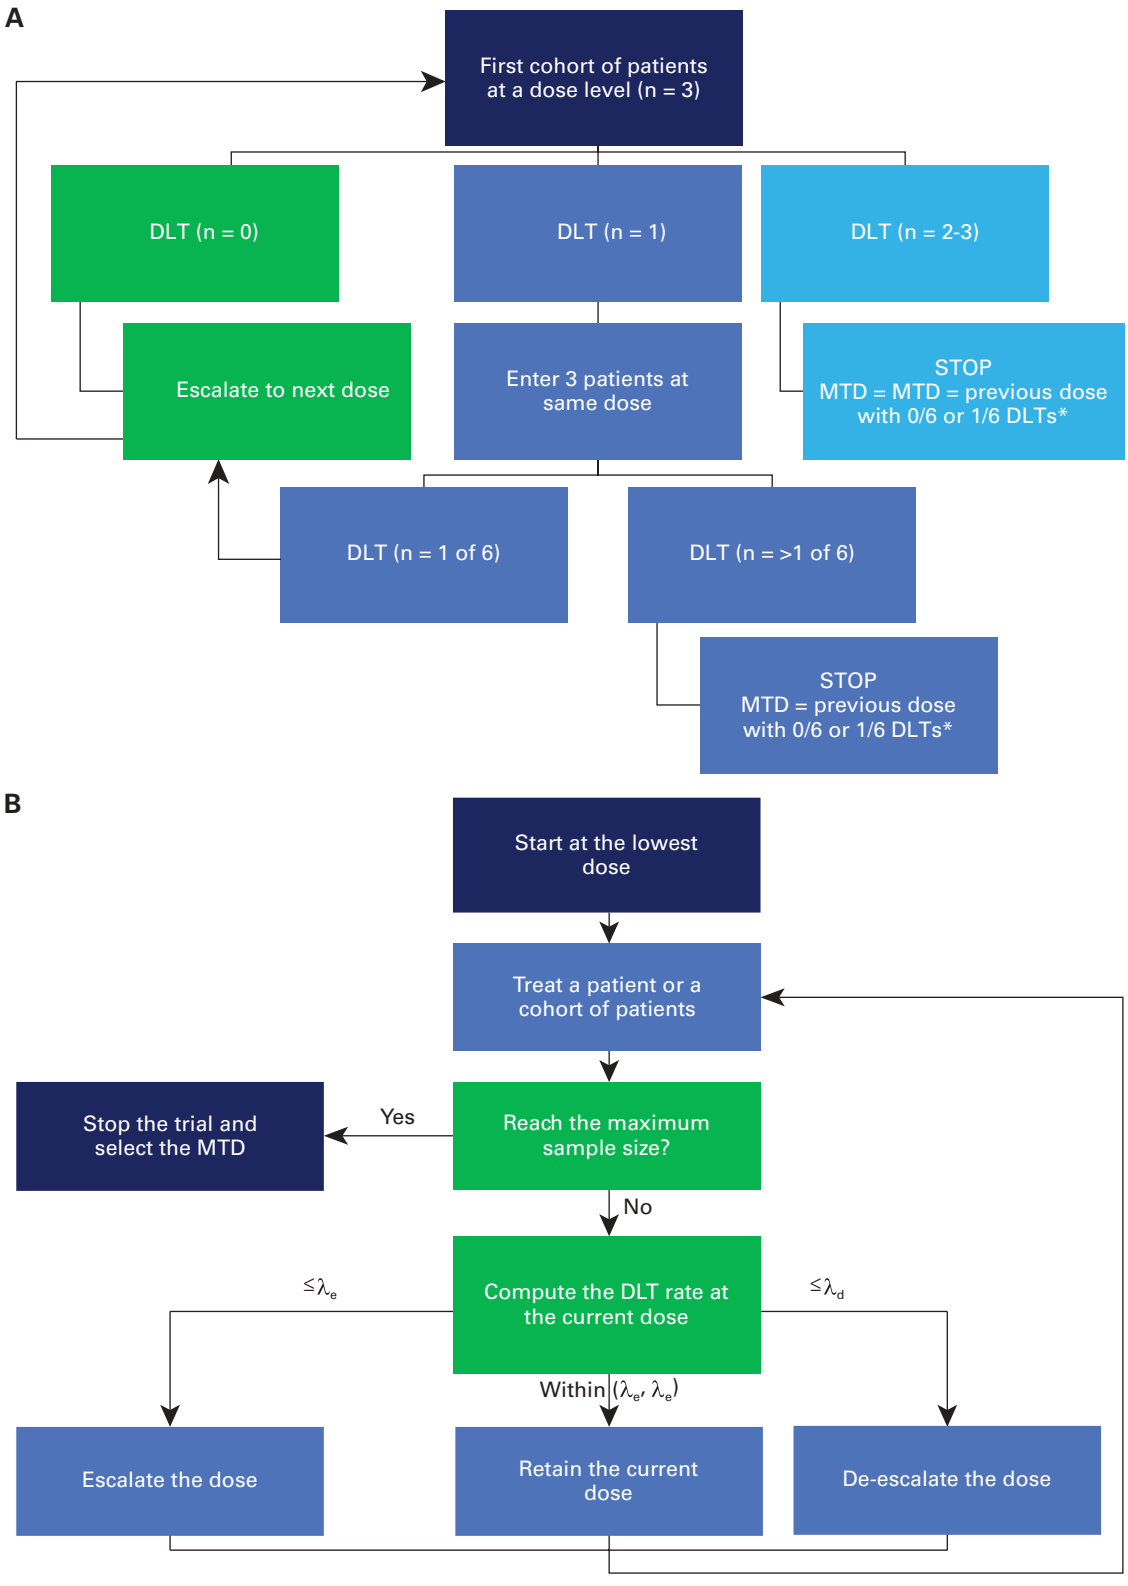
Dose-finding phase 1 trial designs can be classified as algorithm based, model based, or model assisted.[12] Algorithm-based designs use simple prespecified rules for dose escalation and de-escalation, and this class includes the 3 + 3 design (Fig. 5-4A) and its extensions, such as the accelerated titration and the rolling 6 designs. Although commonly used because of their simplicity, they have poor operating characteristics. Model-based designs use a statistical model (eg, logistic model) to estimate the underlying dose-toxicity curve, which is used to allocate patients to doses. These designs include the continuous reassessment method (CRM) and its extensions, as well as the Bayesian logistic regression model (BLRM), and provide excellent operating characteristics but can be difficult to implement in practice. Model-assisted designs combine the simplicity of use of algorithm-based designs with the superior performance of model-based designs and include modified toxicity probability interval (mTPI-2)[13] and BOIN (Fig. 5-4B)[14,15] designs and their extensions (Presenting Case Study 1). These designs use an underlying statistical model to provide a lookup table for dose-escalation and de-escalation decisions based only on the observed number of patients enrolled and experiencing a DLT at a given dose level. The performance and operating characteristics of different designs, such as the probability of correctly identifying the MTD, allocation of a high proportion of patients to the MTD, good overdose control, expected sample size, and study duration (for trials with delayed-onset adverse events) can be evaluated using simulation studies. In all of these dose-finding designs, patients who discontinue early or do not meet predefined criteria for DLT evaluation may be replaced to ensure an adequate number of evaluable patients for dose-escalation decisions. Evaluable patients are those who have received a sufficient amount of investigational treatment to allow a reliable assessment of DLT.

There are two important considerations in phase 1 trial designs: (1) minimization of the total number of patients, because there is little likelihood that enrolled patients will benefit from participating in the trial, and (2) minimization of the number of patients who experience serious adverse events.

Until recently, the most commonly used phase 1 dose-escalation design was the 3 + 3 design, which was developed in the 1950s. It is an algorithm-based design, in which cohorts of three patients are entered in the trial at dose levels beginning with the prespecified initial dose level. If there is no observed DLT in all three patients treated at the specified dose, the next cohort of three patients is entered at the next higher dose level. If two of three patients experience a DLT at a specified dose, then the adverse event rate associated with that dose is considered unacceptable, and the dose level below it (if any was tested) is considered the MTD. If one of the three patients experiences a DLT, an additional cohort of three patients is entered at the same dose level. If no DLT is seen among the additional three patients, the next cohort of patients will be treated at the next higher dose level; otherwise, the toxicity is considered unacceptable, and the dose level below it is considered the MTD. If the starting dose is too low and/or the spacing of doses is too short relative to the steepness of the dose-response curve, it is possible a large number of patients will be enrolled at doses that likely have no therapeutic benefit. In response to this concern, an accelerated titration design was proposed, in which the cohort size for the initial dose level is a single patient, and subsequent patients are treated at the next higher dose level until a grade 2 or worse drug-related adverse event is observed. Once this happens, a standard 3 + 3 design is implemented starting at the next lower dose level from that where the grade 2 or worse adverse event was observed. These designs are generally used for treatments in which there is some human experience with the agent, and the toxicity profile is manageable.

Another design option is the continual reassessment method, which uses a Bayesian approach (refer to the discussion on Bayesian statistics later in this chapter) and is a model-based design. Although there are many variations of continual reassessment methods, the basic idea is to specify an acceptable probability of a DLT (eg, 20% or 33%), specify a mathematic model for the dose-response curve,

Figure 5-4 Typical Dose-Finding Phase 1 Design Algorithms



(A) 3 + 3 phase 1 trial design. Note that patients who are non-evaluable for DLTs may be replaced. (B) BOIN design.
Abbreviations: BOIN, Bayesian optimal interval; DLT, dose-limiting toxicity; MTD, maximum tolerated dose.
*Six patients must be treated at a dose level before it can be declared an MTD.

and update the mathematic estimate of the dose-response curve after each patient experiences a DLT. The dose level for the next patient (or cohort) who will be treated is the one at which the estimated probability of a DLT is closest to the specified target. The advantage of this method is that it produces more-accurate estimates of the MTD and minimizes the number of patients who are treated at nontherapeutic levels or levels that are too toxic. In addition, these methods are good approaches for testing combination drugs. The continual reassessment method and partial-order approaches require submission of DLT data to statisticians in real time to determine the dose assignment for the next patient, which makes the application of these designs logistically challenging.

The BOIN design is simple to implement and has better performance than the 3 + 3 design.[14] This design computes probability intervals defined as underdosing, proper dosing, and overdosing. Dose-escalation decisions are easily made on the basis of these dosing intervals; they can be described using simple lookup tables for ease of application. Observed DLT rate at the current dose level can then be compered to these intervals, or alternatively DLT counts can be compared to the pre-specified lookup table. The BOIN design tends to treat fewer patients at doses greater than the MTD and is more likely than the 3 + 3 design to identify the true MTD. It is also easy to implement because the tables are generated before the trial starts, so there is no need to perform real-time computation to determine the dose level to treat the next patient (or cohort). The website www.trialdesign.org provides an easy-to-use app for BOIN and its extensions.[16]

For some biologic or targeted treatments, toxicity across the anticipated therapeutic dose range may be limited. In these settings, dose finding focuses less on identifying an MTD and more on determining a dose or dose range that produces adequate biological activity with acceptable tolerability. The goal is to identify an OBD, which is the lowest dose that achieves the desired biological effect without unnecessary toxicity. This approach is particularly relevant for targeted therapies and immunotherapies, where therapeutic effects depend on modulation of specific biologic pathways rather than on dose-dependent cytotoxicity.

Backfilling is an strategy used to support dose optimization in this context. Backfilling refers to the enrollment of additional participants at previously tested dose levels to gather more detailed information on safety, tolerability, pharmacokinetics, and pharmacodynamic activity. Traditionally, backfilling occurs after an MTD is identified, but newer designs such as BOIN Backfill allow backfilling to occur while dose escalation is still ongoing. Allowing backfill enrollment in parallel with escalation improves efficiency because escalation does not need to pause while additional data are collected at lower or intermediate doses. This approach strengthens the evidence base used to select the RP2D or OBD.

Recent regulatory initiatives, including Project OPTIMUS, highlight the importance of rigorous dose optimization for targeted and immune therapies. These initiatives encourage the use of strategies such as backfilling and biomarker informed expansion cohorts so that the RP2D reflects both biological activity and longer term tolerability rather than relying primarily on acute toxicity. Successful implementation depends on factors such as biomarker availability, reliable assays for biological response, and transparent criteria for selecting doses to expand. When applied carefully, these approaches can improve confidence that the dose carried forward into phase 2 studies is both active and well tolerated.

PRESENTING CASE STUDY 1

An investigator is designing a phase 1 trial of a novel cytotoxic chemotherapy agent for patients with advanced solid tumors. Preclinical studies suggest dose-dependent antitumor activity, but human toxicity is uncertain. The protocol defines a dose-limiting toxicity (DLT) as any grade 3 or higher nonhematological toxicity attributable to treatment, or grade 4 hematological toxicity lasting more than 7 days, assessed during cycle 1 (28 days). The target DLT rate is 25%. Five dose levels (DL1 through DL5) are prespecified using modified Fibonacci increments.

To illustrate how design choice affects patient allocation, consider the following hypothetical pattern of observed DLTs.

A. What happens under a 3 + 3 design

The trial starts at DL1. Suppose 0 of 3 patients experience a DLT, so the trial escalates to DL2. Again, 0 of 3 report a DLT, so it escalates to DL3. At DL3, suppose 1 of 3 patients experiences a DLT. Under 3 + 3, the cohort expands to 6 at DL3. If no additional DLTs occur, DL3 has 1 of 6 DLTs and escalation proceeds to DL4. At DL4, suppose 2 of 3 patients experience a DLT. DL4 is then considered too toxic, and DL3 is declared the maximum tolerated dose (MTD). In this example, the 3 + 3 design reaches DL4 quickly, but it can treat multiple patients at doses that may later prove too toxic or at early doses that may be subtherapeutic.

B. What happens under Bayesian Optimal Interval (BOIN) with a 25% target

Escalation and de-escalation decisions are based on a prespecified decision table calibrated to the target toxicity. Starting at DL1 and DL2 with 0 of 3 DLTs would typically lead to escalation, similar to 3 + 3. The difference emerges at DL3. With

a 25% target, observing 1 DLT among 3 patients is treated as a signal of potential overdosing, and the design recommends de-escalation to DL2 rather than automatically expanding DL3. The next cohort is treated at DL2 to gather additional information. If DL2 continues to show an acceptably low DLT rate, escalation back to DL3 can occur, but only when the accumulated evidence supports that DL3 is near the target toxicity. In practical terms, BOIN may be more conservative in the face of early toxicity signals, which can reduce exposure to overly toxic doses and concentrate enrollment near doses that appear acceptable.

C. What happens under continual reassessment method (CRM)

CRM also targets a prespecified DLT rate but uses a statistical model to update the estimated dose-toxicity relationship as data accrue. After observing 1 of 3 DLTs at DL3, CRM would typically revise the dose-toxicity curve upward and may recommend treating the next cohort at DL2 or DL3 depending on the posterior estimate. The potential advantage is more efficient learning about the dose-toxicity relationship, but it requires real-time statistical updating and timely dose assignment.

D. Selecting the Recommended Phase 2 Dose (RP2D)

Even if a design identifies an MTD, the RP2D may be informed by additional data, including expansion cohorts, cumulative toxicities, and pharmacokinetic or pharmacodynamic findings. This is one reason modern phase 1 programs often separate the technical selection of an MTD from the clinical decision about the RP2D.

Formal simulation studies are often used to compare the operating characteristics of dose-escalation designs across a range of toxicity scenarios, including their ability to identify the true MTD and control overdosing. Such evaluations are beyond the scope of this chapter, but the example illustrates how different design frameworks can lead to distinct escalation paths and patient allocation even when starting from the same observed data.

KEY POINTS

- Phase 1 trial objectives are as follows:
  1. Identify the safe dose or MTD of a novel therapy or therapy combination.
  2. Ascertain a dose or dose range for subsequent phase 2 studies.
  3. Determine clinical drug behavior through pharmacokinetic and/or biomarker studies.
  4. Assess preliminary antitumor efficacy.

PHASE 2 TRIALS

Phase 2 trials encompass a wide array of trial designs. These range from small single-arm trials with a dozen patients to RCTs with several hundred patients. Nevertheless, there are common features that characterize a phase 2 trial. The primary endpoint is related to efficacy or drug activity, the sample size is moderately small relative to the corresponding definitive phase 3 trial, the efficacy endpoint is short term and/or not definitive for patient benefit, and the study relies on historical experience as context for judging whether the result is promising enough to carry forward to a phase 3 trial. This is the type of trial that will be considered phase 2 for the purposes of this discussion.

Phase 2 trial objectives are as follows:

- Assess the antitumor efficacy/activity of a therapeutic intervention.
- Gain additional experience with the regimen or collect further toxicity data.
- Make a go or no-go decision regarding the further development of a therapeutic regimen.
- Provide data for an effect-size estimate for a subsequent phase 3 study.
- Assess biomarkers in a larger and more homogeneous patient population.

STUDY OBJECTIVES AND PATIENT POPULATION

The general objective of a phase 2 trial is to evaluate the potential efficacy of a drug or regimen in a specific patient population. The patient population is usually somewhat narrowly defined (eg, patients with recurrent glioblastoma). Typically, patients enrolled in phase 2 trials have experienced treatment failure with at least one or two standard therapies. However, there are

scenarios in which a phase 2 trial is conducted with patients with newly diagnosed disease who have not yet been treated (eg, in diseases with no effective therapy or when a new agent is to be added to the standard of care). Finally, a phase 2 study may be used to evaluate an established treatment in a different patient population (eg, a different type of cancer, a subtype of cancer defined by a genetic or another biological marker).

STUDY OUTCOME MEASURES

The overarching goal of a phase 2 study is to determine whether there is potential anticancer efficacy for the treatment approach under study. Therefore, the outcome measure incorporated into the study design tends to be a marker of therapeutic response, such as tumor measurements on radiology or validated blood-based tumor markers. In addition, a phase 2 study provides an opportunity to collect adverse event data on a larger group of participants than typically included in a phase 1 study, and the adverse events associated with longer-term drug administration can also be assessed. Therefore, toxicity data, survival data, and biomarkers and surrogate markers of efficacy are often included in the design of these studies.

STUDY ENDPOINTS

As noted, the primary endpoint of a phase 2 trial is a measure of potential efficacy or anticancer activity. The specific endpoint balances the ability to assess it in a relatively short time (ie, weeks, months) and its validity as a measure of long-term benefit. Many trials for solid tumors use tumor response (complete or partial), as assessed by imaging, as the primary endpoint, which usually can be ascertained within 3 to 6 months from the time a patient starts treatment. For neoadjuvant trials, a common endpoint is pathological complete response, which is determined by pathological examination of tissue obtained at the time of surgery. There are also trials that use other endpoints; some examples are 3-month PFS rate or 6-month disease-free survival (DFS) rate.

The most common methodology for determining tumor response in solid tumors is RECIST 1.1 (Table 5-4). Most response definitions for solid tumors are based on the change in size of measurable lesions over the course of a trial. Tumor responses are classified as complete response, partial response, stable disease, progressive disease, or unevaluable. Determining disease response status on the basis of RECIST depends on targeted and nontargeted lesions. A targeted lesion must be measurable. If there is more than one measurable lesion, a maximum of five lesions are selected.[17] A measure of disease is the sum of the largest diameter of the targeted lesions. All other lesions (either nonmeasurable lesions or measurable lesions not designated as targeted) are called nontargeted. The RECIST criteria depend on the changes in the size of the targeted lesions as well as on the changes in nontargeted lesions.[17] In cancer immunotherapy trials, a modified consensus guideline (ie, iRECIST, where responses assigned have a prefix of "i" for immune) has been developed by the RECIST Working Group.[18] Different response criteria are necessary for specific tumor types, such as the Response Assessment in Neuro-Oncology (RANO) criteria for brain tumors and the Prostate Cancer Working Group 3 (PCWG3) criteria for metastatic castration-resistant prostate cancer (mCRPC). Hematological malignancies also require tailored response criteria depending on the disease type. Regardless of the criteria used, the trial design must specify how and when a response will be assessed. The assessment of the primary endpoint must be performed the same way for all patients within the trial and should be reasonably comparable to what was used in other trials or how it was assessed in historical controls. In addition, especially in multicenter phase 3 open-label trials, blinded independent central review (BICR) of tumor responses is often adopted to overcome potential biases associated with locally performed tumor response evaluations.[19]

Table 5-4 RECIST 1.1 Definitions of Response and Disease

Response	Target Lesions	Nontarget Lesions
CR	Disappearance of all target lesions	Disappearance of all nontarget lesions and normalization of tumor marker level
PR	At least a 30% decrease in the sum of diameters of target lesions, taking as reference the baseline sum of diameters	Persistence of ≥1 nontarget lesion and/or maintenance of tumor marker level above the normal limits
PD	At least a 20% increase in the sum of diameters of target lesions, taking as reference the smallest sum on study; in addition to the relative increase of 20%, the sum must also demonstrate an absolute increase of at least 5 mm	Unequivocal progression of existing nontarget lesions; appearance of ≥1 new lesion is also considered progression
SD	Neither sufficient shrinkage to quality for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum diameters during the study	NA

Abbreviations: CR, complete response; NA, not applicable; PD, progressive disease; PR, partial response; RECIST, Response Evaluation Criteria in Solid Tumors; SD, stable disease.

Sometimes, a phase 2 trial uses a tumor biomarker as the primary endpoint. For example, prostate cancer trials often use the increase, progression, or recurrence of prostate-specific antigen (PSA) levels at a specific time, such as 3 or 6 months, as a phase 2 endpoint. PSA progression is typically defined as a confirmed increase of 25% or greater in the PSA level from the nadir (lowest PSA level observed after starting treatment), with an absolute increase of 2 ng/mL or more. A biomarker is a single trait or composition of traits, often called a signature, used to determine disease status. These traits may include an assessment of tumor genomics or genetic aberrations or a molecular assessment of circulating tumor DNA. There is heightened interest in biomarkers for targeted therapies, which may have specific mechanisms of action that are measured by a variety of assays, possibly from blood or tumor samples that can be obtained quickly and easily. The rationale is that if the mechanism of action is truly understood for a targeted treatment, it should be possible to measure the effect of the treatment on the intended target. Biomarkers have many different uses in cancer research. In phase 2 studies, biomarkers are most commonly used as the primary endpoint as surrogates for treatment efficacy. However, the appropriate use of biomarkers as surrogate endpoints requires specific criteria that may be difficult to validate. A full discussion of these issues is beyond the scope of this chapter, but in general, one should be cautious when evaluating claims of effectiveness based on biomarkers or other surrogate endpoints.[20] For guidance on the appropriate use of surrogate endpoints in cancer drug and biological approvals, the FDA provides detailed recommendations in Clinical Trial Endpoints for the Approval of Cancer Drugs and Biologics: Guidance for Industry.[20]

TRADITIONAL SINGLE-ARM PHASE 2 DESIGN

A commonly used phase 2 design is a single-arm trial using historical outcomes as points of reference for the design and interpretation of the trial. The primary analysis is to compare the observed outcome in the single-arm trial with the historical control value to determine if there is a statistically significant difference. For example, suppose the primary endpoint is tumor response, and the historical tumor response rate for the standard-of-care regimen is p_0. Furthermore, suppose p_1 is the minimum tumor response rate that would represent meaningful improvement compared with the standard of care. In other words, if there is evidence that the new treatment response rate is higher than p_0, it would be of interest for further study. In addition, investigators want reasonable power to reject the null hypothesis if the true treatment response rate is p_1.

The hypothesis-testing paradigm assumes that at the end of the trial, one will conclude that either (1) the true response rate for the regimen is greater than p_0 or (2) there is no evidence that the response rate for the regimen differs from p_0. The design parameters must also include a specification of α and the desired power (see "Hypothesis Testing" section earlier in the chapter). The false-positive error rate is the probability of falsely concluding that the true response rate for the regimen is greater than p_0, when in fact, it is equal to p_0. Power is the probability of correctly concluding that the true response rate for the regimen is greater than p_0, when in fact, it is greater than p_0. For phase 2 trials, α is typically set at 10%. The power is evaluated at p_1, the target response rate of interest. Phase 2 trials typically are designed with high power, often 90%. The possibility of relatively high error rates is accepted, because smaller sample sizes are yielded and because the results of a phase 2 trial will be confirmed in

Table 5-5 **Examples of Single-Stage Phase 2 Designs**

Design Criteria				Resulting Design	
p_0	p_1	α	Power[a]	n	r
0.1	0.25	0.05	0.9	55	10
0.1	0.25	0.05	0.8	40	8
0.1	0.25	0.1	0.9	40	7
0.1	0.25	0.1	0.8	31	6
0.1	0.25	0.05	0.9	33	7
0.1	0.25	0.05	0.8	25	6
0.1	0.25	0.1	0.9	25	5
0.1	0.25	0.1	0.8	18	4
0.5	0.7	0.05	0.9	53	33
0.5	0.7	0.05	0.8	37	24
0.5	0.7	0.1	0.9	39	24
0.5	0.7	0.1	0.8	28	18

Abbreviations: α, type I (false-positive, one-sided) error rate if $p = p_0$; n, smallest sample size that satisfies design criteria; p_0, response rate under null hypothesis; p, response rate under alternative hypothesis; r, minimum number of responses required to reject null hypothesis and conclude that $p > p_0$ using the exact test for one proportion.

[a]Power refers to the probability of rejecting the null hypothesis if $p = p_1$.

a phase 3 trial. However, differences between p_0 and p_1 have considerably greater impacts on the sample size than the values of α and power (Tables 5-5 and 5-6). The larger the difference between p_0 and p_1, the smaller the required sample size. A balance needs to be considered between the desire for smaller sample sizes and the ability to detect differences between p_0 and p_1 that would be of clinical interest.

Table 5-6 CIs for True Response Rates

Observed Rate = 10%			Observed Rate = 50%		
n	*r*	95% CI (%)	n	*r*	95% CI (%)
10	1	0.3-44.5	10	5	18.7-81.3
20	2	1.2-31.7	20	10	27.2-72.8
30	3	2.1-31.7	30	15	31.3-68.7
40	4	2.8-23.7	40	20	33.8-66.2
50	5	3.3-21.8	50	25	35.5-64.5
60	6	4.9-17.6	60	30	39.8-60.2

Abbreviations: CI, confidence interval; n, sample size; *r*, observed number of responses.

The primary endpoint of a phase 2 trial may not be a binary outcome, such as tumor response; rather, it may be based on a time-to-event endpoint, such as PFS. Unfortunately, there are some cancers for which the median time to death or progression is measured in weeks or months. If historical data suggest that the median PFS with standard of care is 3 months, this can be recast in a way that parallels testing a tumor response rate. Specifically, a median survival of 3 months is equivalent to specifying that the percentage of patients alive and progression free at 3 months, p_0, is 50%. It is relatively straightforward to convert a hypothetical improvement in the median PFS with the new treatment into a value of p_1 at 3 months, the percentage of patients who are progression free at 3 months.

As mentioned previously, it would not be good practice in reporting the results of a clinical trial to merely provide the *P* value for comparing p_1 with p_0 or merely state that the null hypothesis has been rejected and there is evidence that the new treatment has a higher tumor response rate than the standard-of-care treatment. It is important to also report an estimate of the response rate for the tested treatment as well as its corresponding CI. Knowing the estimate of the tumor response rate of the new treatment allows investigators to place this in context with a host of other factors before deciding whether additional trials are warranted. The estimated response rate is relatively imprecise for phase 2 trials because of the small sample sizes and provides only a rough indication of the response rate. The CI can be computed using standard binomial distribution.

The term optimal relates to a mathematic criterion, which sometimes leads to a design with an imbalance in the sizes of stages that seems impractical, for example, by assigning 70% of the enrollment to the first stage. In such cases, there are almost always alternatives that are mathematically not quite optimal but are more appealing in terms of the split between stages while still

Table 5-7 Examples of Two-Stage Phase 2 Designs (Optimal Simon Design)

Design Criteria				Resulting Design			
				First Stage		Overall	
p_0	p_1	α	Power[a]	n_1	r_1	n	*r*
0.10	0.25	0.05	0.9	21	2	66	10
0.10	0.25	0.10	0.9	21	2	50	7
0.25	0.45	0.10	0.9	22	6	57	19
0.40	0.6	0.10	0.9	25	11	66	32
0.50	0.7	0.10	0.9	24	13	61	36

Abbreviations: α, one-sided type I (false-positive) error rate if $p = p_0$; n, total sample size after both stages; n_1, sample size for first stage; p_0, response rate under null hypothesis (usually based on external control group rate); p_1, response rate under alternative hypothesis; *r*, minimum number of responses required to reject null hypothesis and conclude that $p > p_0$; r_1, if r_1 or fewer responses are observed during stage I, the trial is stopped early for futility (if r_1 or fewer responses are observed by the end of stage II, then no further investigation of the drug is warranted).
[a]Power refers to the probability of rejecting the null hypothesis if $p = p_1$.

satisfying the other design parameters. For example, another commonly used approach is to minimize the maximum possible sample size; this is called a minimax design. The reader is referred to the work of Ivanova[21] for sample size computation based on different designs, including the optimal Simon design (Table 5-7).

ADDITIONAL PHASE 2 DESIGNS

A Bayesian Optimal Phase 2 (BOP2) design considers a flexible Bayesian approach for a phase 2 clinical trial. The BOP2 design accommodates various types of endpoints, including binary, ordinal, and survival endpoints, within a unified framework.[22,23] It allows for incorporating prior information and adjusting the trial based on accumulating data while controlling the type I error rate. The BOP2 design demonstrates higher power and lower risk of incorrect trial termination compared with existing Bayesian designs and allows for pretrial enumeration of stopping boundaries. In contrast, the Simon two-stage design, a frequentist approach, is simpler and more rigid and used for trials with binary outcomes only. It does not accommodate real-time data adjustments or a range of endpoint types as BOP2 does.

In addition to single-arm designs, whether BOP2 or Simon two stage, phase 2 trials are increasingly using randomization to allocate patients to two or more different arms. The reasons motivating randomized phase 2 designs with multiple therapeutic arms are numerous. Perhaps the most compelling reason for a randomized phase 2 trial is the uncertainty in or even absence of (eg, in a newly defined population based on molecular characteristics) outcome estimates from the historical data. For a more rigorous pilot evaluation of efficacy, the so-called randomized screening phase 2 design has been advocated and is increasingly being used.[24] To maintain a relatively small sample size, this design features larger type I (eg, up to 20%) and type II (20%) errors than typically used in single-arm trials, while protecting against an overly large type I error that would essentially nullify the screening effect or overly large type II error that runs a higher risk of dismissing a potentially useful regimen. However, a positive result in a randomized phase 2 trial, even with a robust endpoint such as OS, should not be seen as conclusive. Such positive findings should be interpreted similarly to interim analyses in phase 3 trials, requiring stricter criteria for positivity. Further validation through a phase 3 trial is generally necessary and expected.

Additionally, some studies do not plan to compare the arms even when randomization is used. In this case, each arm is regarded as an independent trial of a regimen. These trials aim to identify the most promising treatment among experimental options, not to compare them directly. Each treatment arm targets the same patient population, and random assignment is simply a mechanism to ensure that the arms enroll patients with similar characteristics. These are essentially parallel single-arm phase 2 trials. Such designs are often referred to as a randomized phase 2 selection design or pick-the-winner design[25] (Table 5-8). The noncomparative nature allows one to ensure the selected treatment is likely superior without confounding as a result of randomization. This design suits situations where no experimental regimen is initially preferred. Additionally, any chosen regimen must meet a minimum efficacy threshold compared with historical controls before further testing.

Table 5-8 Minimum Sample Size (per Arm) for Simon's Pick-the-Winner Randomized Phase 2 Designs[a]

	Two Arms (p_1, p_2)		Three Arms (p_1, p_2, p_3)	
Difference ($p_2 - p_1$)	Power[b] = 0.80	Power = 0.90	Power = 0.80	Power = 0.90
0.10	36	82	68	123
0.15	16	37	31	55
0.20	9	21	17	31

Abbreviations: p_1, lower (lowest) response rate, 0.4; p_2, higher (highest) response rate.
[a]A conventional type I error rate is not defined for pick-the-winner randomized phase 2 designs because no formal null hypothesis is tested. These designs are intended for treatment selection rather than hypothesis testing, and their operating characteristics are summarized by the probability of correct selection rather than false-positive control.
[b]Power refers to the probability that the arm with highest true response rate has the highest observed response rate.

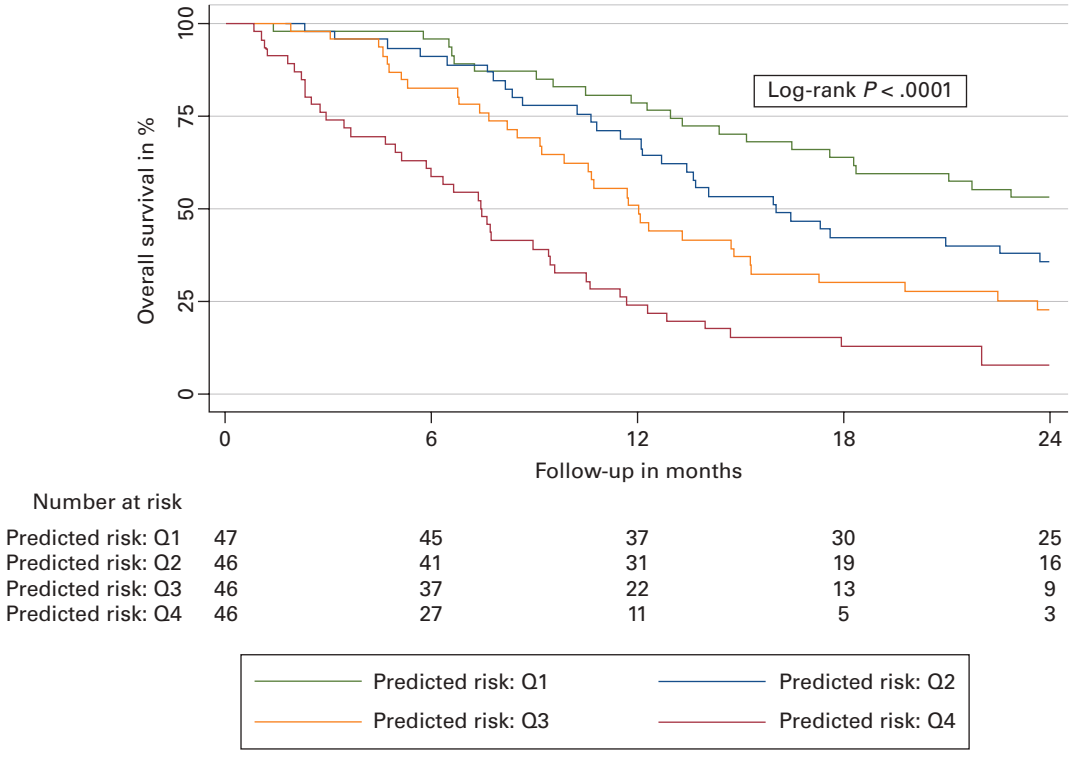
BIOMARKER-BASED PHASE 2 DESIGNS AND MASTER PROTOCOLS

Recently, there have been several innovative designs in oncology trials that incorporate biomarkers.[26,27] Biomarkers may be prognostic or predictive. A prognostic biomarker affects the risk of the outcome regardless of treatment choice, whereas a predictive biomarker changes the outcome in response to a particular targeted treatment. Prognostic biomarkers are related to the natural history of the disease and can be used to identify high-risk patients, so enriching the patient population for those with the biomarker can make it easier to detect a signal because of the higher event rate. For a biomarker to be prognostic, it must have a statistically significant association with the outcome, regardless of treatment (Fig. 5-5). In contrast, predictive biomarkers are associated with treatment and help to identify a subset of patients who are more likely to respond to a specific treatment. That is, if the biomarker is predictive for a particular therapy, then a biomarker subgroup (positive or negative) is expected to have a stronger efficacy signal, with no or little efficacy in the biomarker-negative group. Predictive biomarkers are often determined

from large randomized trials by testing for the interaction term of the treatment biomarker in logistic regression (for a binary outcome) or in a proportional hazards model (for a time-to-event outcome). To evaluate whether a biomarker is predictive, it is necessary to have four groups of patients: (1) those with the biomarker who receive the treatment of interest, (2) those with the biomarker who do not receive the treatment of interest, (3) those without the biomarker who receive the treatment of interest, and (4) those without the biomarker who do not receive the treatment of interest (Fig. 5-5).

Figure 5-5 Kaplan-Meier Survival Curves According to Biomarker-Based Prognostic Score



Note that patient outcomes are stratified in quartiles according to individual predicted risk of mortality.

Phase 2 trials might use enrichment designs, enrolling patients with specific biomarkers indicative of a response to targeted treatments. These designs require quick, precise biomarker assessment and confidence in their relevance to treatment benefits (Table 5-9). However, issues arise if the biomarker screening is not accurate, potentially affecting response rates or excluding benefiting patients. Another approach, marker-stratified design, involves biomarker screening and randomized treatments within biomarker-defined strata, allowing for assessments of treatment benefits relative to biomarker status. This approach demands larger sample sizes but aids in identifying patients who benefit and determining the correct biomarker threshold. Strategy designs incorporate biomarkers differently, using them post-determination for treatment selection. These designs and their variations are detailed in various reviews and articles and are increasingly being applied in both phase 2 and 3 trials.

Master protocols have been used because of their operational efficiency. Generally speaking, master protocols include multiple parallel drug sub-trials designed and conducted under one protocol. Common master protocols include basket and umbrella designs and multistage multiphase designs. Another important class is the platform trial, which evaluates multiple therapies within a single trial infrastructure, often using a shared control group, and allows treatment arms to be added or dropped over time using prespecified decision rules. Platform trials can improve efficiency and speed identification of promising treatments, but they introduce additional statistical and operational complexities that must be carefully prespecified, and shared controls may be susceptible to temporal bias if trial conduct or patient mix changes over time. A high-profile example is the I-SPY 2 trial in breast cancer. Basket trials are designed to enroll patients with similar tumor molecular characteristics across multiple tumor locations, and the patients are treated with the same biomarker-targeted treatment (Fig. 5-6). In such trials, it is likely that there is an arm for each cancer type, and the trial is essentially conducting parallel single-arm studies. Umbrella trials enroll patients with a single tumor origin or histology and test many different treatments. Patients are matched to a treatment on the basis of the biomarker their tumor contains. The advantage of an umbrella trial is that it can test many different biomarker-treatment

Table 5-9 **Factors Affecting Success of Biomarker-Driven Trials**	
Factors	**Key Points and Impact on Trial Success**
Analytically validated biomarker assay	Positive if validated, negative if not. Analytical validation is a prerequisite for credible classification and reproducible results.
Known actionable target	Positive if known, negative if unknown. Actionability supports a clear biological rationale for enrichment or matching.
Large magnitude of difference in clinical outcome	Positive if large, negative if small. Bigger effects are easier to detect and less sensitive to misclassification or heterogeneity.
Moderate to high prevalence	Positive if moderate to high, negative if lower than expected. Low prevalence drives screen failures, slow enrollment, and early closure risk.
High accrual rate	Positive if high, negative if low. Accrual refers to fast enrollment of eligible patients, not screening volume per se, although low prevalence can force high screening to achieve adequate accrual.
Baseline and longitudinal biomarker collection	Positive if baseline plus longitudinal, negative if baseline only. Longitudinal sampling better captures evolving disease biology and resistance.
Prognostic or genomic model as stratification factor: homogeneity within strata	Positive. Improves interpretability and precision by reducing within stratum heterogeneity.
Prognostic or genomic model as stratification factor: heterogeneity across strata	Positive. Creates clinically distinct strata, supports effect modification evaluation, and improves design efficiency.
Validated cutoff point of biomarker	Positive if well validated, negative if not. Unstable cutoffs increase misclassification and reduce reproducibility.
Near real-time readout from assay	Positive if near real time, negative if delayed. Turnaround time affects feasibility, timely assignment, and accrual.
Strong stakeholder buy-in	Positive if strong, negative if weak. Buy-in is critical in biomarker trials, especially master protocols requiring multi-party coordination.

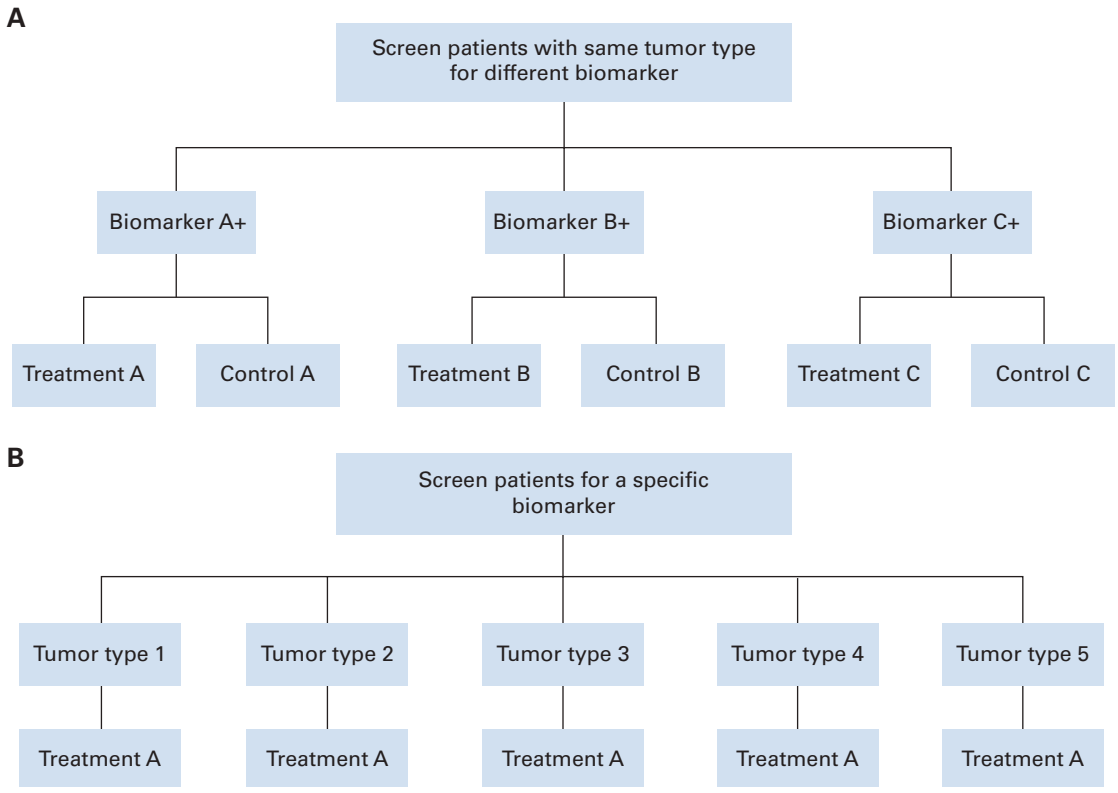
combinations within a single protocol rather than having to have a separate protocol for each different marker-treatment combination. An example of an umbrella trial is Lung-MAP.[28] In contrast, a basket trial tests a single treatment and single biomarker across different tumor origins or histologies. Similarly, an advantage of a basket trial is that it more efficiently tests the biomarker-treatment combination across different tumor types compared with having a separate protocol for each. Examples of basket trials include NCI-MATCH,[29] which evaluates targeted therapies across multiple tumor types based on specific genetic alterations, such as *BRAF* V600–mutated tumors,[30] and the ASCO TAPUR trial.[31]

BIAS IN PHASE 2 TRIALS

Among all the phases of therapeutic development, single-arm phase 2 trials are fraught with the potential for bias. The major source of bias is the absence of contemporaneous randomized comparison groups. Historical outcomes vary widely for many reasons, and past experience may reflect many factors besides the agents being tested. These can include the eligibility criteria defining the patient population; the definition, timing, and methods used to assess outcome; standards of supportive care that vary by institution and over time; the use of surrogate endpoints; and, of course, simple random variation. This is more pronounced for endpoints other than tumor response rates because tumor response rates are less affected by difference in prognostic factors than endpoints such as PFS and OS. Even in the absence of any systematic bias (an ideal unlikely to be achieved), the random outcomes observed in relatively few patients could lead to many false conclusions. One should be cautious in using single-arm designs to evaluate cancer combination therapies,[32] because it can be particularly difficult to attribute positive outcomes solely to the combination therapies under investigation, when an existing single agent is at least somewhat active. The aforementioned factors, including small sample sizes and patient selection biases, could further skew results in these settings and thus frequently yield inconclusive or misleading results in evaluating combination therapies.

Figure 5-6 Umbrella and Basket Trial Designs



(A) Illustration of an umbrella trial design in which patients with the same tumor type are tested for different biomarkers and then are assigned to a treatment group that targets the biomarker. In this example, patients are randomly assigned to a treatment versus control arm. An alternative design could be a single-arm design with the patients with a particular biomarker receiving treatment meant to target that biomarker. (B) Illustration of a basket trial design in which all patients are tested for a particular biomarker and then are entered into a cohort for their tumor type. All patients receive the same targeted treatment that is believed to potentially benefit patients with tumors with the biomarker. This shows each cohort is a single-arm trial, but the cohort could be randomly assigned to treatment and control arms.

The most observable of these are false-positive results, that is, agents that look promising in phase 2 trials but then fail to be effective in phase 3 trials. Less observable, but just as unfortunate, are agents that, in truth, are effective but fail to show positive results in phase 2 trials. Randomized control arms are sometimes used in phase 2 trial settings to remove potential sources of bias resulting from historical control comparisons[26]; however, they introduce additional variability in the treatment effect estimate. As a result, they typically require larger sample sizes and may use a higher type I error rate to maintain sufficient power to identify promising agents in the phase 2 setting. They may also appeal less to potential participants because patients are less likely to receive an experimental therapy with a randomized design.[33,34]

Randomized phase 2 trials are increasingly recommended to reduce bias by incorporating a control group, particularly for combination therapies, heterogeneous populations, and time-to-event endpoints (Presenting Case Study 2). However, single-arm designs remain acceptable in specific contexts, such as rare cancers, novel agents, or when robust historical data are available. As reported by Grayling et al,[33] despite the push for randomization, only 28% of randomized comparative phase 2 trials have reported positive outcomes, compared with 72.7% of single-arm trials, underscoring the potential for overestimation of efficacy in single-arm studies.

Nevertheless, even randomized phase 2 oncology trials often overestimate treatment effects relative to subsequent phase 3 trials. Liang et al[34] found that treatment effects for PFS and OS in randomized phase 2 trials were, on average, 26% to 27% larger than those observed in phase 3 trials. This overestimation is influenced by factors such as optimism bias, publication bias, and differences in trial designs and patient populations. Moreover, the staged development paradigm, where promising phase 2 results drive progression to phase 3 trials, inherently selects treatments with inflated early effect sizes. Addressing these challenges requires cautious interpretation of phase 2 results, the application of statistical adjustments, and rigorously designed phase 3 trials to ensure robust validation of findings.

PRESENTING CASE STUDY 2

A clinical investigator is designing a phase 2 trial to evaluate the activity of a novel immunotherapy agent as monotherapy for patients with advanced stage cancer. Phase 1 trials have established the RP2D, and preliminary safety data are reassuring.

Historical data indicate that the current standard-of-care treatment has a response rate of 20%, providing a benchmark for comparison. The investigator is considering a single-arm trial to efficiently determine whether the new therapy demonstrates a meaningful improvement over this threshold while minimizing the number of patients exposed to an unproven treatment. A practical choice for the primary endpoint is objective response rate (ORR) assessed at a prespecified time point using Response Evaluation Criteria in Solid Tumors (RECIST) 1.1 or, for immunotherapy, iRECIST, because response can often be evaluated within months. Alternatively, if response is uncommon or not the most clinically relevant signal, the endpoint could be a short-term time-to-event measure such as 3-month progression-free survival (PFS) rate, which can be framed similarly to a binary endpoint for design purposes.

To enhance trial efficiency, the investigator plans to incorporate a futility stopping rule, allowing early termination if interim results suggest the immunotherapy agent is unlikely to be superior to the standard of care. However, concerns remain about whether a single-arm design will provide sufficiently robust evidence to justify further development or if a randomized controlled trial (RCT) would be more appropriate.

What factors would inform your selection of optimal trial design for evaluating a new therapy?

Selecting between a single-arm trial and an RCT involves balancing feasibility (smaller sample size in single-arm trials) with the strength of evidence generated (stronger evidence in randomized trials). Given the goal of assessing whether the new immunotherapy agent outperforms the 20% historical response rate, a single-arm design may initially seem appealing. However, this choice comes with limitations that must be carefully evaluated.

Hypothetical example: single-arm phase 2 design

Suppose the primary endpoint is ORR. Let $p_0 = 0.20$ represent the historical benchmark, and let $p_1 = 0.35$ represent the minimum ORR that would be considered promising. A common approach is a two-stage design with early stopping for futility, which specifies a one-sided type I error (often around 0.10) and high power (often around 0.90) to detect p_1. For example, the trial could enroll an initial stage of patients and stop early if too few responses are observed and otherwise continue to the full sample size. This provides a concrete go or no-go rule while limiting exposure if the regimen is inactive.

Advantages of a single-arm trial

- Efficiency and feasibility: A single-arm trial requires fewer patients, making it faster and more resource efficient, particularly for rare diseases or early-phase trials.
- Early signal of activity: If response rates significantly exceed 20%, this can justify further development in a larger study.
- Use of a futility rule: An early stopping rule allows the trial to terminate if activity seems insufficient, reducing unnecessary patient exposure.

Limitations of a single-arm trial

- Lack of a concurrent control group: Relying on historical data assumes that the 20% benchmark is comparable to the current patient population. Differences in patient selection, treatment patterns, time trends, or response assessment can introduce bias and reduce comparability.
- Potential for overestimation: Response rates in single-arm trials may seem inflated because of selection bias or unmeasured confounders.
- Regulatory and clinical credibility: Regulatory agencies often prefer RCTs for definitive evidence because single-arm studies may not provide sufficient comparative effectiveness data.

Advantages of an RCT

- Stronger evidence of efficacy: Randomization minimizes bias by ensuring balanced patient characteristics between treatment arms.
- Comparability with standard of care: Directly comparing the new therapy with existing treatment provides more reliable evidence for decision-making.
- More generalizable results: An RCT reduces confounding factors and allows for robust assessment of clinical benefit.

Limitations of an RCT

- Larger sample size and higher cost: More patients and resources are required to adequately power the study.
- Potential ethical concerns: If the new therapy is expected to be superior, randomly assigning patients to the standard of care may raise ethical questions.

Hypothetical example: randomized phase 2 design

If historical response estimates are uncertain or the population is evolving, a randomized phase 2 screening design can compare the novel immunotherapy against a concurrent control while keeping the sample size modest by using a higher type I error and type II error than in phase 3. For example, the trial might randomize patients 1:1 to immunotherapy versus standard of care, using ORR or a short-term PFS milestone as the primary endpoint, and prespecify a one-sided type I error as high as 0.20 with power around 0.90 to identify a promising regimen for phase 3 confirmation. A positive finding would be considered a screening signal rather than definitive proof, similar in spirit to an interim look that requires confirmation in a later-phase trial.

Considering these advantages and limitations, how should you proceed?

For this trial, a single-arm design may be appropriate for generating an early efficacy signal, but it must be carefully justified given the reliance on historical controls. Historical control estimates based on studies from similar institutions, a recent timeframe, a larger sample size, and multiple studies reporting similar estimates would enhance the credibility of a single-arm trial. Incorporating a futility rule can improve efficiency by stopping the trial early if the agent fails to show promise. However, if the goal is to provide definitive evidence of superiority, an RCT would be preferable, ensuring a robust comparison against the standard of care. The choice ultimately depends on feasibility, regulatory expectations, and the strength of evidence required to support further development.

In this scenario, a single-arm phase 2 trial with a prespecified futility rule is an appropriate initial approach to efficiently screen for activity, assuming the historical response benchmark is well defined and relevant. If the observed signal is encouraging but uncertainty about historical comparability remains, a randomized phase 2 design should follow to generate more robust comparative evidence for further development.

KEY POINTS

- The typical sample sizes used in phase 2 trials provide imprecise estimates of outcome.
- Basket and umbrella trials efficiently evaluate several treatment-marker or treatment-histology combinations.
- Results among phase 2 trials, especially single-arm trials, are difficult to compare because so many factors can vary from trial to trial.

PHASE 3 TRIALS

Phase 3 clinical trials are typically randomized clinical trials, which are the gold standard of clinical research. In general, these studies are designed to change the practice of medicine and, as such, are designed to demonstrate and confirm the safety and efficacy of a treatment strategy for approval by regulatory authorities. The classic goal of a phase 3 trial is to compare an experimental treatment with a standard treatment.

STUDY OBJECTIVES AND PATIENT POPULATION

The primary objective of a phase 3 trial is to establish the efficacy of a treatment regimen in a specific patient population compared with an accepted standard-of-care treatment. The patient population is usually narrowly defined as patients with a particular stage of cancer and in a particular clinical scenario (eg, patients with metastatic colon cancer who have received no prior therapy). The alternative hypothesis for a typical phase 3 trial is that the new therapy will be more efficacious than the currently used standard therapy, known also as a superiority trial. Following this, the null hypothesis would be that the new therapy has the same efficacy as the standard therapy. The phase 3 clinical trial is then designed to reject the null hypothesis.

STUDY OUTCOME MEASURES

In phase 3 trials, the interest is to demonstrate prolongation in survival or reduced pain and improved quality of life for patients. Therefore, the outcome considered for a phase 3 trial must be as definitive as possible, with no or minimal variability or room for interpretation. In phase 3 trials, OS is defined as the time interval between random assignment and death or last follow-up. Note that OS events include deaths resulting from any cause and not just those resulting from the cancer of interest. Pivotal phase 3 trials can be designed around other outcomes if these have been validated as meaningful outcomes or as surrogates for meaningful outcomes. The design of clinical trials to validate correlative studies, biomarkers, or surrogate markers can be complex and is discussed later in this chapter. A list of surrogate endpoints that were the basis of drug approval or licensure is maintained by the FDA and can be used when considering potential surrogate endpoints in different settings.[35]

STUDY ENDPOINTS

Phase 3 clinical trials intend to establish whether the treatment being investigated provides a direct clinical benefit to patients above the standard of care. The patient population for a phase 3 trial is composed of people for whom the treatment is intended to be used. Typically, phase 3 trials have fewer restrictions on patient eligibility than phase 1 and 2 trials. The current trend is to reduce unnecessary eligibility requirements so that the trial results will be more generalizable to the target clinical population.[36] In the oncology setting, an improvement in survival is often the gold standard for demonstrating such a benefit. However, other endpoints are also used to demonstrate clinical benefit while yielding efficiencies in trial design. Other endpoints commonly used in phase 3 trials include, but are not limited to, the following:

- PFS: the time from random assignment to date of disease progression or death resulting from any cause, whichever occurs first. PFS is generally used in advanced-disease settings.
- DFS: the time from random assignment to date of disease relapse/recurrence or death resulting from any cause, whichever occurs first. DFS is generally used in adjuvant settings.
- Event-free survival: the time from random assignment to date of the event of interest, which may include other outcomes in addition to death and disease progression, whichever occurs first.

The advantage of using an outcome other than OS is that it can be observed before death and so can speed up trial completion. However, the interpretation of clinical benefit using other outcomes is more difficult. Superiority in terms of time to progression, PFS, or DFS can occur despite a therapy causing more deaths resulting from toxicity, and superiority of PFS or DFS can occur as a result of a more favorable safety profile, without any therapeutic effect on the cancer. Often, PFS or DFS may not be an established surrogate endpoint for OS, meaning that it is not known whether an improvement in these endpoints actually correlates with an improvement in OS. This makes it unclear whether an improvement in PFS or DFS really represents a direct clinical benefit to patients, especially in the presence of treatment toxicities. Endpoints may be subject to assessment bias, so additional trial design considerations are important, including patient and physician blinding, independent endpoint review committees, and regular disease evaluations.

Patient-reported outcomes use questionnaires to measure how a patient feels and functions; therefore, patient-reported outcomes can also be important for assessing the direct clinical benefit of a treatment being evaluated in a clinical trial. These instruments must undergo rigorous development and testing to ensure that they are measuring what is expected and that they are reliable. Several distinct aspects of patient-reported outcomes are important for understanding the benefits and toxicities of treatment, including the burden of disease symptoms, physical functioning and the ability to perform activities of daily life, and symptomatic adverse events. Blinding in the trial design is important for these outcomes to avoid assessment bias, and completeness of data collection is crucial to minimize the effect of missing patient-reported outcome data and the biases that this may introduce.

STUDY DESIGN PRINCIPLES

The primary goal of a phase 3 trial is to provide a comparison of treatments that is free of many biases that occur when trying to compare phase 2 trials conducted at different times, at different institutions, among different patient populations, and so on. Randomization is the gold standard for the best design in clinical trials because it minimizes bias. It balances

baseline known and unknown prognostic factors in patients between the treatment groups although some imbalances may occur by chance alone.

The most common randomization strategy is equal allocation among treatment arms, or one-to-one randomization. From the standpoint of statistical power, this is the most efficient allocation that results in the smallest sample size, as well as the most compatible one with the notion of clinical equipoise. A common variation of simple randomization is stratified randomization, which seeks to ensure even greater balance between arms by randomly assigning patients within strata defined by factors that strongly predict outcome. In addition, the randomization may be in blocks, which generally refers to a form of stratification designed to keep the number of patients allocated to each arm balanced over time. Stratification and blocking are most useful in small trials, in which random imbalances large enough to skew the composition of the treatment arms are possible. When the trials become larger (several hundred patients), these devices are largely superfluous because it becomes highly unlikely that the arms will become meaningfully imbalanced by chance. Another alternative randomization procedure is dynamic allocation. This type of randomization is considered adaptive because assignment of a patient to a treatment arm is influenced by the current balance of allocated treatments.

Departures from equal allocation sometimes occur, for example, a two-to-one allocation between the experimental and control arms. Most commonly, this is justified with the argument that it makes the trial more attractive to potential patients and their physicians, particularly when there is no way to get access to an experimental agent except through participation in the trial. It also allows one to generate more experience with the new agent. However, this argument seems to presume that the experimental therapy is likely to be more effective than the standard therapy, which contradicts the principle of equipoise. Furthermore, as mentioned, a two-to-one allocation will require a larger sample size than one-to-one randomization, with all other trial parameters being the same.

Other common, but by no means necessary, components of a phase 3 design include the use of a placebo and the implementation of blinded (to the patient) or double-blinded (to both the patient and physician) treatment assignments. Although random assignment can help ensure that treatment arms are balanced with respect to patient characteristics at the start of the trial, it cannot remove bias that occurs after the start of the trial, when differences arise between arms with respect to the conduct of the trial or the evaluation of trial data. This bias can be entirely unintentional and unconscious, but it reflects behavior by either patients or physicians that compromises the benefits of randomization. The susceptibility of trials to bias can vary considerably depending on the endpoint in question. For example, placebo effects and ascertainment bias are probably unlikely to affect a trial in which mortality is the primary endpoint. In contrast, assessment of tumor response without blinding to treatment assignment could be subject to subtle bias, and studies with self-reported quality-of-life endpoints are obviously prone to placebo effects.

The use of a placebo as the control arm in therapeutic oncology trials is extremely rare because usually some form of therapy is available, even if it has limited efficacy. A placebo control is much more likely to be used in adjuvant trials or in trials of combination therapy in which a new agent is being added to an existing combination. Although one may question the extent to which placebo effects play a role in such settings, if a placebo is feasible, it adds credibility to a trial, even if the likelihood of placebo effects is small. Placebos are more commonly used for double-blind evaluation of oral therapies, where placebos can be made identical in appearance to the medication. In some cases, of course, the nature of the treatments differs largely that neither a placebo nor blinding is feasible. Blinding may also be a deterrent to patients' willingness to participate, and all of these factors must be carefully evaluated when designing the clinical trial.

INTENTION TO TREAT

The most acceptable primary analysis of a phase 3 trial is using the intention-to-treat principle. This approach includes all patients enrolled in an arm of a randomized trial, no matter what happens thereafter; for example, if patients are unable to receive the full course of treatment, they cross over to another treatment, and so on. Because any of these contingencies can be related to the treatment itself and to the effectiveness of the treatment, an unbiased analysis must incorporate that information. For example, if a new drug is potentially effective, but many patients will not take it because of its adverse effects, then as a practical matter it may not be as effective as a drug with fewer adverse effects.

Nevertheless, alternative secondary analyses may be undertaken that deviate from the intention-to-treat principle. To emphasize, these are secondary analyses performed after the completion of the primary intention-to-treat analysis. Secondary analyses may involve an evaluation of a subset of patients (eg, those who received a minimum amount of therapy) or definition of the treatment groups according to the treatment actually received instead of the treatment to which patients were randomly assigned. These secondary analyses can be informative but must be interpreted cautiously and are problematic when the results differ markedly from those of the primary intention-to-treat analysis.

Other subset analyses may be undertaken to evaluate whether treatment differences, if any, vary according to other factors, such as disease stage, age, or presence of a biomarker. Even if specified in advance, the results of such subset analyses must be interpreted cautiously. Phase 3 studies are almost never large enough to have reliable power in subsets of patients; conversely, examining many subsets of patients in a trial with an overall negative result can lead to spurious findings that are caused merely

by random fluctuation. Instead, forest plots can be an effective approach to show the consistency (or any inconsistency) of the treatment effects (eg, HR) over diverse factors rather than showing statistical significance in a specific subgroup.

INTERIM ANALYSIS

Randomized phase 3 trials can be large, expensive, and take several years to complete. For this reason, most phase 3 trials have a provision for interim analysis at one or more points, with the possibility of terminating the trial early. The indications for early termination can be varied and are generally specified in advance. These may include strong evidence that the experimental therapy is better than the control therapy, strong evidence that it is worse, or a determination that the trial will not be conclusive (futility). Interim analyses are also ethically important because early information may be sufficient to alter trial conduct or even clinical practice.

A number of statistical approaches to interim analysis, known as group sequential design, codify the timing and nature of the analyses and the threshold required to terminate the trial early. If the trial is to be stopped early because of evidence that the experimental therapy is superior, the overall false-positive rate (type I error rate) for the trial needs to be quantified and controlled because multiple sequential analyses of the data without adjustment can lead to an increase in type I error rates. Because small sample sizes are subject to much random variation, the threshold for stopping a trial early generally involves a high degree of statistical significance, meaning type I error rates that are much lower than a standard .05 level of significance (eg, as low as .001 or .0001). In addition, if a proportion of the type I error rate is "spent" during interim analyses, then the significance level for the final analysis will be lower than the stated trial value of α. For example, a decision may be that the overall trial should have a type I error rate of 5% with one planned interim analysis in which the threshold for stopping the trial will be $P < .01$. Because .01 was spent on the interim analysis, the level of evidence required at the end of the study is $P < .04$. This ensures that the overall trial will have the desired level of significance of .05 (.01 for the interim analysis and .04 for the final analysis). The threshold significance levels at the interim analyses and final analysis constitute the stopping boundaries. Among the various α spending approaches used in group sequential designs, the Lan-DeMets α spending function with O'Brien-Fleming boundaries is the most commonly applied in randomized phase 3 trials.[37,38] This method allows for flexible interim analysis timing while maintaining statistical rigor, setting more conservative early stopping boundaries and preserving most of the type I error rate for the final analysis.

Interim analyses may also indicate that the observed difference between treatment arms is smaller than initially hypothesized or that there is little evidence of a meaningful difference. On the basis of accumulated data and assumptions about the true treatment effect, it is possible to estimate the probability of ultimately demonstrating superiority. If this probability is too low, the trial may be terminated early to avoid unnecessary time and expense, a decision referred to as stopping for futility. However, it is important to distinguish an inability to demonstrate a difference from proving equivalence. A trial stopped early for futility may yield inconclusive results. In some cases, completing the trial, even when a treatment benefit seems unlikely, may be justified if doing so strengthens the evidence supporting the absence of benefit.

The interim analysis plan for a phase 3 trial should be prespecified and is considered an integral part of the trial design. However, the decision to stop a trial early involves complex and important issues that cannot be summarized in a simple statistical test. Typically, the results of an interim analysis will be reviewed by a data and safety monitoring board. The role of this board is to independently review the results of an interim analysis, consider the results in context with a host of other factors (eg, scientific, ethical, legal, financial), and make a recommendation about whether to continue the trial. Additional factors leading to trial termination include poor accrual or the clinical question becoming irrelevant during the course of the trial because of new scientific findings.

Please refer to the "Presenting Case Studies" sections for examples of interim analyses from completed randomized phase 3 trials that were stopped early for efficacy (PACIFIC) or futility (KEYNOTE-598).

MULTIPLICITY

Multiplicity in clinical trials refers to the challenge of managing multiple statistical analyses within a single study. This situation often arises when researchers test several hypotheses or conduct multiple comparisons between treatment groups. The primary concern with multiplicity is the increased risk of type I errors (false positives) where a treatment seems to be effective, but this has merely occurred by chance. This risk increases with each additional hypothesis tested, potentially leading to erroneous conclusions about a drug's efficacy or safety. In clinical research, especially in phase 3 trials, such errors can have significant implications. A false positive might suggest that a treatment is beneficial when it is not, potentially leading to the adoption of ineffective or even harmful medical interventions. Conversely, excessive caution in avoiding false positives can result in false negatives, overlooking genuinely effective treatments. To address these challenges, various statistical methods have been developed and used in different contexts. Each of these methods requires careful consideration and planning to ensure the integrity and validity of a trial's conclusions, while maintaining statistical rigor.

In trials with multiple primary endpoints, α splitting is a common method. It involves dividing the overall type I error probability (α) among the various endpoints to maintain the overall error rate within acceptable limits. For instance, in a trial with

two coprimary endpoints, the α level of 0.05 might be split into two 0.025 segments for each endpoint. This ensures that the probability of making at least one type I error across all endpoints remains controlled. This approach, however, can lead to a loss of power, so it is essential to balance the need for error control with the potential reduction in statistical power.

Group sequential designs are particularly relevant here. These designs incorporate several planned interim analyses at certain points in the trial. At each interim analysis, data are evaluated to determine whether the trial should be stopped early for reasons of efficacy or futility or sometimes safety. The use of group sequential methods allows for early stopping while controlling the overall type I error rate through statistical methods such as the O'Brien-Fleming or Pocock boundaries. These methods adjust the criteria for significance at each interim analysis, typically making it more stringent to stop early for efficacy.

Subgroup analyses in phase 3 trials are crucial for understanding treatment effects in different patient segments. However, they raise concerns about multiple testing and the potential for spurious findings. To address this, statistical adjustments are often made. One common approach is the hierarchical or stepwise testing method,[39,40] where primary endpoints are tested first, followed by key secondary endpoints and then subgroup analyses. This method controls the type I error rate across the hierarchy of tests. Additionally, using prespecified hypotheses and limiting the number of subgroups analyzed can help to reduce the risk of false positives.

Additional discussions of multiplicity in the context of translational research can be found in the "Translational Medicine Studies" section. Please refer to the Case Studies section for an example of multiplicity control from the PACIFIC trial, a randomized phase 3 trial in locally advanced non–small cell lung cancer (NSCLC).

DESIGN OPTIONS

Equivalence and noninferiority designs do not attempt to establish that a new treatment is superior to a standard treatment but instead aim to establish that the new treatment has equivalent efficacy or is noninferior compared with a standard treatment or that its efficacy is only slightly worse than that of a standard treatment. Although most phase 3 trials are undertaken with an underlying goal of demonstrating a difference between treatment arms, there are circumstances in which the goal is merely to demonstrate that one therapy is equivalent, or at least not inferior, to another. The main motivation to designing noninferiority trials is that the new treatment or device might be less toxic, less inconvenient, less expensive, or less invasive, but less effective, than the standard treatment.

It is impossible to design a trial to demonstrate that two therapies are equivalent, and, in reality, it is highly unlikely. Instead, one specifies the smallest difference that would be of practical clinical significance, for example, a 5% difference in 10-year survival, and then designs a trial that has high power to reject the null hypothesis (low type II error rate) if such a difference truly exists. A successful trial from the standpoint of equivalence would then reject the null hypothesis if a true difference exists. Note that the concept of a false-positive or false-negative conclusion is, in a way, reversed from the usual design perspective, and the typical rates of type I and type II errors used in such designs might need to be reconsidered. Equivalence studies are notoriously large because the difference in outcome said to define equivalence is typically smaller than the difference hypothesized for a superiority trial, which dramatically affects the sample size. A trial with an equivalency threshold set at a 5% difference requires a sample size four times as large as that for a superiority trial powered to detect a 10% difference.

An alternative to an equivalency design that requires a somewhat smaller sample size is the noninferiority design (Table 5-10).[41] In this case, one specifies a noninferiority margin, which provides the maximum acceptable loss in efficacy for the new treatment compared to the control. The trial is designed by formulating a null hypothesis that the new therapy has that level of inferiority, or worse, and then is powered to reject the null hypothesis for a specified alternative assumption (which might be equivalence, a lesser degree of inferiority, or even superiority). This usually results in a smaller sample size than that needed for an equivalence design, partly because it involves a one-sided hypothesis test but often by claiming a wider limit of acceptability for noninferiority than for equivalence.[41] For example, if the study is designed with an noninferiority margin of .20 and assuming p_0 (proportion of response in the standard arm) = .50 (also for p_1 proportion in experimental arm = same as the standard arm), equal allocation between the two arms, one-sided $\alpha = 0.05$, and power of .90, then a total of 214 participants (107 per arm) is required.

Table 5-10 Required Sample Size (per Arm) for Noninferiority Trials With Binomial Endpoint

Allowable Difference or Noninferiority Margin ($p_0 - p_1$)	Sample Size per Arm
0.20	107
0.15	191
0.10	428
0.05	1713

Note: $p_0 = 0.50$, $\alpha = 0.05$, and power = 0.90. Computation was completed using binomial noninferiority tool (https://stattools.crab.org/R/Binomial_Non_Inferiority.html).

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

After having demonstrated noninferiority or equivalence, one might then proceed to show that one treatment is less toxic or preferred by patients because of improved quality of life to justify selecting one treatment over another.[42-45]

Please refer to the "Practical Interpretations for Clinical Trials" section for an example of a noninferiority design from the completed randomized phase 3 trial (RTOG-0415).

PRACTICAL INTERPRETATIONS FOR CLINICAL TRIALS

Here we describe three recent randomized phase 3 clinical trials to illustrate the use and implications of interim analyses, with the PACIFIC trial (ClinicalTrials.gov identifier NCT02125461) as an example of early stopping for superiority and KEYNOTE-598 (ClinicalTrials.gov identifier NCT03302234) as an example of early stopping for futility. Because both trials had coprimary endpoints of PFS and OS, as well as planned interim analyses, they also illustrate the use of multiple comparison adjustment approaches, such as α splitting and α recycling, to control the overall type I error rate. The RTOG-0415 trial (ClinicalTrials.gov identifier NCT00331773) comparing hypofractionated radiotherapy (H-RT) with conventional radiotherapy (C-RT) in men with low-risk prostate cancer is an example of a trial with a noninferiority design.

PACIFIC Trial: Early Stopping for Superiority

The PACIFIC trial was a landmark study that redefined the standard of care for patients with stage III unresectable NSCLC. This phase 3 randomized, double-blind trial evaluated whether durvalumab, administered as consolidation therapy after platinum-based chemoradiotherapy, could improve clinical outcomes. Patients were randomly assigned in a 2:1 ratio to receive durvalumab or placebo for up to 12 months. The trial's coprimary objectives were to determine whether durvalumab could delay disease progression, as measured by PFS, and extend OS. With coprimary endpoints of PFS and OS, the statistical framework split the overall $\alpha = 5\%$ type I error equally between these endpoints to ensure strict control of the false-positive findings rate. Additional statistical techniques, such as a hierarchical hypothesis testing framework and α exhaustive recycling strategy, were also used and enabled reallocation of α from a rejected hypothesis to subsequent endpoints lower in the hierarchy of endpoints and prespecified hypothesis tests.

To evaluate the coprimary endpoints at different stages of data maturity, the study was designed with interim analyses at four data cutoff points. The first interim PFS analysis occurred after approximately 30 months, when 367 PFS events had been observed, and only PFS was analyzed to maintain the integrity of subsequent OS analyses. The first interim analysis for OS was performed at the same time as the primary (final) PFS analysis at approximately 36 months, with subsequent interim and final OS analyses scheduled as OS events accumulated. This staged approach ensured that clinically meaningful results could be shared in a timely manner without jeopardizing the statistical validity of long-term findings and other endpoints.

The interim analysis,[46] based on the first data cutoff point (February 13, 2017) when the accrual target was met (N = 713) and 371 PFS events were observed, demonstrated that durvalumab significantly improved PFS compared with placebo (median, 16.8 vs 5.6 months; HR, 0.52; $P < .001$), with a manageable safety profile. This early result was critical in establishing durvalumab as the new standard of care, allowing it to reach patients sooner. Without this planned interim analysis, the trial's findings might have been delayed, potentially postponing access to a life-extending therapy for patients with limited treatment options.

Long-term results, published in *Journal of Clinical Oncology* in 2022, reinforced the interim findings, demonstrating consistent and durable benefits. Durvalumab significantly improved OS (HR, 0.72; 95% CI, 0.59-0.89), and the 5-year survival rates were substantially higher for durvalumab compared with placebo. The alignment between PFS and OS findings highlighted the utility of PFS as a surrogate endpoint for OS, particularly in a setting where durable disease control translated into meaningful survival gains. These results underscored the robustness of the trial design and the reliability of the interim findings as predictors of long-term outcomes.

The PACIFIC trial exemplifies the power of a well-designed clinical trial to drive meaningful advancements in patient care. By combining innovative statistical methodologies with a rigorous testing framework, the trial not only delivered reliable and impactful results but also accelerated the adoption of an effective therapy. The consistency between the interim and long-term results further validates the trial's approach and highlights the importance of integrating early- and late-phase analyses in oncology research.

We note that although the PFS coprimary endpoint was met at the first interim analysis, the study had already completed full enrollment at that time. The positive interim analysis results were announced without having to wait for the final analysis time point, which is often referred to as early stopping of a trial. Early stopping does not necessarily preclude longer term follow-up for additional endpoints, such as the coprimary OS endpoint, or other important secondary endpoints. In trials where interim analyses occur before completion of enrollment, early stopping at an interim analysis has the additional advantage of reducing the trial sample size.

KEYNOTE-598 Trial: Early Stopping for Futility

KEYNOTE-598 is an example of a trial that was stopped early for futility. It was a randomized, double-blind, phase 3 trial in which patients with previously untreated metastatic NSCLC with a programmed cell death ligand 1 (PD-L1) tumor proportion

score of 50% or greater and no sensitizing *EGFR* or *ALK* aberrations were randomly allocated 1:1 to receive pembrolizumab plus ipilimumab or pembrolizumab plus placebo every 6 weeks for up to 18 doses. The coprimary endpoints were PFS and OS. With a planned sample size of 568 participants, the trial was designed to achieve 87% power to detect an HR of 0.69 for PFS in favor of pembrolizumab plus ipilimumab treatment with one-sided α of 0.006 with one planned interim analysis for superiority and to achieve 90% power to detect an HR of 0.7 with a one-sided type I error α of 0.019 with two planned interim analyses. The family-wise type I error rate was one-sided $\alpha = 0.025 = 0.019 + 0.006$, which is an example of α splitting, where portions of the overall α level are allocated to different endpoints or interim analyses.[42] Additional information and discussion of statistical methods for designing clinical trials with multiple endpoints can be found in the FDA guidance document.[43]

At the time of the first interim analysis, 568 participants were randomly assigned (284 per arm), and 272 deaths were observed in both arms. Both PFS and OS appeared to be similar at the first interim analysis; the median PFS was 8.2 and 8.4 months in the two arms, and the median OS was 21.4 and 21.9 months, respectively. Although the protocol did not specify a futility analysis, futility criteria and a formal analysis were requested by the external data and safety monitoring committee. Results of the futility analysis showed that the addition of ipilimumab to pembrolizumab in this setting was unlikely to demonstrate efficacy, and the trial was stopped early for futility. Lack of difference between arms can be seen in the Kaplan-Meier estimates of OS in the two arms (Fig. 5-7 from the report by Boyer et al[47]).

Pembrolizumab plus ipilimumab or placebo for metastatic non-small-cell lung cancer with PD-L1 tumor proportion score ≥50%: randomized, double-blind phase III KEYNOTE-598 study. *J Clin Oncol*. 2021;39(21):2327-2338. doi:10.1200/JCO.20.03579

RTOG-0415: Noninferiority Trial

RTOG-0415 trial was a phase 3 randomized noninferiority study comparing H-RT with C-RT in men with low-risk prostate cancer. The trial aimed to determine whether H-RT, a shorter and more convenient treatment schedule (70 Gy in 28 fractions), was noninferior to the standard C-RT regimen (73.8 Gy in 41 fractions) in terms of 5-year DFS.[44,45]

The rationale for conducting a noninferiority trial in this context stems from several key factors. C-RT schedules require 40 to 45 treatments over 8 to 9 weeks, posing significant time and cost burdens to patients. Advances in imaging and radiation delivery

have enhanced precision, reducing risk to normal tissues and making hypofractionation, which involves fewer treatments with higher doses per fraction, a viable alternative. Additionally, the radiobiology of prostate cancer, with its low α/β ratio, suggests it is particularly well suited to H-RT. A noninferiority design allowed the trial to formally evaluate whether H-RT could achieve comparable DFS outcomes to C-RT while offering the added benefits of greater convenience, reduced cost, and broader accessibility, positioning H-RT as a potential new standard of care.

The trial was powered to detect noninferiority with 90% power and a one-sided type I error of 5%. The noninferiority margin was set at a 7.65% absolute difference in 5-year DFS rates, corresponding to an HR of 1.52. This margin was chosen based on approximately half the absolute 5-year DFS improvement observed in contemporary dose-escalation superiority trials (15% difference) in similar patients. The sample size of 1067 patients accounted for up to 10% ineligibility or missing data, with definitive analysis planned after observing 238 DFS events.

The trial included three planned interim analyses after 60, 120, and 179 DFS events. These analyses allowed early stopping for noninferiority (if H-RT was deemed comparable to C-RT) or futility (if noninferiority could not be achieved). At the third interim analysis, with 185 DFS events observed (78% of the planned total), the data monitoring committee recommended early disclosure of results. At this stage, the criterion for rejecting the null hypothesis of inferiority ($P \leq .011$) was met, supporting the conclusion that H-RT was noninferior to C-RT.

After a median follow-up of 12.8 years, the trial demonstrated that H-RT was noninferior to C-RT for 5-year DFS. The 12-year DFS rates were 56.1% for C-RT and 61.8% for H-RT (HR, 0.85; 95% CI, 0.71-1.03; $P < .001$ for noninferiority). H-RT also significantly reduced biochemical failure rates compared with C-RT (9.9% vs 17.0%; HR, 0.55; 95% CI, 0.39-0.78; $P < .001$). OS rates were similar between arms, with 12-year OS rates of 69.9% for H-RT and 68.7% for C-RT (HR, 1.01; 95% CI, 0.82-1.24).

The findings of RTOG-0415 established H-RT as a safe and effective alternative to C-RT for low-risk prostate cancer. With comparable outcomes in DFS, OS, and adverse events and the added benefit of a shorter treatment schedule, H-RT offered a more convenient option for patients while maintaining oncological efficacy. These results have important implications for standardizing radiotherapy regimens in this patient population.

KEY POINTS

- Phase 3 clinical trials are typically randomized and are designed to be pivotal; that is, they aim to demonstrate and confirm the safety and efficacy of a treatment strategy to obtain approval by regulatory authorities.
- Phase 3 study outcomes/endpoints should be previously validated as meaningful and selected to minimize variability in interpretation.
- Phase 3 trials require careful consideration of study design parameters, including randomization, blinding, and choice of endpoint, to minimize bias in the assessment of the treatment benefit.

ADAPTIVE DESIGNS

Recently, there has been an increased use of adaptive designs in oncology trials, particularly in phase 1 and 2 trials (Table 5-11). Adaptive trials are those that include a provision for change in key trial design parameters during their conduct by using current accumulated data. The modification in design is intentionally planned and is prespecified at the planning stage of the trial to achieve scientific validity. In adaptive designs, frequent looks at the data will be undertaken during trial execution, and modifications of the design of the trial generally fall into the following areas[48]: randomization ratio (adaptive randomization), adding or dropping of treatment arms, sample size re-estimation, population enrichment, and interim analysis (stopping rules for safety, efficacy, or futility). These rules should be applied to only one of the design elements. Both frequentist and Bayesian approaches (also refer to the "Bayesian Statistics" section) can be used, although adequate statistical resources must be dedicated if adaptive designs are used because extensive simulation will be used to fine tune key trial characteristics during trial conduct.

Table 5-11 **Examples of Adaptive Designs**

Design	Idea
Continual reassessment method	Model-based dose escalation to estimate the MTD
BOIN designs	Model-assisted dose-finding design to estimate MTD
Group sequential	Include options to stop the trial early for safety, futility, or efficacy
Sample size re-estimation	Adjust sample size to ensure the desired power
Multiarm multistage	Explore multiple treatments, doses, durations, or combinations with options to "drop losers" or "select winners" early

Design	Idea
Population enrichment	Narrow down recruitment to patients more likely to benefit (most) from the treatment
Biomarker adaptive	Incorporate information from or adapt based on biomarkers
Adaptive randomization	Shift allocation ratio toward more promising or informative treatment(s)
Adaptive dose ranging	Shift allocation ratio toward more promising or informative dose(s)
Seamless phase 1/2	Combine safety and activity assessment into one trial
Seamless phase 2/3	Combine selection and confirmatory stages into one trial

Abbreviations: BOIN, Bayesian optimal interval; MTD, maximum tolerated dose.

In adaptive trials that use outcome-adaptive randomization, the allocation of patients to treatment assignment depends on provisional or definitive outcomes observed thus far. Trials that use adaptive randomization start by randomly assigning patients in equal proportions to each arm. As outcome data on these patients accumulate, the randomization scheme is altered so that it favors the arms in which the strength of the evidence that the response rate is greater than p_0 or greater than the control arm is greatest. Conversely, it reduces the likelihood that a patient would be randomly assigned to the arm in which the strength of evidence is weakest and, ultimately, may drop arms altogether if the strength of evidence falls too low. Adaptive randomization has been used in biomarker-based designs, such as in the I-SPY2 trial[49] in breast cancer, so that patients with certain biomarker profiles who respond more favorably to certain treatments would be randomly assigned more frequently to those agents. Although adaptive randomization seems like a rational way to select among competing experimental regimens, in practice, it is often difficult to conduct such a trial because of practical challenges, and special statistical methods must be used to provide proper inference with such a design. The different agents likely have different sponsors and advocates, all of whom naturally have a principal interest in their own agents and may be reluctant to cede control of their evaluation to an external process. Others have some ethical discomfort with the notion of unequal allocation based on evidence of efficacy, believing that this violates the principle of clinical equipoise (ie, that one truly is unable to say which treatment is better for the patient population to be enrolled). In addition, it has some disadvantages. The first is that although, theoretically, it minimizes the number of patients randomly assigned to ineffective treatment, the overall sample size for a trial with adaptive randomization is larger than that for a trial with fixed randomization, as is true for upfront unequal randomization allocations (eg, 1:2). Because it is possible that imbalance will be in the wrong direction, with more patients assigned to the inferior treatment arm, a run-in period with 1:1 randomization may be required before a stable estimate in favor of one of the arms is obtained. There are many other issues, and there is a split among statisticians regarding whether the benefits of adaptive randomization outweigh the drawbacks.[50-52]

Adaptations in phase 3 trials may differ depending on whether the changes are made blinded or unblinded to the available data on treatment differences; for example, increasing the sample size because of a lower-than-expected overall event rate has a minimal effect on the final analysis because it does not actually use the treatment differences. In contrast, unblinded adaptation is subject to greater scrutiny and requires careful attention to statistical methodology and operational procedures to ensure that the results are free from bias. Several types of adaptations in late-stage clinical trials have been considered. Seamless phase 2/3 clinical trials combine the phase 2 trial (which may involve dose selection from among multiple doses) and the phase 3 trial (which uses the final selected dose for inference). This can be operationally efficient because it eliminates time between phases 2 and 3, and it can be statistically efficient because the data from the two stages are combined for inference. Sample size re-estimation designs allow for an increase in the sample size based on interim assessments of the treatment effect, particularly when the interim treatment effect is in a promising zone in which the study may be underpowered. An adaptive population enrichment design allows for restricting enrollment to a biomarker-based subgroup at an interim analysis, if it seems that the patients positive for the biomarker may benefit from treatment and the patients negative for the biomarker do not.

BAYESIAN STATISTICS

Most of the familiar statistical concepts and applications encountered in medical research are based on a frequentist view of statistics and probability. From the frequentist perspective, probability is a quantity that reflects the underlying long-term frequency with which an event will occur under repeated observation. This frequency is governed by unknown, but fixed, parameters that define a probability distribution. For example, in a frequentist view, the probability that the flip of a coin will result in heads up is equal to the number of times heads is observed when the coin is flipped a large number of times. If the coin is fair, this probability will be one-half, which will equal the proportion of heads we observe in a large number of flips. The statistical procedures derived from this perspective are all based on relating observed data to the fixed parameters of the probability model that generates the data.

Bayesian statistics also seek to relate observed data to the probability model that generates the data. The term Bayesian derives from a basic theorem known as the Bayes rule, which was formulated by the Reverend Thomas Bayes in the mid-18th century. The Bayesian formulation allows the incorporation of a more subjective notion of probability. The notion of probability is a measure of the strength of one's belief in a single outcome, for example, the probability that it will rain tomorrow. It also allows the application of this view of probability to unknown parameters governing a probability distribution, for example, the probability that the rate of response to a treatment exceeds a specified value. This is not a meaningful concept in a frequentist framework, where the response rate is viewed as a fixed number.

The Bayesian approach to statistical inference involves three basic steps[53]:

1. Specification of a probability distribution for the unknown parameter (called a prior distribution) based on existing knowledge
2. Collection of data
3. Use of the data to update the prior distribution, resulting in a posterior distribution (or updated probability distribution for the unknown parameter)

A simple example involves an imperfect diagnostic test. For a randomly selected individual, it would be reasonable to assume that the probability that this person has a disease is equal to the prevalence of the disease (the prior distribution). After the test is performed, the result will be either positive or negative (the data). This information can be used to recalculate the probability that the person has the disease, which is no longer equal to the disease prevalence (the posterior distribution).

Most clinical trials are designed and analyzed on the basis of a frequentist approach. Basically, there is a null hypothesis and an alternative hypothesis. The null hypothesis would be that there is no difference in outcome between the two treatment arms. A two-sided alternative hypothesis would be that there is a difference in outcome between the two treatment arms. The data are collected, and a *P* value is computed on the basis of the observed data, which are compared with the level of significance to determine whether the null hypothesis will be rejected. Again, the *P* value is the probability of observing the data obtained or data more extreme (more in favor of the alternative hypothesis), assuming that there is no difference in outcome between the treatment arms. If this value is sufficiently small (lower than the level of significance), we conclude that there is evidence against the null hypothesis. This means that we would reject the hypothesis that the two treatment arms have similar outcomes.

The Bayesian approach would be used to determine a probability distribution for the difference in outcome between the two treatment arms; this is called the prior distribution. Often, a noninformative prior is used, which essentially assumes that all possible differences in outcomes between the two arms are equally likely. Once data are obtained, a new distribution, the posterior distribution, is generated that combines the information in the prior distribution and the data. This posterior distribution describes the likelihood of each possible difference in outcome between the two treatment arms. The posterior distribution is then used to decide which treatment arm has better outcomes. For example, using the posterior distribution, the probability that arm A is better than arm B can be computed. If this probability is large, for example, there is a 90% chance that arm A has better outcomes than arm B, the decision is then that arm A is the better treatment.

Frequentist designs evaluate the evidence against the null hypothesis by determining how likely it would have been to obtain the results observed, or more extreme results, assuming that the null hypothesis were true. Small *P* values mean that the result is unlikely if the null hypothesis is true, and so, it is taken as evidence against the assumption that the treatments yield the same outcomes. Bayesian designs allow a calculation of the probability that one treatment is better than the other. However, these designs require investigators to state a prior distribution for the possible differences in outcomes between the two treatment arms.

The potential controversy in applying Bayesian methods to medical research lies in the specification of the prior distribution, which is allowed to incorporate subjective judgments about the quantity under investigation. Many statisticians argue that prior beliefs about an unknown quantity represent a form of bias that should be avoided in scientific research; others argue that ignoring prior knowledge is in itself a bias. It is possible to use a Bayesian framework in a way that minimizes the use of information contained in prior beliefs, thereby letting the data speak for themselves. This is done by choosing a prior distribution that is said to be uninformative with respect to the quantity under study (also sometimes called a flat prior). Interestingly, statistical procedures conducted using uninformative priors are often similar, or even identical, to those conducted within a frequentist framework, and they produce similar results. They simply use different mathematical machinery and terminology. When Bayesian methods have been used in the design or analysis of a research study, one should always be able to ascertain the nature of the prior distribution. If a subjective or informative prior distribution has been used, its rationale and appropriateness should be carefully considered, and it should be recognized that the choice of a prior distribution could influence the interpretation and conclusions of the study.

Bayesian methods have become more popular, particularly for phase 1 and 2 studies that use adaptive designs. They are somewhat less common for phase 3 studies although the FDA does provide guidance documents for Bayesian analyses of phase 3 trials, which require more pre-specification.

TRANSLATIONAL MEDICINE STUDIES

A formal definition of translational medicine is an "interdisciplinary branch of the biomedical field supported by three main pillars: benchside, bedside and community."[54] In oncology, translational studies are often focused on evaluating whether measurable attributes of a patient or a patient's disease at a particular time are associated with subsequent outcomes and eventually the clinical benefit of treatments. These attributes may be measured before the start of treatment, possibly with a view toward predicting the therapy most likely to be effective, or after treatment has been initiated, with the intent of predicting whether the treatment is working. Often the attributes being investigated are not clinically apparent and must be assessed using various testing approaches, including imaging, immunohistochemistry, gene expression, or any of a wide range of other clinical or laboratory investigations.

Translational studies can be conducted throughout the entire span of therapeutic development and can be conducted independently of therapeutic trials (eg, using biomarkers from tissue samples available through a tumor bank) but are also often explicitly incorporated as secondary or exploratory objectives in therapeutic trials. The potential range of research questions that can be posed in such correlative studies is broad, and the statistical methods and designs vary greatly depending on the study research questions, disease setting, and the data being collected and may not involve an actual analysis of correlation as the name may suggest. Below we give several examples of a basic measure of correlation and illustrate some common pitfalls in the evaluation of correlation, including the relationship between correlation and causation and the issue of multiple comparisons.

Correlation

Correlation is often used as a generic term to describe almost any type of association, but in statistics, it has a more precise definition and most commonly refers to the linear association between two continuous measures. Correlation between two variables (x and y) can be visualized using an x-y scatterplot, which is a visual representation of how one variable varies as a function of the other variable.[55] The Pearson correlation coefficient r is a measure of the linear correlation between two variables; a value of +1 means perfect correlation, a value of 0 means no correlation, and a value of −1 means perfect inverse correlation. The associated value r^2 ranges from 0 to 1 and is interpreted as the proportion of the variation in one variable that is explained by variation in another. For r^2, variation is measured by the sum of squared deviations from the mean, but there are many other measures of variation. The degree of correlation is a function of three factors: (1) the magnitude of the association (ie, whether the change in one variable is associated with a large or small change in the other), (2) the consistency of the relationship (ie, whether the changes are consistent or highly variable), and (3) the linearity of the relationship. The first two factors pertain generally to any measure of correlation. The third, linearity, is an important consideration for the Pearson correlation coefficient; one can, for example, envision two variables with a perfect quadratic association (eg, $y = x^2$). In this case, the variables are definitely associated, but the correlation coefficient r will be 0 (Fig. 5-8).

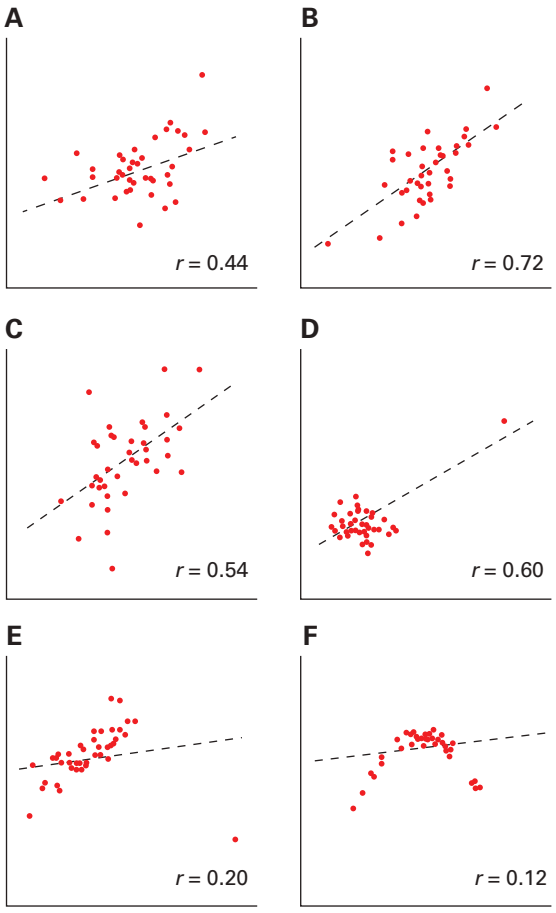
In studies of agreement (eg, when two measurement techniques are applied to the same subject with the goal of determining agreement of measurements), correlation is often an inappropriate measure of agreement; for example, when measuring weight in different units (eg, pounds and kilograms) with extremely accurate scales, measurements would be highly correlated but would not agree, because the measurement units are different. In such situations, the Bland-Altman plot, which examines the difference between two measurements versus the average, can be used.[56]

Correlation and Causation

Correlative studies are common in the development of targeted therapies. These therapies are designed around specific attributes of tumors, which can be quantified by measuring some biological parameter referred to as the biomarker. It may be possible to establish a clear correlation between this biomarker and prognosis. It may also be possible to establish that a targeted therapy has an effect on the biomarker in a direction that would imply a more favorable prognosis. Taking these two correlations together, it might appear that this is a clear indication that the therapy would be effective for that cancer, but this is not necessarily the case. The common saying "correlation is not causation" means that just because two things are correlated does not necessarily mean that one causes the other. Establishing causal relations is complex, and methods from causal inference, which is a branch of statistics that considers assumptions, mechanisms, study designs, and estimation strategies to allow researchers to draw causal conclusions, are often used.[57]

A familiar analogy would be the association of elevated blood pressure and cholesterol levels with various forms of cardiovascular disease. Although there are many drugs that lower blood pressure and cholesterol levels (biomarkers in this scenario), there is no guarantee that these drugs will be effective in lowering the risk of cardiovascular disease (clinically meaningful outcome). For this to be true, the elevation of blood pressure or cholesterol levels must be part of the causal pathway to the cardiovascular event (Fig. 5-9),[58] not just a marker or symptom of the severity of the disease process. The same must hold true for the effect of a targeted therapy on a cancer biomarker to be considered an indicator of efficacy; that is, the biomarker must reflect at least part of the direct causal pathway by which growth or spread of the tumor has an effect on the survival of the patient.

Figure 5-8 Scatterplot Examples of Linear Correlation



The six graphs illustrate possible correlations between two variables, *x* and *y*. The dashed line indicates the least squares line fit to the data, and *r* is the Pearson correlation coefficient. (A) Data have a positive correlation of moderate strength. (B) Compared with the data in panel (A), there is an increased slope in the data and a stronger correlation. (C) Data have the same slope as the data in panel (B), but the correlation is weaker (ie, the points have more variability about the best fitting line). (D) Computed correlation is stronger than that in the bulk of the data because of the influence of one outlier point. If this point were removed, the correlation would be smaller. (E) Correlation with the outlier is weaker than the correlation for the remainder of the data. If the outlier were removed, the correlation would increase. (F) There is a strong nonlinear relationship in the data, but the correlation is weak, because the correlation measures the strength of linear relationship.

Correlative Biomarker Studies

Many correlative studies are designed to evaluate potential biomarkers. Two important types of biomarkers are used in correlative studies: prognostic and predictive biomarkers. A prognostic biomarker is associated with the outcome, regardless of the type of treatment administered. An example of a prognostic marker would be metastatic status for a survival outcome; in general, patients with metastatic disease have shorter survival than patients who have localized disease, regardless of the type of treatment they receive. A predictive biomarker is used to select a specific treatment for a patient. If the patient has the biomarker, a particular

treatment will provide benefit, and if the patient does not have the marker, no or little benefit will result from the treatment. An example of a predictive biomarker is *HER2* status for women with breast cancer. If a woman has *HER2*-positive breast cancer, she obtains benefit (ie, longer survival) if treated with trastuzumab. In contrast, a woman who has *HER2*-negative breast cancer does not experience benefit from trastuzumab treatment. The goal of a biomarker study is to identify either prognostic or, preferably, predictive markers.

There are two common methods to include a biomarker in a clinical trial. Integrated biomarkers are used to evaluate a specific hypothesis in a study (eg, association of the biomarker with patient outcomes), with the goal of either discovering an association of the biomarker with the outcome or validating that a previously observed association exists between the biomarker and the outcome. Integrated biomarkers are integrated into the study design with planned objectives. Integral biomarkers, in contrast, are part of the study design, assessed in real time and used for patient stratification or to make treatment decisions in a clinical trial. One way this might happen is to use the biomarker to screen patients for trial entry. Specifically, if it is thought that only patients with the marker will potentially benefit from the treatment, then patients with the marker will be enrolled and those without the marker will not be enrolled. For example, *HER2* status (positive vs negative) was used in trastuzumab trials to screen patients who were eligible to enroll. Another example of an integral biomarker was the use of Oncotype DX recurrence score to determine treatment cohorts in the TAILORx trial and other biomarkers in the ASCO TAPUR trial. Additionally, planned use of a biomarker in the primary analysis, even if not used for eligibility or randomization, is an example of integral biomarker use. Division of the patient population by the biomarker may show that one group benefits from the treatment, whereas the other group does not. Use of integrated and integral biomarkers in prospective trials can provide information on causality, unlike exploratory translational analyses.

More detailed discussion regarding biomarker-driven phase 2 designs can be found in the "Phase 2 Trials" section.

Multiple Comparisons in Omic Studies

Advances in molecular technology have made it possible to assess hundreds, thousands, or even millions of potential biomarkers within reasonable limits of expense and time. This is particularly true in the field of genomics, in which single chips have the ability to simultaneously quantify the expression of 20,000 genes or to genotype more than 1 million single-nucleotide polymorphisms. Although some sophisticated statistical methodology may underlie the quantification of gene expression or assignment of a genotype, the basic methodology for evaluating a correlation with outcome could be based on a simple t or χ^2 test that is repeated thousands or hundreds of thousands of times.

From the hypothesis-testing point of view, if each of these tests of association has a positive (type I) error rate set at a conventional level, such as 5%, then the number of false-positive correlations found will be enormous. For example, consider a gene expression study of 20,000 genes that are to be correlated with tumor response with the aim of determining one or more markers that signal a high likelihood of treatment failure. Even if the 20,000 genes have been selected to represent a range of plausible causal pathways, only a small fraction is likely to be truly correlated with outcome. As an order-of-magnitude calculation, the number of false-positive correlations that will result from 20,000 hypothesis tests conducted with a 5% type I error rate is 1000, which is far too many to represent practical progress.

Although it is obvious in this setting that some measure must be taken to decrease the number of false-positive correlations, it is not always clear the specific target to be set. For example, if one insists that the rate of any false-positive correlation must be 5%, then a simple, although conservative, method is to apply the Bonferroni correction, which divides the nominal single-test error rate by the number of tests. In the example at hand, this would mean conducting each test with a type I error rate of 0.0000025. Although there are methods to make this conservative adjustment more accurate, it is not clear that this is even a reasonable goal. For example, it seems unduly conservative to demand that the rate of even a single false-positive result across 20,000 tests be only 5%. Unless the size of the study is increased, a reduction in the false-positive error rate by four orders of magnitude will increase the false-negative error rate, perhaps to the point at which correlations of a plausible magnitude cannot be detected.

Another method of controlling false-positive correlations considers the error rate among the tests that have been declared positive (ie, not among all hypotheses tested). This is called the false discovery rate. With this approach, if there were 100 positive tests, a false discovery rate of 5% would mean that, on average, five would be falsely positive. Most researchers would consider such a result highly successful. In fact, 10 positive tests with a false discovery rate of 20% to 30% could be considered an excellent result and would greatly reduce the scale of the subsequent studies required to replicate and validate the findings. The false discovery rate method is generally less conservative than a strict Bonferroni adjustment, although as previously noted, there are ways to calibrate the Bonferroni approach (eg, through permutation) to make it more comparable to the false discovery rate approach.

Although examples have been described previously in which the need to account for multiple tests is obvious, the problem of false-positive correlations remains even when dealing with 5 to 10 biomarkers. Explicit accounting of the multiple tests is often omitted in such situations, but this does not obviate the need for independent replication and validation of any apparent correlation.

KEY POINTS

- Common measures of correlation assess the linear correlation between variables. Lack of linear correlation does not necessarily mean that the variables are not related.
- Measures of correlation may be sensitive to a few outlying observations.
- Correlation, by itself, does not imply causation. Even though a biomarker may be correlated with both treatment and outcome, this is not sufficient to establish that the biomarker is a useful surrogate endpoint.
- Multiple comparisons increase the type I error above the desired significance level if the *P* values (or significance level) are not adjusted.

STATISTICAL ANALYSIS METHODS

In this section, we discuss some of the more important and advanced statistical methods that are common in oncology studies. Of course, all of these are themselves the subjects of entire books; therefore, only the most basic features of these methods can be covered here. The greater part of this section is devoted to the analysis of survival or time-to-event data, which are ubiquitous in the evaluation of clinical research. Some other advanced methods that may be encountered are also covered.

A common feature of the analytic methods discussed here is that they can be extended to incorporate the simultaneous effects of multiple variables on outcome, referred to as regression analysis. Regression analysis involving multiple variables is frequently referred to as multivariable analysis, in contrast with univariable analysis, which considers only one variable at a time. Many investigators erroneously use the term multivariate analysis rather than multivariable analysis. A multivariate analysis refers to the simultaneous analysis of multiple outcome variables, which is rarely done in medical research. Adjustment for multiple variables is particularly important in comparative studies using retrospective or other nonrandomized data or in the development of predictive models to evaluate multiple possibly correlated factors.

BINARY DATA ANALYSIS

In contrast to time-to-event analysis, there are occasions when the outcome of a clinical trial or other exercise may be summarized by the presence or absence of an event, outcome, or characteristic. This dichotomization of outcome is said to constitute binary data. Such data do not necessarily exclude aspects of time. For example, if outcome can be ascertained for all patients, then the occurrence of an event during a defined period can be a binary outcome. This is referred to as risk, but binary outcomes can refer to things other than risk. For instance, two groups of patients with breast cancer might be compared with respect to the percentage of patients with estrogen receptor–positive disease. The same or similar statistical methods may be applied to both scenarios.

χ^2 ANALYSIS

For basic statistical analysis of binary endpoints, such as comparing one or more groups in terms of the risk of an event or the percentage with a certain characteristic, the most common methodology is based on the χ^2 test. For small sample sizes, the accuracy of *P* values from the χ^2 analysis may be in doubt, and the Fisher exact test is the most common alternative although it is generally quite conservative.

Like the log-rank test for survival analysis, the basic methods associated with binary data provide a test of equality but not necessarily a measure of effect. The most straightforward measure of effect is the simple difference in proportions. Other common measures of effect associated with binary outcomes[59] must be used with some caution in typical applications involving clinical data. For example, if p is the risk of an event, then the odds of the event are $p/(1 - p)$. Conversely, if c is the odds of an event, then the risk of the event is $c/(1 + c)$. In certain epidemiological settings, where p is small, the ratio of the odds of an event between groups (odds ratio) will be approximately equal to the ratio of the risks (relative risk) and is a standard measure of association or effect. In clinical settings, however, the values of p associated with risk are not necessarily small. Although the same underlying statistical methods may be applicable, the odds ratio in such settings may be nonintuitive or even misleading. For example, consider a patient group with a risk of recurrence of 90% compared with another group with a risk of recurrence of 80%. The odds ratio for risk of recurrence is 2.25, but clearly, the risk of recurrence is not nearly doubled. Similar considerations apply when interpreting an HR in survival analysis. If the risk of an event is not too large, then an HR will approximate a risk ratio; however, the divergence between a risk ratio and an HR is not as dramatic as that between a risk ratio and an odds ratio. For example, a risk ratio of 2.0 (0.4/0.2) corresponds to an odds ratio of 2.67 and to an HR of 2.25 (under an exponential assumption).

KEY POINT

- Binary data analysis is used for outcomes with yes/no or binary responses. The χ^2 or Fisher exact test is used to compare proportions between groups. Logistic regression is used to model the odds of a response, where the effect of a covariate is summarized through an odds ratio.

SURVIVAL ANALYSIS

Because of the potentially long temporal course of the disease, a large part of the evaluation of cancer and its treatment involves extended periods of follow-up, often spanning many years. Measures of therapeutic efficacy or prognostic value are frequently defined by the percentage of patients alive at a particular time or alive and free of recurrence at a particular time. Conversely, one might be interested in the median time to death, recurrence, or some other defining event. Often, it is not possible to observe all patients until the defining event occurs or even until they have reached a specified length of follow-up.

The analysis of data related to the duration of time until an event is generically referred to as a time-to-event analysis or survival analysis. The methods used in such an analysis must take into account that some patients will not be observed until the time of the event but will provide partial information about the length of that time, that is, the length of time from the start of follow-up until the time of analysis. The discontinuation of follow-up before a defining event is called censoring. The proportion of event times that are censored may range from near zero in settings where almost all patients die or have recurrent disease to more than 90% in settings with excellent survival.

The most common graphical way to represent survival data is the survival curve. This is an estimate of the underlying survival function $S(t)$ that defines the probability of surviving past time t or, more generally, that the time to a defining event exceeds t. Although this is the way that data are visualized, the statistical analysis of such data is more often based on a related quantity called the hazard function $\lambda(t)$, which is the underlying rate at which events occur among the population of patients at risk. This is feasible because there is a well-defined and fundamental mathematic relationship between the survival function and hazard function; intuitively, if the rate of events increases, then the probability of surviving without that event decreases.

The most common methods associated with displaying and analyzing time-to-event data are described below. There are two key assumptions underlying all these methods. One is that the censoring of event times, if they occur, is not related to the subsequent occurrence of the event, that is, that the reason for censoring is noninformative with respect to what happens afterward. One particular example of a violation of this principle is censoring a survival time because of a change in therapy just before a patient experiences the expected event (eg, disease progression or death). Another fundamental principle of survival analysis, because survival is a predictive quantity, is that only past information can be used in modeling and analyzing future events. An example in which the latter principle is not met would be dividing patients into two groups, depending on whether they had a tumor response, and evaluating time to death from the time of initiation of therapy. Because tumor response is not known at the initiation of therapy, this will lead to a biased comparison, sometimes known as immortal time bias. The solution is to start survival after a fixed time period so that tumor response is known at the start time, called a landmarked analysis, although other more complex methods have been developed as well.

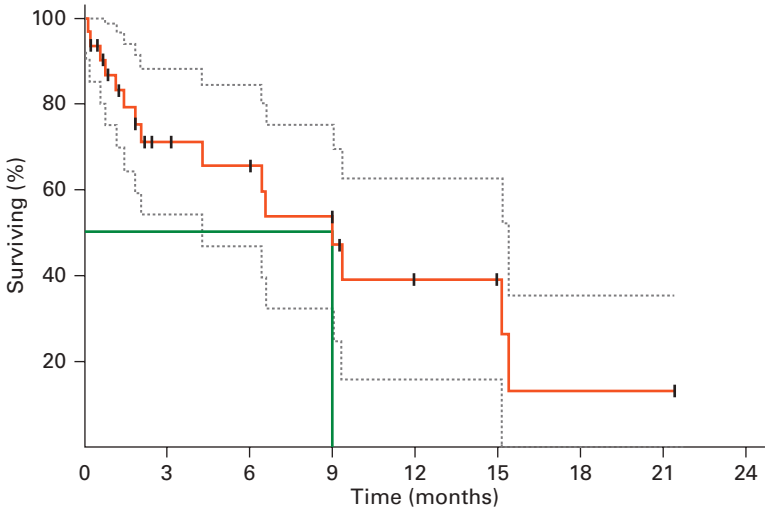
KAPLAN-MEIER CURVES

The universal standard for providing estimates of survival curves is the Kaplan-Meier estimator (also called the product-limit estimator). This is typically plotted as a step function, with a step occurring at every unique death time (Fig. 5-10). The calculation involved in the Kaplan-Meier estimator is actually quite simple; the height of each step is the height of the curve at the previous step multiplied by the proportion of patients at risk at the particular death time who survive beyond that time. The number of patients at risk at a particular point is the number of patients who have not died or have been censored before that time. For example, suppose the time until death or censoring is measured to the nearest week. If the estimated survival probability just before 14 weeks is 0.6, there are 10 patients who have not died or been censored before 14 weeks, and one patient dies at 14 weeks, then the height of the curve drops at that time from 0.6 to 0.54 ($0.6 \times [9/10]$). In plots of Kaplan-Meier curves, it is common to indicate points of censoring with tick marks or provide a table indicating the numbers of patients at risk at convenient benchmarks.

Because the Kaplan-Meier estimate is the product of fractions with progressively smaller denominators, the precision of the estimate decreases over time. This is readily apparent if CIs are provided because the CIs will grow increasingly wider over time. In almost all cases, the CIs provided with a Kaplan-Meier curve are based on pointwise estimates of the variability of the survival estimate; it is generally not correct to infer that the bands contain the entirety of the true survival curve with the stated level of confidence. The step after the last observed time of death is often extended as far as the last censoring time, although technically, the estimate is undefined after the last death. As previously noted, the steps in the right-hand tail of the estimated curve become steeper as the number of patients at risk decreases. If the last patient under observation dies, then the estimated survival probability drops to zero at that point.

Although the previous discussion referred only to deaths, the Kaplan-Meier method readily encompasses the concepts of PFS, DFS, and event-free survival. For example, the estimate of DFS counts both deaths and relapses as events, and the curve steps down whenever either event occurs, using the same calculation. The term OS is usually meant to refer to a survival curve that counts only deaths as events. The Kaplan-Meier method should not be used when the intent is to estimate the probability of being free of a particular kind of event (eg, a particular cause of death). This is a competing risks problem and requires the use of methods described later in the chapter.

Figure 5-10 Survival Curve Plot and Related Quantities



Orange line is an example of a Kaplan-Meier curve for a group of 33 patients. At any time point, the curve estimates the probability of surviving at least as long as that time. Gray lines indicate the 95% CIs for the survival probability calculated at each point. Tick marks indicate times at which surviving patients were last known to be alive and are censored. Green line indicates how median survival would be calculated. In this curve, the survival probability drops to less than 50% at 9 months.
Abbreviation: CI, confidence interval.

Comparing Kaplan-Meier Curves

The comparison of survival curves can be approached in several ways: (1) by comparing the estimated survival probability at a fixed point in time; (2) by comparing the time at which the estimated survival probability is a fixed value, usually the median; or (3) by comparing the survival curves across the entire period of follow-up. Although the first two methods provide convenient descriptive metrics, in general, they should be avoided for statistical testing unless there is a strong justification for focusing on a particular survival time or percentile; focusing on a single metric ignores the rest of the survival distribution, which leads to reduced power and sometimes bias. The third method is suitable and preferable for statistical inference because it uses all the available data.

The most common way to compare whether survival curves differ between groups is the nonparametric log-rank statistic, which compares DFS in a hypothetical clinical trial of an experimental compared with a control treatment. Perhaps somewhat surprisingly, this statistic is not based directly on the calculated survival estimates; rather, it is based on a comparison of the number of events observed in one group with the number of events that would have been expected in that group if the deaths occurred solely in proportion to the numbers of patients at risk. A difference that is too extreme (as reflected in a *P* value) provides evidence that the underlying event rates in the groups are different. The standard log-rank test is most sensitive to situations in which the event rates in the groups differ by the same ratio across time. There are weighted versions of this test that are appropriate if the differences are expected to occur primarily during the early or later periods of follow-up; however, the intent to use a weighted log-rank test should be specified before observing where the differences in event rates occur.

The comparison of survival curves is a special case of hazard rate analysis, performed through Cox proportional hazards regression, which is discussed later. In fact, the log-rank test is also a test of the equality of hazard rates in the two groups. Cox proportional hazards model rely on the assumption that the ratio of hazards in the two groups is constant over time. Deviations from this assumption, called nonproportional hazards, can often be seen using Kaplan-Meier plots and manifest through crossing curves (Fig. 5-11A and B).

COMPETING RISKS AND CUMULATIVE INCIDENCE

As noted previously, when there are multiple types of events that define event-free survival, or multiple causes of death, then probabilities associated with a specific type of event or a specific cause of death should not be estimated with the Kaplan-Meier approach. For example, suppose one is interested in comparing breast cancer mortality as opposed to all-cause mortality (the complement of OS) between two treatment groups. The relevance of this comparison might be debated because cause-of-death classification can be fairly subjective. A common but incorrect approach to this problem is to censor patients at the time of death resulting from a cause other than breast cancer and to plot the complement of the resulting Kaplan-Meier curve as a

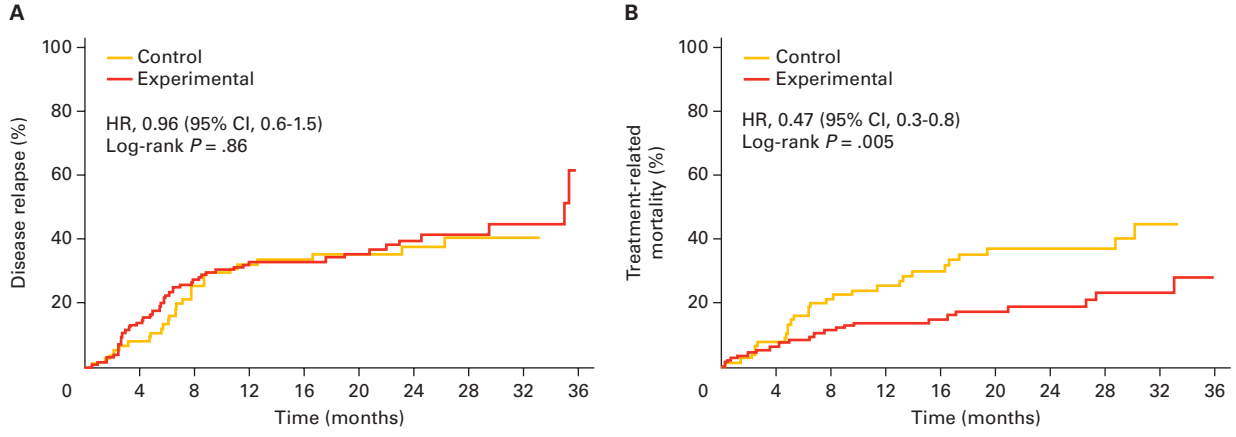
representation of cumulative breast cancer mortality over time. The problem with this approach is that patients who die as a result of other causes are not even hypothetically at risk of future death as a result of breast cancer. The implicit assumption that they are, which is appropriate for the standard types of censoring, results in an overestimation of the probability of death resulting from breast cancer.

The correct calculation of cumulative incidence in the competing risks setting must take into account the probability of remaining at risk (or being event free). When this is done, the sum of the cumulative incidence probability for each type of event is exactly the complement of the event-free survival probability. For example, at any point in time, (1) the OS probability, (2) the probability of death resulting from breast cancer, and (3) the probability of death resulting from a cause other than breast cancer will sum to 100%.

Although Kaplan-Meier methods are generally inappropriate for generating estimates of cumulative incidence in the presence of competing risks, the comparison of cumulative incidence curves is properly handled using the same previously discussed log-rank statistic, with events other than the type of interest being censored at the time of their occurrence. This seeming contradiction relates to the fact that in neither case is the log-rank statistic based directly on the estimates of the event probabilities themselves. Rather, it is based on the relative numbers of events that occur in each patient group, given the numbers of patients remaining at risk in each group over time. Therefore, it is appropriate, for this purpose, to censor patients who experience competing events at the time of the event, because they are no longer at risk of the event of interest.

At the risk of making the issue seem overly complicated, it should be noted that in the competing risks setting, the results of statistical analysis may not always seem concordant with the visual interpretation of cumulative incidence curves (Fig. 5-11). This is because incidence is a composite result of (1) the rate at which events occur among those at risk (the hazard rate) and (2) the size of the population at risk. For example, consider a setting in which toxic regimens with potentially fatal complications are used in a setting with high rates of relapse. The events of death as a result of relapse and death resulting from a cause other than relapse constitute competing risks (Fig. 5-12). Suppose one regimen is much more effective than the other in preventing relapse but has the same underlying toxicity based on a hazard rate analysis showing equivalent hazard rates for death resulting from a cause other than relapse in the two groups. In this case, the cumulative incidence of death resulting from a cause other than relapse will seem higher in the group receiving the more effective therapy. This is because the effectiveness of the therapy in preventing relapse places more patients at risk of death resulting from a cause other than relapse.

Figure 5-12 Plot of Cumulative Incidence Curves for Competing Risks



Data are decomposed into the two competing risks of (A) relapse and (B) treatment-related mortality. Most of the improvement in DFS in the experimental arm is attributable to a decrease in treatment-related mortality; there is no observed difference in the rate of relapse between arms among those at risk of relapse.
Abbreviations: CI, confidence interval; HR, hazard ratio.

The intent of the previous example is not to imply that the hazard rate analysis is correct or that the cumulative incidence analysis is misleading. The important point is that competing risks should not be evaluated in isolation. Factors that influence one type of event may or may not influence another type, and an informed interpretation of data from a competing risks setting should consider each type of event. Furthermore, a complete analysis should evaluate not only the underlying rates of the event types, which may be biologically more meaningful, but also the net outcome reflected in their cumulative incidence, which may affect clinical interpretation.

KEY POINTS

- Survival analysis techniques are used to analyze outcomes describing the time until an event occurs, which may be subject to censoring or competing risks.
- Although Kaplan-Meier curves are the universal standard for graphically representing time-to-event endpoints, the statistical analysis of such curves is usually not based on a direct comparison of the curves themselves. Rather, the comparison is based on the underlying hazard rate (the rate of events among patients remaining at risk) using the log-rank test.
- Comparisons of cumulative incidence curves are performed similarly to comparisons of survival curves.

MULTIVARIABLE REGRESSION MODELS

Although many clinical trials can be analyzed using only the abovementioned methods, there are many settings in which one wishes to incorporate more information about patient characteristics than just the treatment arm to which the patients were assigned. This is particularly true in adjusting for imbalances at randomization or identifying prognostic factors of clinical outcomes. Although accounting for these imbalances is in no way a substitute for randomization, it is helpful, nevertheless, to evaluate the extent to which patient characteristics influence the difference, or lack of difference, among treatment groups. In other cases, the interest is not in comparing the arms of a clinical trial but in determining factors that are predictive of better or worse survival. This information is useful in designing trials, counseling patients about their likely prognosis, or gaining increased biological understanding.

Two commonly used models are the proportional hazards and logistic regression models. Like other regression models, the Cox regression model relates patient characteristics, called covariates, to outcome, which is a time-to-event outcome, such as survival or PFS. These models can accommodate any number of variables. A Cox model summarizes the association between a variable and the outcome with an HR. The Cox model might include either fixed or time-dependent covariates. Fixed covariates are measured at baseline, whereas time-dependent covariates measure the variable through the trial. When these measurements are updated over time, this covariate might provide a more accurate prognosis of a patient's hazard of dying than having only baseline measurements.[60] In clinical trials, only baseline covariates are adjusted. An exception might be the measurement of serial biomarkers during the trial and relating recent biomarker values to subsequent outcomes. The method for incorporating covariate effects on a binary outcome is logistic regression. A logistic model summarizes the association between a variable and the outcome with an odds ratio.

There are two strategies in modeling the relationship between a covariate and time-to-event endpoints in competing risks. They model the dependence of either the cause-specific hazard function or the subdistribution hazard function. Both approaches are valid although they will have different interpretations and might have different associations. In the first approach, k regression models can be fitted to the kth cause of interest. In each of the Cox models, the event times for the other competing risks are censored. In the second approach, the kth event type can be modeled using the Fine-Gray subdistribution hazard. This approach allows for modeling the effect of covariates on the cumulative function.[61] An important feature of this approach is that patients who experience a competing event remain in the risk set (instead of being censored), although they are in fact no longer at risk of the event of interest.

KEY POINTS

- Cox regression is used to model the hazard rate in time-to-event outcomes, where the effect of a covariate can be summarized through an HR.
- Logistic regression is used to model the odds of a response, where the effect of a covariate is summarized through an odds ratio.

EVALUATION OF BIOMARKERS

In the evaluation of a biomarker, the goal is to determine whether it can discriminate among patients. For a prognostic biomarker, an evaluation is performed to determine whether the biomarker can distinguish between patients who have good prognosis and those who have poor prognosis. If the outcome of interest is binary (eg, good vs poor prognosis), the discrimination ability is determined using the area under the curve of a receiver operator characteristic (ROC) curve. ROC curves apply to biomarkers that have continuous values. The ROC curve plots the true-positive rate against the false-positive rate for various threshold values (eg, values that would determine whether a patient has a good vs poor prognosis). The true-positive rate is also called sensitivity, which is the ability of the marker to predict the outcome of interest when that outcome actually occurs (eg, the marker would classify a patient as having a good prognosis and that patient actually did have a good prognosis). The false-positive rate is determined as 1-specificity. Specificity is the ability of the marker to classify the patient as not having the outcome of interest when the patient does not have the outcome of interest. A biomarker that has perfect discriminatory ability has an area under the curve of 1. This means that it always correctly classifies patients according to the event of interest. If the event is prognosis, the biomarker can perfectly predict the patients with a good prognosis and patients with a poor prognosis. A biomarker that has

no discriminatory ability is one with an area under the curve of 0.5. This means that its ability to predict whether a patient has the outcome of interest is the same as flipping a fair coin. Area under the curve analysis is used to determine the performance of prognostic biomarkers. In general, for a prognostic biomarker to potentially be useful in clinical practice, it requires a high area under the curve level (perhaps >0.80), although this cutoff depends on the setting.

To determine the potential utility of a biomarker in a clinical trial, it is good to evaluate the strength of the association of the biomarker with the outcome of interest. When the outcome is a time-to-event outcome, the strength of the association will be determined with an HR from a Cox model and by computing a measure of predictive accuracy using the Harrell C-index or integrated time-dependent area under the curve.[62] To determine whether the marker is prognostic, there must be a statistically significant association with the outcome, regardless of treatment. Thus, there would be an association regardless of the treatment the patient received.

KEY POINTS

- The discriminatory ability of a prognostic biomarker is measured by computing the area under the curve for an ROC curve. The closer the area under the curve is to 1, the better the discriminatory ability.
- To determine whether a biomarker is prognostic, an association between the biomarker and the outcome of interest must be established.
- To determine whether a biomarker is predictive, a statistically significant interaction must be established between biomarker status (present vs absent) and the treatment of interest (received vs did not receive) with respect to the outcome of interest.

LONGITUDINAL DATA ANALYSIS

In many studies, patients may be assessed repeatedly over extended periods. Data that arise from repeated measurements of the same patient over time are called longitudinal data or, sometimes, clustered data. Common examples of such data would be quality-of-life assessments or the evaluation of biomarker levels over time. Pharmacokinetic data are a specialized case of longitudinal data; there are specific methods for analysis of these data that are beyond the scope of this chapter.

It is possible to perform a useful analysis of longitudinal data using basic statistical methods, for example, by comparing groups at a fixed point or by comparing estimates at two time points using paired tests. However, such methods may not allow one to evaluate the trajectory of the quantity being studied as a whole and do not fully accommodate common features of longitudinal data, such as missing data, variable times of assessment, and risk factors that also change over time. To analyze all the data simultaneously, one must account for the fact that repeated observations from the same patient are likely correlated. For example, one patient may report a relatively high quality of life during the entire period of study and another may report a low quality of life, although both patients may experience a similar change over time.

Appropriately accounting for this within-patient correlation is not necessarily straightforward, and the methods involved may be quite complex and are beyond what can be presented in detail here. There are two fairly common approaches to handling longitudinal data analysis. Although the nomenclature may vary, one is generally referred to as a linear mixed-model approach and the other as a generalized estimating equation approach. The term mixed in the former refers to the simultaneous estimation of parameters that model the mean effects (the effects of clinical interest) and parameters that model the within-patient correlation structure of the data. One must make explicit assumptions about the latter, and the results may be sensitive to that assumption. The generalized estimating equation approach makes less explicit assumptions about the correlation structure. This is an advantage, particularly if one has no particular interest in the correlation structure itself, which is often the case when the interest is in comparing outcomes between groups or evaluating the effects of other factors on outcome.

KEY POINT

- Longitudinal data analysis is used to model outcomes that are assessed repeatedly over time. These methods must account for missing data commonly occurring in this setting, as well as for the correlation between measurements in the same individual.

SUMMARY

Statistical considerations comprise a key component in the design and analysis of clinical research studies. Proper study design allows one to control the systematic and random factors that affect patient outcomes in clinical studies, and proper analysis allows one to make the best possible judgment about which factors are more important. Few oncologists engaged in clinical research have sufficient statistical training or knowledge to do this on their own, which is why statisticians are in high demand in medical research and are considered vital to the research endeavor. Statisticians are also frequently engaged in evaluating research proposals for funding purposes and in reviewing research papers for publication in medical journals.

Although most clinical studies published in major medical journals likely involved a statistician in the design and conduct of the study and the review of the article, it is still essential for the practicing oncologist to have some rudimentary familiarity with common statistical concepts and terminology, which is the goal of this chapter. Such knowledge will enhance the oncologist's ability to evaluate the medical literature, explain treatment options to patients, and make informed decisions about joining research studies available to the community.

HIGH-YIELD TAKEAWAYS

- Most phase 1 designs identify an MTD based on DLTs, while the RP2D is often finalized later using expansion cohort safety and pharmacokinetic and pharmacodynamic data, and for some targeted therapies the goal is an OBD rather than an MTD.
- The 3 + 3 design is simple but can be inefficient, model assisted designs such as BOIN use prespecified decision tables and can improve patient allocation and overdose control.
- High-quality trials require a prespecified objective, clinically meaningful endpoint, appropriate design, justified sample size, and a prespecified statistical analysis plan.
- A *P* value quantifies evidence against a null hypothesis, it does not measure effect size or clinical importance, and statistical significance does not guarantee clinical benefit.
- Survival endpoints require methods that account for censoring, commonly Kaplan-Meier estimation, log-rank testing, and Cox regression, with method choice guided by the estimand and study design.

CLINICAL TRIALS AND BIOSTATISTICS

5

CHAPTER SUMMARY GUIDE

KEY POINTS

- The primary objective of a clinical study is the principal clinical research question or the hypothesis to be tested.
- The primary outcome measure is the variable that will be measured during the clinical trial and on which the study endpoint will be based.
- Study endpoints are clinically meaningful results obtained after the study intervention.
- A false positive (type I error) is when the null hypothesis is true and incorrectly rejected; it is designated as α.
- A false negative (type II error) is when the null hypothesis is false and incorrectly not rejected; it is designated as β.
- Statistical contributions to the clinical trial design are essential, and trial design development is a collaboration between clinical investigators and the statistician.
- The American Statistical Association's six principles of statistical significance and *P* values are as follows[9]:

    1. *P* values can indicate how incompatible the data are with a specified statistical model.
    2. *P* values do not measure the probability that the studied hypothesis is true or the probability that the data were produced by random chance alone.
    3. Scientific conclusions and business or policy decisions should not be based only on whether a *P* value passes a specific threshold.
    4. Proper inference requires full reporting and transparency.
    5. A *P* value, or statistical significance, does not measure the size of an effect or the importance of a result.
    6. By itself, a *P* value does not provide a good measure of evidence regarding a model or hypothesis.

- Phase 1 trial objectives are as follows:

    1. Identify the safe dose or MTD of a novel therapy or therapy combination.
    2. Ascertain a dose or dose range for subsequent phase 2 studies.
    3. Determine clinical drug behavior through pharmacokinetic and/or biomarker studies.
    4. Assess preliminary antitumor efficacy.

- The typical sample sizes used in phase 2 trials provide imprecise estimates of outcome.
- Basket and umbrella trials efficiently evaluate several treatment-marker or treatment-histology combinations.
- Results among phase 2 trials, especially single-arm trials, are difficult to compare because so many factors can vary from trial to trial.
- Phase 3 clinical trials are typically randomized and are designed to be pivotal; that is, they aim to demonstrate and confirm the safety and efficacy of a treatment strategy to obtain approval by regulatory authorities.
- Phase 3 study outcomes/endpoints should be previously validated as meaningful and selected to minimize variability in interpretation.
- Phase 3 trials require careful consideration of study design parameters, including randomization, blinding, and choice of endpoint, to minimize bias in the assessment of the treatment benefit.
- Common measures of correlation assess the linear correlation between variables. Lack of linear correlation does not necessarily mean that the variables are not related.
- Measures of correlation may be sensitive to a few outlying observations.
- Correlation, by itself, does not imply causation. Even though a biomarker may be correlated with both treatment and outcome, this is not sufficient to establish that the biomarker is a useful surrogate endpoint.
- Multiple comparisons increase the type I error above the desired significance level if the *P* values (or significance level) are not adjusted.
- Binary data analysis is used for outcomes with yes/no or binary responses. The χ^2 or Fisher exact test is used to compare proportions between groups. Logistic regression is used to model the odds of a response, where the effect of a covariate is summarized through an odds ratio.

- Survival analysis techniques are used to analyze outcomes describing the time until an event occurs, which may be subject to censoring or competing risks.
- Although Kaplan-Meier curves are the universal standard for graphically representing time-to-event endpoints, the statistical analysis of such curves is usually not based on a direct comparison of the curves themselves. Rather, the comparison is based on the underlying hazard rate (the rate of events among patients remaining at risk) using the log-rank test.
- Comparisons of cumulative incidence curves are performed similarly to comparisons of survival curves.
- Cox regression is used to model the hazard rate in time-to-event outcomes, where the effect of a covariate can be summarized through an HR.
- Logistic regression is used to model the odds of a response, where the effect of a covariate is summarized through an odds ratio.
- The discriminatory ability of a prognostic biomarker is measured by computing the area under the curve for an ROC curve. The closer the area under the curve is to 1, the better the discriminatory ability.
- To determine whether a biomarker is prognostic, an association between the biomarker and the outcome of interest must be established.
- To determine whether a biomarker is predictive, a statistically significant interaction must be established between biomarker status (present vs absent) and the treatment of interest (received vs did not receive) with respect to the outcome of interest.
- Longitudinal data analysis is used to model outcomes that are assessed repeatedly over time. These methods must account for missing data commonly occurring in this setting, as well as for the correlation between measurements in the same individual.

CHAPTER TABLES AND IMAGES

Table 5-1 Hypothesis Test Decisions and Error Types

		Truth Based on Population (Universe)	
		Null Hypothesis Is True	**Null Hypothesis Is False**
Decision based on sample (data)	Reject the null hypothesis	Type I error	Correct decision (power)
	Do not reject the null hypothesis	Correct decision	Type II error

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 5-2 **Choosing a Statistical Analysis Approach**

Endpoint Type	One Predictor	Multiple Predictors or a Single Continuous Predictor
Binary (yes vs no)	χ^2 test or Fisher exact test	Logistic regression
Time to event	Log-rank test	Cox proportional hazards regression
Continuous	*t* test or Wilcoxon test	Linear regression
Paired/correlated data	Continuous: paired *t* test or signed rank test; binary: McNemar test	Mixed models or generalized mixed models
Categorical or ordinal	χ^2 test or Fisher exact test	Multinomial regression or proportional odds regression
Count data	Poisson or negative binomial regression	Poisson or negative binomial regression

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 5-3 **Description of Common Statistical Tests**

Outcome	Setting	Test	Definition and Description
Continuous	Comparing means	Two-sample *t* test	Used to compare means between two groups for a quantitative variable; normal distribution and equal variance in each group are assumed; an unequal variance *t* test can be used if unequal variances are expected in the two groups; generally robust to small sample size and nonnormal distributions, but sensitive to outlying values, which inflate estimates of variability
		Paired *t* test	Used to compare paired quantitative data; for example, a paired *t* test can be used to determine whether there is a nonzero change in a quantitative characteristic measured before and after treatment in each patient; same sensitivity to outlying values as the two-sample *t* test
Continuous	Comparing medians or distributions	Wilcoxon rank sum (Mann-Whitney)	Nonparametric alternative to the two-sample *t* test; less sensitive to outlying values than the two-sample *t* test, although can be somewhat more conservative compared with *t* test (eg, if the data are normally distributed)
		Wilcoxon signed rank	Nonparametric alternative to the paired *t* test; less sensitive to outlying values than the paired *t* test, although somewhat more conservative
Binary	Comparing proportions	χ^2	Used to compare proportions between two or more groups; fairly robust to small sample sizes, unless there is an imbalance between groups
		Fisher exact	Used to compare proportions with small sample sizes; a commonly used rule of thumb is to use the Fisher exact test if <5 observations are expected in any of the cells of a contingency table; this test may be somewhat more conservative compared with the χ^2 test
		McNemar	Used to compare paired proportions; for example, a binary characteristic assessed before and after treatment in each patient; it is based only on the discordant pairs (where outcome is different) and is not used to assess concordance
Time to event	Comparing survival distribution	Log rank	Used to compare survival distributions between two or more groups; also, the Kaplan-Meier approach is used to estimate the survival distribution (curve)

Table 5-4 **RECIST 1.1 Definitions of Response and Disease**

Response	Target Lesions	Nontarget Lesions
CR	Disappearance of all target lesions	Disappearance of all nontarget lesions and normalization of tumor marker level
PR	At least a 30% decrease in the sum of diameters of target lesions, taking as reference the baseline sum of diameters	Persistence of ≥1 nontarget lesion and/or maintenance of tumor marker level above the normal limits
PD	At least a 20% increase in the sum of diameters of target lesions, taking as reference the smallest sum on study; in addition to the relative increase of 20%, the sum must also demonstrate an absolute increase of at least 5 mm	Unequivocal progression of existing nontarget lesions; appearance of ≥1 new lesion is also considered progression
SD	Neither sufficient shrinkage to quality for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum diameters during the study	NA

Abbreviations: CR, complete response; NA, not applicable; PD, progressive disease; PR, partial response; RECIST, Response Evaluation Criteria in Solid Tumors; SD, stable disease.

Table 5-5 **Examples of Single-Stage Phase 2 Designs**

Design Criteria				Resulting Design	
p_0	p_1	α	Power[a]	n	*r*
0.1	0.25	0.05	0.9	55	10
0.1	0.25	0.05	0.8	40	8
0.1	0.25	0.1	0.9	40	7
0.1	0.25	0.1	0.8	31	6
0.1	0.25	0.05	0.9	33	7
0.1	0.25	0.05	0.8	25	6
0.1	0.25	0.1	0.9	25	5
0.1	0.25	0.1	0.8	18	4
0.5	0.7	0.05	0.9	53	33
0.5	0.7	0.05	0.8	37	24
0.5	0.7	0.1	0.9	39	24
0.5	0.7	0.1	0.8	28	18

Abbreviations: α, type I (false-positive, one-sided) error rate if $p = p_0$; n, smallest sample size that satisfies design criteria; p_0, response rate under null hypothesis; p, response rate under alternative hypothesis; r, minimum number of responses required to reject null hypothesis and conclude that $p > p_0$ using the exact test for one proportion.

[a]Power refers to the probability of rejecting the null hypothesis if $p = p_1$.

Table 5-7 **Examples of Two-Stage Phase 2 Designs (Optimal Simon Design)**

Design Criteria				Resulting Design			
				First Stage		Overall	
p_0	p_1	α	Power[a]	n_1	r_1	n	r
0.10	0.25	0.05	0.9	21	2	66	10
0.10	0.25	0.10	0.9	21	2	50	7
0.25	0.45	0.10	0.9	22	6	57	19
0.40	0.6	0.10	0.9	25	11	66	32
0.50	0.7	0.10	0.9	24	13	61	36

Abbreviations: α, one-sided type I (false-positive) error rate if $p = p_0$; n, total sample size after both stages; n_1, sample size for first stage; p_0, response rate under null hypothesis (usually based on external control group rate); p_1, response rate under alternative hypothesis; r, minimum number of responses required to reject null hypothesis and conclude that $p > p_0$; r_1, if r_1 or fewer responses are observed during stage I, the trial is stopped early for futility (if r_1 or fewer responses are observed by the end of stage II, then no further investigation of the drug is warranted).

[a]Power refers to the probability of rejecting the null hypothesis if $p = p_1$.

Table 5-8 **Minimum Sample Size (per Arm) for Simon's Pick-the-Winner Randomized Phase 2 Designs**[a]

	Two Arms (p_1, p_2)		Three Arms (p_1, p_2, p_3)	
Difference ($p_2 - p_1$)	**Power[b] = 0.80**	**Power = 0.90**	**Power = 0.80**	**Power = 0.90**
0.10	36	82	68	123
0.15	16	37	31	55
0.20	9	21	17	31

Abbreviations: p_1, lower (lowest) response rate, 0.4; p_2, higher (highest) response rate.
[a]A conventional type I error rate is not defined for pick-the-winner randomized phase 2 designs because no formal null hypothesis is tested. These designs are intended for treatment selection rather than hypothesis testing, and their operating characteristics are summarized by the probability of correct selection rather than false-positive control.
[b]Power refers to the probability that the arm with highest true response rate has the highest observed response rate.
Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 5-9 **Factors Affecting Success of Biomarker-Driven Trials**	
Factors	**Key Points and Impact on Trial Success**
Analytically validated biomarker assay	Positive if validated, negative if not. Analytical validation is a prerequisite for credible classification and reproducible results.
Known actionable target	Positive if known, negative if unknown. Actionability supports a clear biological rationale for enrichment or matching.
Large magnitude of difference in clinical outcome	Positive if large, negative if small. Bigger effects are easier to detect and less sensitive to misclassification or heterogeneity.
Moderate to high prevalence	Positive if moderate to high, negative if lower than expected. Low prevalence drives screen failures, slow enrollment, and early closure risk.
High accrual rate	Positive if high, negative if low. Accrual refers to fast enrollment of eligible patients, not screening volume per se, although low prevalence can force high screening to achieve adequate accrual.
Baseline and longitudinal biomarker collection	Positive if baseline plus longitudinal, negative if baseline only. Longitudinal sampling better captures evolving disease biology and resistance.
Prognostic or genomic model as stratification factor: homogeneity within strata	Positive. Improves interpretability and precision by reducing within stratum heterogeneity.
Prognostic or genomic model as stratification factor: heterogeneity across strata	Positive. Creates clinically distinct strata, supports effect modification evaluation, and improves design efficiency.
Validated cutoff point of biomarker	Positive if well validated, negative if not. Unstable cutoffs increase misclassification and reduce reproducibility.
Near real-time readout from assay	Positive if near real time, negative if delayed. Turnaround time affects feasibility, timely assignment, and accrual.
Strong stakeholder buy-in	Positive if strong, negative if weak. Buy-in is critical in biomarker trials, especially master protocols requiring multi-party coordination.

Table 5-11 **Examples of Adaptive Designs**	
Design	**Idea**
Continual reassessment method	Model-based dose escalation to estimate the MTD
BOIN designs	Model-assisted dose-finding design to estimate MTD
Group sequential	Include options to stop the trial early for safety, futility, or efficacy
Sample size re-estimation	Adjust sample size to ensure the desired power
Multiarm multistage	Explore multiple treatments, doses, durations, or combinations with options to "drop losers" or "select winners" early
Population enrichment	Narrow down recruitment to patients more likely to benefit (most) from the treatment
Biomarker adaptive	Incorporate information from or adapt based on biomarkers
Adaptive randomization	Shift allocation ratio toward more promising or informative treatment(s)
Adaptive dose ranging	Shift allocation ratio toward more promising or informative dose(s)
Seamless phase 1/2	Combine safety and activity assessment into one trial
Seamless phase 2/3	Combine selection and confirmatory stages into one trial

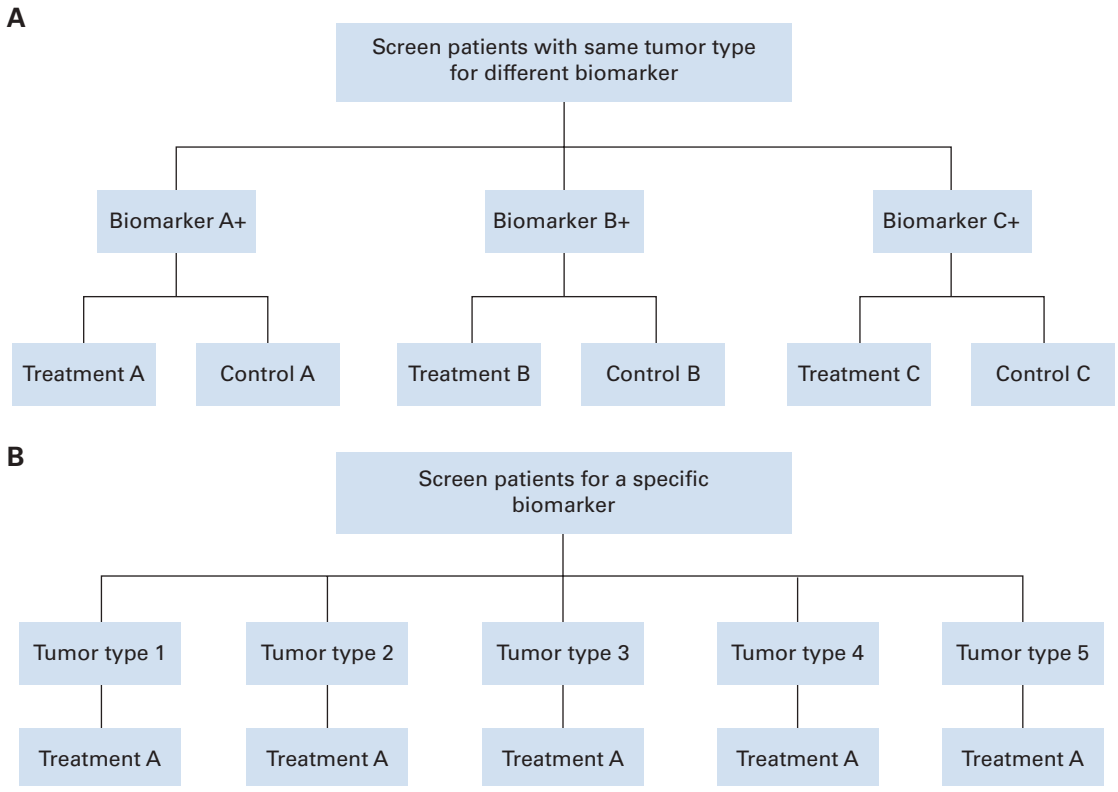
Figure 5-6 Umbrella and Basket Trial Designs



(A) Illustration of an umbrella trial design in which patients with the same tumor type are tested for different biomarkers and then are assigned to a treatment group that targets the biomarker. In this example, patients are randomly assigned to a treatment versus control arm. An alternative design could be a single-arm design with the patients with a particular biomarker receiving treatment meant to target that biomarker. (B) Illustration of a basket trial design in which all patients are tested for a particular biomarker and then are entered into a cohort for their tumor type. All patients receive the same targeted treatment that is believed to potentially benefit patients with tumors with the biomarker. This shows each cohort is a single-arm trial, but the cohort could be randomly assigned to treatment and control arms.

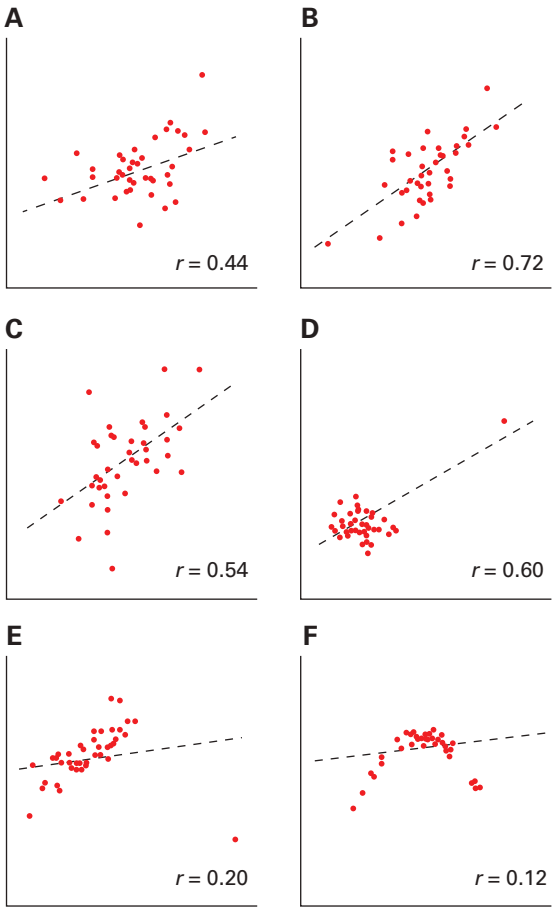
Figure 5-8 Scatterplot Examples of Linear Correlation



The six graphs illustrate possible correlations between two variables, *x* and *y*. The dashed line indicates the least squares line fit to the data, and *r* is the Pearson correlation coefficient. (A) Data have a positive correlation of moderate strength. (B) Compared with the data in panel (A), there is an increased slope in the data and a stronger correlation. (C) Data have the same slope as the data in panel (B), but the correlation is weaker (ie, the points have more variability about the best fitting line). (D) Computed correlation is stronger than that in the bulk of the data because of the influence of one outlier point. If this point were removed, the correlation would be smaller. (E) Correlation with the outlier is weaker than the correlation for the remainder of the data. If the outlier were removed, the correlation would increase. (F) There is a strong nonlinear relationship in the data, but the correlation is weak, because the correlation measures the strength of linear relationship.

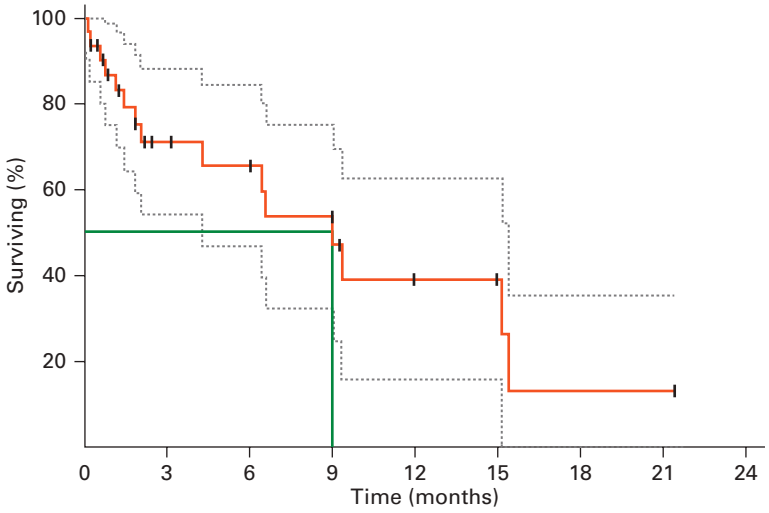
Figure 5-10 Survival Curve Plot and Related Quantities



Orange line is an example of a Kaplan-Meier curve for a group of 33 patients. At any time point, the curve estimates the probability of surviving at least as long as that time. Gray lines indicate the 95% CIs for the survival probability calculated at each point. Tick marks indicate times at which surviving patients were last known to be alive and are censored. Green line indicates how median survival would be calculated. In this curve, the survival probability drops to less than 50% at 9 months.
Abbreviation: CI, confidence interval.

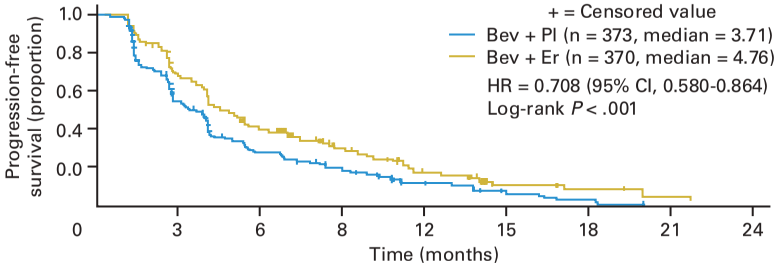
Figure 5-11 Plots to Compare Survival Curves

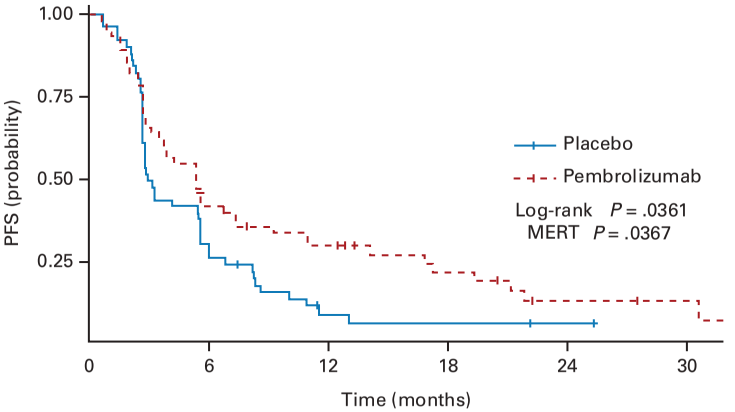
A PH



No. at risk									
Bev + Er	370	180	80	43	20	5	3	1	0
Bev + Pl	373	143	57	28	15	6	3	0	0

	Bevacizumab + Placebo (n = 373)		Bevacizumab + Erlotinib (n = 370)	
Time Since Random Allocation	Patients With Event	Kaplan-Meier Percent Event Free (Pointwise 95% CI)	Patients With Event	Kaplan-Meier Percent Event Free (Pointwise 95% CI)
3 months	138 (37.0%)	54.1 (48.2-59.6)	92 (24.9%)	68.4 (62.7-73.4)
6 months	200 (53.6%)	28.2 (22.7-33.9)	160 (43.2%)	40.2 (34.1-46.2)
9 months	216 (57.9%)	19.3 (14.3-24.9)	177 (47.8%)	30.2 (24.2-36.5)
12 months	226 (60.6%)	12.1 (7.8-17.5)	193 (52.2%)	17.8 (12.3-24.1)

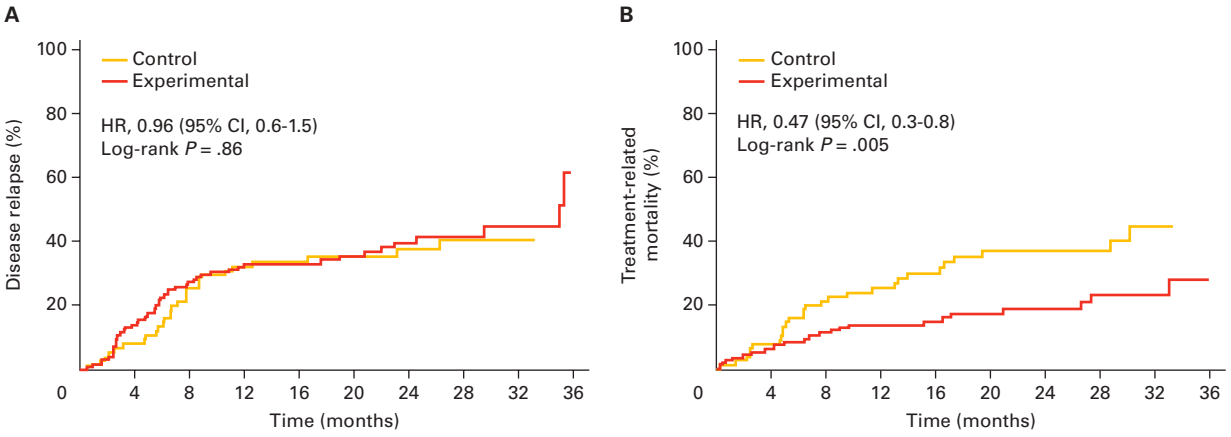
B Non-PH



No. at risk						
Placebo	52	15	3	2	1	0
Pembrolizumab	55	21	14	8	3	2

(A) PH assumption is satisfied. (B) PH assumption is violated.
Abbreviation: CI, confidence interval; HR, hazard ration; MERT, mixed effects regression tree; PH, proportional hazards.
Data adapted from (A) Johnson BE, Kabbinavar F, Fehrenbacher L, et al. ATLAS: randomized, double-blind, placebo-controlled, phase IIIB trial comparing bevacizumab therapy with or without erlotinib, after completion of chemotherapy, with bevacizumab for first-line treatment of advanced non-small-cell lung cancer. *J Clin Oncol*. 2013;31(31):3926-3934, figure 3. Reprinted from (B) Galsky MD, Mortazavi A, Milowsky MI, et al. Randomized double-blind phase II study of maintenance pembrolizumab versus placebo after first-line chemotherapy in patients with metastatic urothelial cancer. *J Clin Oncol*. 2020;38:16, figure 2A.

Figure 5-12 Plot of Cumulative Incidence Curves for Competing Risks



Data are decomposed into the two competing risks of (A) relapse and (B) treatment-related mortality. Most of the improvement in DFS in the experimental arm is attributable to a decrease in treatment-related mortality; there is no observed difference in the rate of relapse between arms among those at risk of relapse.

Abbreviations: CI, confidence interval; HR, hazard ratio.

GENETIC TESTING FOR HEREDITARY CANCER SYNDROMES

6

Lisle Nabell, MD, and Bita Nehoray, MS, CGC

RECENT UPDATES

- Cancer-specific mortality in a population-based sample[1] of 77,955 patients with breast (n = 70,272), colorectal (n = 5,822), and pancreatic (n = 1,861) cancers with *ATM, CHEK2*, and *PALB2* pathogenic germline variants (PGVs; please note that this abbreviation will be used throughout the chapter to indicate pathogenic and likely pathogenic germline variants unless otherwise indicated), was assessed and cancer mortality rates were similar for PGV carriers versus genetically tested patients with each cancer type. The study utilized SEER data from California and Georgia for individuals with stage 0-IV breast, colorectal, or pancreatic cancer between 2013 and 2019 with a mean follow-up of 3.9 years. Separate models (random effects model and fixed effects models) were used to calculate hazard ratios for three different breast cancers (estrogen receptor negative/progesterone receptor positive/HER-2 negative; HER2-positive; and triple negative), colorectal, and pancreatic cancers. By the fixed effects models triple-negative breast cancer cases with *ATM* PGVs had a higher mortality (hazard ratio 3.7), but not by random effects models (hazard ratio 1.2). Authors advised caution in inferring generalizability given the data was limited to two states, selection effects for those who received genetic testing, and shorter follow-up for more recently diagnosed cases due to censoring for survival after 2021.
- In a prospective cohort study[2] of 188 adolescents and young adults (AYA; age 39 years and younger) with *CDH1* PGVs, cancer-specific outcomes were not different in individuals with signet ring cell lesions managed with endoscopic surveillance versus those who underwent prophylactic total gastrectomy (PTG). Among the 104 in the surveillance group, occult signet ring cells were detected by endoscopic biopsy in 37 (36%), and none of the individuals who were undergoing surveillance developed an advanced gastric cancer. Of the 67 who underwent PTG, 62 (93%) had occult signet ring cell lesions, compared to 31/65 (48%) with signet ring cell lesions detected on preoperative endoscopy. In the PTG group, one patient had carcinoma in situ and four (6%) had no cancer detected on the gastrectomy specimen. Those who elected to have PTG were more likely to have signet ring cell lesions detected on preoperative endoscopy (P = .025). Given the low prevalence of advanced gastric cancers in this cohort, the authors postulate that AYA with signet ring cell lesions are at risk of overtreatment with PTG and that more research is needed to identify factors influencing the progression of signet ring cell precursors to advanced diffuse-type gastric cancer.
- Data derived from 217,824 participants in the All of Us Research Initiative were reviewed to assess the prevalence and clinical manifestations of Lynch syndrome (LS).[3] A total of 615 carriers (0.3%) of mismatch repair PGVs were identified, that is, 1 in 354 individuals. Analyses to evaluate phenotypic expression were limited to individuals with available medical records (n = 162,970), for which there were 457 individuals with PGVs, with the majority accounted for by *MSH6* and *PMS2*: 10.9% (50/457) in *MLH1*, 8.7% (40/457) in *MSH2*, 35.4% (162/457) in *MSH6*, and 44.8% (205/457) in *PMS2*. Probability of cancer development was time-to-first cancer by genotype, noting carriers of LS PGVs have higher probabilities of developing any cancer as compared noncarriers, but most pronounced for LS-associated cancers. Consistent with the literature, higher probabilities were observed with *MLH1* and *MSH2* as compared to *MSH6* and *PMS2*. Majority of the carriers in this study (up to 63.2%) had no medical records indicating LS, underscoring the need for optimizing the detection and management of individuals with LS discovered on genetic-testing panels. There is a need for optimizing the detection of individuals with LS.

▶ A prospective cohort study[4] to assess the utility of annual non-contrast whole-body MRI for screening in individuals with Li-Fraumeni syndrome (LFS) demonstrated that this modality aids in the detection of asymptomatic localized cancers: 162 individuals with LFS (127 adults, 35 pediatrics) from three academic medical centers in the United States underwent 477 non-contrast whole-body MRIs between 2012 and 2022, with 73% undergoing three or more during the study period. Follow-up studies were carried out for 55.6% of individuals, with rates of follow-up interventions decreasing with consecutive whole-body MRIs. Of the 37 types of cancers diagnosed in 33 individuals, 40.5% were detected by whole-body MRI; and 86% (13/15) were asymptomatic and were treated with curative intent. Authors endorse the use of this screening tool as part of a multimodal approach as recommended by recognized LFS guidelines. Similarly, a large single-center retrospective study[5] evaluating the use of whole-body MRI for adults with LFS reinforced its use[4] as a screening modality as it demonstrated high negative predictive value; 325 whole-body MRIs were performed in 75 adults from January 2012 to January 2024. Of the 325, 112 demonstrated abnormalities, with the majority (89/112) being benign incidental findings (that prompted 53 additional imaging tests) and the remaining 23 were noted to be lesions of concern. Nine of the concerning lesions were ultimately identified to be cancer (eight primary cancers, two metastatic cancers). In addition, eight interval cancers were diagnosed in seven individuals following a normal whole-body MRI scan. As a stand-alone tool, the authors reported whole-body MRI to have 95.5% specificity, 97.4% negative predictive value, and 42.9% sensitivity. While this study supports the continued use of whole-body MRI in this patient population, the authors call for the development of a novel early detection tool (such as cell-free DNA technology) to complement whole-body MRI and/or inform the diagnostic pathway in this population.

OVERVIEW

During the past two decades, the availability of clinical genetic counseling and testing for hereditary cancer predisposition syndromes has had a major impact on the practice of medical and preventive oncology. Recent large studies have shown that up to 13.3% of patients with solid tumors and 17% of patients with recurrent or metastatic cancer have pathogenic germline variants (PGVs).[6,7] In addition, a study from the UK BioBank identified that about 0.7% of the unselected general population have PGVs in *BRCA1, BRCA2*, or a mismatch repair gene associated with Lynch syndrome (LS).[8,9] More recent data from the UK BioBank expanding to a larger number of genes identified PGVs in 3.57% of non-cases across 16 genes, with carrier frequencies of 6.28% for those with at least one cancer and 8.36% for those with multiple primary cancers. The identification of patients with an inherited predisposition to cancer informs targeted treatment decisions and future management for patients and their families and is now one of the core elements of oncologic care. ASCO and other organizations have provided statements and guidelines on genetic testing and management.[10-15]

The goals of this chapter include the following:

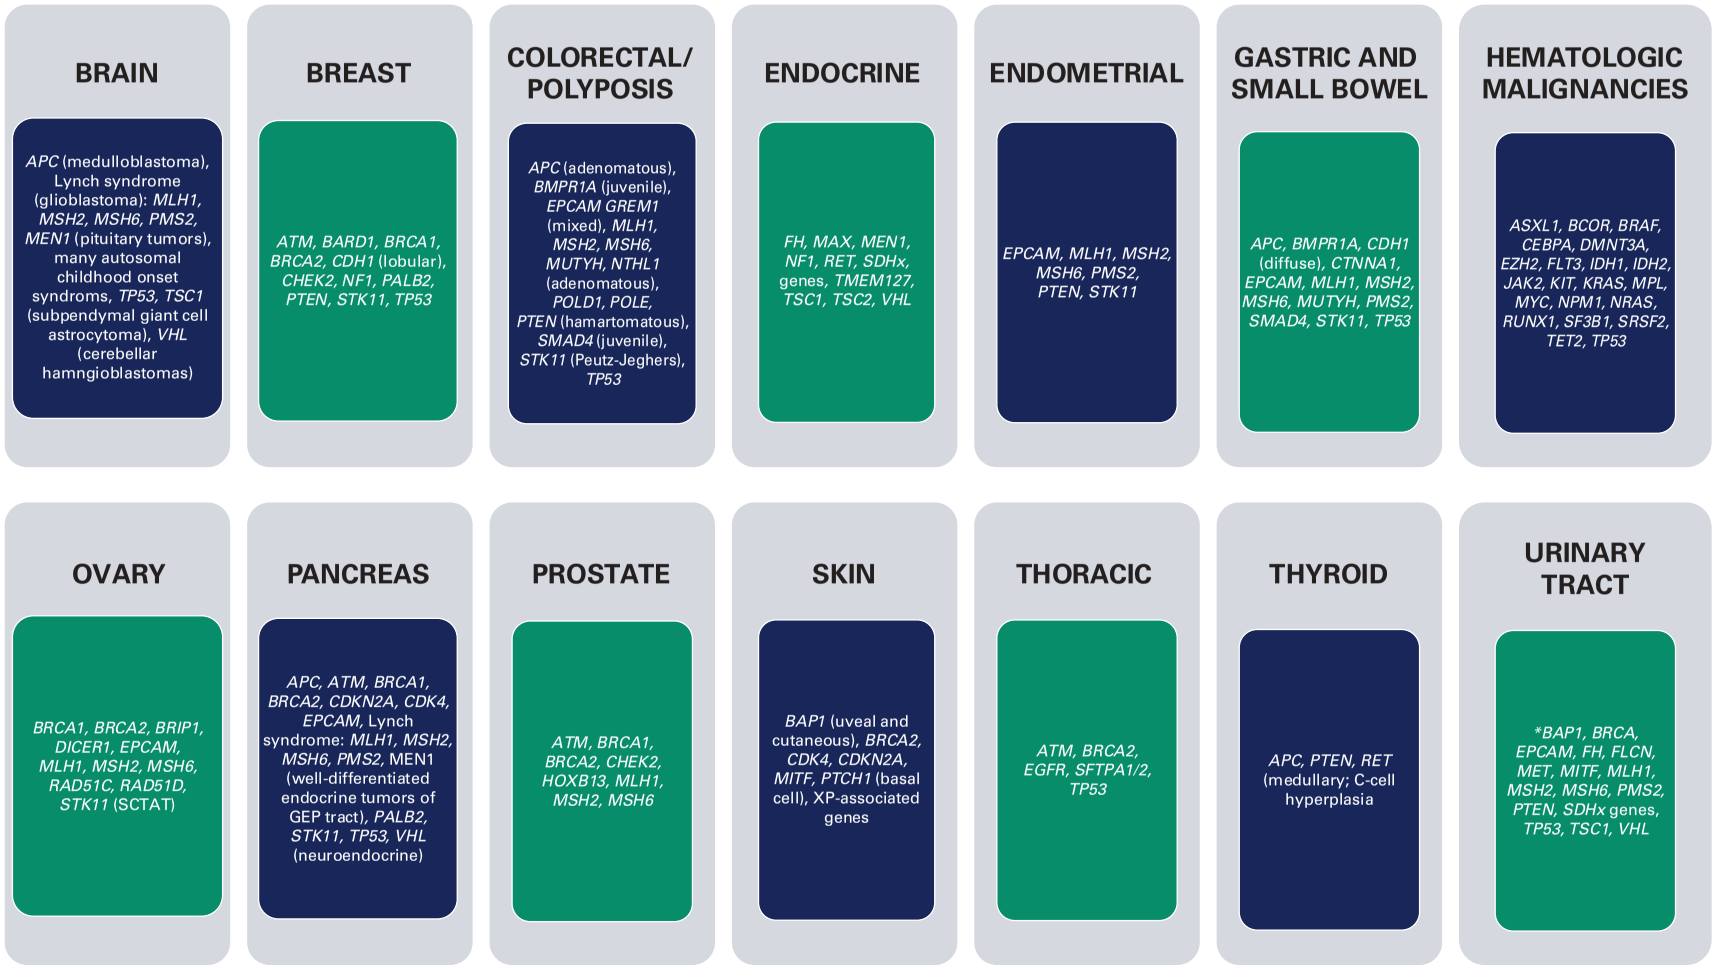
- Review the major principles that guide genetic counseling and testing.
- Highlight the differences between testing and counseling for high- versus moderate-penetrance cancer susceptibility genes.
- Discuss ways of integrating genetic test results into the care of oncology patients.
- Understand the impact of next-generation sequencing (NGS) technologies and tumor biomarker testing on germline analysis.
- Appreciate the ramifications of multigene panel testing for inherited cancer susceptibility and the increased identification of incidental or uncertain genetic findings.
- Recognize the importance of pre- and posttest genetic counseling and relationships with genetic counselors and other genetic specialists.[15,16]

In addition, many of the more common cancer predisposition syndromes are discussed elsewhere, when appropriate. Please refer to the specific chapters for additional information on breast cancer, gastrointestinal cancers, genitourinary cancers, gynecologic cancers, and leukemias (Chapters 10, 13, 14, 15, and 19, respectively).

THE HEREDITARY NATURE OF CANCER

The heritability of cancer has long been recognized, and, through the study of cancer-prone families who demonstrate Mendelian modes of inheritance, more than 100 cancer predisposition genes have been identified.[17] However, only a fraction of the familial risks of cancer is explained by the known high-penetrance cancer predisposition syndromes. For example, in the case of familial breast cancer, 10% of diagnoses are related to high-penetrance PGVs (eg, those of *BRCA1* and *BRCA2*), whereas the remainder are because of moderate-penetrance genes, or multiple factors (eg, additional shared, but currently undetectable or poorly understood, heritable factors, and/or shared environmental factors). Figure 6-1 shows germline PGVs associated with several major tumor types. In addition, Tables 6-1A to D summarize the characteristics of common hereditary cancer syndromes found on multigene panel tests.

Figure 6-1 Cancer Types and Select Associated Genes



Abbreviations: FH, fumarate hydratase, including type 2 papillary, tubular papillary, and collecting-duct carcinoma; FLCN, folliculin, oncocytoma, chromophobe, and oncocytic hybrid tumor; GEP, gastroenteropancreatic; MET, type 1 papillary; SCTAT, sex cord tumors with annular tubules; TSC1, TSC2, renal cell carcinoma, angiomyolipomas, and oncocytoma; XP, xeroderma pigmentosum.
*Urinary tract gene-associated pathologies. Gene-specific pathologies are listed in Tables 6-1A to D.

Table 6-1A **Selected High- and Moderate-Risk Genes, Syndromes, and Management Considerations: A Through C**

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
APC	FAP, AFAP; variant: Turcot syndrome, GAPPS	Colorectal lesions (adenomatous polyposis and cancer), gastric and duodenal/small-bowel lesions (adenomatous polyps and cancer), desmoid tumors, thyroid (particularly cribriform-morula variant of papillary thyroid carcinoma), hepatoblastoma (usually in patients less than 5 years old), pancreatic cancer, medulloblastoma (Turcot syndrome), GAPPS	Colonoscopy (beginning as early as age 10 years) and total colectomy based on polyp burden; upper endoscopy, consideration of small-bowel visualization, thyroid examination, and consideration of ultrasonography; consideration of childhood liver palpation, abdominal ultrasonography, AFP measurement	Genotype-phenotype correlations between classic FAP and AFAP: mutations on the 5′ and 3′ ends of the gene correlate with AFAP; high de novo mutation rate (about 20%-25%); extracolonic features: CHRPE, osteomas, supernumerary teeth, desmoid tumors, epidermoid cysts, gastric fundic gland polyps; chemoprevention not a replacement for colonoscopy and colectomy	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18,19]
*APC**I1307K (c.3920T->A)		Colorectal cancer: moderate penetrance	Colonoscopy every 5 years beginning at age 40 years or earlier depending on family history; lifetime risk 5%-10%	Ashkenazi Jewish founder PGV; not associated with polyposis	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]; Katona et al[20]
ATM	Ataxia telangiectasia	Monoallelic carriers: breast (especially ER-positive), pancreas, possibly ovary, prostate; biallelic carriers: leukemia, lymphoma	Monoallelic carriers: breast screening with annual mammogram at age 40 and breast MRI starting at age 30-35 years or per family history*; pancreas screening beginning at age 50 years (or 10 years prior to earliest exocrine pancreatic cancer in the family); biallelic carriers: AT specialist for multidisciplinary management; consider annual prostate cancer screening at age 40 years	Monoallelic carriers: limited evidence for gastrointestinal cancers; risk of autosomal recessive AT condition in biallelic offspring of heterozygous carriers; AT: childhood cerebellar ataxia, telangiectasias of the conjunctivae, immunodeficiency, sensitivity to radiation	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15,21,22]
AXIN2	AXIN2-associated oligodontia and polyposis	Colorectal lesions (adenomatous polyposis ranging from 10s to 100s and cancer)	Colonoscopy every 2-3 years beginning at age 25-30 years; if polyps are found, every 1 to 2 years with consideration of surgery depending on polyp burden	Patients often also have oligodontia (absence of six or more permanent teeth excluding wisdom teeth) and ectodermal dysplasia	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial and Gastric[18]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
BARD1		ER-negative breast cancer, triple-negative breast cancer	Annual mammogram and consideration of breast MRI starting at age 40 years		NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]
BAP1	*BAP1* tumor predisposition syndrome	Atypical Spitz tumors, uveal melanoma, malignant mesothelioma, cutaneous melanoma, clear cell renal cell carcinoma, basal cell carcinoma	Eye examinations, dermatologic examinations, consideration of abdominal ultrasonography and/or MRI of the kidneys	Limited evidence for possible other associated tumors: non-small cell lung adenocarcinoma, breast cancer, cholangiocarcinoma, meningioma, neuroendocrine carcinoma	NCCN Kidney Cancer,[23] Pilarski et al,[24] Lalloo et al[25]
BMPR1A and *SMAD4*	Juvenile polyposis syndrome	GI lesions (juvenile/hamartomatous polyps and cancer [colorectal, stomach, small bowel])	Colonoscopy and upper endoscopy every 1-3 years beginning at age 12-15 years; surgical management based on polyp burden; HHT screening for *SMAD4* carriers	"Juvenile" refers to polyp histology, not age at onset; *SMAD4* mutations associated with HHT; *SMAD4* PGVs associated with massive gastric polyposis	Haidle et al,[26] NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial and Gastric[18]
BRCA1 and *BRCA2*	Hereditary breast cancer and ovarian cancer syndrome	Breast (*BRCA1*: often triple-negative tumor), male breast, ovarian (epithelial; high-grade serous), fallopian tube, primary peritoneal, prostate (high Gleason score), pancreatic adenocarcinoma	Breast screening with annual mammogram and breast MRI starting at age 25-30 years; male self-examination and clinical breast examination at 35 years; consideration of mammography in males; optional risk-reducing mastectomy in females; risk-reducing BSO between age 35 and 45 years*; PSA measurement and digital rectal examination starting at age 40 years; consideration of chemoprevention (eg, tamoxifen, OCPs); FDA approval of PARP inhibitors for select BRCA-associated breast, ovary, pancreas, prostate cancers; pancreas screening starting at age 50 years or per family history	Founder PGVs in certain populations (eg, Ashkenazi Jewish, Icelandic); risk of autosomal recessive Fanconi anemia with biallelic PGVs	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]
BRIP1		Ovarian (heterozygous carriers)	Consider risk-reducing BSO at age 45-50 years or per family history	Risk of autosomal recessive Fanconi anemia in biallelic offspring of heterozygous carriers	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]

Abbreviations: AFAP, attenuated familial adenomatous polyposis; AFP, alpha-fetoprotein; AT, ataxia telangiectasia; BSO, bilateral salpingo-oophorectomy; CHRPE, congenital hypertrophy of the retinal pigment epithelium; ER, estrogen receptor; FAP, familial adenomatous polyposis; GAPPS, gastric polyposis with APC promoter 1b mutations; HHT, hereditary hemorrhagic telangiectasia; OCP, oral contraceptive pills; PARP, poly ADP ribose polymerase; PGV, pathogenic germline variants; PSA, prostate-specific antigen.

Leukemia/lymphoma predisposition syndromes are not listed; refer to Chapters 19 and 20. Most childhood-onset conditions are not listed; refer to Lindor et al.[27]

*Earlier initiation of breast cancer surveillance should be determined based on personal/family history of breast cancer.[15]

Table 6-1B **Selected High- and Moderate-Risk Genes, Syndromes, and Management Considerations: C Through G**

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
CDH1	Hereditary diffuse gastric cancer syndrome	Diffuse gastric cancer, lobular breast cancer (ER-positive)	A strategy of surveillance upper endoscopy with biopsies of the stomach, consideration of risk-reducing total gastrectomy, breast screening with annual mammography and breast MRI at 30, optional risk-reducing mastectomy	Can manifest as cleft palate	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15,19]
CDKN2A, CDK4	FAMMM syndrome	Melanoma and dysplastic nevi, pancreatic adenocarcinoma	Dermatologic examination, pancreas screening recommended beginning at age 40 years*	Risk of melanoma may be independent of genetic test result; *CDKN2A* (p16) founder PGV in the Netherlands; PGVs affecting p14ARF are associated with a different spectrum of tumors, including melanoma, sarcomas, nervous system tumors, and possibly breast cancer; consider full-body MRI and brain MRI for those with p14ARF PGVs	Goldstein et al,[28] Vasen et al,[29] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostates[15]
CHEK2		Breast cancer	For truncating pathogenic variants, breast screening with annual mammography at age 40 years and breast MRI starting at age 30-35 years, or per family history. Consider prostate cancer screening starting at age 40	Genotype-phenotype: different risks for truncating mutations versus missense mutations; Limited evidence for association with prostate, thyroid, and renal cancers, possibly leukemia and plasma cell neoplasms	Zeng et al,[30] Hanson et al,[31] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostates,[15] AlDubayan et al[32]
CHEK2 (low penetrance, including I157T/470T>C; S428F/ c.1283C>T; and T476M/ c.1427C>T)		Breast cancer; possibly leukemia and plasma cell neoplasms	Low-penetrance missense CHEK2 variants may not be actionable. Studies demonstrate the lifetime breast cancer risk is less than 20%. Management recommendations should be based on clinical assessment and family history	Genotype-phenotype: different risks for truncating mutations vs missense mutations; limited evidence for association with prostate, thyroid, and renal cancers	Zeng et al,[30] Hanson et al,[31] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreas,[15] AlDubayan et al[32]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
FH	HLRCC	Cutaneous leiomyomata, uterine leiomyomata, renal tumors (type 2 papillary, tubule-papillary, collecting-duct carcinomas; unilateral, solitary lesions); rare paraganglioma/ pheochromocytoma	Dermatologic and gynecologic examinations; evaluate for changes suggestive of leiomyosarcoma; medication or resection of leiomyomata, imaging for and surgical management of renal tumors; abdominal MRI (preferred) or CT, both exams with and without IV contrast, annually starting at age 8-10 years and performed every 3 years	FH enzyme assay might be helpful in some situations. Risk for uterine leiomyosarcoma is unclear. Biallelic FH PGVs cause a recessive disorder known as FH deficiency metabolic disorder, profound developmental delay, seizures, and fumaric aciduria	Kamihara et al,[33] Barrisford et al,[34] NCCN Kidney Cancer
FLCN	BHD syndrome	Benign cutaneous findings (fibrofolliculomas, trichodiscomas/ angiofibromas, perifollicular fibromas, acrochordons), pulmonary cysts, renal tumors (oncocytoma, chromophobe, oncocytic hybrid tumors)	No consensus at this time. Dermatologic care, imaging for and surgical management (nephron sparing) of renal tumors	Fibrofolliculomas are specific to BHD. Predisposition to multiple lung cysts may present as spontaneous pneumothorax. Renal tumors are multifocal, bilateral, and slow growing. Other features include parotid lesions, oral papules, and thyroid lesions. Data are unclear regarding colon cancer. There are possible genotype/phenotype correlations	van de Beek et al,[35] Sattler and Steinlein,[36] NCCN Kidney Cancer
GREM1	Hereditary mixed polyposis syndrome	Multiple polyps of multiple and mixed morphologies, including serrated lesions, Peutz-Jeghers polyps, juvenile polyps, conventional adenomas and colorectal adenocarcinoma	Colonoscopy every 2-3 years beginning at age 25-30 years unless polyps are found; consider total colectomy based on polyp burden	Founder PGV in Ashkenazi Jewish individuals; duplication spanning the 3′ end of the SCG5 gene and a region upstream of the *GREM1* locus	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]

Abbreviations: BHD, Birt-Hogg-Dube; ER, estrogen receptor; FAMMM, familial atypical mole melanoma syndrome; FH, fumarate hydratase; HLRCC, hereditary leiomyomatosis and renal cell cancer; IV, intravenous; OCP, oral contraceptive pills; PGV, pathogenic germline variants.

Leukemia/lymphoma predisposition syndromes are not listed; refer to Chapters 19 and 20. Most childhood-onset conditions are not listed; refer to Lindor et al.[27]

*Earlier initiation of breast cancer surveillance should be determined based on personal/family history of breast cancer.[15]

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 6-1C **Selected High- and Moderate-Risk Genes, Syndromes, and Management Considerations: M Through P**

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
MBD4	*MBD4*-associated neoplasia syndrome or *MBD4* biallelic PGVs	Colorectal polyposis, AML, uveal melanoma	Colonoscopy every 2-3 years starting at age 18-20 years, consider CBC at diagnosis, ophthalmology exam at diagnosis and annually	Unknown risks for heterozygous carriers	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
MEN1	MEN-1	GEP tract, well-differentiated endocrine tumors, pituitary tumors (prolactinoma), parathyroid tumors, carcinoid tumors, adrenocortical tumors	Biochemical testing with emphasis on pancreatic and pituitary hormones and calcium, imaging of chest and abdomen every 1-3 years starting at age 8-15 years, brain MRI every 3-5 years starting at age 5 years, medical management of endocrinopathies, parathyroidectomy in setting of hyperparathyroidism	Primary hyperparathyroidism, hypercalcemia, oligomenorrhea/amenorrhea, galactorrhea, Zollinger-Ellison syndrome (gastrinoma), insulinoma, glucagonoma, VIP-secreting tumor (VIPomas); other features: skin (angiofibromas, collagenomas), lipomas, CNS lesions (meningioma, ependymoma), leiomyomas	Giusti et al[37] and NCCN Neuroendocrine and Adrenal Tumors[38]
MET (*c-MET*)	HPRC	Papillary renal cancer (multifocal, bilateral, type 1 papillary)	Imaging, surgical management		Coleman and Russo,[39] NCCN Kidney Cancer[40]
MLH1/MSH2/MSH6/PMS2/EPCAM	Lynch syndrome (formerly, HNPCC); variant: Muir-Torre syndrome; variant: Turcot syndrome; variant: CMMR-D syndrome (biallelic PGVs; recessive inheritance)	Colorectal, endometrial ovarian (epithelial), stomach, small bowel, urothelial, pancreas, hepatobiliary tract, sebaceous neoplasms of the skin (Muir-Torre syndrome), glioblastoma (Turcot syndrome), prostate	Colonoscopy every 1-2 years starting at age 20-25 years* (*MLH1* and *MSH2*) or every 1-3 years starting at age 30-35 years* (*MSH6* and *PMS2*); hysterectomy, and risk-reducing BSO (*MLH1, MSH2*) insufficient evidence and decision for risk-reducing hysterectomy and BSO for *MSH6* should be individualized); endometrial biopsy every 1-2 years starting at age 30-35 years can be considered upper endoscopy every 2-4 years starting at age 30-40 years; consideration of urinalysis or urine cytology, consider skin exam every 1-2 years (age to start surveillance can be individualized), and aspirin for chemoprevention (optimal dose to be determined); except for *PMS2*, pancreas screening starting at age 50 years or earlier if there is a family history of pancreatic cancer in a first- or second-degree relative; consider annual prostate cancer screening at age 40 years	Tumor analyses with IHC staining, MSI analysis, somatic tumor genetic analysis, *BRAF* V600E somatic analysis, MLH1 promoter hypermethylation analysis; Amsterdam criteria I and II, revised Bethesda guidelines; recommendations for universal screening of colorectal and endometrial cancers; risk of autosomal recessive CMMR-D syndrome (cafe-au-lait macules, solid tumors, hematologic cancers) in offspring	NCCN Genetic/Familial High-Risk Assessment: Colorectal[18]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
MLH3/MSH3	*MLH3*-and *MSH3*-associated polyposis	Biallelic PGV carriers: colorectal lesions (adenomatous polyposis and cancer); recently discovered so unclear	Colonoscopy every 2-3 years beginning at age 25-30 years unless polyps; consider total colectomy based on polyp burden	*MSH3* tumors exhibit EMAST (MSI of di- and tetranucleotide repeats); *MLH3* tumors did not	Olkinuora et al,[41] NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
MUTYH	MAP	Biallelic PGV carriers: colorectal lesions (adenomatous polyposis and cancer; serrated and hyperplastic polyps also described), stomach, duodenal lesions (adenomatous polyps, cancer)	Colonoscopy every 1-2 years, starting at age 25-30 years; consider total colectomy based on polyp burden; upper endoscopy beginning at age 30-35 years	Phenotypically similar to AFAP; two northern European founder PGVs; no increased colorectal cancer risk in heterozygous carriers	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
NF1	Neurofibromatosis type 1	Cutaneous neurofibromas, plexiform neurofibromas, optic nerve and other CNS gliomas, malignant peripheral nerve sheath tumors, breast (moderate risk), others: GIST, leukemia, paraganglioma/ pheochromocytoma	Neurofibromatosis type 1 specialist for management, physical and ophthalmologic examinations; imaging; surgical management; breast screening with annual mammography starting at age 30 years and breast MRI from ages 30-50 years, per family history*	Cafe-au-lait macules, axillary and inguinal freckling, iris Lisch nodules, learning disabilities, scoliosis, tibial dysplasia, vasculopathy	Friedman,[42] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostates[15]
NTHL1	*NTHL1*-associated polyposis	Biallelic PGV carriers: colorectal lesions (less than 50 adenomatous polyps and cancer)	Colonoscopy every 2-3 years beginning at age 25-30 years unless polyps; consider total colectomy based on polyp burden; EGD at age 30-35 years every 1-4 years based on findings; education regarding importance of prompt reporting of any abnormal uterine bleeding or postmenopausal bleeding; no other screening recommendations have been made to date for breast or the other extracolonic cancers	c.268c>T (p.GIn90*) variant is the most common truncating PGV and has higher prevalence in European cohorts. Tumors have mutation signature (COSMIC Signature 30). There are possible increased risks for breast, endometrial, basal cell, hematologic and cervical cancers, meningioma and bladder tumors	Grolleman et al,[43] NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
PALB2		Breast cancer (particularly ER-positive), ovarian cancer, pancreatic cancer	Breast screening with annual mammogram and breast MRI with and without contrast starting at age 30; optional risk-reducing mastectomy in females; consideration of risk-reducing BSO between age 45 and 50 years. Pancreatic surveillance may be considered with or without family history of pancreatic cancer. Consider prostate cancer screening starting at age 40	Risk of autosomal recessive Fanconi anemia in biallelic offspring of heterozygous parents	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
POLE/POLD1	Polymerase proofreading-associated polyposis	Colorectal lesions (attenuated adenomatous polyposis and cancer), duodenal (adenomas and cancer), endometrial cancer	Colonoscopy every 2-3 years beginning at age 25-30 years unless polyps; consider total colectomy based on polyp burden; baseline upper endoscopy beginning at age 25-30 years; education regarding importance of prompt reporting of any abnormal uterine bleeding or postmenopausal bleeding	Two recurrent PGVs have been identified: *POLE* p.L424V and *POLD1* p.S478N. Nearly all the described PGVs are activating mutations in the exonuclease domain. It is probably associated with brain tumors and possibly endometrial and breast cancers	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
PTCH1 *SUFU*	Gorlin syndrome/ nevoid basal cell carcinoma syndrome	Jaw (odontogenic) keratocysts, basal cell carcinomas, medulloblastoma PNET desmoplastic	Referral to a specialist for management; physical examination, avoidance of sun exposure and at least annual dermatologic examination, surgical management	Other features: congenital skeletal anomalies, cleft lip/palate, cerebral/falx calcifications, macrocephaly with frontal bossing, polydactyly, intellectual disability, lymphomesenteric or pleural cysts, palmar/ plantar pits, cardiac fibromas, ovarian fibromas, ocular abnormalities	Evans and Farndon[44] and Foulkes et al[45]
PTEN	Cowden syndrome/PTEN hamartoma tumor syndrome	Breast cancer, thyroid cancer (most often follicular), endometrial cancer, colorectal lesions (hamartomas, ganglioneuromas, cancer), renal cell carcinoma	Annual thyroid examination and ultrasonography starting at age 12 years, endometrial screening with random biopsy and ultrasonography starting at age 35 years, optional hysterectomy, colonoscopy every 5 years beginning at age 35 years unless polyps, renal ultrasonogram every 1-2 years starting at age 40 years	Major and minor criteria (tumors, physical and dermatologic/ mucocutaneous findings, developmental disability); macrocephaly, Bannayan-Riley-Ruvalcaba syndrome, PTEN-related *Proteus* syndrome, autism spectrum disorder, Lhermitte-Duclos disease	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]

Abbreviations: AFAP, attenuated familial adenomatous polyposis; AML, acute myeloid leukemia; BSO, bilateral salpingo-oophorectomy; CBC, complete blood count; CMMR-D, constitutional mismatch repair deficiency; CNS, central nervous system; EGD, esophagogastroduodenoscopy; EMAST, elevated microsatellite alterations at selected tetranucleotides; GEP, gastroenteropancreatic; GIST, gastrointestinal stromal tumor; HNPCC, hereditary nonpolyposis colorectal cancer; HPRC, hereditary papillary renal carcinoma; IHC, immunohistochemistry; MAP, MUTYH-associated polyposis; *MEN-1*, multiple endocrine neoplasia type 1; MEN1, menin 1; MSI, microsatellite instability; NF1, neurofibromin 1; PGV, pathogenic germline variants; PNET, primitive neuroectodermal tumors; VIP, vasoactive intestinal peptide.

Leukemia/lymphoma predisposition syndromes are not listed; refer to Chapters 19 and 20. Most childhood-onset conditions are not listed; refer to Lindor et al.[27]

*Earlier initiation of breast cancer surveillance should be determined based on personal/family history of breast cancer.[15]

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 6-1D **Selected High- and Moderate-Risk Genes, Syndromes, and Management Considerations: R Through V**

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
RAD51C		ER-negative breast cancer, triple-negative breast cancer, ovarian cancer	Annual mammogram and consideration of breast MRI starting at age 40 years; risk-reducing salpingo-oophorectomy at age 45-50 years	Risk of autosomal recessive Fanconi anemia	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]
RAD51D		Breast cancer, ovarian cancer	Annual mammogram and consideration of breast MRI starting at age 40 years; risk-reducing salpingo-oophorectomy at age 45-50 years		NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]
RB1	Retinoblastoma	Retinoblastoma (trilateral disease: cooccurrence of pinealoblastoma), bone or soft-tissue sarcomas, melanoma, others	Ophthalmologic examination and imaging; care by a multidisciplinary team; avoidance of radiation	Usually bilateral or multifocal disease; mosaic forms; therefore, analysis of tumor tissue and blood is important; RNA studies may also be recommended; low-penetrance mutations identified; parent-of origin effect in some families	Lohmann and Gallie,[46] Knudsen,[47] Abramson et al,[48] and Abramson and Frank[49]
RET	MEN-2; three subtypes: MEN-2A (aka, Sipple syndrome), familial medullary thyroid carcinoma, MEN-2B	Medullary thyroid carcinoma (multifocal, bilateral) and primary C-cell hyperplasia, pheochromocytoma (bilateral) (MEN-2A and 2B), parathyroid adenoma/hyperplasia (hyperparathyroidism, hypercalcemia, renal stones; MEN-2A)	Prophylactic thyroidectomy (varies from infancy to age 5 years, depending on specific *RET* PGV; genotype-phenotype correlations); surgical management of identified disease, serum calcitonin concentration, consideration of eligibility for treatment with kinase inhibitors, biochemical screening and imaging for pheochromocytoma and parathyroid abnormalities	Genotype-phenotype correlations MEN-2A: MTC in early adulthood; FMTC: MTC in middle age; MEN-2B: MTC in early childhood, mucosal neuromas (lips, tongue), dysmorphic features (large lips, "marfanoid" body habitus), GI ganglioneuromatosis; *RET* gene loss of function PGVs also associated with Hirschsprung disease	Eng and Plitt[50] and Wells et al[51]
SDHB/ SHDC/ SDHD/ SDHA/ SDHAF2, MAX, TMEM127	Hereditary paraganglioma/ pheochromo-cytoma syndrome	PGL-sympathetic and parasympathetic PCC, GISTs, renal clear cell carcinoma, and other less well-defined cancer risks such as papillary thyroid carcinoma	*SDHA* appears to have lower penetrance than other SDHx PGVs; screening in this population such as plasma-free fractionated metanephrines or 24-hour urine fractionated metanephrines (optional dopamine or 3-methoxytyramine) to screen for secreting PGL/PCC and whole-body MRI for PGL, PCC, renal cell carcinoma, and GIST is controversial because of conflicting guidelines	Secretory and nonsecretory PGL, high blood pressure, headache, anxiety, profuse sweating, palpitations, pallor; *SDHB*: high risk of malignant transformation; *SDHD*: parent-of-origin effect, disease-causing when paternally inherited; *SDHAF2*: possible parent-of-origin effect (paternal inheritance)	Hanson et al[52] and Amar et al[53]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
STK11 (LKB1)	PJS	GI lesions (PJS-type hamartomatous polyps; colorectal, stomach, small-bowel cancer), breast, pancreas, gynecologic (ovarian SCTAT sex cord tumor with annual tubules), cervix (minimum deviation adenocarcinoma), uterus, testes (Sertoli cell), lung	Colonoscopy and upper endoscopy with small-bowel visualization every 2-3 years beginning at about age 18 years, breast screening with annual mammography and breast MRI beginning at age 30, pancreas screening beginning at about age 30-35 years, gynecologic examination and annual pelvic ultrasonogram beginning at about age 18-20 years, annual testicular examination, including in the pediatric setting	Mucocutaneous hyperpigmentation of mouth, lips, nose, eyes, genitalia, fingers; may fade after puberty	McGarrity et al,[54] NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric,[18] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate
TP53	LFS	Soft tissue and bone sarcomas, breast cancer, brain cancer, adrenocortical carcinoma, leukemia, other cancers (GI, genitourinary, lung, lymphomas, thyroid, neuroblastoma, skin)	Screening beginning in childhood with comprehensive physical exam including neurological exam and CBC with differential every 3-4 months until age 18 years; annual full-body and brain MRI; ultrasound abdomen and pelvis every 3-4 months; blood biochemistry if unsatisfactory ultrasound quality; in adults (18 years or older), comprehensive physical exam every 6 months, ultrasound of the abdomen and dermatologic exam annually; blood biochemistry if unsatisfactory ultrasound quality; breast screening with annual breast MRI and mammography beginning at age 20 and 30 years, respectively; consideration of risk-reducing mastectomy; CBC with differential every 3-6 months in patients with prior cytotoxic chemotherapy or radiation exposures; physical examination, including dermatologic and neurologic examinations; pancreatic surveillance if an affected close relative; colonoscopy and upper endoscopy every 2-5 years starting at age 25 years; annual whole-body MRI with brain MRI, consideration of radiation avoidance, if clinically appropriate	Classic LFS criteria; Chompret criteria; consider genetic testing in *BRCA*-negative, isolated, early-onset breast cancer (age less than 31 years); breast cancers more likely to be ER, progesterone receptor, and HER2/neu receptor positive; consider additional *TP53* variant workup for individuals with variant allele fraction below heterozygous range (typically <30%) and/or in when LFS clinical criteria are not met	Schneider et al,[55] Li and Fraumeni,[56] Chompret et al,[57] Villani et al,[58] Kratz et al,[59] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreatic and Prostate[15] and Achatz et al[60]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
TSC1 and *TSC2*	TSC	Kidney: renal cell carcinomas, angiomyolipomas (benign and malignant), epithelial cysts, oncocytoma (benign adenomatous hamartoma)	TSC specialist for management: imaging; dermatologic, dental, ophthalmologic examinations; echocardiography; electrocardiography; consideration of eligibility for treatment with mTOR inhibitors, surgical management	Skin (hypomelanotic macules, facial angiofibromas, shagreen patches, cephalic plaques, ungual fibromas); brain (cortical dysplasias, subependymal nodules and subependymal giant cell astrocytomas, seizures, intellectual disability/developmental delay, autism spectrum disorder, psychiatric illness); heart (rhabdomyomas, arrhythmias); lungs (lymphangioleiomyomatosis); genotype-phenotype correlations: higher risk of renal cell carcinoma in TSC2; possible association with neuroendocrine tumors	Northrup et al[61] and NCCN Kidney Cancer[23]
VHL	VHL syndrome	Clear cell renal cell carcinoma, pheochromocytoma, paragangliomas, pancreatic neuroendocrine tumors	Biochemical screening, imaging of the abdomen and CNS, renal sparing management of kidney cancers; consideration of belzutifan for prevention	Hemangioblastomas of the brain, spinal cord, and retina; renal cysts; pancreatic cysts; endolymphatic sac tumors; epididymal and broad ligament cysts; genotype-phenotype correlations: VHL type 1, type 2A, type 2B, type 2C with different risks of pheochromocytoma or renal cell carcinoma	Van Leeuwaarde et al[62] and NCCN Kidney Cancer[23]

Abbreviations: CNS, central nervous system; ER, estrogen receptor; FMTC, familial medullary thyroid carcinoma; GI, gastrointestinal; GIST, gastrointestinal stromal tumor; LFS, Li-Fraumeni syndrome; MEN-2, multiple endocrine neoplasia type 2; mTOR, mechanistic target of rapamycin; NF1, neurofibromin 1; PCC, pheochromocytoma; PGL, paraganglioma; PGV, pathogenic germline variants; PJS, Peutz-Jeghers syndrome; SCTAT, sex cord tumors with annular tubules; TSC, tuberous sclerosis complex; VHL, von Hippel-Lindau.
Leukemia/lymphoma predisposition syndromes are not listed; refer to Chapters 19 and 20. Most childhood-onset conditions are not listed; refer to Lindor et al.[27]

Outside the high-penetrance syndromes, shared heritable factors present in some families may include PGVs in moderate-penetrance genes and single nucleotide polymorphisms (SNPs).[15,63,64] Dozens of moderate-penetrance genes whose PGVs generally confer a modest degree of cancer risk with a relative risk of 2–5 have been identified. Although genetic testing for PGVs in such moderate-penetrance genes was not routinely undertaken in the past, with NGS and commercial multigene panel analyses, clinical evaluation of these genes has now become common. However, the value of testing for PGVs in some moderate-penetrance genes remains unproven because neither the clinical validity (ie, the accuracy with which a genetic test predicts the development of cancer) nor the clinical utility (ie, the degree to which the use of the genetic test informs clinical decision-making and leads to improved health outcomes) has been clearly proven.[15]

Reliable data about cancer risks (ie, disease penetrance) may help inform medical management; however, current risk estimates for *BRCA1* and *BRCA2* may not apply to PGV carriers in the general population because of selection bias in historical research designs, which commonly included only the highest-risk families.[65] Expanded multigene platforms and broader testing criteria have enabled increased identification of patients with inherited risk factors and allow for emerging genotype-phenotype associations and cancer risk/penetrance estimates.

Expert groups like the NCCN and American College of Medical Genetics and Genomics have guidelines for practitioners to institute intensive screening and other prevention measures in patients with PGVs in moderate-penetrance genes, including genotype-specific considerations with regards to *CHEK2* and *ATM*.[15,21,31] Cancer risk estimates and management recommendations for high- and moderate-penetrance genes are updated continuously.

Through genome-wide association studies, hundreds of additional low-penetrance genetic loci, usually in the form of SNPs, have been identified for nearly all the common malignancies. These low-penetrance loci are often associated with only a slight increase in risk of cancer (relative risk, approximately 1.1-1.5) and are largely derived from individuals of European ancestry.[66] Given the limited clinical validity and utility of SNPs with such small effect sizes, clinical testing for individual risk loci is not routinely performed, although research efforts are underway to incorporate low-penetrance risk alleles into models for risk stratification for public health programs and cancer screening, which may eventually make this feasible.[67] Some commercial laboratories now include polygenic risk scores using cancer risk SNPs in their test results for select patient populations, creating some controversy because their clinical validity and utility have not been demonstrated in prospective trials, and they may be primarily derived from testing in those of European ancestry at present. Additional work is ongoing to validate scores for other populations.[25]

KEY POINTS

- High-penetrance cancer predisposition genes account for up to 10%-20% of all cancer diagnoses.
- Familial risks outside the high-penetrance syndromes may be related to moderate-risk alleles and additional shared hereditable and/or environmental factors. Empiric risk assessment to account for familial risk may be indicated.
- Consider clinical validity and utility of genes when selecting a multigene panel.
- Inclusion of moderate-penetrance genes associated with a two- to fivefold increased risk of specific cancers is commonplace for panel testing.
- Cancer risk estimates and management recommendations for high- and moderate-penetrance genes are updated continuously.

GENETIC COUNSELING

The National Society of Genetic Counselors (NSGC) has defined genetic counseling as the "process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease."[68] The traditional model of genetic counseling for hereditary cancer syndromes includes pre- and posttest consultations with a genetic counselor, sometimes in conjunction with a gastroenterologist, surgeon, medical oncologist, advanced practice provider, and/or a geneticist. However, because of increases in the volume of patients who meet criteria for germline genetic testing, expanded pathways for testing and service delivery are emerging:

- Telemedicine, video, and telephone-based methods
- Genetic-testing stations in clinic, manned by personnel such as genetic counseling assistants[69,70]
- Group counseling and testing
- Genetic counseling provided by other practitioners, such as nurse counselors and oncologists, in the context of coordinated patient care[13]
- Genomic testing of oncology patients through NGS analyses of tumor, and sometimes nontumor, specimens for the purpose of clinical trial eligibility and guiding treatment decisions

GENETICS IN MEDICAL ONCOLOGY PRACTICE

Historically, the role of the medical oncologist in germline testing has been primarily to obtain family histories and identify patients appropriate for referral for genetic evaluation. However, increasing indications for germline testing, the relative shortage

of genetics providers, and the findings of potential germline results on somatic tumor testing are combining to bring germline testing into the medical oncologist's practice. Multiple studies have been conducted for "mainstreaming" of germline testing, which often consists of testing being ordered in the setting of the oncology visit (sometimes referred to as "point-of-care" testing) and genetics professionals reviewing results and consulting as needed for positive or complex results.[71-73] Marked reductions in time to testing and time to results have been reported with this approach.[74,75] Although this model seems to be acceptable in most cases, shortcomings such as the need for additional physician education[76,77] and lack of cascade testing for relatives of those with an identified PGV have also been identified.[78] Non-genetics professionals may not obtain sufficient informed consent from patients in this setting,[79] and testing of family members and prevention screening practices specific to a given germline variant may not be within the scope of many oncology practices and may require referral for longitudinal follow-up in a high-risk genetics clinic. In addition, oncology clinics may not have processes in place to notify patients or families about reclassifications of variants of uncertain significance (VUSs). Considering these issues, alternative models for large-scale germline testing continue to be under investigation to provide these essential components of care for oncology patients and their families.

Resources to find genetic specialists include the NSGC (www.findageneticcounselor.com) and the American Board of Genetic Counseling (https://abgc.learningbuilder.com/Search/Public/MemberRole/Verification). Resources to learn more about cancer genetics and risk assessment include the ASCO Education Cancer Genetics Program, the NSGC, and the National Human Genome Research Institute.

Regardless of which clinician provides genetic risk assessment, the principles of genetic counseling should be at the foundation of the patient interaction.

PRETEST GENETIC COUNSELING

Pretest genetic counseling traditionally includes the following:

- A complete medical history (personal and family history and pertinent physical exam findings) with personalized discussions of prior genetic testing
- Data analysis and risk assessment
- Education regarding differential diagnoses and genes
- Discussion of testing options and the likelihood of different testing outcomes, followed by selection of appropriate analyses and laboratories and informing patients about accuracy/limitations, costs, expected turnaround time for results, and alternatives to testing
- Discussion of the potential test implications in the context of that family history, including the risks, benefits, and limitations of genetic testing
- Exploration of the medical, psychosocial, familial, and possible financial consequences of testing

Pretest informed consent is always a vital step in helping patients and families determine whether genetic testing (and what extent of testing) is right for them.[80] Some states require informed consent before genetic testing (eg, New York),[13,81] and pretest genetic counseling is one of the ways to fulfill this requirement. To meet clinical guidelines, which recommend universal testing for an expanding number of cancers, pretest education using a short (<10 minutes) video, ideally in close collaboration with genetics professionals to provide results disclosure and posttest counseling/risk assessment, may be another acceptable way to communicate the essential elements for pretest informed consent. In a randomized study of prostate patients with cancer receiving genetic testing using a custom 67-gene panel with results disclosure by a genetics professional, no statistically significant differences were observed between the pretest video education arm and the standard pretest genetic counseling arm in terms of genetic testing uptake, genetics knowledge, and family communication, despite a possible trend in favor of standard pretest genetic counseling with regard to satisfaction and psychological impact.[82] Similarly, the MAGENTA study demonstrated that there were no significant differences in posttest distress (anxiety, depression, or decisional regret) for those who had pretest genetic counseling and those who did not have pretest genetic counseling (although it is important to note that the absence of counseling is distinct from informed consent). The MAGENTA study also showed that there was no difference in distress for those without PGV in whom posttest counseling was omitted.[83]

The collection of family history is an important part of genetic cancer risk assessments and may be performed as part of an initial patient consultation for many oncology patients. The recommended key elements for a minimum adequate cancer family history are highlighted in an ASCO expert statement and should help oncologists to identify patients who would benefit from referral to clinical cancer genetics specialists.[84] These key elements include information on the following:

- First-degree relatives: siblings, parents, children
- Second-degree relatives: grandparents, aunts, uncles, grandchildren, nieces, nephews, half-siblings
- Both maternal and paternal sides of the family
- Ethnicity
- Current ages or ages at death

- Consanguineous relationships
- For each cancer case in the family, establish the following:
  - Age at cancer diagnosis
  - Type of primary cancer (organ, histology and relevant histology features if known, bilaterality)
  - Results of any cancer predisposition testing in any relative

Particularly, it is standard to evaluate at least three generations of a patient's maternal and paternal lineages. Family history should be taken at diagnosis and updated periodically.

In addition, individuals of certain ancestries may have higher risks for specific hereditary syndromes because of the presence of founder PGV, such as the common *BRCA1* (c.68_69delT and c.5266dupC) and *BRCA2* (c.5946delT) founder PGV in the Ashkenazi Jewish population (carrier rate 1:40)[85]; therefore, the knowledge of Ashkenazi Jewish ancestral background may have an impact on testing eligibility and risk assessment. Finally, family structures may be truncated for a variety of reasons (see below), so threshold of when to offer germline genetic testing may be lower among individuals with limited female family structure.

Reasons for truncated family history could include the following:

- Number of births and miscarriages or terminations
- Sex (a paucity of female family members may explain a lack of gynecologic cancers)
- Adoption, divorce, early death from noncancer causes, or estrangement
- Sperm or egg donation

Selecting an ideal DNA source and test methodology are important considerations before genetic testing is ordered. A modestly improved PGV detection rate has been recognized through use of multigene panels that combine DNA and RNA analyses, which requires use of a blood specimen.[86,87] Furthermore, blood- or saliva-based testing is not typically ideal for patients with certain hematologic malignancies; a tissue sample may be required to avoid false-negative or false-positive results in those with leukemia or lymphoma, or those with mosaic results on blood- or saliva-based testing.

POSTTEST GENETIC COUNSELING

Elements of posttest genetic counseling include the following:

- Disclosure and interpretation of test results
- Education about medical risks and management options (screening, risk reduction, therapeutic implications), including appropriate referrals and resources
- Investigation of the psychological reaction and familial repercussions related to the test results, and an opportunity for the clinician to provide emotional support to the patient and family
- Planning for communication of the genetic test results and implications to at-risk family members[88]

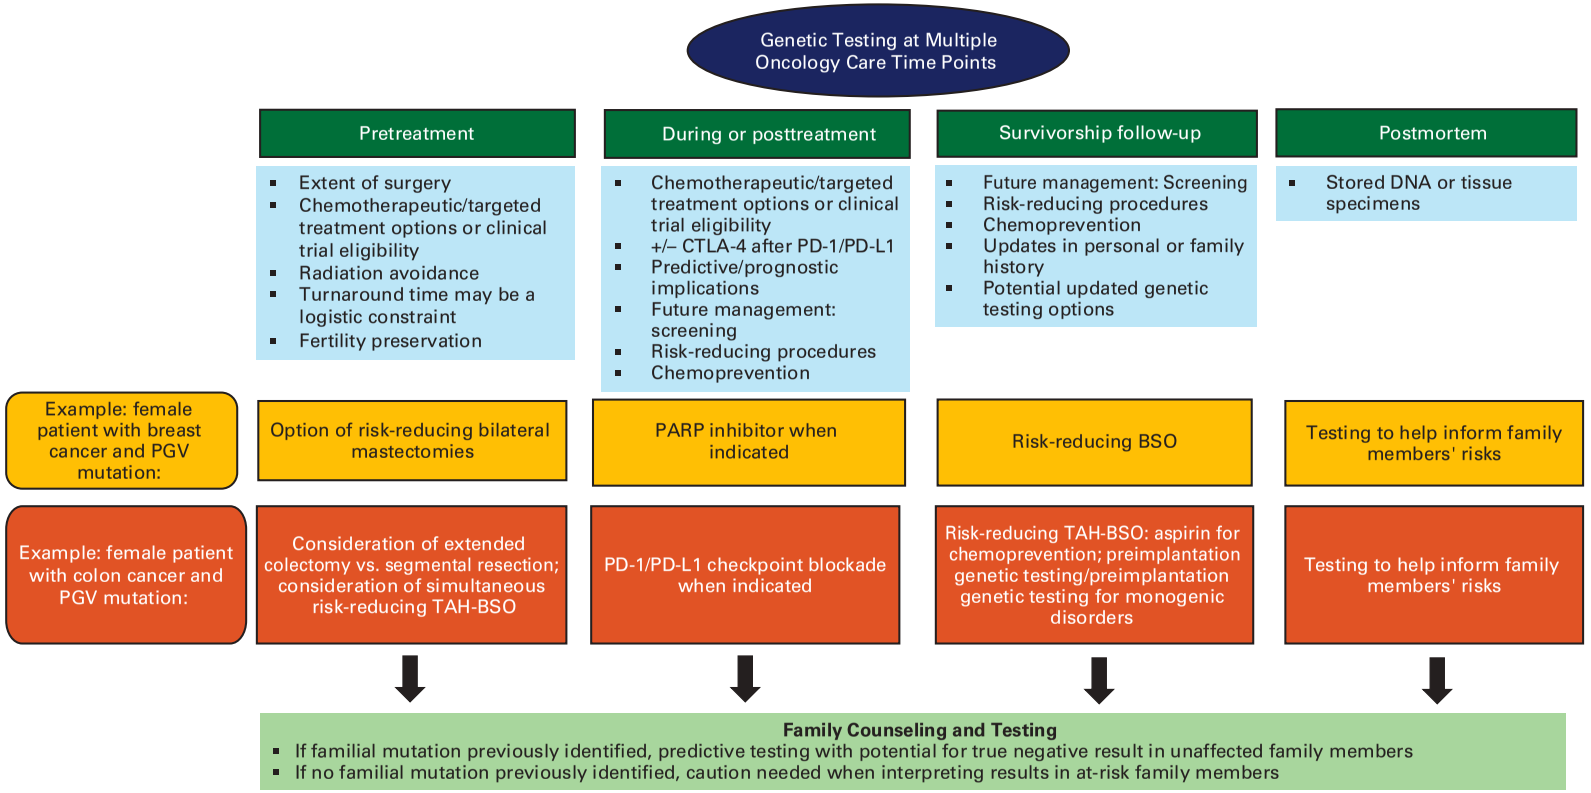
Even for patients who have negative or inconclusive results on genetic testing, posttest genetic counseling may still be critically important, because patients and families may still be considered at increased risk for disease and negative psychological reactions. Importantly, most family histories of cancer are not explained by PGVs in the known high-penetrance cancer predisposition genes. As such, many cases of familial breast cancer or familial colorectal cancer (CRC) remain unexplained, but individuals in these families may still qualify for enhanced management based on the empirical risk estimates or established screening guidelines that are based on family history of an increased risk for cancer and need for increased cancer surveillance. Because of the possibility that an individual with cancer may test negative for a PGV in a cancer susceptibility gene even though there is one running in their family (this is known as a phenocopy), consideration of additional genetic testing among other affected family members may be warranted. Failure for patients to understand the uninformative nature of a negative or inconclusive genetic test result may lead to nonadherence to medical recommendations.[16]

Although the model presented above is the classic posttest counseling process, use of tumor-normal tissue testing and regulations allowing patients direct access to results without interpretation may compromise this process. Providers need to be prepared to address and correct potential misinterpretations of results by patients in these settings.

INCORPORATING GENETIC COUNSELING AND TESTING INTO THE CARE OF THE ONCOLOGY PATIENT

Germline test results are increasingly desired, not only to guide personalized screening decisions for patients and their families but also to guide targeted therapeutics. Genetic counseling can occur at multiple points in the oncology setting, so it is important for an oncologist to determine, in conjunction with the patient, when genetic counseling and testing are most appropriate. However, because the peridiagnostic period may be emotional and overwhelming for patients, genetic counseling and testing may need to be completed at a later time (Fig. 6-2).

Figure 6-2 Incorporating Genetic Counseling and Testing Into the Care of Patients With Cancer



Abbreviations: BSO, bilateral salpingo-oophorectomy; PARP, poly-ADP ribose polymerase; PD-1/PD-L1, programmed cell death protein 1/programmed death ligand 1; PGV, pathogenic germline variant; TAH, total abdominal hysterectomy.

PERIDIAGNOSIS OR PRETREATMENT COUNSELING AND TESTING

Identification of an inherited cancer predisposition syndrome may affect treatment decisions, including the following:

- Extent of surgery (eg, mastectomy for breast cancer paired with a contralateral risk-reducing mastectomy)
- Need for surgery (eg, emerging data suggesting microsatellite instability-high [MSI-H] rectal cancer may be treated with immunotherapy alone)
- Preoperative chemotherapy and/or targeted therapy choices

TREATMENT PERIOD

Genetic testing may allow patients and physicians to make informed decisions about chemotherapy and targeted therapeutic options and sequencing. Examples include the following:

- Poly ADP ribose polymerase (PARP) inhibitors and PGVs in the *BRCA* pathway
- Immunotherapy and microsatellite unstable cancers such as those related to LS
- Belzutifan and von Hippel-Lindau syndrome–related cancers[89]

These therapeutic options are discussed in greater detail in the appropriate disease site chapters.

POSTTREATMENT AND SURVIVORSHIP FOLLOW-UP PERIOD

Once a patient has completed treatment and is receiving follow-up care, genetic evaluation may assist in making decisions about the following:

- Future cancer surveillance and screening
- Prevention options such as chemoprevention
- Risk-reducing surgeries to manage the risk for new primary cancers

Although genetic evaluation for some individuals might not be indicated at the time of their cancer diagnosis, changes in their dynamic personal or family histories may lead to a referral for genetic testing in the future. Finally, it is important to note that updates in genetic testing (eg, new risk genes, new methodologies) may become available throughout a patient's oncology follow-up period.

It may be reasonable to consider re-referral for updated genetic evaluation and possibly repeat genetic testing in relation to the following:

- Roughly every 5 years for those with concerning personal or family history who have negative or inconclusive results on previous germline testing (or those who have PGVs that do not explain the personal and/or family history)
- New cancer diagnosis in the patient or family member
- New identification of PGV in family member
- For anyone tested before 2015 who likely did not have multigene panel testing using NGS

IDENTIFYING APPROPRIATE PATIENTS FOR REFERRAL TO GENETIC COUNSELING AND TESTING

Although most cancers are not caused by high-penetrance cancer predisposition syndromes, it is crucial for oncologists to be familiar with common "red flag" indications for referral for genetic counseling. These include the following:

- Early or unusual age at cancer diagnosis
- Multiple primary cancers (bilateral, synchronous, and/or metachronous diagnoses)
- Multiple individuals with related cancers in multiple generations
- Finding on somatic testing that is concerning for germline origin
- Unique features, including the following:
  - Certain numbers and types of gastrointestinal polyps
  - Certain dermatologic features
  - Certain neoplastic pathologies
- Certain ancestries (ie, those known to have founder PGVs)

For many common types of hereditary cancers, NCCN has published criteria for when referrals for genetic counseling and testing should be considered. In addition, some third-party payers have established their own criteria for when genetic testing is deemed medically indicated, which may not necessarily be congruent with NCCN guidelines. Although taking a thorough medical

and family history is important and will aid in identifying possible red flags, it is important for clinicians to realize that not all individuals or families who have a PGV actually fit into the classic syndrome phenotype descriptions.

With NGS being performed on patient tumors and sometimes germline specimens, a substantial number of patients are found to carry PGVs in genes that would have not been suspected based on their personal or family histories. For example, targeted NGS of matched tumor and germline specimens for 76 known cancer predisposition genes identified that 17.5% of patients with advanced cancer (182 of 1,040 patients) had an actionable PGV; 55.5% of these would not have been detected using clinical genetic testing guidelines alone.[90] The Mayo Clinic report of multigene panel testing in 2,984 patients with a solid tumor cancer identified PGVs in 397 of them (13.3%).[6,90] However, these studies included variants of low-penetrance genes and carriers of variants that only had recessive risks of cancer, so the actionability was indirect or lesser for some reported carriers.

Table 6-2 describes the prevalence of cancer susceptibility PGVs for unselected patients with specific types of cancer. Several studies on specific cancer types have recommended germline genetic testing of all patients with certain cancer subtypes, including the following:

- Epithelial ovarian, fallopian tube, and primary peritoneal cancer
- Metastatic prostate cancer
- Triple-negative breast cancer
- Pancreatic adenocarcinoma
- Colorectal, endometrial, gastric, or brain cancer diagnosed before age 50 years
- Myelodysplastic syndrome or acute myelogenous leukemia before age 50 years
- Nonclear cell renal cell carcinoma
- Paraganglioma/pheochromocytoma
- Medullary thyroid cancer
- Adrenocortical cancer
- Choroid plexus carcinoma

Specific pathologies associated with germline changes are listed in Table 6-3.

Table 6-2 Prevalence of Cancer Susceptibility Pathogenic Germline Variants for Unselected Patients

Cancer Type	Patients With Germline Variants, N/Total Patients	PGV Prevalence, %
Breast	83/959[91]	8.65-10.8
	494/4,581[92]	
Triple-negative breast	267/1,824[93]	14.60
Lung (advanced cancer only)	222/5,118[94]	4.3-5.8
	448/7,668[92]	
Colon	305/5,303[95]	5.8-9.9
	105/1,058[96]	
Prostate	247/2,887[95]	8.6-17.3
	620/3,607[97]	
Osteosarcoma	281/1,044[98]	28.00
Renal	85/1,336[92]	6.40
Pancreatic (adenocarcinoma)	273/3,535[99]	7.7-14.1
	25/177[92]	
Bladder/urothelial (advanced cancer only)	79/1,188[100]	6.6-14
	80/586[101]	
Ovarian	60/515 (*BRCA1/BRCA2* only)[92]	11.7-13.8
	380/2,756[92]	
Endometrial	76/1,542[102]	4.9-9.2
	35/381[92]	
Head/neck	51/1,218[92]	4.20
Cholangiocarcinoma	36/8,401[92]	4.30
Esophageal	36/747[92]	4.80
Gastric	48/243[103,104]	19.80

Abbreviation: PGV, pathogenic germline variant.

Table 6-3 **Genetic Cancer Predisposition Syndromes and Selected Associated Pathologies**

Neoplastic or Preneoplastic Pathologies	Associated Genetic Syndromes and Genes
High-grade or poorly differentiated ductal breast cancer with estrogen receptor, progesterone receptor, and HER2/neu negativity	Hereditary breast and ovarian cancer syndrome (*BRCA1*); *BARD1, PALB2, RAD51C, RAD51D*
Lobular breast cancer	Hereditary diffuse gastric cancer syndrome (*CDH1*)
High-grade serous (papillary serous) ovarian	Hereditary breast and ovarian cancer syndrome (*BRCA1, BRCA2*)
Clear cell or endometrioid ovarian cancers	Lynch syndrome (*MLH1, MSH2, MSH6, PMS2, EPCAM*)
Ovarian sex cord tumors with annular tubules	Peutz-Jeghers syndrome (*STK11*)
Clear cell or endometrioid endometrial cancers	Lynch syndrome (*MLH1, MSH2, MSH6, PMS2, EPCAM*)
Uterine leiomyomas	Hereditary leiomyoma renal cell carcinoma syndrome (*FH*)
Minimal deviation adenocarcinoma (adenoma malignum of the cervix)	Peutz-Jeghers syndrome (*STK11*)
Colorectal cancer with tumor-infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring cells, medullary growth pattern	Lynch syndrome (*MLH1, MSH2, MSH6, PMS2, EPCAM*)
Lauren diffuse type/signet ring cell/linitus plastica gastric cancer	Hereditary diffuse gastric cancer syndrome (*CDH1*); *CTNNA1*
Hamartomatous gastrointestinal polyps	Peutz-Jeghers syndrome (*STK11*); juvenile polyposis syndrome (*BMPR1A, SMAD4*); Cowden syndrome (*PTEN*)
Pancreatic neuroendocrine tumors	Multiple endocrine neoplasia type 1 (*MEN1*); von Hippel-Lindau (*VHL*)
Renal papillary type I carcinoma	Hereditary papillary renal cancer syndrome (*MET*)
Renal papillary type II, collecting duct, tubulopapillary carcinomas	Hereditary leiomyomatosis and renal cell carcinoma syndrome (*FH*)
Renal clear cell carcinoma	von Hippel-Lindau (*VHL*)
Renal oncocytoma	Birt-Hogg-Dube syndrome (*FLCN*); tuberous sclerosis complex (*TSC1, TSC2*)
Renal angiomyolipoma	Tuberous sclerosis complex (*TSC1, TSC2*)
Renal chromophobe	Birt-Hogg-Dube syndrome (*FLCN*)
Sertoli cell tumors of the testes	Peutz-Jeghers syndrome (*STK11*)
Medullary thyroid cancer	Multiple endocrine neoplasia type 2 (*RET*)
Cribriform-morular variant of papillary thyroid carcinoma	Familial adenomatous polyposis (*APC*)
Follicular thyroid cancer	Cowden syndrome (*PTEN*)
Medulloblastoma	Turcot syndrome variant of familial adenomatous polyposis (*APC*); Nevoid basal carcinoma syndrome (Gorlin) (*PTCH1*)
Glioblastoma	Turcot syndrome variant of Lynch syndrome (*MLH1, MSH2*, MSH6, *PMS2, EPCAM*); Li-Fraumeni syndrome (*TP53*)
Basal cell carcinoma	Xeroderma pigmentosum (multiple xeroderma pigmentosum-associated genes); Nevoid basal carcinoma syndrome (Gorlin) (*PTCH1*)
Sebaceous adenoma, sebaceous carcinoma, keratoacanthoma	Muir-Torre syndrome variant of Lynch syndrome (*MLH1, MSH2, MSH6, PMS2, EPCAM*)
Fibrofolliculomas	Birt-Hogg-Dube syndrome (*FLCN*)
Facial trichilemmomas	Cowden syndrome (*PTEN*)

Not all guidelines give the same recommendations. The American Society of Breast Surgeons has recommended that all women with breast cancer be offered germline genetic testing, and the US Preventive Services Task Force has recommended that, for women with a personal or family history of breast, ovarian, tubal, or peritoneal cancer or who have an ancestry associated with *BRCA1* or *BRCA2* genetic PGVs, primary care clinicians should use a brief familial risk assessment to evaluate the need for genetic counseling referral. More recently, ASCO and the Society for Surgical Oncology have recommended that *BRCA1/BRCA2* testing be performed in all breast patients with cancer aged 65 years or younger, and that it be considered in those over 65 years of age who may require treatment with PARP inhibitors.[105] Similarly, NCCN recommends considering germline testing for all patients with CRCs. Given these recommendations, it is important that genetic counseling models evolve and that clinicians who provide cancer-focused genetic counseling be skilled in discussing the implications of identified PGVs with patients and families, even in the absence of a significant history of cancer.

As genetic testing costs have dropped, there have been calls for general population screening for hereditary cancer risk, but there are pros and cons to this recommendation.

Pros:

- Testing may save lives and may be cost-effective.[106]
- A total of 80%-90% of patients who tested positive for hereditary cancer risk had not received prior testing.[107,108]
- Of those who test positive, 50%-70% would not have met published guidelines for clinical testing.[107,108]

Cons:

- The clinical utility of identifying lower-penetrance variants is undetermined.
- How to translate risk identification to uptake of clinical prevention in the general population is unclear.
- There is an insufficient number of cancer genetics providers to support general population testing.
- Underserved populations will be more likely to have uncertain results, lower access to genetic counseling, and lower access to screening for identified hereditary risks.

ETHICAL PRINCIPLES AND CHALLENGES IN GENETIC COUNSELING

Although there are multiple principles of ethics that come into play in the field of cancer-focused genetic counseling, the four key concepts are autonomy, nonmaleficence, equity, and duty to warn.

KEY POINTS

- Genetic counseling is a communication process that helps patients make informed genetic testing decisions and adapt to having a genetic condition.
- Genetic counseling is guided by principles of autonomy, nonmaleficence, equity, and duty to warn and has traditionally included pre- and posttest discussions.
- Thorough medical and family histories to assess for red flags are vital for accurate genetic risk assessments.

PHENOTYPIC AND TUMOR-DRIVEN ANALYSES

A patient's tumor pathology may provide the initial signal of the possibility of an inherited cancer predisposition syndrome. For example, triple-negative (ie, estrogen receptor–negative, progesterone receptor–negative, and human epidermal growth factor receptor 2/neu–negative) breast cancers are associated with an increased incidence of *BRCA1, BARD1, RAD51C*, and *RAD51D* PGVs, and genetic testing is considered medically indicated for all women who have this type of cancer. Similarly, all patients with medullary thyroid cancer should be referred for genetic testing of the *RET* gene. Individuals with 10-20 or more cumulative adenomatous colorectal polyps qualify for panel-based genetic testing, which includes *APC, MUTYH*, and multiple genes more rarely associated with adenomatous polyposis such as *MSH3, NTHL1, POLE, POLD1*, and others.

TUMOR ANALYSIS INFORMS GERMLINE SUSCEPTIBILITY: THE CASE OF LS

The hallmark feature of tumors associated with LS (previously known as hereditary nonpolyposis CRC) is the presence of MSI resulting from the accumulation of DNA insertions and deletions in the genome, especially at regions of repetitive DNA known as microsatellites, driven by deficient mismatch repair (dMMR). However, providers should appreciate that one in 10 CRCs in patients with LS is microsatellite stable, and so LS may be missed if only MSI is used for identification of this population.[109] Identification of dMMR may be pursued either through a polymerase chain reaction–based technique that assesses MSI at a designated set of markers by studying large numbers of microsatellites included in NGS tumor tests, or through immunohistochemistry (IHC) staining of the four DNA MMR proteins (MLH1, MSH2, MSH6, and PMS2) to assess loss of expression of one or more of them. MSI and MMR IHC analyses are highly concordant; however, a benefit of MMR IHC is that the pattern of protein loss

can sometimes help inform which of the LS genes may be malfunctioning as a result of germline or somatic events. On the other hand, both MSI and MMR IHC performed in a patient's tumor can be particularly helpful in the interpretation/classification of rare MMR variants identified on germline testing.

Screening of all CRCs by MSI polymerase chain reaction, MSI NGS, or MMR IHC analysis, along with MMR IHC for endometrial cancer and MMR IHC or MSI for gastroesophageal and small-bowel cancers, is recommended by the College of American Pathologists and ASCO to screen for eligibility for immune checkpoint inhibitor therapy.[18,110] For patients with a screening test result showing dMMR, various algorithms have been developed to guide subsequent evaluations, including the following:

- When IHC testing shows loss of MLH1/PMS2 expression, BRAF V600E somatic testing (for appropriate tumor types), followed by MLH1 promotor hypermethylation testing if BRAF is wild type
- MLH1 promoter hypermethylation alone when IHC testing shows loss of MLH1/PMS2 expression
- Immediate germline genetic testing for all patients
- If other testing (including germline testing) does not identify an explanation for the dMMR tumor, subsequent somatic analysis of the MMR genes to identify individuals with dMMR due to somatic loss of function of both alleles of one of the MMR genes[18]

Although tumor testing will continue to have a role identifying somatic pathogenic/likely pathogenic variants targetable by pharmaceutical agents, expert opinion is increasingly moving toward universal germline testing for all patients with CRC to screen for LS and rarer CRC syndromes using a multigene panel testing approach. A study of 3,310 patients with colorectal adenocarcinoma in Ohio demonstrated that universal tumor screening alone will miss 38.6% of colorectal patients with cancer with hereditary cancer syndromes, including 6.3% with LS.[111] Ranganathan et al[109] showed that 10% (10 of 99) of CRCs among individuals with LS were mismatch repair proficient (MMR-P), with 100% concordance between microsatellite-stable status and retained MMR protein staining. The majority of MMR-P tumors were observed in association with PGVs in *MSH6* and *PMS2.* A total of 33% (three of nine) of MMR-P CRCs did not meet testing criteria for LS.[109] However, in the absence of a universal germline testing approach, germline genetic testing for LS and other CRC predisposition genes should routinely be considered in the presence of early-onset disease (younger than 50 years) or a significant family history, even in patients with intact MMR in their tumors.[111]

TUMOR NGS: IMPLICATIONS FOR GERMLINE SUSCEPTIBILITY

NGS of tumors (ie, somatic pathogenic/likely pathogenic variant profiling or tumor genomic profiling) to help define therapeutic targets is increasingly commonplace across many tumor types in medical oncology. Somatic pathogenic/likely pathogenic variant profiling is available commercially and through academic institutions and generally consists of a multigene panel incorporating numerous genes previously implicated in carcinogenesis. Many of these genes will also be associated with germline cancer predisposition syndromes. Tumor sequencing may be performed with or without a matched normal specimen and could also be performed in the setting of whole-genome/whole-exome platforms.

Guidelines are available to help identify patients who need to be referred to cancer geneticists for germline genetic testing based on somatic pathogenic/likely pathogenic variant findings in their tumors.[112] Determination of referral considers the following:

- Frequency with which somatic findings are also present in the germline
- Variant allele fractions
- Variants considered likely pathogenic or pathogenic in ClinVar (particularly founder PGVs) or truncating variants, if new
- Whether the variant is present in a tumor associated with the gene's phenotype
- Patient's age at diagnosis

Some tumor testing laboratories are applying these guidelines and indicating that variants might be present in the germline on their reports, while others do not. Tumor testing results can be reviewed systematically to identify cases that need to be referred for germline genetic testing. However, because of variations of somatic testing platforms, gene coverage, and variant interpretation, the absence of somatic tumor pathogenic/likely pathogenic variants in inherited cancer susceptibility genes does not exclude the possibility of all PGVs, which may be detectable with currently available germline testing platforms. In a retrospective cohort study of 2023 patients with cancer who underwent germline testing and previously had tumor DNA sequencing, 8.1% of PGVs were missed by tumor sequencing.[113]

Somatic pathogenic/likely pathogenic variant profiling may also reveal variant patterns that predict the presence of a cancer susceptibility syndrome. For example, high burden on somatic profiling may identify hypermutated tumors, which may result from dMMR/MSI-H, a marker of LS, a somatic cause of MSI, or another rare cause of high tumor variant burden like somatic and/or *POLE* and *POLD1* PGVs.[114] As such, somatic pathogenic/likely pathogenic variant profiling that

reveals the presence of a hypermutated tumor should prompt MMR IHC or MSI testing and, if appropriate, genetic referral. Bioinformatic tools that predict MSI from somatic pathogenic/likely pathogenic variant profiling are incorporated into many somatic pathogenic/likely pathogenic variant profiling tests to help clinicians identify tumors with dMMR/MSI-H. Sixteen percent of patients with MSI-H tumors were found to have LS, in a large study of 15,045 patients with cancer representing more than 50 tumor types who underwent MSI testing by NGS on the tumor tissue and germline genetic testing on normal tissue and blood.[115]

PATHOGENIC GERMLINE VARIANTS IDENTIFIED ON TUMOR—NORMAL OR LIQUID BIOPSY

Increasingly, the use of molecular diagnostic tests to identify tumor targets for standard-of-care or other available precision therapies or to determine clinical trial eligibility for novel targeted therapeutics involves tumor DNA and germline DNA sequencing in parallel. In liquid tumor testing, this is more specifically circulating tumor DNA tested in parallel to germline DNA. These tests are often sent directly by the medical oncology team, with this practice referred to as mainstreaming. While, in these settings, germline DNA sequencing is not required to identify clinically actionable variants in the tumor, it can be useful to filter out unimportant variation in the germline DNA from the tumor DNA. As such, providers should be aware of whether the test they are ordering performs germline DNA sequencing and should discuss with their patients the potential to identify germline mutations associated with hereditary cancer risks. They should also be aware that some paired testing is done only for germline subtraction and does not report PGVs. After completion of testing, providers should be careful to review results with an eye for PGVs in common cancer predisposition genes. While some of these identified on tumor testing will be somatic only, many will also be found in the germline and should be followed up with referral to genetic counseling if the patient wants. Increasingly, many laboratories performing either matched tumor DNA (or circulating tumor DNA) and germline DNA sequencing will report PGVs, while others, especially those sequencing tumor only, may provide some indication on reports that an identified pathogenic variant could be germline and should be evaluated. Some studies have found that patients tested through mainstreaming programs may be less likely to complete posttest genetic counseling.[74] Data from Liu et al[116] have demonstrated that Black and Hispanic patients are less likely to seek genetic counseling than White patients and trend toward fewer family members benefiting from cascade testing.

KEY POINTS

- Evaluation for LS may start with tumor screening for MSI or dMMR, although universal multigene panel testing for all CRCs is gaining acceptance.
- Somatic tumor testing can potentially reveal PGVs that may be of significance for a patient and/or family members.
- The absence of somatic tumor pathogenic/likely pathogenic variants does not exclude the possibility of all identifiable PGVs. Genetic counseling and germline testing may still be warranted.

GERMLINE ANALYSES

SPECIMENS AND LABORATORY STANDARDS

Germline genetic testing platforms vary greatly from laboratory to laboratory, with notable differences in analytic coverage, specific genes analyzed, and even reporting standards for pathogenicity. For germline genetic testing, the most used biospecimen is blood because of its high DNA yield and, for some laboratories, the ability to incorporate RNA analysis to further evaluate cryptic regions and VUSs. Commercial laboratories are increasingly offering germline genetic analyses on saliva specimens; however, not all analyses may be validated for all sample types. Tissue, rather than blood or saliva, is necessary for germline analysis in patients who have undergone allogeneic bone marrow or stem cell transplantation or those with a hematologic malignancy, as all blood DNA and approximately two-thirds of saliva DNA are from lymphocytes. In addition, follow-up testing to germline testing performed on blood and/or saliva may be warranted in cases of PGVs identified at low variant allele frequencies to determine origin of the variant (eg, post-zygotic mosaicism, clonal hematopoiesis, or circulating tumor DNA). Alternative sources of germline DNA include the following:

- A skin punch biopsy specimen obtained for fibroblast culture
- Banked DNA or DNA extracted from formalin-fixed paraffin-embedded normal tissue
- Hair follicles or fingernails (in some laboratories)

Complete testing often is not possible in these cases, because variability in storage and extraction can interfere with analysis of copy number and large rearrangement.

RNA analysis is now available at some of the large commercial germline genetic testing companies as part of the original multigene panel test for a subset of genes or in follow-up to multigene panel testing to clarify uncertain or negative results. Although incorporation of RNA analysis is not currently a necessary laboratory standard per American College of Medical Genetics and

Genomics (ACMG) or other professional societies, this can sometimes help clarify the pathogenicity of splice site or missense variants or identify deep intronic variants that would have been missed by DNA testing alone.[87]

GERMLINE GENETIC TEST RESULTS

Pathogenic or Deleterious Variant

- Altered gene function and protein product are associated with disease risk, although genotype-phenotype associations should be carefully considered.
- Patients should be informed of disease risks, medical management implications, and familial ramifications.

Likely Pathogenic or Suspected Deleterious Variant

- There is high suspicion but not complete certainty about the pathogenicity.
- Patients should be informed of disease risks, medical management implications, and familial ramifications.
- Some caution must be taken when counseling a patient and family members, as reclassification to VUS or benign downgrading is possible. However, established medical management interventions, if available, should be implemented in the same manner as they are offered to patients with pathogenic variants.

Variant of Uncertain Significance

- The laboratory does not have enough data to allow for clinical classification or interpretation of the variant's effect.
- Patients and family members should be counseled about the ambiguity of the result and the continued need to interpret risk based on the personal and family history.
- The patients should not be managed as if they had tested positive for a PGV in the gene but, instead, should be managed based on their personal and family history of cancer. Predictive testing should not be offered to at-risk relatives for VUS results, although relatives may be tested to generate segregation analysis evidence for VUS reclassification.
- Clinical germline testing may still be indicated for other family members in the presence of additional red flags.
- With time and access to additional data, many laboratories reclassify these variants, and most VUSs are eventually reclassified as being benign.[117] A general recommendation is that patients and families found to have germline VUSs should check every 1 to 5 years depending on various factors (eg, changes to personal and/or family history, contact from the laboratory) with the healthcare provider who ordered the genetic test to inquire about updates in variant classification.[117]
- RNA analysis, if not previously performed, may be able to assist in the reclassification of certain VUSs, particularly those VUSs that may impact splicing on cryptic intronic regions that are not routinely analyzed by currently established reporting standards.
- Some laboratories do not report VUS results.
- Some laboratories do not perform active variant curation, so the provider or the patient needs to prompt the laboratory for assessment for reclassification.

Likely Benign Variant

- If an alteration is detected, but the laboratory has a low suspicion of it being associated with disease, it is a likely benign variant. Of note, laboratories usually do not report likely benign variants.

Reduced-Penetrance PGVs

Investigation into genotype-phenotype correlations is yielding insights into PGVs in high-risk genes with lower-than-expected cancer risks, termed reduced-penetrance pathogenic variants (RPPVs), that may modify associated cancer risk. For example, specific *BRCA1/2* PGVs have only two to four times increased breast cancer risk as compared with the higher risks associated with truncating variants.[118] These RPPVs have a new framework to standardize their interpretation and reporting, which, in turn, may lead to additional personalization of management recommendations and guidelines that prevent both under- and overtreatment. Knowledge of the specific variant within the cancer risk gene will therefore be of increasing importance, as guidelines may vary for different variants within the same gene.

Increased Risk Allele

Another result that may be found on genetic test results, although not part of the ACMG variant classification system, is an increased risk allele. This is defined as a variant that is not expected to directly cause a genetic condition on its own, but scientific evidence indicates that it can lead to a predisposition to develop the genetic condition in combination with other genetic variants or factors. Some of these increased risk alleles may have conditional recommendations for screening. For example, individuals with *SPINK1* variants may be candidates for pancreatic surveillance if they have a personal history of pancreatitis.

Negative/Normal Result

- No alterations of clinical or uncertain significance are reported.
- Negative results may be uninformative, and the patient and their family members may still harbor a PGV that the current technology cannot detect or for which they were not tested. There could be a predisposing gene variant in a different affected family member, or the patient may also have other significant polygenic or nongenetic familial risk factors.
- When an individual is being tested for a previously identified, familial PGV, a negative result is considered a true-negative result, and, for the specific syndrome-associated cancers, the individual is generally presumed to be back at the risk level of the general population. However, it is increasingly important to ensure proper selection of a germline testing platform that is capable of detecting a previously identified PGV. Notable examples include *MSH2* inversions and deep intronic variants that may be missed by standard DNA sequencing and del/dup platforms.
- It is important to understand that true-negative results were historically described in the setting of families with variants in high-penetrance genes, such as *BRCA1*. In families with moderate-penetrance genetic variants (eg, *CHEK2* variants), individuals who do not carry the familial variant may still be recommended to pursue cancer surveillance on the basis of family history, because the entire familial risk may not be attributed to the identified germline variant.[119]

PRESENTING CASE STUDY

Patient 1

A 40-year-old woman with a family history of breast cancer, in her maternal grandmother at age 68, presents to the outpatient oncology clinic following a recent diagnosis of stage II, hormone receptor–positive, HER2-negative invasive ductal carcinoma of the left breast. She undergoes germline genetic testing to guide surgical decisions and assess risk for future cancers. Testing reveals a heterozygous VUS in the *ATM* gene. She is anxious regarding treatment options and is requesting guidance on how this will impact management of her cancer in terms of breast-conserving therapy versus mastectomy and her future risk of cancer.

Patient 2

A 46-year-old woman with a history of hypertension and family history of a paternal uncle with prostate cancer and an elderly aunt with ovarian cancer presents with newly diagnosed, early stage I right breast cancer that is strongly hormone receptor positive and HER2-negative. She is concerned about management options and undergoes germline genetic testing, which demonstrates a heterozygous pathogenic variant in *BRCA2*.

Compare and contrast the risks associated with a VUS to a known pathogenic variant in terms of management of the current cancers and indication for future management of new cancers in these two patients.

The above patient cases illustrate how genetic testing can be used to refine cancer development risk and influence the patients' approach to decision-making and future surveillance.

Comparative analysis of cases

Patient 1 has a VUS in the *ATM* gene that may or may not be related to an increased risk of cancer development. The impact of this VUS may change over time with additional information, and assessment of the variants should be carried out by using the ClinVar database to evaluate any updated information. Review of this variant demonstrates that 10 independent laboratories have classified the variant as a VUS, with no labs reporting it as pathogenic or likely pathogenic. Thus, the VUS should not be a factor in raising the risk of other cancers in the future, and the patient's decision-making regarding breast conservation versus mastectomy should consider both her personal preference and the expertise of her breast cancer team. There is no indication of conducting tests in other family members, performing additional imaging for surveillance, or repeating tests in the future.

Patient 2 has a pathogenic variant that is associated with an increased risk of breast cancer in addition to other *BRCA2*-related cancers.

Women who are carriers for a pathogenic variant in *BRCA2* have an increased risk of breast, ovarian, and pancreatic cancers, as well as melanoma. The *BRCA2* variant may not influence the patient's consideration of optimal surgery for

her present breast cancer, as outcomes for breast conservation as compared to mastectomies have similar results, but she will face a slightly higher risk of contralateral breast cancer and should undergo annual breast MRI in addition to mammograms in the future if she elects for breast-conserving therapy. This information may aid her in her decision of how best to manage her cancer. She should also undergo risk-reducing bilateral salpingo-oophorectomy and consider pancreatic cancer screening beginning at age 50.

Contrasting analysis of cases

These cases illustrate recommended management processes in contrasting scenarios involving a pathogenic variant and a VUS not known to be associated with an increased risk of cancer. It is important to know how to interrogate a VUS for the most updated information to convey to patients for optimal management. In addition, detection of a pathogenic variant should inform development of a comprehensive management plan for early detection and/or risk-reducing purposes.

Conclusion

Genetic information is increasingly being utilized to assess future risks of cancer development and, with appropriate genetic counseling and help from healthcare providers, it can help patients make optimal decisions for their cancer care management. New pathogenic variants may require initiation of specific imaging or management strategies.

APPROACHES TO GERMLINE GENETIC TESTING

Genetic Testing Using Multigene Panels

In contrast to phenotype-driven testing, NGS technologies have enabled the use of multigene panels for germline analysis wherein multiple cancer susceptibility genes are assessed simultaneously. Disease-specific multigene panels for nearly all the common cancers (ie, breast, ovarian, uterine, colon, kidney, prostate) as well as pan-cancer panels are now widely available through commercial laboratories. The ease of use, cost, and time efficiency associated with multigene panel testing for cancer susceptibility have resulted in a dramatic increase in the application of this testing approach. It is an especially useful approach when significant genetic heterogeneity exists, or multiple genes or syndromes may be implicated based on phenotype or family history. On the other hand, multigene panels also have some limitations.

Additional information is available at Bedrosian et al[105] and Tung et al,[10] and NCCN HBOPP[15] and HCEG[18] guidelines referenced earlier in the chapter.

Pretest Genetic Counseling and Informed Consent

The in-depth discussion provided for single-gene testing in the traditional model of genetic counseling is not possible for a panel that may include 80 genes or more.

Unexpected Results

For panels that include high-penetrance genes such as *TP53* (associated with multiple tumors and childhood cancers) and *CDH1* (associated with recommended management by risk-reducing total gastrectomy), an unexpected positive result without pretest discussion and preparation may result in distress and anxiety. This is particularly the case when a patient's personal or family history is not in line with the hereditary syndrome identified using the multigene panel. For example, if a *CDH1* PGV is unexpectedly identified in a patient who has no personal or family history of diffuse gastric cancer or lobular breast cancer, the patient and healthcare provider are left with a clinical conundrum about accurate cancer risk estimates; current estimates are lower; and endoscopic surveillance can be considered as an alternative to risk-reducing total gastrectomy.

Another unexpected result is the presence of a variant at a low allele fraction. This can be due to constitutional mosaicism (in which the change may be present in germ cells and therefore could be passed on to offspring with associated cancer risks), circulating tumor DNA in patients with active disease, or clonal hematopoiesis of indeterminate potential, which can be associated with its own risks of leukemia and cardiac disease. Genetic consultation is appropriate in these instances to help clarify the source of the variant.

LIMITED UNDERSTANDING OF MODERATE-PENETRANCE GENES

Multigene panels generally include moderate-penetrance genes for which the associated cancer spectrum, lifetime risks, age-associated penetrance, and appropriate management recommendations have not been fully defined. Importantly, the presence or absence of a variant in a moderate-penetrance gene may not provide clarity with respect to a patient's personal and family history of cancer and their future cancer risk.

Genetic VUS

Multigene testing results in a higher incidence of VUS results, leading to additional difficulties with the interpretation of results.

Genetic Variants Associated With Reproductive Risks

Some genes included on multigene panels may be associated with severe autosomal recessive conditions when biallelic variants are inherited but associated with no or possibly limited disease risks when in monoallelic form (Table 6-4). In addition, established cancer risk genes can have different risks in heterozygotes and homozygotes, such as hereditary breast-ovarian cancer (heterozygous change in *BRCA2*) and Fanconi anemia (homozygous changes in *BRCA2*). It is important that clinicians make the patient and family members aware of the reproductive risks so that family planning options can be investigated, if desired.

Table 6-4 Genes With Autosomal Recessive Disease Risk

Gene	Syndrome
ATM	Ataxia telangiectasia
BLM	Bloom syndrome
BRCA1, BRCA2, BRIP1, PALB2, RAD51C	Fanconi anemia
FH	Fumarate hydratase deficiency
MLH1, MSH2, EPCAM, MSH6, PMS2	Constitutional mismatch repair deficiency syndrome
MUTYH, NTHL1, MSH3, MLH3, MBD4	MUTYH-associated polyposis, etc
NBN	Nijmegen breakage syndrome
WRN	Werner syndrome
DDB2, ERCC1, ERCC2, ERCC3, ERCC4, ERCC5, POLH, XPA, XPC	Werner syndrome

PHENOTYPE-DIRECTED GENETIC TESTING

Increasingly, all testing is performed using multigene panel testing, with the main question being the size of the panel, which can be either a tumor specific or a more extensive pan-cancer panel. Decisions regarding the size of the panel and whether to include genes for which there are no management guidelines can be made on the basis of personal and family history of cancer and the patient's comfort level with uncertainty (more genes lead to a higher rate of VUS results, and the inclusion of genes without known management guidelines can lead to results for which there are no surveillance recommendations). Multigene testing options can therefore include the following:

- A large multidisease panel may be used, which may be considered in patients with complex personal and family history, where multiple genetic risks are being considered and where patient tolerance of uncertainty is favorable.
- A small disease-specific panel may be used, which follows a more phenotype-based approach for genetic testing wherein the selection of genes to be analyzed is based on the patient's personal or family cancer history.
- Another approach is an ancestry-specific founder variant panel. Founder variants are genetic alterations observed with high frequency in a distinct group that is or was geographically or culturally isolated. While this is rarely used now for patients with cancer, because multigene panel testing is more thorough and can identify PGVs that would be missed by ancestry-based testing, it has utility for population testing in high-risk populations.
- Cascade testing pertains to families with a previously identified PGV; in these cases, cascade testing (testing only for a known familial PGV) can be undertaken, but it may not be sufficient when the personal and/or family history of cancer is not fully explained by the familial PGV.

OTHER CONSIDERATIONS RELATED TO GERMLINE GENETIC ANALYSES

Multiple Actionable Findings in the Same Individual

With the increasing use of large multigene panels for testing, p patients who have PGVs in more than one cancer risk gene are now being identified. One term for this condition is multilocus inherited neoplasia allele syndrome (MINAS). A systemic review of the literature in this area included 385 individuals with multiple PGVs. Most (287) of the subjects had at least one PGV in *BRCA1* or *BRCA2*, but other involved genes varied. Clinical phenotypes were usually consistent with those of the individual genes involved, but some individuals did have multiple tumors or unusual tumor presentations, suggestive of complex interactions between the involved genes.[120]

Secondary Findings on Genome and Exome Analyses

Through clinical exome and whole-genome sequencing, PGVs may be uncovered in genes unrelated to the primary medical reason for testing; these findings have been termed secondary or incidental findings. Considerable debate has been prompted regarding the extent to which primary data should be analyzed for secondary findings and which, if any, PGVs discovered should be disclosed to patients. In an effort to standardize the reporting of actionable information from clinical genomic sequencing, in 2021, the ACMG designated over 70 medically actionable genes[121] in which PGVs are recommended to be reported because of the high likelihood of severe disease that may be preventable if identified before symptoms appear.[122] The ACMG recommendations provide patients the opportunity to opt out of the analyses of genes unrelated to the indication for testing, with the decision to be made during the process of informed consent before testing. Of note, 24 of the current ACMG and Genomics reportable genes are associated with cancer predisposition syndromes, highlighting the relevance of these recommendations to the field of medical oncology.

Germline Variant Classification Resources

The standardization of variant classification is a substantial challenge in the field of germline genetics because, at this time, a particular variant could be classified as pathogenic/likely pathogenic by one laboratory but as a VUS by another laboratory. Given the current inconsistencies among clinical molecular laboratories and clinical genomic sequencing analyses that have been highlighted, integration of multiple lines of support using standardized methods is necessary to classify genetic alterations into one of five categories: pathogenic, likely pathogenic, uncertain significance (VUS), likely benign, and benign (see earlier discussion about these classifications). To meet this challenge, the National Institutes of Health has supported the formation of a resource called ClinGen, an authoritative central resource aimed at defining the clinical relevance of genomic variants for use in precision medicine and research.[123]

The cornerstone of ClinGen is ClinVar, a free Web-based archive that is maintained by the National Center for Biotechnology Information that reports on interpretations of clinical significance of variants and allows deposition and retrieval of variant data and annotations.[124]

Other resources that may be useful to clinicians in variant interpretation include the following:

- The InSiGHT database (focused on the MMR genes of LS)
- UMD TP53 variant database
- ENIGMA variant database

DIRECT-TO-CONSUMER GERMLINE GENETIC ANALYSES

Direct-to-consumer genetic testing has challenged the traditional practical and ethical frameworks established in the field of clinical genetics. Traditionally, direct-to-consumer genetic tests are advertised and sold directly to individuals, without supervision by a healthcare professional. Saliva collection kits allow consumers to send their specimens directly to commercial laboratories; results generally are returned by mail, email, or phone. Initially, direct-to-consumer companies were told by the FDA that they could not report medically important variants, including cancer susceptibility genes, so direct-to-consumer genetic testing companies grew to offer panels of common SNPs for recreational genetics and ancestry purposes. Now, companies have been FDA approved to offer direct-to-consumer testing for targeted high-risk variants, including common *BRCA1* and *BRCA2* PGVs. Unfortunately, reporting partial *BRCA1* and *BRCA2* results for a few common PGVs or simply the presence of common founder PGVs in *MUTYH* may lead individuals to conclude that they have no risk, despite having been tested for only a few of the thousands of known PGVs. These targeted tests cannot rule out a hereditary cancer syndrome in an individual.

There is an emerging area of "consumer-initiated, physician-mediated" testing where a commercial laboratory advertises testing directly to consumers and contracts with a physician service to approve the tests ordered through the laboratory website. Some of these companies provide posttest genetic counseling to individuals with PGVs or others with concerns about their results as part of the cost of the test. However, companies offering consumer-initiated, physician-mediated testing typically avoid the overhead of reporting results in electronic health records, offering physician support for results, going through insurance reimbursement, and integrating with the healthcare system in other ways. It is increasingly common for patients to come to their physicians' seeking explanations of results from genetic testing that they have sought out independently.

TESTING OF MINORS

The appropriate age for germline testing can vary depending on the gene in question. For some conditions that have manifestations in childhood, such as familial adenomatous polyposis and Li-Fraumeni syndrome, testing for children or even infants is appropriate. For most hereditary cancer syndromes that have increased risk in adulthood, testing at or after age 18 years is appropriate.

PREIMPLANTATION GENETIC TESTING

Some individuals may consider using genetic test results to inform reproductive decisions. In vitro fertilization with preimplantation genetic testing of embryos has been used by many families in the setting of inherited cancer predisposition syndromes.

This process ensures that only embryos without the known familial PGV are transferred, thus substantially reducing the chance of passing on the cancer syndrome to the child. The use of donor gametes (ie, eggs, sperm), adoption, or prenatal diagnosis through chorionic villus sampling or amniocentesis are other family planning options that some individuals might consider.

INSURANCE COVERAGE AND PROTECTIONS

Most third-party payers include some level of coverage for genetic counseling and testing services. Some payers have established personal and family history criteria that must be met for medical necessity to be established; others may follow suggested testing guidelines that have been published by groups such as NCCN. Some payers require the involvement of a genetic counselor or geneticist in the pretest counseling and testing process.

Federal legislation through the Genetic Information Nondiscrimination Act (2008) and, in some cases, additional state legislation provide protection against genetic discrimination by one's employer and health insurance provider.[125] Unfortunately, protection against discrimination by life, disability, and long-term care insurance providers is not universal in the US at this time. This lack of protection may be a particular concern for some unaffected individuals who may be pursuing presymptomatic genetic testing.

RACIAL AND ETHNIC DISPARITIES

Notable disparities by race/ethnicity have been identified in terms of cancer mortality, referrals for genetic counseling, uptake of genetic counseling and genetic testing, and subsequent cancer screening and risk-reducing surgeries.[116,126-128] In a study of young breast cancer survivors, the most frequent reason for not using genetic services was lack of physician recommendation, with a higher proportion of Black women reporting no physician recommendation (n = 172, 50.6%) compared with White/other (n = 203, 39.1%; $\chi^2 = 10.97$, $P < .001$).[116,126] Disparities were observed in genetic services utilization in a random sample of young breast cancer survivors.[129,130] Uptake of recommended genetic counseling was lower among non-White patients with cancer compared with non-Hispanic White patients with cancer after disclosure of new PGVs from 2,239 patients undergoing matched tumor-normal testing in a large prospective cohort study, with the lowest uptake among Black patients (odds ratio [OR], 0.60; 95% CI, 0.37-0.97; $P = .036$). Uptake of genetic testing among a cohort of individuals at risk for hereditary cancer was significantly higher at sites offering a point-of-care testing model compared with sites with a genetic counseling referral model (34% POC vs 11% referral, $P < 0.001$). Non-Hispanic Black patients had lower odds of testing compared with non-Hispanic White patients (adjusted OR = 0.84; 95% CI, 0.71-1.00; $P = 0.049$) at genetic counseling referral sites; however, this disparity was not observed at POC sites.[70] Strategies to reduce barriers, including different workflows such as point-of-care testing and pretest educational video models, may increase uptake of genetic testing and mitigate existing health disparities.[70,116]

SOURCES OF DISPARITIES IN HEREDITARY GENETICS AND GENOMICS

- Differences in tumor characteristics
- Higher rates of VUS in minority populations leading to uninformative testing
- Awareness of genetics and perceived importance of genetic testing
- Education, cost, and socioeconomic barriers
- Medical mistrust
- Physician and healthcare provider recommendation
- Access to genetic counseling
- Language barriers
- Lack of awareness of family history

NEW STRATEGIES AND APPROACHES TO MITIGATE DISPARITIES

- Increased referrals for genetic counseling to improve access
- Testing materials and counseling available in the patient's primary language
- Culturally targeted interventions to support testing uptake and results dissemination
- Public health programs to mitigate financial barriers
- Initiatives to empower minority communities by improving knowledge of cancer risk factors[131]
- Alternative modes of genetic testing delivery, such as point-of-care testing, which can improve access for working patients, rural patients, and those with limited access to genetic counseling[70]

KEY POINTS

- Germline variants typically fall into one of five categories: pathogenic, likely pathogenic, uncertain significance (VUS), likely benign, and benign.
- Recommendations for management and predictive testing differ substantially based on the classification of the variant and should be assessed carefully.

- Multigene panel testing is challenging the traditional pretest counseling method and phenotype-directed approach to genetic testing, and it may be a cost- and time-efficient method.
- Multigene testing can result in unexpected PGVs, PGVs in genes that do not account for the personal/family history, and a higher VUS incidence.
- Inconsistencies in genetic variant classification are an important challenge that clinicians must understand.
- The Genetic Information Nondiscrimination Act of 2008 provides protection against genetic discrimination by an individual's employer and health insurance provider.
- Racial and ethnic disparities exist for oncology patients eligible for genetic counseling and testing, which should be minimized for optimal cancer prevention and treatment.

HIGH-YIELD TAKEAWAYS

- Regardless of site of origin, MSI-H or dMMR tumors (by IHC or molecular testing) have a higher likelihood of response to PD-1 inhibitors and may be due to LS or be sporadic from epigenetic silencing.
- PARP inhibitors work in *BRCA*-mutated tumors by preventing single-strand break repair, converting them to double-stranded breaks during replication that for BRCA-deficient cells results in cell death, known as synthetic lethality.
- Dedicated germline testing is the gold standard for detecting PGVs and is superior to liquid biopsies or tumor-normal sequencing.
- Testing for PGVs in *BRCA1* and *BRCA2* is indicated for all patients with ovarian and pancreatic cancers, as well as for patients with breast and prostate cancers who are diagnosed at a young age, have triple-negative disease (breast), have male breast cancer, have a suggestive family history, and/or are candidates for therapy with PARP inhibitors.
- Widely accepted options for risk management include high-risk screening of the breasts with MRI, risk-reducing mastectomy, risk-reducing bilateral salpingo-oophorectomy, and risk-reducing medications such as tamoxifen or aromatase inhibitors.
- LS is characterized by increased risk of colorectal, endometrial, ovarian, gastric, small bowel, pancreatic, hepatobiliary, and urothelial cancers, as well as glioblastoma and sebaceous cutaneous neoplasms. Consider germline genetic testing for all colorectal and endometrial cancers.
- Key components of risk management include colonoscopies every 1 to 3 years, consideration of aspirin chemoprevention, risk-reducing hysterectomy/bilateral salpingo-oophorectomy, and upper endoscopy.

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

GENETIC TESTING FOR HEREDITARY CANCER SYNDROMES

6

CHAPTER SUMMARY GUIDE

KEY POINTS

- High-penetrance cancer predisposition genes account for up to 10%-20% of all cancer diagnoses.
- Familial risks outside the high-penetrance syndromes may be related to moderate-risk alleles and additional shared hereditable and/or environmental factors. Empiric risk assessment to account for familial risk may be indicated.
- Consider clinical validity and utility of genes when selecting a multigene panel.
- Inclusion of moderate-penetrance genes associated with a two- to fivefold increased risk of specific cancers is commonplace for panel testing.
- Cancer risk estimates and management recommendations for high- and moderate-penetrance genes are updated continuously.
- Genetic counseling is a communication process that helps patients make informed genetic testing decisions and adapt to having a genetic condition.
- Genetic counseling is guided by principles of autonomy, nonmaleficence, equity, and duty to warn and has traditionally included pre- and posttest discussions.
- Thorough medical and family histories to assess for red flags are vital for accurate genetic risk assessments.
- Evaluation for LS may start with tumor screening for MSI or dMMR, although universal multigene panel testing for all CRCs is gaining acceptance.
- Somatic tumor testing can potentially reveal PGVs that may be of significance for a patient and/or family members.
- The absence of somatic tumor pathogenic/likely pathogenic variants does not exclude the possibility of all identifiable PGVs. Genetic counseling and germline testing may still be warranted.
- Germline variants typically fall into one of five categories: pathogenic, likely pathogenic, uncertain significance (VUS), likely benign, and benign.
- Recommendations for management and predictive testing differ substantially based on the classification of the variant and should be assessed carefully.
- Multigene panel testing is challenging the traditional pretest counseling method and phenotype-directed approach to genetic testing, and it may be a cost- and time-efficient method.
- Multigene testing can result in unexpected PGVs, PGVs in genes that do not account for the personal/family history, and a higher VUS incidence.
- Inconsistencies in genetic variant classification are an important challenge that clinicians must understand.
- The Genetic Information Nondiscrimination Act of 2008 provides protection against genetic discrimination by an individual's employer and health insurance provider.
- Racial and ethnic disparities exist for oncology patients eligible for genetic counseling and testing, which should be minimized for optimal cancer prevention and treatment.

CHAPTER TABLES AND IMAGES

Table 6-1A Selected High- and Moderate-Risk Genes, Syndromes, and Management Considerations: A Through C

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
APC	FAP, AFAP; variant: Turcot syndrome, GAPPS	Colorectal lesions (adenomatous polyposis and cancer), gastric and duodenal/small-bowel lesions (adenomatous polyps and cancer), desmoid tumors, thyroid (particularly cribriform-morula variant of papillary thyroid carcinoma), hepatoblastoma (usually in patients less than 5 years old), pancreatic cancer, medulloblastoma (Turcot syndrome), GAPPS	Colonoscopy (beginning as early as age 10 years) and total colectomy based on polyp burden; upper endoscopy, consideration of small-bowel visualization, thyroid examination, and consideration of ultrasonography; consideration of childhood liver palpation, abdominal ultrasonography, AFP measurement	Genotype-phenotype correlations between classic FAP and AFAP: mutations on the 5′ and 3′ ends of the gene correlate with AFAP; high de novo mutation rate (about 20%-25%); extracolonic features: CHRPE, osteomas, supernumerary teeth, desmoid tumors, epidermoid cysts, gastric fundic gland polyps; chemoprevention not a replacement for colonoscopy and colectomy	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18,19]
*APC**I1307K (c.3920T->A)		Colorectal cancer: moderate penetrance	Colonoscopy every 5 years beginning at age 40 years or earlier depending on family history; lifetime risk 5%-10%	Ashkenazi Jewish founder PGV; not associated with polyposis	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]; Katona et al[20]
ATM	Ataxia telangiectasia	Monoallelic carriers: breast (especially ER-positive), pancreas, possibly ovary, prostate; biallelic carriers: leukemia, lymphoma	Monoallelic carriers: breast screening with annual mammogram at age 40 and breast MRI starting at age 30-35 years or per family history*; pancreas screening beginning at age 50 years (or 10 years prior to earliest exocrine pancreatic cancer in the family); biallelic carriers: AT specialist for multidisciplinary management; consider annual prostate cancer screening at age 40 years	Monoallelic carriers: limited evidence for gastrointestinal cancers; risk of autosomal recessive AT condition in biallelic offspring of heterozygous carriers; AT: childhood cerebellar ataxia, telangiectasias of the conjunctivae, immunodeficiency, sensitivity to radiation	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15,21,22]
AXIN2	AXIN2-associated oligodontia and polyposis	Colorectal lesions (adenomatous polyposis ranging from 10s to 100s and cancer)	Colonoscopy every 2-3 years beginning at age 25-30 years; if polyps are found, every 1 to 2 years with consideration of surgery depending on polyp burden	Patients often also have oligodontia (absence of six or more permanent teeth excluding wisdom teeth) and ectodermal dysplasia	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial and Gastric[18]
BARD1		ER-negative breast cancer, triple-negative breast cancer	Annual mammogram and consideration of breast MRI starting at age 40 years		NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
BAP1	*BAP1* tumor predisposition syndrome	Atypical Spitz tumors, uveal melanoma, malignant mesothelioma, cutaneous melanoma, clear cell renal cell carcinoma, basal cell carcinoma	Eye examinations, dermatologic examinations, consideration of abdominal ultrasonography and/or MRI of the kidneys	Limited evidence for possible other associated tumors: non-small cell lung adenocarcinoma, breast cancer, cholangiocarcinoma, meningioma, neuroendocrine carcinoma	NCCN Kidney Cancer,[23] Pilarski et al,[24] Lalloo et al[25]
BMPR1A and *SMAD4*	Juvenile polyposis syndrome	GI lesions (juvenile/hamartomatous polyps and cancer [colorectal, stomach, small bowel])	Colonoscopy and upper endoscopy every 1-3 years beginning at age 12-15 years; surgical management based on polyp burden; HHT screening for *SMAD4* carriers	"Juvenile" refers to polyp histology, not age at onset; *SMAD4* mutations associated with HHT; *SMAD4* PGVs associated with massive gastric polyposis	Haidle et al,[26] NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial and Gastric[18]
BRCA1 and *BRCA2*	Hereditary breast cancer and ovarian cancer syndrome	Breast (*BRCA1*: often triple-negative tumor), male breast, ovarian (epithelial; high-grade serous), fallopian tube, primary peritoneal, prostate (high Gleason score), pancreatic adenocarcinoma	Breast screening with annual mammogram and breast MRI starting at age 25-30 years; male self-examination and clinical breast examination at 35 years; consideration of mammography in males; optional risk-reducing mastectomy in females; risk-reducing BSO between age 35 and 45 years*; PSA measurement and digital rectal examination starting at age 40 years; consideration of chemoprevention (eg, tamoxifen, OCPs); FDA approval of PARP inhibitors for select BRCA-associated breast, ovary, pancreas, prostate cancers; pancreas screening starting at age 50 years or per family history	Founder PGVs in certain populations (eg, Ashkenazi Jewish, Icelandic); risk of autosomal recessive Fanconi anemia with biallelic PGVs	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]
BRIP1		Ovarian (heterozygous carriers)	Consider risk-reducing BSO at age 45-50 years or per family history	Risk of autosomal recessive Fanconi anemia in biallelic offspring of heterozygous carriers	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]

Abbreviations: AFAP, attenuated familial adenomatous polyposis; AFP, alpha-fetoprotein; AT, ataxia telangiectasia; BSO, bilateral salpingo-oophorectomy; CHRPE, congenital hypertrophy of the retinal pigment epithelium; ER, estrogen receptor; FAP, familial adenomatous polyposis; GAPPS, gastric polyposis with APC promoter 1b mutations; HHT, hereditary hemorrhagic telangiectasia; OCP, oral contraceptive pills; PARP, poly ADP ribose polymerase; PGV, pathogenic germline variants; PSA, prostate-specific antigen.
Leukemia/lymphoma predisposition syndromes are not listed; refer to Chapters 19 and 20. Most childhood-onset conditions are not listed; refer to Lindor et al.[27]
*Earlier initiation of breast cancer surveillance should be determined based on personal/family history of breast cancer.[15]

Table 6-1B **Selected High- and Moderate-Risk Genes, Syndromes, and Management Considerations: C Through G**

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
CDH1	Hereditary diffuse gastric cancer syndrome	Diffuse gastric cancer, lobular breast cancer (ER-positive)	A strategy of surveillance upper endoscopy with biopsies of the stomach, consideration of risk-reducing total gastrectomy, breast screening with annual mammography and breast MRI at 30, optional risk-reducing mastectomy	Can manifest as cleft palate	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15,19]
CDKN2A, CDK4	FAMMM syndrome	Melanoma and dysplastic nevi, pancreatic adenocarcinoma	Dermatologic examination, pancreas screening recommended beginning at age 40 years*	Risk of melanoma may be independent of genetic test result; *CDKN2A* (p16) founder PGV in the Netherlands; PGVs affecting p14ARF are associated with a different spectrum of tumors, including melanoma, sarcomas, nervous system tumors, and possibly breast cancer; consider full-body MRI and brain MRI for those with p14ARF PGVs	Goldstein et al,[28] Vasen et al,[29] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostates[15]
CHEK2		Breast cancer	For truncating pathogenic variants, breast screening with annual mammography at age 40 years and breast MRI starting at age 30-35 years, or per family history. Consider prostate cancer screening starting at age 40	Genotype-phenotype: different risks for truncating mutations versus missense mutations; Limited evidence for association with prostate, thyroid, and renal cancers, possibly leukemia and plasma cell neoplasms	Zeng et al,[30] Hanson et al,[31] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostates,[15] AlDubayan et al[32]
CHEK2 (low penetrance, including I157T/470T>C; S428F/ c.1283C>T; and T476M/ c.1427C>T)		Breast cancer; possibly leukemia and plasma cell neoplasms	Low-penetrance missense CHEK2 variants may not be actionable. Studies demonstrate the lifetime breast cancer risk is less than 20%. Management recommendations should be based on clinical assessment and family history	Genotype-phenotype: different risks for truncating mutations vs missense mutations; limited evidence for association with prostate, thyroid, and renal cancers	Zeng et al,[30] Hanson et al,[31] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreas,[15] AlDubayan et al[32]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
FH	HLRCC	Cutaneous leiomyomata, uterine leiomyomata, renal tumors (type 2 papillary, tubule-papillary, collecting-duct carcinomas; unilateral, solitary lesions); rare paraganglioma/ pheochromocytoma	Dermatologic and gynecologic examinations; evaluate for changes suggestive of leiomyosarcoma; medication or resection of leiomyomata, imaging for and surgical management of renal tumors; abdominal MRI (preferred) or CT, both exams with and without IV contrast, annually starting at age 8-10 years and performed every 3 years	FH enzyme assay might be helpful in some situations. Risk for uterine leiomyosarcoma is unclear. Biallelic FH PGVs cause a recessive disorder known as FH deficiency metabolic disorder, profound developmental delay, seizures, and fumaric aciduria	Kamihara et al,[33] Barrisford et al,[34] NCCN Kidney Cancer
FLCN	BHD syndrome	Benign cutaneous findings (fibrofolliculomas, trichodiscomas/ angiofibromas, perifollicular fibromas, acrochordons), pulmonary cysts, renal tumors (oncocytoma, chromophobe, oncocytic hybrid tumors)	No consensus at this time. Dermatologic care, imaging for and surgical management (nephron sparing) of renal tumors	Fibrofolliculomas are specific to BHD. Predisposition to multiple lung cysts may present as spontaneous pneumothorax. Renal tumors are multifocal, bilateral, and slow growing. Other features include parotid lesions, oral papules, and thyroid lesions. Data are unclear regarding colon cancer. There are possible genotype/phenotype correlations	van de Beek et al,[35] Sattler and Steinlein,[36] NCCN Kidney Cancer
GREM1	Hereditary mixed polyposis syndrome	Multiple polyps of multiple and mixed morphologies, including serrated lesions, Peutz-Jeghers polyps, juvenile polyps, conventional adenomas and colorectal adenocarcinoma	Colonoscopy every 2-3 years beginning at age 25-30 years unless polyps are found; consider total colectomy based on polyp burden	Founder PGV in Ashkenazi Jewish individuals; duplication spanning the 3′ end of the SCG5 gene and a region upstream of the *GREM1* locus	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]

Abbreviations: BHD, Birt-Hogg-Dube; ER, estrogen receptor; FAMMM, familial atypical mole melanoma syndrome; FH, fumarate hydratase; HLRCC, hereditary leiomyomatosis and renal cell cancer; IV, intravenous; OCP, oral contraceptive pills; PGV, pathogenic germline variants.

Leukemia/lymphoma predisposition syndromes are not listed; refer to Chapters 19 and 20. Most childhood-onset conditions are not listed; refer to Lindor et al.[27]

*Earlier initiation of breast cancer surveillance should be determined based on personal/family history of breast cancer.[15]

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 6-1C **Selected High- and Moderate-Risk Genes, Syndromes, and Management Considerations: M Through P**

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
MBD4	*MBD4*-associated neoplasia syndrome or *MBD4* biallelic PGVs	Colorectal polyposis, AML, uveal melanoma	Colonoscopy every 2-3 years starting at age 18-20 years, consider CBC at diagnosis, ophthalmology exam at diagnosis and annually	Unknown risks for heterozygous carriers	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
MEN1	MEN-1	GEP tract, well-differentiated endocrine tumors, pituitary tumors (prolactinoma), parathyroid tumors, carcinoid tumors, adrenocortical tumors	Biochemical testing with emphasis on pancreatic and pituitary hormones and calcium, imaging of chest and abdomen every 1-3 years starting at age 8-15 years, brain MRI every 3-5 years starting at age 5 years, medical management of endocrinopathies, parathyroidectomy in setting of hyperparathyroidism	Primary hyperparathyroidism, hypercalcemia, oligomenorrhea/amenorrhea, galactorrhea, Zollinger-Ellison syndrome (gastrinoma), insulinoma, glucagonoma, VIP-secreting tumor (VIPomas); other features: skin (angiofibromas, collagenomas), lipomas, CNS lesions (meningioma, ependymoma), leiomyomas	Giusti et al[37] and NCCN Neuroendocrine and Adrenal Tumors[38]
MET (*c-MET*)	HPRC	Papillary renal cancer (multifocal, bilateral, type 1 papillary)	Imaging, surgical management		Coleman and Russo,[39] NCCN Kidney Cancer[40]
MLH1/MSH2/MSH6/PMS2/EPCAM	Lynch syndrome (formerly, HNPCC); variant: Muir-Torre syndrome; variant: Turcot syndrome; variant: CMMR-D syndrome (biallelic PGVs; recessive inheritance)	Colorectal, endometrial ovarian (epithelial), stomach, small bowel, urothelial, pancreas, hepatobiliary tract, sebaceous neoplasms of the skin (Muir-Torre syndrome), glioblastoma (Turcot syndrome), prostate	Colonoscopy every 1-2 years starting at age 20-25 years* (*MLH1* and *MSH2*) or every 1-3 years starting at age 30-35 years* (*MSH6* and *PMS2*); hysterectomy, and risk-reducing BSO (*MLH1, MSH2*) insufficient evidence and decision for risk-reducing hysterectomy and BSO for *MSH6* should be individualized); endometrial biopsy every 1-2 years starting at age 30-35 years can be considered upper endoscopy every 2-4 years starting at age 30-40 years; consideration of urinalysis or urine cytology, consider skin exam every 1-2 years (age to start surveillance can be individualized), and aspirin for chemoprevention (optimal dose to be determined); except for *PMS2*, pancreas screening starting at age 50 years or earlier if there is a family history of pancreatic cancer in a first- or second-degree relative; consider annual prostate cancer screening at age 40 years	Tumor analyses with IHC staining, MSI analysis, somatic tumor genetic analysis, *BRAF* V600E somatic analysis, MLH1 promoter hypermethylation analysis; Amsterdam criteria I and II, revised Bethesda guidelines; recommendations for universal screening of colorectal and endometrial cancers; risk of autosomal recessive CMMR-D syndrome (cafe-au-lait macules, solid tumors, hematologic cancers) in offspring	NCCN Genetic/Familial High-Risk Assessment: Colorectal[18]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
MLH3/MSH3	*MLH3*-and *MSH3*-associated polyposis	Biallelic PGV carriers: colorectal lesions (adenomatous polyposis and cancer); recently discovered so unclear	Colonoscopy every 2-3 years beginning at age 25-30 years unless polyps; consider total colectomy based on polyp burden	*MSH3* tumors exhibit EMAST (MSI of di- and tetranucleotide repeats); *MLH3* tumors did not	Olkinuora et al,[41] NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
MUTYH	MAP	Biallelic PGV carriers: colorectal lesions (adenomatous polyposis and cancer; serrated and hyperplastic polyps also described), stomach, duodenal lesions (adenomatous polyps, cancer)	Colonoscopy every 1-2 years, starting at age 25-30 years; consider total colectomy based on polyp burden; upper endoscopy beginning at age 30-35 years	Phenotypically similar to AFAP; two northern European founder PGVs; no increased colorectal cancer risk in heterozygous carriers	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
NF1	Neurofibromatosis type 1	Cutaneous neurofibromas, plexiform neurofibromas, optic nerve and other CNS gliomas, malignant peripheral nerve sheath tumors, breast (moderate risk), others: GIST, leukemia, paraganglioma/ pheochromocytoma	Neurofibromatosis type 1 specialist for management, physical and ophthalmologic examinations; imaging; surgical management; breast screening with annual mammography starting at age 30 years and breast MRI from ages 30-50 years, per family history*	Cafe-au-lait macules, axillary and inguinal freckling, iris Lisch nodules, learning disabilities, scoliosis, tibial dysplasia, vasculopathy	Friedman,[42] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostates[15]
NTHL1	*NTHL1*-associated polyposis	Biallelic PGV carriers: colorectal lesions (less than 50 adenomatous polyps and cancer)	Colonoscopy every 2-3 years beginning at age 25-30 years unless polyps; consider total colectomy based on polyp burden; EGD at age 30-35 years every 1-4 years based on findings; education regarding importance of prompt reporting of any abnormal uterine bleeding or postmenopausal bleeding; no other screening recommendations have been made to date for breast or the other extracolonic cancers	c.268c>T (p.GIn90*) variant is the most common truncating PGV and has higher prevalence in European cohorts. Tumors have mutation signature (COSMIC Signature 30). There are possible increased risks for breast, endometrial, basal cell, hematologic and cervical cancers, meningioma and bladder tumors	Grolleman et al,[43] NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
PALB2		Breast cancer (particularly ER-positive), ovarian cancer, pancreatic cancer	Breast screening with annual mammogram and breast MRI with and without contrast starting at age 30; optional risk-reducing mastectomy in females; consideration of risk-reducing BSO between age 45 and 50 years. Pancreatic surveillance may be considered with or without family history of pancreatic cancer. Consider prostate cancer screening starting at age 40	Risk of autosomal recessive Fanconi anemia in biallelic offspring of heterozygous parents	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
POLE/POLD1	Polymerase proofreading-associated polyposis	Colorectal lesions (attenuated adenomatous polyposis and cancer), duodenal (adenomas and cancer), endometrial cancer	Colonoscopy every 2-3 years beginning at age 25-30 years unless polyps; consider total colectomy based on polyp burden; baseline upper endoscopy beginning at age 25-30 years; education regarding importance of prompt reporting of any abnormal uterine bleeding or postmenopausal bleeding	Two recurrent PGVs have been identified: *POLE* p.L424V and *POLD1* p.S478N. Nearly all the described PGVs are activating mutations in the exonuclease domain. It is probably associated with brain tumors and possibly endometrial and breast cancers	NCCN Genetic/Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric[18]
PTCH1 *SUFU*	Gorlin syndrome/ nevoid basal cell carcinoma syndrome	Jaw (odontogenic) keratocysts, basal cell carcinomas, medulloblastoma PNET desmoplastic	Referral to a specialist for management; physical examination, avoidance of sun exposure and at least annual dermatologic examination, surgical management	Other features: congenital skeletal anomalies, cleft lip/palate, cerebral/falx calcifications, macrocephaly with frontal bossing, polydactyly, intellectual disability, lymphomesenteric or pleural cysts, palmar/ plantar pits, cardiac fibromas, ovarian fibromas, ocular abnormalities	Evans and Farndon[44] and Foulkes et al[45]
PTEN	Cowden syndrome/PTEN hamartoma tumor syndrome	Breast cancer, thyroid cancer (most often follicular), endometrial cancer, colorectal lesions (hamartomas, ganglioneuromas, cancer), renal cell carcinoma	Annual thyroid examination and ultrasonography starting at age 12 years, endometrial screening with random biopsy and ultrasonography starting at age 35 years, optional hysterectomy, colonoscopy every 5 years beginning at age 35 years unless polyps, renal ultrasonogram every 1-2 years starting at age 40 years	Major and minor criteria (tumors, physical and dermatologic/ mucocutaneous findings, developmental disability); macrocephaly, Bannayan-Riley-Ruvalcaba syndrome, PTEN-related *Proteus* syndrome, autism spectrum disorder, Lhermitte-Duclos disease	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]

Abbreviations: AFAP, attenuated familial adenomatous polyposis; AML, acute myeloid leukemia; BSO, bilateral salpingo-oophorectomy; CBC, complete blood count; CMMR-D, constitutional mismatch repair deficiency; CNS, central nervous system; EGD, esophagogastroduodenoscopy; EMAST, elevated microsatellite alterations at selected tetranucleotides; GEP, gastroenteropancreatic; GIST, gastrointestinal stromal tumor; HNPCC, hereditary nonpolyposis colorectal cancer; HPRC, hereditary papillary renal carcinoma; IHC, immunohistochemistry; MAP, MUTYH-associated polyposis; *MEN-1*, multiple endocrine neoplasia type 1; MEN1, menin 1; MSI, microsatellite instability; NF1, neurofibromin 1; PGV, pathogenic germline variants; PNET, primitive neuroectodermal tumors; VIP, vasoactive intestinal peptide.

Leukemia/lymphoma predisposition syndromes are not listed; refer to Chapters 19 and 20. Most childhood-onset conditions are not listed; refer to Lindor et al.[27]

*Earlier initiation of breast cancer surveillance should be determined based on personal/family history of breast cancer.[15]

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 6-1D **Selected High- and Moderate-Risk Genes, Syndromes, and Management Considerations: R Through V**

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
RAD51C		ER-negative breast cancer, triple-negative breast cancer, ovarian cancer	Annual mammogram and consideration of breast MRI starting at age 40 years; risk-reducing salpingo-oophorectomy at age 45-50 years	Risk of autosomal recessive Fanconi anemia	NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]
RAD51D		Breast cancer, ovarian cancer	Annual mammogram and consideration of breast MRI starting at age 40 years; risk-reducing salpingo-oophorectomy at age 45-50 years		NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate[15]
RB1	Retinoblastoma	Retinoblastoma (trilateral disease: cooccurrence of pinealoblastoma), bone or soft-tissue sarcomas, melanoma, others	Ophthalmologic examination and imaging; care by a multidisciplinary team; avoidance of radiation	Usually bilateral or multifocal disease; mosaic forms; therefore, analysis of tumor tissue and blood is important; RNA studies may also be recommended; low-penetrance mutations identified; parent-of origin effect in some families	Lohmann and Gallie,[46] Knudsen,[47] Abramson et al,[48] and Abramson and Frank[49]
RET	MEN-2; three subtypes: MEN-2A (aka, Sipple syndrome), familial medullary thyroid carcinoma, MEN-2B	Medullary thyroid carcinoma (multifocal, bilateral) and primary C-cell hyperplasia, pheochromocytoma (bilateral) (MEN-2A and 2B), parathyroid adenoma/hyperplasia (hyperparathyroidism, hypercalcemia, renal stones; MEN-2A)	Prophylactic thyroidectomy (varies from infancy to age 5 years, depending on specific *RET* PGV; genotype-phenotype correlations); surgical management of identified disease, serum calcitonin concentration, consideration of eligibility for treatment with kinase inhibitors, biochemical screening and imaging for pheochromocytoma and parathyroid abnormalities	Genotype-phenotype correlations MEN-2A: MTC in early adulthood; FMTC: MTC in middle age; MEN-2B: MTC in early childhood, mucosal neuromas (lips, tongue), dysmorphic features (large lips, "marfanoid" body habitus), GI ganglioneuromatosis; *RET* gene loss of function PGVs also associated with Hirschsprung disease	Eng and Plitt[50] and Wells et al[51]
SDHB/ SHDC/ SDHD/ SDHA/ SDHAF2, MAX, TMEM127	Hereditary paraganglioma/ pheochromo-cytoma syndrome	PGL-sympathetic and parasympathetic PCC, GISTs, renal clear cell carcinoma, and other less well-defined cancer risks such as papillary thyroid carcinoma	*SDHA* appears to have lower penetrance than other SDHx PGVs; screening in this population such as plasma-free fractionated metanephrines or 24-hour urine fractionated metanephrines (optional dopamine or 3-methoxytyramine) to screen for secreting PGL/PCC and whole-body MRI for PGL, PCC, renal cell carcinoma, and GIST is controversial because of conflicting guidelines	Secretory and nonsecretory PGL, high blood pressure, headache, anxiety, profuse sweating, palpitations, pallor; *SDHB*: high risk of malignant transformation; *SDHD*: parent-of-origin effect, disease-causing when paternally inherited; *SDHAF2*: possible parent-of-origin effect (paternal inheritance)	Hanson et al[52] and Amar et al[53]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
STK11 (*LKB1*)	PJS	GI lesions (PJS-type hamartomatous polyps; colorectal, stomach, small-bowel cancer), breast, pancreas, gynecologic (ovarian SCTAT sex cord tumor with annual tubules), cervix (minimum deviation adenocarcinoma), uterus, testes (Sertoli cell), lung	Colonoscopy and upper endoscopy with small-bowel visualization every 2-3 years beginning at about age 18 years, breast screening with annual mammography and breast MRI beginning at age 30, pancreas screening beginning at about age 30-35 years, gynecologic examination and annual pelvic ultrasonogram beginning at about age 18-20 years, annual testicular examination, including in the pediatric setting	Mucocutaneous hyperpigmentation of mouth, lips, nose, eyes, genitalia, fingers; may fade after puberty	McGarrity et al,[54] NCCN Genetic/ Familial High-Risk Assessment: Colorectal, Endometrial, and Gastric,[18] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, Pancreatic, and Prostate
TP53	LFS	Soft tissue and bone sarcomas, breast cancer, brain cancer, adrenocortical carcinoma, leukemia, other cancers (GI, genitourinary, lung, lymphomas, thyroid, neuroblastoma, skin)	Screening beginning in childhood with comprehensive physical exam including neurological exam and CBC with differential every 3-4 months until age 18 years; annual full-body and brain MRI; ultrasound abdomen and pelvis every 3-4 months; blood biochemistry if unsatisfactory ultrasound quality; in adults (18 years or older), comprehensive physical exam every 6 months, ultrasound of the abdomen and dermatologic exam annually; blood biochemistry if unsatisfactory ultrasound quality; breast screening with annual breast MRI and mammography beginning at age 20 and 30 years, respectively; consideration of risk-reducing mastectomy; CBC with differential every 3-6 months in patients with prior cytotoxic chemotherapy or radiation exposures; physical examination, including dermatologic and neurologic examinations; pancreatic surveillance if an affected close relative; colonoscopy and upper endoscopy every 2-5 years starting at age 25 years; annual whole-body MRI with brain MRI, consideration of radiation avoidance, if clinically appropriate	Classic LFS criteria; Chompret criteria; consider genetic testing in *BRCA*-negative, isolated, early-onset breast cancer (age less than 31 years); breast cancers more likely to be ER, progesterone receptor, and HER2/neu receptor positive; consider additional *TP53* variant workup for individuals with variant allele fraction below heterozygous range (typically <30%) and/or in when LFS clinical criteria are not met	Schneider et al,[55] Li and Fraumeni,[56] Chompret et al,[57] Villani et al,[58] Kratz et al,[59] NCCN Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreatic and Prostate[15] and Achatz et al[60]

Genes	Syndromes	Associated Neoplasms	Management Considerations	Other Notes	References
TSC1 and *TSC2*	TSC	Kidney: renal cell carcinomas, angiomyolipomas (benign and malignant), epithelial cysts, oncocytoma (benign adenomatous hamartoma)	TSC specialist for management: imaging; dermatologic, dental, ophthalmologic examinations; echocardiography; electrocardiography; consideration of eligibility for treatment with mTOR inhibitors, surgical management	Skin (hypomelanotic macules, facial angiofibromas, shagreen patches, cephalic plaques, ungual fibromas); brain (cortical dysplasias, subependymal nodules and subependymal giant cell astrocytomas, seizures, intellectual disability/developmental delay, autism spectrum disorder, psychiatric illness); heart (rhabdomyomas, arrhythmias); lungs (lymphangioleiomyomatosis); genotype-phenotype correlations: higher risk of renal cell carcinoma in TSC2; possible association with neuroendocrine tumors	Northrup et al[61] and NCCN Kidney Cancer[23]
VHL	VHL syndrome	Clear cell renal cell carcinoma, pheochromocytoma, paragangliomas, pancreatic neuroendocrine tumors	Biochemical screening, imaging of the abdomen and CNS, renal sparing management of kidney cancers; consideration of belzutifan for prevention	Hemangioblastomas of the brain, spinal cord, and retina; renal cysts; pancreatic cysts; endolymphatic sac tumors; epididymal and broad ligament cysts; genotype-phenotype correlations: VHL type 1, type 2A, type 2B, type 2C with different risks of pheochromocytoma or renal cell carcinoma	Van Leeuwaarde et al[62] and NCCN Kidney Cancer[23]

Abbreviations: CNS, central nervous system; ER, estrogen receptor; FMTC, familial medullary thyroid carcinoma; GI, gastrointestinal; GIST, gastrointestinal stromal tumor; LFS, Li-Fraumeni syndrome; MEN-2, multiple endocrine neoplasia type 2; mTOR, mechanistic target of rapamycin; NF1, neurofibromin 1; PCC, pheochromocytoma; PGL, paraganglioma; PGV, pathogenic germline variants; PJS, Peutz-Jeghers syndrome; SCTAT, sex cord tumors with annular tubules; TSC, tuberous sclerosis complex; VHL, von Hippel-Lindau.
Leukemia/lymphoma predisposition syndromes are not listed; refer to Chapters 19 and 20. Most childhood-onset conditions are not listed; refer to Lindor et al.[27]
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 6-2 **Prevalence of Cancer Susceptibility Pathogenic Germline Variants for Unselected Patients**

Cancer Type	Patients With Germline Variants, N/Total Patients	PGV Prevalence, %
Breast	83/959[91]	8.65-10.8
	494/4,581[92]	
Triple-negative breast	267/1,824[93]	14.60
Lung (advanced cancer only)	222/5,118[94]	4.3-5.8
	448/7,668[92]	
Colon	305/5,303[95]	5.8-9.9
	105/1,058[96]	
Prostate	247/2,887[95]	8.6-17.3
	620/3,607[97]	
Osteosarcoma	281/1,044[98]	28.00
Renal	85/1,336[92]	6.40
Pancreatic (adenocarcinoma)	273/3,535[99]	7.7-14.1
	25/177[92]	
Bladder/urothelial (advanced cancer only)	79/1,188[100]	6.6-14
	80/586[101]	
Ovarian	60/515 (*BRCA1/BRCA2* only)[92]	11.7-13.8
	380/2,756[92]	
Endometrial	76/1,542[102]	4.9-9.2
	35/381[92]	
Head/neck	51/1,218[92]	4.20
Cholangiocarcinoma	36/8,401[92]	4.30
Esophageal	36/747[92]	4.80
Gastric	48/243[103,104]	19.80

Abbreviation: PGV, pathogenic germline variant.

Table 6-3 **Genetic Cancer Predisposition Syndromes and Selected Associated Pathologies**	
Neoplastic or Preneoplastic Pathologies	**Associated Genetic Syndromes and Genes**
High-grade or poorly differentiated ductal breast cancer with estrogen receptor, progesterone receptor, and HER2/neu negativity	Hereditary breast and ovarian cancer syndrome (*BRCA1*); *BARD1, PALB2, RAD51C, RAD51D*
Lobular breast cancer	Hereditary diffuse gastric cancer syndrome (*CDH1*)
High-grade serous (papillary serous) ovarian	Hereditary breast and ovarian cancer syndrome (*BRCA1, BRCA2*)
Clear cell or endometrioid ovarian cancers	Lynch syndrome (*MLH1, MSH2, MSH6, PMS2, EPCAM*)
Ovarian sex cord tumors with annular tubules	Peutz-Jeghers syndrome (*STK11*)
Clear cell or endometrioid endometrial cancers	Lynch syndrome (*MLH1, MSH2, MSH6, PMS2, EPCAM*)
Uterine leiomyomas	Hereditary leiomyoma renal cell carcinoma syndrome (*FH*)
Minimal deviation adenocarcinoma (adenoma malignum of the cervix)	Peutz-Jeghers syndrome (*STK11*)
Colorectal cancer with tumor-infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring cells, medullary growth pattern	Lynch syndrome (*MLH1, MSH2, MSH6, PMS2, EPCAM*)
Lauren diffuse type/signet ring cell/linitus plastica gastric cancer	Hereditary diffuse gastric cancer syndrome (*CDH1*); *CTNNA1*
Hamartomatous gastrointestinal polyps	Peutz-Jeghers syndrome (*STK11*); juvenile polyposis syndrome (*BMPR1A, SMAD4*); Cowden syndrome (*PTEN*)
Pancreatic neuroendocrine tumors	Multiple endocrine neoplasia type 1 (*MEN1*); von Hippel-Lindau (*VHL*)
Renal papillary type I carcinoma	Hereditary papillary renal cancer syndrome (*MET*)
Renal papillary type II, collecting duct, tubulopapillary carcinomas	Hereditary leiomyomatosis and renal cell carcinoma syndrome (*FH*)
Renal clear cell carcinoma	von Hippel-Lindau (*VHL*)
Renal oncocytoma	Birt-Hogg-Dube syndrome (*FLCN*); tuberous sclerosis complex (*TSC1, TSC2*)
Renal angiomyolipoma	Tuberous sclerosis complex (*TSC1, TSC2*)
Renal chromophobe	Birt-Hogg-Dube syndrome (*FLCN*)
Sertoli cell tumors of the testes	Peutz-Jeghers syndrome (*STK11*)
Medullary thyroid cancer	Multiple endocrine neoplasia type 2 (*RET*)
Cribriform-morular variant of papillary thyroid carcinoma	Familial adenomatous polyposis (*APC*)
Follicular thyroid cancer	Cowden syndrome (*PTEN*)
Medulloblastoma	Turcot syndrome variant of familial adenomatous polyposis (*APC*); Nevoid basal carcinoma syndrome (Gorlin) (*PTCH1*)
Glioblastoma	Turcot syndrome variant of Lynch syndrome (*MLH1, MSH2*, MSH6, *PMS2, EPCAM*); Li-Fraumeni syndrome (*TP53*)
Basal cell carcinoma	Xeroderma pigmentosum (multiple xeroderma pigmentosum-associated genes); Nevoid basal carcinoma syndrome (Gorlin) (*PTCH1*)
Sebaceous adenoma, sebaceous carcinoma, keratoacanthoma	Muir-Torre syndrome variant of Lynch syndrome (*MLH1, MSH2, MSH6, PMS2, EPCAM*)
Fibrofolliculomas	Birt-Hogg-Dube syndrome (*FLCN*)
Facial trichilemmomas	Cowden syndrome (*PTEN*)

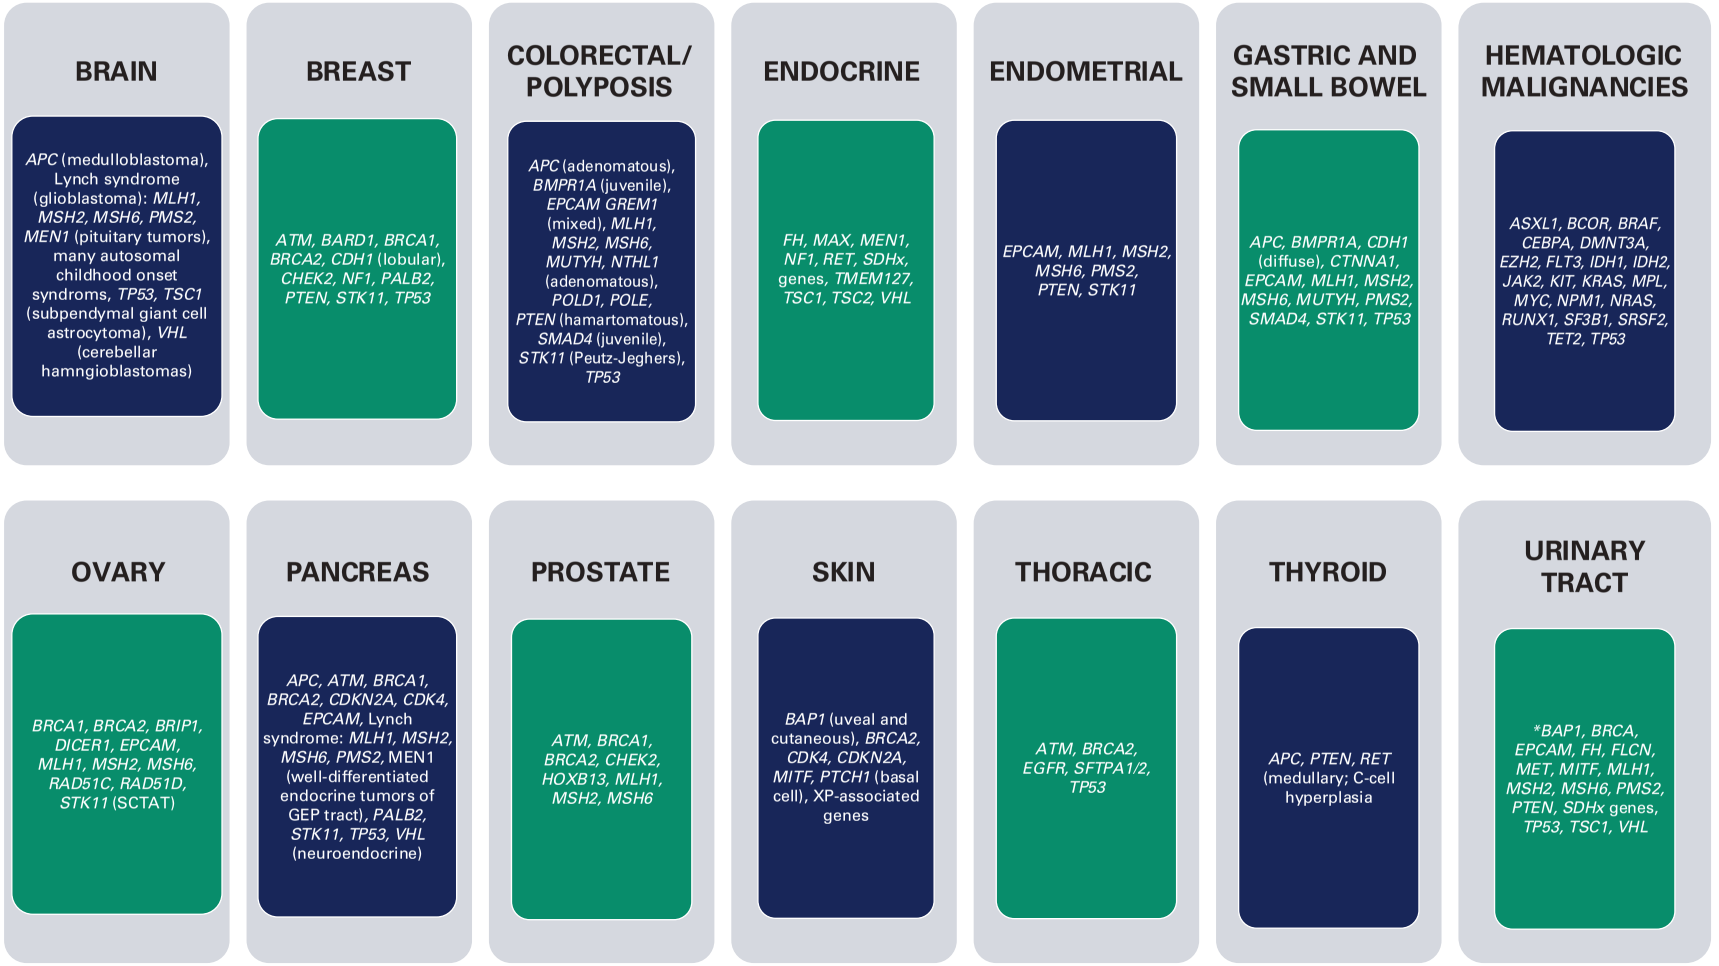
Table 6-4 **Genes With Autosomal Recessive Disease Risk**

Gene	Syndrome
ATM	Ataxia telangiectasia
BLM	Bloom syndrome
BRCA1, BRCA2, BRIP1, PALB2, RAD51C	Fanconi anemia
FH	Fumarate hydratase deficiency
MLH1, MSH2, EPCAM, MSH6, PMS2	Constitutional mismatch repair deficiency syndrome
MUTYH, NTHL1, MSH3, MLH3, MBD4	MUTYH-associated polyposis, etc
NBN	Nijmegen breakage syndrome
WRN	Werner syndrome
DDB2, ERCC1, ERCC2, ERCC3, ERCC4, ERCC5, POLH, XPA, XPC	Werner syndrome

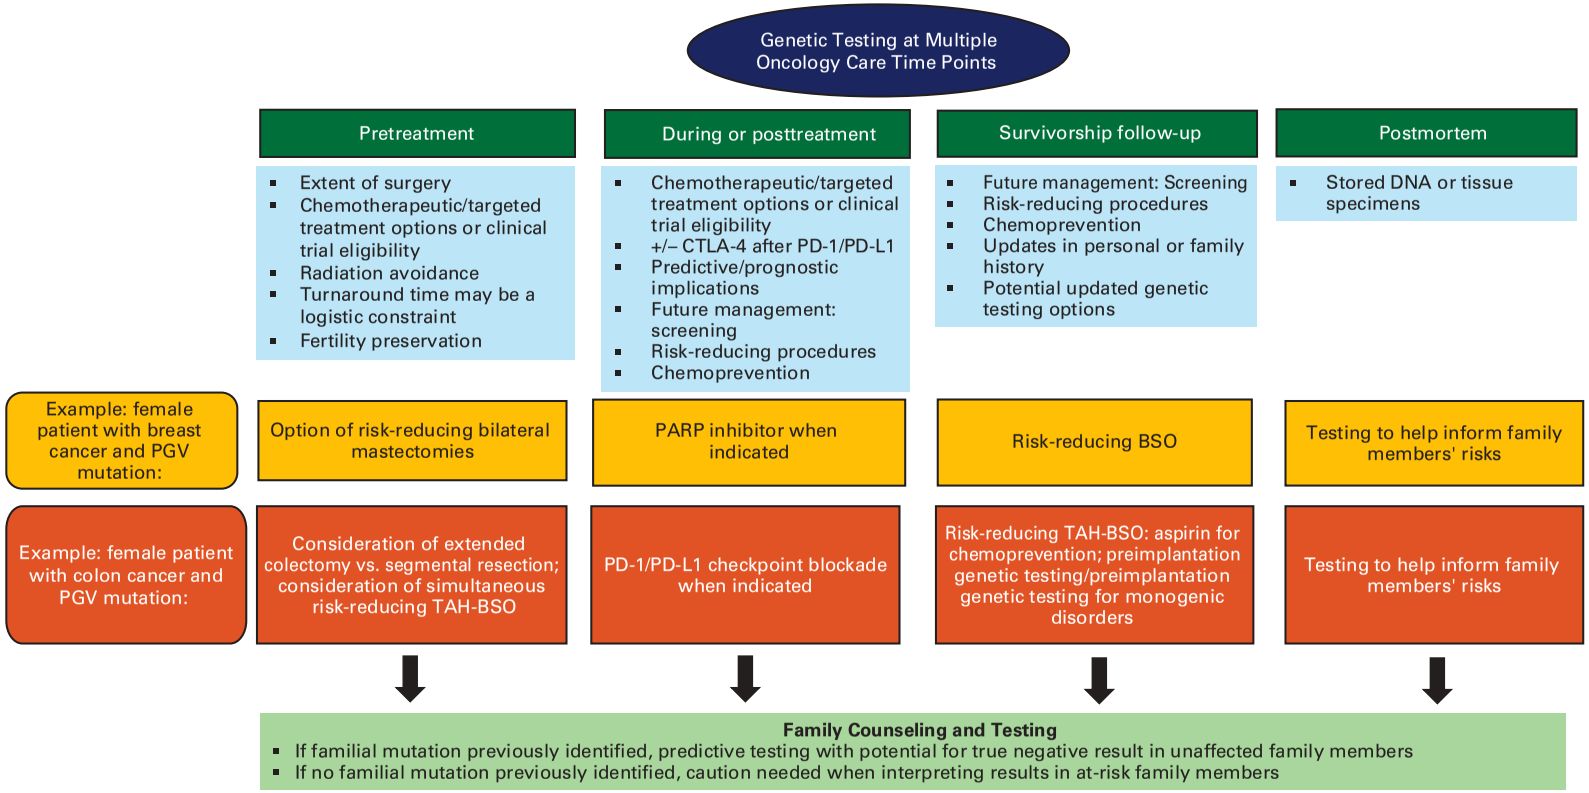
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 6-1 Cancer Types and Select Associated Genes



Abbreviations: FH, fumarate hydratase, including type 2 papillary, tubular papillary, and collecting-duct carcinoma; FLCN, folliculin, oncocytoma, chromophobe, and oncocytic hybrid tumor; GEP, gastroenteropancreatic; MET, type 1 papillary; SCTAT, sex cord tumors with annular tubules; TSC1, TSC2, renal cell carcinoma, angiomyolipomas, and oncocytoma; XP, xeroderma pigmentosum.
*Urinary tract gene-associated pathologies. Gene-specific pathologies are listed in Tables 6-1A to D.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 6-2 Incorporating Genetic Counseling and Testing Into the Care of Patients With Cancer



Abbreviations: BSO, bilateral salpingo-oophorectomy; PARP, poly-ADP ribose polymerase; PD-1/PD-L1, programmed cell death protein 1/programmed death ligand 1; PGV, pathogenic germline variant; TAH, total abdominal hysterectomy.

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

CANCER IN THE OLDER ADULT 7

Jimmy Hwang, MD, and Joel Saltzman, MD

RECENT UPDATES

- The updated ASCO geriatric oncology guidelines recommend that patients with cancer aged 65 years or older undergo a geriatric assessment; identified impairments should have geriatric assessment–guided management included in their care plan. The Practical Geriatric Assessment is one potential tool to implement geriatric assessments and guide management in clinical practice.
- A geriatric assessment can reduce treatment-related toxicity and patient-reported symptoms as well as can improve clinical outcomes. Eighty-six percent of patients reported at least one symptom of moderate or greater severity before initiating treatment. Patients who received geriatric assessment recommendations had decreased symptomatic toxicities compared with those who did not (usual care plus geriatric assessment without summary or treatment recommendations).[1]
- Older women with high-risk early breast cancer benefit from adjuvant chemotherapy, but treatment is complicated by adverse effects, resulting in dose reductions and delays. The recommended relative dose intensity (RDI) is 85% or higher for curative-intent chemotherapy. Older patients who received low RDI had inferior survival outcomes. Therefore, it is important to preserve dose intensity and identify and intervene on behalf of patients at risk for receiving low RDI.[2]
- The GIANT (EA2186) Trial[3,4] was recently presented, and it incorporated a baseline geriatric and quality of life assessment on treatment outcomes in patients with treatment-naive metastatic pancreatic cancer. In this study, patients who were considered vulnerable underwent a de-intensified treatment regimen.[4,5] There was no difference in the two chemotherapy treatment arms. Baseline geriatric vulnerabilities and quality-of-life scores correlated with overall survival (OS) and were not captured by physician-rated Eastern Cooperative Oncology Group performance status. The strongest correlation was seen with baseline nutritional status, function, depression scores, and all quality-of-life measures.
- A study evaluating more than 17,000 patients in the ACCENT/IDEA database was reported, focusing on comparing the benefits of oxaliplatin-fluoropyrimidine chemotherapy as adjuvant therapy in stage III colon cancer in patients who were 70 years old or older to the younger patients. In the 4,340 patients who were at least 70 years old and were enrolled on these clinical trials, the time to disease recurrence was similar to that in the younger patients, suggesting a similar anticancer benefit. However, the older patients had more frequent severe diarrhea, neutropenia, and mucositis, discontinued treatment earlier, and had a shorter OS, disease-free survival, and survival after recurrence. Taken together, these results suggest that fit, older patients can benefit from adjuvant oxaliplatin-based chemotherapy, but decisions should be based on individual discussions of risk and benefit.[3]
- In women aged 70 years and older with a higher risk for breast cancer recurrence based on a Genomic Grade Index, the ASTER70s randomized phase III study demonstrated that endocrine adjuvant therapy was non-inferior to 12 weeks of chemotherapy, followed by endocrine therapy, in terms of survival, with a median follow-up of 7.8 years. As anticipated, there were more severe toxicities in patients receiving chemotherapy.[6]
- SWOG 1826 demonstrated nivolumab-AVD was superior to brentuximab vedotin-AVD in patients older than 60 with advanced stage classical Hodgkin lymphoma. Two-year OS was 96% in N-AVD versus 85% in BV-AVD. In addition, the regimen was better tolerated.[7]

OVERVIEW

Geriatric oncology strives to improve care delivery and outcomes for older adults with cancer. Consensus is lacking on the specific chronological age that defines the older adult patient population with cancer. In developed countries, age 65 years or older

is generally accepted; in the United States, Medicare insurance eligibility is used as the common benchmark. The International Society of Geriatric Oncology (SIOG) defines a geriatric oncology patient as an adult aged 70 years or older with cancer. This cutoff can vary from 55 to 80 years and is highly dependent on social determinants of health and environmental exposures. Some refer to this as the biological age.[8] Accelerated aging can occur early, especially in patients with cancer, depending on the treatment modality used (eg, bone marrow transplantation can cause premature aging). Overall, cancer is a major health concern for older adults and is the second leading cause of death in the United States after heart disease.[9]

QUICK FACTS

- Age is the single most important risk factor for developing cancer.
- Twenty percent of the US population will be older than 65 years (70 million people) by 2030.
- Age 65 years or older: 60% of all newly diagnosed cancers and 70% of all cancer-related deaths.[10]
- Median age at cancer diagnosis: 68 to 74 years.
- Median range of age at death: 70 to 79 years.[9,10]
- Competing comorbidities can result in risk of polypharmacy and drug interaction.
- Decreased physiological reserve compromises the ability to tolerate cancer treatments.
- Health care providers' reluctance to provide cancer treatment to older adults results in age bias.
- Barriers to accessing care include transportation, fixed income, insufficient supplemental insurance coverage, and lack of access to technology.[9,11]

Communication between health care providers and older patients may be hampered by hearing, vision, cognition deficits and access to modern technology.[12] In addition, age-related concerns of patients and caregivers (eg, falls, cognitive impairment, and polypharmacy) are not generally accessed and addressed by oncology teams despite influencing unfavorable outcomes for older adults with cancer.[9-11] The older adult with cancer often has an older caregiver, and cancer diagnosis often affects the health-related quality of life of both individuals.[13-15]

These challenges have contributed to the definition of geriatric oncology as a true subspecialty, leading to the development of National Comprehensive Cancer Network (NCCN), SIOG, and ASCO guidelines that address special considerations for older adults with cancer.[16,17] Given the increasing number of older adults with cancer and the limited workforce of geriatricians available for co-management, it is imperative that oncology teams know how to integrate geriatric principles into oncology care for older adults with cancer and their caregivers.[18]

PRESENTING CASE STUDY

A 73-year-old woman with a medical history notable for hypertension, hyperlipidemia, hypothyroidism, and Barrett esophagus is diagnosed with locally advanced pancreatic adenocarcinoma encasing the celiac artery and extending along the hepatic artery. Staging scans do not identify evidence of distant metastases. Celiac plexus neurolysis is performed, resulting in good control of abdominal and back pain in combination with fentanyl patch and oxycodone. Next-generation sequencing does not show targetable mutations that would impact therapeutic recommendations.

Given this patient's age and locally advanced pancreatic cancer, what key factors would you consider when deciding on the initial treatment approach?

Comprehensive geriatric assessments (CGAs) are recommended for patients with cancer who are 65 years or older as part of systemic therapy evaluation. The geriatric assessment–driven intervention study demonstrated significantly decreased grade 3 and higher toxicity and greater chemotherapy completion rates in patients who underwent CGA before chemotherapy initiation compared with patients managed in the standard manner. Other randomized studies and meta-analyses have confirmed these findings.[19,20]

CGA confirms that the patient is frail, with a fatigue, resistance, ambulation, illness, and the loss of weight scale score of 5. Her Charlson comorbidity index is 5.

The Cancer and Aging Research Group (CARG) chemotoxicity calculator indicates a high risk of grade 3 to 5 toxicity:

- Standard-dose polychemotherapy, 92%; single-agent chemotherapy, 86%
- Reduced-dose polychemotherapy, 86%, single-agent chemotherapy, 78%

What treatment approach would you recommend, and how would you balance efficacy with minimizing harm?

The patient begins full-dose, single-agent gemcitabine, which she tolerates well, with essentially no toxicity aside from mild fatigue. The disease stabilized for 6 months, but the patient experiences mounting cytopenias. She is then treated with radiation and concurrent capecitabine, which controls the disease for 15 months without therapy before evidence of local progression.

This patient has unresectable disease; therefore, the goals of therapy are non-curative in nature. Without treatment, locally advanced pancreatic cancer induces suffering. However, the CGA and CARG chemotoxicity calculator suggest that polychemotherapy is likely to cause significant toxicity. Therapy in this case was personalized to balance these concerns. The GIANT trial (ECOG-ACRIN EA2186) revealed a high degree of frailty in this patient population. Eastern Cooperative Oncology Group performance status was not as strongly correlated with survival as baseline quality-of-life scores. The strongest correlations with survival were related to baseline nutritional status, depression, and functional status.

RELATIONSHIP BETWEEN AGING AND CANCER

The molecular, cellular, and physiological changes that are part of the aging process also predispose individuals to cancer. The landmark report by Hanahan and Weinberg[21] (refer to Chapter 2: Molecular Biology) delineates the hallmarks of cancer; however, a majority of these hallmarks represent common denominators of aging as well.[22] Carcinogenesis is a multistep process that includes initiation, followed by promotion and progression to disease. The various theories that link aging and cancer include the following[23-27]:

- Longer duration of carcinogenic exposure: Aging allows the time necessary for the accumulation of cellular events to result in neoplasms.
- Altered susceptibility of aging cells to carcinogens: Aging increases the susceptibility of normal cells and tissue to transformation into cancerous cells.
- Decreased ability to repair DNA: Aging cells are more likely to have an impaired ability to repair DNA.
- Oncogene activation or amplification or decrease in tumor-suppressor gene activity: These processes may be altered in an older individual, resulting in increased action, promotion, or differential clonal evolution.
- Telomere shortening and genetic instability: The functions of telomeres and telomerase are intimately involved in senescence and neoplastic processes. Telomeres shorten progressively as cells age, beginning at age 30 years, with a loss of approximately 1% per year. Because the major function of telomeres is to protect the stability of the more internal coding sequences (ie, allowing cells to divide without losing genes), this loss may lead to genetic instability, which may promote mutations in oncogenic or tumor-suppressor gene sequences. Telomere length is a predictor of death in people aged 60 years or older.[26]
- Immune system changes with age; this has major implications for the efficacy of cancer treatments (Table 7-1).
- Immunosenescence: This is a combination of changes within the immune system that occur with age that is characterized by changes in the bone marrow, the relative abundance of specific immune cell subsets, and circulating cytokines, resulting in a remodeling of the adaptive immune system.[27]
- Cellular senescence: There is an accumulation of changes in individual cells that leads to an irreversible cell-cycle arrest. Senescent cells can compromise tissue renewal capacity and secrete multiple factors (eg, interleukin-1 [IL-1] and matrix metalloproteinase 3) that alter tissue homeostasis and create a tissue environment that synergizes with mutation accumulation to facilitate malignant transformation.

Table 7-1 Age-Related Immune Phenotypes With Potential to Influence Immunotherapeutic Efficacy

Immunosenescence	Associated Phenotypes	Potential Consequences
Thymus	↑ Adiposity and epithelial cell attrition	↓ Naive T-cell pools with potential to recognize novel tumor antigens
	↓ Reduced IL-7 and mature T-cell production	
Bone marrow	↑ Myeloid: lymphoid progenitors	↓ Potential for adaptive immune responses to recognize novel tumor antigens
	↓ B-cell maturation	

Immunosenescence	Associated Phenotypes	Potential Consequences
T cells	↑ Memory: naive cells	↓ Diminished recognition and responses to novel tumor antigens
	↑ Immunosuppressive Tregs	↑ Antigen recall because of a larger memory pool
	↓ T-cell repertoire (two to fivefold)	
B cells	↑ Memory: Precursor cells	↓ Antibody production and diversity may limit response to novel tumor antigens
	↑ Proinflammatory B cells ($TNF\alpha^+$)	↑ Inflammation and autoantibody production may increase the probability of irAEs
	↓ Antibody production, diversity, and avidity	
Innate immunity	↓ Chemotaxis, phagocytosis of debris	↓ Activation and reduced diversity of tumor-specific $CD8^+$ cytotoxic T cells
	↓ Antigen presentation	
Inflammaging	↑ Chronic low-level inflammation	↑ Tumor mutagenesis by inflammatory mediators
	↑ Serum IL-6, IL-8, IL-18, TNFα, CRP	↓ Cytokine production in response to tumor antigens
Cellular senescence	↓ Telomere length and proliferation	↓ Expansion of responding B and T cells
	↑ Expression of cell-cycle inhibitors ($p16^{INK4a}$ and $p21^{CIP/KIP}$)	↓ Expansion of responding B and T cells
	↑ Proinflammatory cytokine and matrix remodeling factors	↑ Tumor metastasis, expansion, or recruitment of repressive immune cells (Tregs and MDSCs)

Abbreviations: CRP, C-reactive protein; IL, interleukin; irAE, immune-related adverse event; MDSC, myeloid-derived suppressor cell; TNF, tumor necrosis factor; Treg, regulatory T cell; ↓, decreased; ↑, increased.

AGE-RELATED PHYSIOLOGICAL CHANGES

A decline in physiological functioning begins at the age of 30 years and continues at a rate of approximately 1% per year. The aging process occurs at a different rate in each person, as does the loss of individual organ reserve.[28,29] Changes of aging include but are not limited to changes in bone marrow, liver, and kidney function; thinning skin; increased bruising; decreased cardiac reserve; reduction in cardiac myocytes; increased vascular stiffness; and decreased gastrointestinal motility and absorption.[30,31]

KEY POINTS

- Physiological changes of aging can begin at age 30 years and vary by organ system and individual.
- Organ system changes must be considered when deciding on both the cancer treatment modality (surgery, radiation therapy, systemic treatment) and the type and dose of medications selected for both the cancer treatment and comorbidities.
- Multiple organ systems experience changes. With aging, many people experience changes in their kidney and liver function, which can result in decreased drug clearance and lead to increased cancer treatment–related adverse events.
- Bone marrow reserve is compromised in older adults, leading to a greater decline in blood cell counts compared with those of younger patients, which can complicate surgery, radiation therapy, and/or systemic cancer treatments.

TREATMENT APPROACHES

SURGERY

Surgery is a frequently used treatment modality and can offer the potential for a curative approach for older adults with cancer. Concomitant comorbidities, impaired wound healing, and decreased physiological reserve can contribute to prolonged hospital stays and rehabilitation after surgical and other procedures. Postoperative delirium is of particular concern and can occur in up to 50% of surgical patients with cancer, a majority of whom are older adults. Functional status is an important consideration when assessing surgical risk. Patients with frailty have poor postoperative outcomes and decreased long-term survival, especially those with early-stage cancers.[32] With regard to wound healing, inflammatory and proliferative responses are decreased, remodeling occurs to a lesser degree, and collagen formation is qualitatively different from that in younger individuals.[33,34] The normal repair process initiated by inflammation requires intact sensory nerves that stimulate increased blood flow and

growth-factor production. Loss of sensory neurons and comorbidities such as diabetes and vascular disease can contribute to delayed wound healing.

A review of patients undergoing surgery for rectal cancer, which included 36,315 patients, found that age above 65 years was associated with a statistically significant increase in both anastomotic leak and postoperative death. The American Geriatrics Society Task Force[35] and the American College of Surgeons provide general guidelines for older adults undergoing surgery, which are also applicable to older patients with cancer who are undergoing surgery.[36,37]

A growing body of evidence also supports the use of geriatric and frailty[38] assessment measures collected preoperatively to predict surgery complications and plan for possible supportive care interventions in advance.[39-42] Refer to the "Geriatric Assessment and Screening Tools" section for more details.

RADIATION THERAPY

Radiation therapy may be used both as a primary modality with either curative or palliative intent and as an effective adjunct to surgery and/or chemotherapy. Radiation therapy and/or locoregional treatment modalities such as ablation/chemoembolization represent particularly attractive treatment options for older adults because they provide noninvasive local therapy with potentially limited systemic adverse effects. The risk of adverse effects with radiation therapy is highly dependent on the location of the tumor being treated and the radiation exposure of proximal structures.

Specialized approaches may be used in the older adult population to mitigate the adverse effects of treatment,[43] to improve adherence, and to minimize daily transportation requirements. For example, a stereotactic radiosurgery (SRS) approach, such as stereotactic body radiation therapy (SBRT), has been found to have excellent local control for patients with early-stage non-small-cell lung cancer and localized prostate cancer.[44,45] For patients with brain metastases, SRS is associated with fewer fractions and lesser toxicity compared with whole brain radiotherapy (WBRT).[46] Therefore, for older adults, especially those who are frail or prefrail, SBRT and SRS are options that may limit the associated morbidity and mortality risk of anesthesia and surgery or WBRT, respectively. Hypofractionation is also a relevant treatment option for older adults who may lack the physical reserve needed to attend daily treatment sessions for several weeks. By shortening the required number of radiation therapy treatment visits, the use of hypofractionation can substantially improve older adults' compliance with and tolerance of treatment.[47]

Radiation therapy is an important treatment modality in older adults with cancer. Radiation-related toxicity and adverse effects depend on the type and dose of radiation used and the location of cancer. Radiation therapy can pose significant procedural, travel, and financial toxicity. In one trial, frail patients were more likely to receive treatment other than standard of care, and 28% of the time a comprehensive geriatric assessment led to modifications in the treatment plan.[48] A prospective study of 314 patients older than 65 years who received definitive prostate radiotherapy were found to have higher grade radiation toxicity if the comprehensive geriatric examination identified comorbidities.[49] Therefore, radiation oncologists have an opportunity to advance geriatric oncology by incorporating geriatric and frailty assessments to limit toxicities and improve quality of life.

SYSTEMIC THERAPY

Older adults are consistently underrepresented in clinical trials; therefore, many of the treatment data for this population are extrapolated from studies in predominantly younger, healthier patients.[50,51] The SIOG and European Organization for Research and Treatment of Cancer task force have put forth suggestions for clinical trial design and endpoints in geriatric oncology research, suggesting that oncology trials be conducted without an upper age limit, include quality of life measures, and report decreases in cancer-related symptoms.[52]

Age-related physiological changes, including decreases in renal and hepatic function and increased sensitivity to neurotoxicity, lead to unique considerations in treating older patients with cancer. In addition, polypharmacy related to underlying medical conditions may contribute to chemotherapy-related toxicity.[53] For example, an older adult treated for hypertension with three antihypertensive medications becomes hypotensive and dizzy while receiving chemotherapy because of decreased oral intake, resulting in orthostatic hypotension. The patient then falls and experiences a hip fracture. This example of a complex geriatric oncology case with a poor outcome and increased morbidity risk will become increasingly common if we are unable to recognize high-risk situations for older adults undergoing cancer treatment.

Chemotherapy

The ASCO guideline entitled "Practical Assessment and Management of Vulnerabilities in Older Patients Receiving Chemotherapy: ASCO Guideline for Geriatric Oncology" provides practical assessment and treatment best practices for older adults with cancer who are receiving chemotherapy.[16] The SIOG task force has also published guidelines for dose modification of chemotherapy agents for older patients with cancer.

Important considerations to consider when prescribing chemotherapy in older adults:

- Oral agent bioavailability may be compromised as a result of alterations in motility and absorption and conversion into active drug components.

- Interactions with other commonly prescribed medications among older adults, such as H2 blockers, antacids, and proton pump inhibitors, should be considered to ensure safe and effective use of oral chemotherapy agents.
- Higher likelihood of interaction with chemotherapy agents in patients with polypharmacy.[53]
- Increased likelihood of chemotherapy toxicity in patients with decreased glomerular filtration rate.
- Older patients with decreased albumin levels may be further predisposed to ifosfamide neurotoxicity in the setting of impaired renal function. Concomitant administration of drugs such as nonsteroidal anti-inflammatory drugs may further compromise renal function. Because lean body mass decreases in older adults, it is important to adjust the dose according to the creatinine clearance rate rather than the creatinine level.
- Acute toxicities, such as nausea and vomiting, occur less frequently in older adults; however, the lack of functional reserve can readily lead to dehydration, orthostatic hypotension, and renal insufficiency.
- Neurotoxicity related to taxanes, platinum agents, vinca alkaloids, high-dose cytarabine; and bortezomib; cardiotoxicity resulting from anthracyclines; and mucositis resulting from fluorouracil are all more common and severe in older patients.[54,55]
- Whether the risk of myelotoxicity increases with age remains a controversial issue, but studies indicate a longer duration of neutropenia in older patients.[53]

Older adults receiving chemotherapy are at risk for increased toxicity, resulting in dose reductions and treatment delays, which increase the likelihood of disease recurrence and death. The recent HOPE study was a prospective multicenter study of 322 patients, age 65 years or older, with early-stage breast cancer who were treated with current standard neoadjuvant/adjuvant chemotherapy regimens.[2] The investigators found that one in five women received low relative dose intensity (RDI) of the chemotherapy agents. Older women with low RDI had higher mortality than women who received at least 85% RDI. This study highlights the importance of identifying patients who are at risk for increased toxicity from chemotherapy. A pretreatment geriatric assessment or geriatric oncology screening tool is useful to predict the risk of toxicity in older patients (please see the "Geriatric Assessment and Screening Tools" section). In a randomized trial of vulnerable (Geriatric-8 [G8] score of 14) older adults receiving chemotherapy for colorectal cancer, geriatric assessment–guided interventions were associated with higher chemotherapy completion rates and improved quality of life and mobility.[56,57]

A recent meta-analysis suggested that a "start slow, go slow" approach to patients who are at risk of excess toxicity may reduce toxicity of treatments without affecting survival in patients with solid tumors.[58]

Targeted Agents

The advances in understanding tumor biology and mutational drivers through next-generation sequencing has allowed the development of more targeted therapy options, including tyrosine kinase inhibitors (TKIs), mammalian target of rapamycin inhibitors, human epidermal growth factor receptor 2–targeted drugs, *BRAF* mutation–targeted drugs, epidermal growth factor receptor inhibitors, and vascular endothelial growth factor inhibitors. These therapy options have been increasingly used in patients with cancer in the last decade, particularly in the treatment of advanced solid tumors, such as lung cancer, breast cancer, and melanoma.[59] As in chemotherapy trials, data for older patients have been extrapolated from trials of predominantly younger patients. In addition, many targeted agents are metabolized by the cytochrome P450 system, increasing the risk of significant drug interactions. Many targeted therapies are oral medications requiring high adherence to dosing to ensure bioavailability and clinical efficacy. Consistent oral dosing requires appropriate functional ability, cognitive status, or direct support to perform. In terms of response to targeted therapies, many studies have shown that older adults benefit from the use of these drugs as much as their younger counterparts.[60] For example, a pooled analysis of trials testing the addition of a CDK4/6 inhibitor to antiestrogen therapy in advanced breast cancer showed similar efficacy among older (age older than 75 years) versus younger participants although with higher rates of toxicity. Older adults required more frequent dose reduction, but without evidence of compromise in benefit.[61] Cardiopulmonary toxicity is also a concern for older adults receiving TKIs such as osimertinib. Older adults can also be dramatically affected by extremity edema associated with new TKIs, such as capmatinib or tepotinib, for advanced non-small-cell lung cancer.

Immuno-Oncological Agents

Immune checkpoint inhibitors (ICIs), which affect immune function, are a new class of immuno-oncological agents used in the treatment of a variety of malignancies.[62] Expression of immune checkpoints on T cells increases with age, making immune checkpoint blockade a promising option for older patients with cancer. However, the effect of both inflammaging and cellular senescence on these agents is not clear. The term age-related immune dysfunction may be used to describe immune-related changes of aging and their potential interaction with immuno-oncological agents. Use in older patients is enhanced by a relatively low-toxicity profile compared with conventional chemotherapy. However, management of immunotherapy toxicity may be more complicated in older patients because of medical comorbidities.[62] In a meta-analysis of nine randomized clinical trials using ICIs comparing the efficacy in younger versus older patients, the authors showed a significant benefit in terms of overall survival (OS)

and progression-free survival in both groups. A recent observational study evaluating patients with advanced-stage lung cancer or melanoma starting single-agent checkpoint inhibitor therapy also showed no difference in the incidence of immune-related adverse events (irAEs) by age (age older than 70 vs. younger than 70 years). The G8 screening tool identified older adults at a higher risk of hospitalization and mortality.[63] The consequences of irAEs may differ by age, as suggested by a retrospective analysis, which showed a survival benefit for younger patients who experienced irAEs that was not observed among older adults with irAEs.[64] ASCO, in collaboration with the NCCN, has issued a clinical practice guideline on the management of irAEs in patients treated with ICIs that can be applied in the older adult population.[65] However, the impact and management of irAEs in the older adult population remain to be fully elucidated.

The challenge with irAEs is that steroids, either intravenous or oral, are often the first line of treatment. This can exacerbate many chronic conditions that older adults experience, such as diabetes, hypertension, and/or lower-extremity edema. It can also worsen the quality of sleep. Older adults may also experience delirium, increased falls, and/or dehydration with high-dose steroids. Steroid-sparing options, particularly for older adults, are urgently needed to treat irAEs, because ICIs are now used in multiple cancer types.

KEY POINTS

- In older patients, comorbidities, impaired wound healing, and decreased physiological reserve contribute to prolonged hospital stays and rehabilitation after surgery.
- Delivery, duration, and dosage of radiation therapy must be carefully planned on the basis of organ function, comorbidities, and geriatric evaluation because adverse effects may be more pronounced in older patients.
- Many chemotherapy toxicities are more common and more severe in older patients. Pretreatment geriatric assessment is useful for predicting the risk of chemotherapy toxicity.
- In older patients, comorbidities and polypharmacy may affect response to cancer therapy, and geriatric assessment is critical in the selection of treatment and dosing.
- Immuno-oncological drugs appear to be safe and less toxic compared with chemotherapy for use in older adults. However, irAEs and the treatment of irAEs can cause significant morbidity and mortality for older adults.

FRAILTY

Frailty characterizes "the group of patients that presents the most complex and challenging problems to the physician and all health care professionals"[66] because of the higher susceptibility to adverse outcomes, such as mortality and institutionalization. Currently, two main models of frailty exist: the phenotype model and the cumulative deficit model.[66]

FRAILTY PHENOTYPE MODEL

The phenotype model is based on a landmark study of 5,210 patients aged 65 years or older within the large prospective Cardiovascular Health Study.[67] A frailty phenotype was established with the following five variables: unintentional weight loss, self-reported exhaustion, low energy expenditure, slow gait speed, and weak grip strength. Patients with three or more of the five factors were considered to be frail, those with one or two factors to be prefrail, and those with no factors to be robust (or not frail). At 3- and 5-year follow-up, those categorized as frail were reported to have worse disability and worse mortality than the other two groups. The mortality rate at 7 years was 12%, 23%, and 43% for the not frail, prefrail, and frail groups, respectively. Phenotypic frailty has been associated with chemotherapy toxicity among older adults with cancer.[68]

CUMULATIVE DEFICIT MODEL

This clinical frailty scale was developed as part of the Canadian Study on Health and Aging, which was a large 5-year prospective cohort study of 10,263 patients designed to investigate the epidemiology and burdens of dementia among older adults in Canada (mean age, 82 years). Frailty was defined using 92 baseline variables of symptoms, signs, abnormal laboratory values, disease states, and disabilities (collectively referred to as deficits). The frailty index was a calculation of the presence or absence of each variable as a proportion of the total (eg, 20 of 92 deficits present gives a frailty index of 20/92 = 0.22). Frailty was defined as the cumulative effect of individual deficits, or "the more likely they are to be frail." Several studies using the deficit accumulation method have demonstrated that a comprehensive geriatric assessment–based deficit accumulation frailty index applied in patients with cancer is predictive of outcomes such as chemotherapy toxicity, hospitalization, mortality, and health-related quality of life.[69-71]

More recently, with the COVID-19 pandemic, Theou et al[72] aimed to reduce personal bias in the frailty classification. They developed a classification tree to improve the reliability of the clinical frailty scale in a variety of health care settings, both inpatient and outpatient. Although not specifically validated in patients with cancer, it is a useful tool for frailty assessment and prognostication.

GERIATRIC ASSESSMENT AND SCREENING TOOLS

Aging is a heterogeneous process that is affected by more than chronologic age.[73] Traditionally, in oncology, Eastern Cooperative Oncology Group (ECOG) performance status and Karnofsky performance status have been used to quantify patient well-being and determine whether patients can tolerate chemotherapy. However, these measures do not capture age-related domains such as risk for falls and cognitive impairment known to affect morbidity and mortality in older patients with cancer. Geriatric assessment is designed to screen and capture the functional age of older adults to identify those with organ reserve limitations, leading to a diminished life expectancy and/or increased risk of hospitalization and functional decline.[16] Geriatric assessment is multidimensional in that it uses validated, patient-reported, and administered measures to capture aging-related domains. Geriatric assessment includes high-priority aging-related domains known to be associated with morbidity and mortality[19,73] in older adults with cancer: functional status; comorbidities; polypharmacy; psychological, cognitive, and nutritional status; socioeconomic issues; and geriatric syndromes. Studies have demonstrated that geriatric assessment can identify older adults with cancer at increased risk for adverse outcomes and increased mortality across varied disease and treatment settings. Cohort studies evaluating older adults starting new chemotherapy regimens inclusive of varied cancer types have shown an association between prechemotherapy geriatric assessment measures and OS as well as early death (within 6 months of treatment). Two large randomized controlled trials demonstrated that prechemotherapy geriatric assessment with guided management recommendations lowers toxicity in older patients receiving chemotherapy for solid tumors.[20,74] This has led to the updated guideline recommendation that all patients with cancer older than 65 years with geriatric assessment–identified impairments should have a geriatric assessment–guided management plan (GAM). A GAM includes using geriatric assessment results to (1) inform cancer treatment decision-making and (2) address impairments through appropriate interventions, counseling, and referrals.[73] The updated ASCO guideline provides a practical approach to the assessment and management of vulnerabilities in older patients with cancer; the expert guideline panel recommends the Practical Geriatric Assessment (PGA) as one potential tool to facilitate the implementation of geriatric assessment and geriatric assessment–guided management in clinical practice (Fig. 7-1).[16,75]

The PGA is a composite tool that was developed to be efficient and therefore effective in various settings. The PGA evaluates seven key domains, including Physical Performance; Functional Status with Independent Activities of Daily Living; Cognitive Function; Comorbidities; Nutritional Status/weight loss; Social Support; Psychosocial Status. These domains may be assessed with information entered by the patient and/or caregiver before the clinician evaluates the patient. Another potentially important aspect of the PGA is the use of a chemotherapy toxicity tool, such as the Cancer and Aging Research Group (CARG) toxicity tool, which may impact decisions regarding chemotherapy regimen, such as single agent versus multiagent therapy, or dose administered.[16,75]

The use of geriatric assessment in all patients older than 65 years with cancer has been inconsistent. Numerous studies have examined the barriers to geriatric assessment, and they have found that the most cited barriers were the time required, the lack of adequate resources, and the lack of relevant knowledge or training.[76]

To increase the use of geriatric assessments, abbreviated screening instruments have been designed to determine who might benefit from full geriatric assessment. The Geriatric-8 (G8) and the Vulnerable Elders Survey-13 (VES-13) are both quick and validated assessments with high sensitivity that can be incorporated into oncological practice. The ELDERS study that demonstrated that a positive G8 screen (score 14 or less) was associated with higher risk of hospital admission (P = .03) and death (P = .01).[63] Patients with a positive screen were found to have a twofold increased risk of functional decline or death during a 2-year follow-up period.[77] Studies have also found that a positive VES-13 screen is also associated with increased treatment toxicity in older adults with cancer.[78] Once identified as being at higher risk through the initial screen, patients may then be triaged appropriately to receive a comprehensive geriatric assessment, be referred to a geriatrician, or establish care in a multidisciplinary geriatric oncology clinic.

Geriatric screening instruments can help identify patients who are at high risk of adverse outcomes and can be used to identify patients who would most benefit from a full geriatric assessment (ie, one that assesses all aging-related domains to guide decision-making and interventions).

KEY POINTS

- ECOG performance status is not a reliable tool for predicting treatment toxicity or functional decline in older adults with cancer.
- It is important to perform a geriatric screening assessment for new older adult patients with cancer to identify those at high risk of treatment-related adverse effects or functional decline and to provide intervention.
- The G8 and VES-13 are two examples of validated abbreviated geriatric screening assessment with high sensitivity that can be incorporated into everyday oncological practice.

USES OF GERIATRIC PRINCIPLES IN CANCER CARE

Various instruments for geriatric assessment have been used for more than a decade to examine multiple endpoints, including serious toxicity from chemotherapy, early mortality, hospitalization, and functional decline.

Figure 7-1 The Practical Geriatric Assessment

PREDICTING CHEMOTHERAPY TOXICITY

There are currently several chemotherapy toxicity tools available to help clinicians obtain specific estimates on the risks of chemotherapy toxicity in older adults. The ASCO guideline recommends the use of one of these chemotherapy toxicity tools for all older adults 65 years or older.[73] Both options are available as online calculators (Table 7-2). The caveat with new accelerated drug releases is the lack of available data for older adult patients.

- CARG chemotherapy toxicity calculator: In a study by the CARG led by Hurria et al,[79,80] geriatric assessment variables, sociodemographic variables, tumor and treatment variables, and laboratory results were incorporated into a model that was predictive for chemotherapy toxicity in 500 older adults. A scoring system was used to risk stratify patients, with the risk score being the percent incidence of grade 3 to 5 toxicity. This identified older adults at low (0-5 points; 30%), intermediate (6-9 points; 52%), or high risk (10-19 points; 83%) of chemotherapy toxicity ($P < .001$).[80]
- CARG breast chemotherapy toxicity calculator: A breast cancer–specific chemotherapy toxicity tool was developed using the same CARG geriatric assessment measures in an observational study of 473 older adults initiating neoadjuvant or adjuvant chemotherapy for stage I to III breast cancer. A scoring system was developed from eight independent predictors of toxicity that identified those at low (0-5 points; 19%), intermediate (6-11 points; 54%), or high risk (≥12 points; 87%) of grade 3 to 5 chemotherapy toxicity.[81]

- Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) chemotherapy toxicity calculator: In another study of 518 older patients with cancer, led by Extermann et al,[82] 24 parameters, including geriatric assessment, were incorporated to create the CRASH score to predict grade 4 hematologic or grade 3 to 4 nonhematologic toxicities. In the CRASH risk categories, patients with low-risk scores had a 7% chance of hematologic and 33% chance of nonhematologic toxicities compared with patients with high-risk scores, with corresponding toxicity risks of 100% and 93%, respectively.

Table 7-2 **Tools Providing Estimates for Chemotherapy Toxicity**

Tool	Items	Study Population	Administration Characteristics	Considerations and Other Evaluation Options
CARG breast cancer toxicity tool: provides estimates for overall risk of grade 3-5 toxicity for older adults receiving adjuvant or neoadjuvant chemotherapy	Eight weighted items (points): • Anthracycline use (1) • Stage II or III (3) • Planned treatment duration >3 months (4) • Abnormal liver function tests (3) • Low hemoglobin <12 g/dL female (3) • Falls in the past 6 months (4) • Limited walking 1 mile (3) • Lack of social support (someone available to give advice in crisis) (3)	Patients aged 65 years or older with stage I-III breast cancer starting neoadjuvant or adjuvant chemotherapy	PRO/administered/ medical record review (<5 minutes); online calculator planned	Only three of eight items required; patient report to be included in history or obtained from GA if conducted
CARG toxicity tool: provides estimates for overall risk of grade 3-5 chemotherapy toxicity	Eleven items: • Previous falls (≥1 vs. none) • Hearing problems (deaf to excellent) • Limitations in walking one block (limited a lot, limited a little, not limited) • Difficulties with taking medications • Interference in social activities by physical health and/or emotional problems (all of the time to none of the time) • Age • Height • Weight • Sex • Cancer type (GI vs. genitourinary vs. other) • Dosage (standard vs. dose reduced), number of chemotherapy agents (monotherapy vs. polytherapy) • Hemoglobin level • Creatinine clearance	Patients aged 65 years or older with solid tumor malignancy or lymphoma starting new chemotherapy regimen (any line)	PRO/administered: 5 minutes; available online: https://www.mycarg.org/?page_id=2405	Can ask GA variables as part of history or include as part of PRO assessment

Tool	Items	Study Population	Administration Characteristics	Considerations and Other Evaluation Options
CRASH tool: provides estimates separately for risk of grade 3 hematologic and grade 3 to 4 nonhematologic toxicity	Assessment of risk of hematologic toxicity includes: • Diastolic blood pressure (>72 mm Hg), IADL score (<26) • LDH concentration (>459 U/L) • Assessment of risk of nonhematologic toxicity includes ECOG PS, MMSE (<30), and MNA (<28); chemotherapy intensity is assessed with MAX2 index	Patients aged 70 years or older with histologically proven cancer starting chemotherapy	PRO/administered: estimated time to completion is on par with full GA (20-30 minutes); available at: https://www.moffitt.org/for-healthcare-professionals/clinical-programs-and-services/senior-adult-oncology-program/senior-adult-oncology-program-tools/	

Abbreviations: CARG, Cancer and Aging Research Group; CRASH, Chemotherapy Risk Assessment Scale for High-Age Patients; EGOG PS, Eastern Cooperative Oncology Group performance status; GA, geriatric assessment; GI, gastrointestinal; IADL, instrumental activities of daily living; LDH, lactate dehydrogenase; MAX2, an index that allows adjusting the toxicity of different chemotherapy regimens for comparison; MMSE, Mini-Mental State Examination; MNA, Mini Nutritional Assessment; PRO, patient-reported outcome.

PREDICTING MORTALITY

Life expectancy is of substantial relevance when considering the benefit of cancer treatment in older adults. There exists great variability in life expectancy within older age groups. For many cancer treatments, there is a time lag to benefit in which patients receive a treatment earlier, to reduce their chance of a poor outcome later. For many adults, the time to benefit from some cancer treatments may be beyond their life expectancy.

Providers routinely overestimate prognosis but may also underestimate life expectancy for those older than age 75 years. For example, in the United States, the middle quartile of life expectancy for a woman aged 75 or 80 years is approximately 13 and 10 years, respectively.[83,84] Incorporating informative tools can enable tailored conversations and allow patients to weigh the value of specific cancer-directed therapy. The ASCO guideline on geriatric oncology recommends that clinicians use one of the validated tools (Schonberg or Lee Index) available at ePrognosis[85] to estimate life expectancy without including cancer as a diagnosis to determine whether patients have adequate life expectancy to expect benefits from specific cancer interventions, including chemotherapy. The most common domains included in indices developed to predict mortality in community-dwelling older adults are age, sex, chronic health conditions (eg, diabetes and chronic obstructive pulmonary disease), functional status, health behaviors and lifestyle factors (eg, smoking status and body mass index), and self-reported health.[74,86] The indices have presence of cancer as a relevant variable; indicating no to the question of cancer presence will allow for non-cancer life expectancy to consider competing risks of mortality.[16] An estimate of life expectancy outside of a cancer-specific estimate allows the oncologist to thoughtfully assemble a patient's prognosis and potential to benefit from treatment. Although the unique trajectory of a patient's illness is unknowable, prognostic estimation can support prognostication and informed decision-making.

PREDICTING FUNCTIONAL DECLINE

Many older adults have considered their wishes for when they may be faced with a serious illness or the end of life. Patients' individual goals, independence, and physical, emotional, and spiritual health are priorities. In a landmark study of patients aged 60 years or older who were terminally ill, researchers found that if the outcome was survival but with severe functional impairment or cognitive impairment, 74.4% and 88.8% of participants, respectively, would not choose treatment.[87] Therefore, it is important to weigh the risks and benefits of different types of cancer treatment and how they can contribute to functional decline.

Geriatric assessment items and brief geriatric assessment–based screening tools (G8 and VES-13) are predictive of functional decline among older adults receiving chemotherapy.[88] Hoppe et al[89] showed that depression and basic and instrumental activities of daily living are associated with early functional decline during chemotherapy. Owusu et al[90] demonstrated that the VES-13 can identify older women with breast cancer at risk for functional decline. Patients who experienced functional decline were more likely to have had lower baseline activities of daily living scores than those who did not experience functional decline, have lower instrumental activities of daily living scores, be Black (49% vs. 29%; $P = .02$), and have no more than a high school education.

DECISION-MAKING AND TREATMENT MANAGEMENT

Geriatric assessment can aid in decision-making for cancer treatment because it has been shown that results from geriatric assessment influence cancer treatment decisions 20% to 47% of the time toward less-intensive therapy.[17]

- In a systematic review by Hamaker et al,[19] the initial cancer treatment plan was modified in 39% of patients based on geriatric assessment evaluation. Two-thirds of these modifications resulted in less intensive treatment, likely an attempt to adjust treatment in patients who had geriatric assessment impairments.[91]
- In the ELCAPA01 study, one of the largest studies evaluating how geriatric assessment influences decision-making, geriatricians conducted a geriatric assessment in 375 older patients with cancer to identify factors associated with dose intensification, decrease, or delay of more than 2 weeks.[86] In multivariate analysis, functional status as assessed by activities of daily living score and presence of malnutrition were independently associated with changes in cancer treatment.[16]

The results of a geriatric assessment can also be used to decrease chemotherapy toxicity.

- A large multicenter study in community oncology clinics in the United States evaluated the effect of an algorithm-guided geriatric assessment–guided management intervention on toxicity from chemotherapy.[74] The GAP study[74] (N = 718) showed that, compared with usual care, providing a geriatric assessment summary and intervention recommendations to oncologists reduced the proportion of patients who experienced grade 3 to 5 toxicity (51% vs. 71%). The relative risk of grade 3 to 5 toxicity for intervention versus usual care was 0.74 (95% CI, 0.64-0.86; *P* = .0001), mostly because of nonhematologic toxicities (relative risk, 0.72; 95% CI, 0.52-0.99; *P* = .045), without compromising OS (72% vs. 75% at 6 months; *P* = .38).[74] A possible mechanism for survival preservation was that geriatric assessment influenced treatment dosing at cycle 1, with more patients in the intervention arm having reduced-intensity regimens but later having fewer dose modifications. This hypothesis is supported by an analysis demonstrating superior survival with early palliative care in non–small cell lung cancer (NSCLC), likely also driven by more use of first line therapy and less use of chemotherapy at the end of life (Temel, NEJM 2010).
- A second study, geriatric assessment-driven intervention (GAIN),[20] which enrolled 613 participants demonstrated that a geriatric assessment–guided management intervention also reduced toxicity from chemotherapy.[20] In this study, the investigators reported a 10.1% reduction in the incidence of grade 3 to 5 toxicity (95% CI, −1.5% to 18.2%; *P* = .02) in the interventional arm compared with patients receiving standard care (50.5% vs. 60.6%). In addition, researchers reported more patients completed advance directives, a secondary endpoint, in the interventional arm compared with those receiving standard care (28.4% vs. 13.3%; *P* < .001; Table 7-3).

Table 7-3 Clinical Trials of Geriatric Assessment

Reference	No. of Pts.	Malignancy	Improved Survival Outcomes?	Comment
Lund et al[56] GERICO	142	Colorectal	NR	Higher rates of chemotherapy completion without delay or reduction
Soo et al[92] INTEGERATE	154	Various	NR	Reduced hospital admission, decreased early discontinuation of chemotherapy due to toxicity
Dumontier et al[93]	160	Hematologic malignancies	No	More likely to have documented goals of care discussions
Corre et al[94] ESOGIA	494	Non-small-cell lung cancer	No	Decreased toxicities (all grades), and fewer toxicity related failures
Bergerot et al[95] GAIN-S	56	Various	No	Improved health-related quality of life

Abbreviation: NR, not reported.

- A geriatric assessment can improve patient- and caregiver-centered outcomes.
- In a large phase 3 study, community oncology practices were randomly assigned to a geriatric assessment model of care versus usual care. As the practices enrolled in the intervention, oncologists received geriatric assessment information and targeted recommendations for aging-related impairments for patients enrolled in the study. The participating patients were aged 70 years or older, had at least one geriatric assessment domain impairment, and were receiving cancer treatment. In the intervention arm, substantially more aging-related concerns were discussed, leading to greater caregiver satisfaction and increased conversations about aging-related concerns.[12]

KEY POINTS

- Neither ECOG performance status nor Karnofsky performance status alone provides an accurate measure of the functional status of an older patient with cancer.
- Older adults highly value preserving functional independence and cognition in addition to survival. A geriatric assessment can be used to predict survival and risk of chemotherapy toxicity in older adults with cancer.
- A geriatric assessment can be used to guide treatment decision-making and interventions for older patients with cancer.
- Several randomized trials have demonstrated the benefit of geriatric assessment in decreasing chemotherapy toxicity for older adults with cancer.
- A geriatric assessment can assist in defining physiological reserve. The 2018 ASCO geriatric oncology guideline suggests that oncologists assess functional status, physical performance and falls, comorbid medical conditions, depression, social activity and support, nutritional status, and cognition as key domains of geriatric assessment.
- Frailty is associated with a severe loss of functional reserve and a lack of tolerance of or resiliency to medical interventions and treatments.

PALLIATIVE CARE AND END-OF-LIFE ISSUES

Palliative care is an essential component of care throughout the disease process and consists of more than end-of-life care. An interdisciplinary palliative care team focuses on improving quality of life for patients facing complex illnesses. Palliative care aims to prevent and relieve suffering through the early identification, assessment, and treatment of pain and other problems, whether physical, psychosocial, or spiritual. Palliative care can be provided regardless of disease stage or cancer-directed therapy plan. Palliative care should be offered to patients facing a complex illness regardless of age. The goals of palliative care for older adults are the same as those for younger adults, and accurate identification of all symptoms is particularly useful. Simplified instruments, such as the Edmonton Symptom Assessment Scale, which assesses nine symptoms common among patients with cancer (ie, pain, fatigue, nausea, depression, anxiety, drowsiness, appetite, well-being, and shortness of breath), are useful in providing a profile of symptom severity over time.

These issues are discussed in further detail in Chapter 9: Palliative Care and Care at the End of Life.

KEY POINT

- Palliative care is an essential component of care throughout the disease process for older patients, and accurately identifying symptoms is critical to alleviating them.

HIGH-YIELD TAKEAWAYS

- Given the patient's stage of life, children and other family members are often integral to goals-of-care conversations.
- Geriatric assessments are key in understanding unrecognized cognitive decline and fall history, as well as in minimizing toxicity associated with standard-of-care therapy.

CANCER IN THE OLDER ADULT 7

CHAPTER SUMMARY GUIDE

KEY POINTS

- Physiological changes of aging can begin at age 30 years and vary by organ system and individual.
- Organ system changes must be considered when deciding on both the cancer treatment modality (surgery, radiation therapy, systemic treatment) and the type and dose of medications selected for both the cancer treatment and comorbidities.
- Multiple organ systems experience changes. With aging, many people experience changes in their kidney and liver function, which can result in decreased drug clearance and lead to increased cancer treatment–related adverse events.
- Bone marrow reserve is compromised in older adults, leading to a greater decline in blood cell counts compared with those of younger patients, which can complicate surgery, radiation therapy, and/or systemic cancer treatments.
- In older patients, comorbidities, impaired wound healing, and decreased physiological reserve contribute to prolonged hospital stays and rehabilitation after surgery.
- Delivery, duration, and dosage of radiation therapy must be carefully planned on the basis of organ function, comorbidities, and geriatric evaluation because adverse effects may be more pronounced in older patients.
- Many chemotherapy toxicities are more common and more severe in older patients. Pretreatment geriatric assessment is useful for predicting the risk of chemotherapy toxicity.
- In older patients, comorbidities and polypharmacy may affect response to cancer therapy, and geriatric assessment is critical in the selection of treatment and dosing.
- Immuno-oncological drugs appear to be safe and less toxic compared with chemotherapy for use in older adults. However, irAEs and the treatment of irAEs can cause significant morbidity and mortality for older adults.
- ECOG performance status is not a reliable tool for predicting treatment toxicity or functional decline in older adults with cancer.
- It is important to perform a geriatric screening assessment for new older adult patients with cancer to identify those at high risk of treatment-related adverse effects or functional decline and to provide intervention.
- The G8 and VES-13 are two examples of validated abbreviated geriatric screening assessment with high sensitivity that can be incorporated into everyday oncological practice.
- Neither ECOG performance status nor Karnofsky performance status alone provides an accurate measure of the functional status of an older patient with cancer.
- Older adults highly value preserving functional independence and cognition in addition to survival. A geriatric assessment can be used to predict survival and risk of chemotherapy toxicity in older adults with cancer.
- A geriatric assessment can be used to guide treatment decision-making and interventions for older patients with cancer.
- Several randomized trials have demonstrated the benefit of geriatric assessment in decreasing chemotherapy toxicity for older adults with cancer.
- A geriatric assessment can assist in defining physiological reserve. The 2018 ASCO geriatric oncology guideline suggests that oncologists assess functional status, physical performance and falls, comorbid medical conditions, depression, social activity and support, nutritional status, and cognition as key domains of geriatric assessment.
- Frailty is associated with a severe loss of functional reserve and a lack of tolerance of or resiliency to medical interventions and treatments.
- Palliative care is an essential component of care throughout the disease process for older patients, and accurately identifying symptoms is critical to alleviating them.

CHAPTER TABLES AND IMAGES

Table 7-1 Age-Related Immune Phenotypes With Potential to Influence Immunotherapeutic Efficacy

Immunosenescence	Associated Phenotypes	Potential Consequences
Thymus	↑ Adiposity and epithelial cell attrition	↓ Naive T-cell pools with potential to recognize novel tumor antigens
	↓ Reduced IL-7 and mature T-cell production	
Bone marrow	↑ Myeloid: lymphoid progenitors	↓ Potential for adaptive immune responses to recognize novel tumor antigens
	↓ B-cell maturation	
T cells	↑ Memory: naive cells	↓ Diminished recognition and responses to novel tumor antigens
	↑ Immunosuppressive Tregs	↑ Antigen recall because of a larger memory pool
	↓ T-cell repertoire (two to fivefold)	
B cells	↑ Memory: Precursor cells	↓ Antibody production and diversity may limit response to novel tumor antigens
	↑ Proinflammatory B cells ($TNF\alpha^{+}$)	↑ Inflammation and autoantibody production may increase the probability of irAEs
	↓ Antibody production, diversity, and avidity	
Innate immunity	↓ Chemotaxis, phagocytosis of debris	↓ Activation and reduced diversity of tumor-specific $CD8^{+}$ cytotoxic T cells
	↓ Antigen presentation	
Inflammaging	↑ Chronic low-level inflammation	↑ Tumor mutagenesis by inflammatory mediators
	↑ Serum IL-6, IL-8, IL-18, TNFα, CRP	↓ Cytokine production in response to tumor antigens
Cellular senescence	↓ Telomere length and proliferation	↓ Expansion of responding B and T cells
	↑ Expression of cell-cycle inhibitors ($p16^{INK4a}$ and $p21^{CIP/KIP}$)	↓ Expansion of responding B and T cells
	↑ Proinflammatory cytokine and matrix remodeling factors	↑ Tumor metastasis, expansion, or recruitment of repressive immune cells (Tregs and MDSCs)

Abbreviations: CRP, C-reactive protein; IL, interleukin; irAE, immune-related adverse event; MDSC, myeloid-derived suppressor cell; TNF, tumor necrosis factor; Treg, regulatory T cell; ↓, decreased; ↑, increased.

Table 7-2 **Tools Providing Estimates for Chemotherapy Toxicity**

Tool	Items	Study Population	Administration Characteristics	Considerations and Other Evaluation Options
CARG breast cancer toxicity tool: provides estimates for overall risk of grade 3-5 toxicity for older adults receiving adjuvant or neoadjuvant chemotherapy	Eight weighted items (points): • Anthracycline use (1) • Stage II or III (3) • Planned treatment duration >3 months (4) • Abnormal liver function tests (3) • Low hemoglobin <12 g/dL female (3) • Falls in the past 6 months (4) • Limited walking 1 mile (3) • Lack of social support (someone available to give advice in crisis) (3)	Patients aged 65 years or older with stage I-III breast cancer starting neoadjuvant or adjuvant chemotherapy	PRO/administered/ medical record review (<5 minutes); online calculator planned	Only three of eight items required; patient report to be included in history or obtained from GA if conducted
CARG toxicity tool: provides estimates for overall risk of grade 3-5 chemotherapy toxicity	Eleven items: • Previous falls (≥1 vs. none) • Hearing problems (deaf to excellent) • Limitations in walking one block (limited a lot, limited a little, not limited) • Difficulties with taking medications • Interference in social activities by physical health and/or emotional problems (all of the time to none of the time) • Age • Height • Weight • Sex • Cancer type (GI vs. genitourinary vs. other) • Dosage (standard vs. dose reduced), number of chemotherapy agents (monotherapy vs. polytherapy) • Hemoglobin level • Creatinine clearance	Patients aged 65 years or older with solid tumor malignancy or lymphoma starting new chemotherapy regimen (any line)	PRO/administered: 5 minutes; available online: https://www.mycarg.org/?page_id=2405	Can ask GA variables as part of history or include as part of PRO assessment

Tool	Items	Study Population	Administration Characteristics	Considerations and Other Evaluation Options
CRASH tool: provides estimates separately for risk of grade 3 hematologic and grade 3 to 4 nonhematologic toxicity	Assessment of risk of hematologic toxicity includes: • Diastolic blood pressure (>72 mm Hg), IADL score (<26) • LDH concentration (>459 U/L) • Assessment of risk of nonhematologic toxicity includes ECOG PS, MMSE (<30), and MNA (<28); chemotherapy intensity is assessed with MAX2 index	Patients aged 70 years or older with histologically proven cancer starting chemotherapy	PRO/administered: estimated time to completion is on par with full GA (20-30 minutes); available at: https://www.moffitt.org/for-healthcare-professionals/clinical-programs-and-services/senior-adult-oncology-program/senior-adult-oncology-program-tools/	

Abbreviations: CARG, Cancer and Aging Research Group; CRASH, Chemotherapy Risk Assessment Scale for High-Age Patients; EGOG PS, Eastern Cooperative Oncology Group performance status; GA, geriatric assessment; GI, gastrointestinal; IADL, instrumental activities of daily living; LDH, lactate dehydrogenase; MAX2, an index that allows adjusting the toxicity of different chemotherapy regimens for comparison; MMSE, Mini-Mental State Examination; MNA, Mini Nutritional Assessment; PRO, patient-reported outcome.

PAIN AND SYMPTOM MANAGEMENT

8

Maura Barry, MD, and Abhishek Kumar, MBBS, FASCO

RECENT UPDATES

- ASCO published guidelines regarding palliative care for patients with cancer, emphasizing early and systematic integration of palliative care, comprehensive assessment, and multidisciplinary management of symptoms.[1]
- NCCN Guidelines on Adult Cancer Pain now advise caution regarding the use of acetaminophen in combination with immunotherapy, as there is evidence that its use may negatively affect the efficacy of cancer treatment.
- ASCO published guidelines regarding the use of cannabis and cannabinoids in combination with guideline-recommended antiemetics for refractory chemotherapy-induced nausea and vomiting.[2]
- ASCO published a rapid guideline update for cancer cachexia recommending low-dose olanzapine to improve weight gain and appetite.[3,4]
- ASCO and the Society for Integrative Oncology (SIO) published a guideline for the management of fatigue in adult survivors of cancer.[5]

OVERVIEW

The management of symptoms in the context of cancer and cancer treatment remains a central priority within any framework for patient-centered cancer care. Suboptimal control of symptoms is associated with early discontinuation and treatment delays, whereas optimal supportive care improves cancer-related outcomes and quality of life (QoL). This chapter reviews the relevant pathophysiology and management of the following symptoms:

- Cancer-related pain, including chemotherapy-induced peripheral neuropathy (CIPN)
- Nausea and vomiting
- Cancer-related fatigue
- Cachexia
- Diarrhea associated with cancer and cancer therapy
- Oral mucositis
- Dyspnea
- Dermatological adverse effects
- Management of hormone-deprivation symptoms

Chapter 4 covers the management of immune-related adverse effects and Chapter 9 offers further review of palliative and end-of-life care.

SYMPTOM MONITORING

PATIENT-REPORTED SYMPTOMS

The clinical team often underestimates patient symptom burden and severity and may fail to recognize a patient's whole symptom complex, especially if the symptom is less readily perceptible.[6,7] Studies in which patients self-report their symptoms using validated questions or scales, such as patient-reported outcome (PRO) measures (eg, Clinical Align Pain Assessment, Brief Pain Inventory; Table 8-1), offer a mechanism by which all members of a clinical team can gain a more holistic picture of a person's cancer experience. PROs and other patient-reported measures are the gold standard for pain assessment, the downstream effect of pain on functional outcomes, and QoL.[8] A randomized trial of adults receiving outpatient chemotherapy[9,10] found that the

systematic collection of PROs, together with electronic alerts to the clinic team and printed reports to the physician, resulted in improved QoL, fewer emergency department visits, fewer hospitalizations, longer duration of palliative chemotherapy, and superior quality-adjusted survival. Furthermore, studies have demonstrated the feasibility of implementing PROs in the inpatient and community settings.[11] Hence, PROs should be integrated into every patient encounter to assess progress and adjust management accordingly.

Table 8-1 Examples of Validated Pain Instruments in Cancer Patients[12]

Instrument Name	Constructs Measured	Estimated Completion Time
Brief Pain Inventory Short Form	Pain severity, pain interference with physical and affective functioning, pain location	5 minutes
Edmonton Symptom Assessment System–Revised	Current pain severity, pain location	1 minute
Short-Form McGill Pain Questionnaire	Pain quality, pain location, pain severity	5-10 minutes
Verbal analog scales	Pain level	1 minute
Verbal rating scales	Pain level	1 minute
Wong-Baker FACES Pain Rating Scale[a]	Pain level	1 minute

[a]Validated in pediatric care; age 3 years or older.

KEY POINTS

- Clinicians may inadvertently miss or underestimate the severity of patient symptoms.
- Symptom monitoring using PROs improves QoL and overall survival for patients who have advanced cancer.
- Daily patient-reported global symptom monitoring is feasible in hospitalized patients and outpatient settings who have advanced cancer.

CANCER-RELATED PAIN

Pain (ie, an unpleasant sensory and emotional experience and a complex biopsychosocial phenomenon) is the most common symptom associated with cancer.

Up to 90% of patients who have advanced cancer will experience moderate to severe pain,[13] making optimal pain management a key priority in cancer care. A multimodal approach to cancer patients with pain using pharmacological and non-pharmacological interventions is strongly recommended. Depending on the complexity and severity of the pain, expert consultation may be required (eg, pain management, palliative care, and other services like interventional radiologists).

PAIN ASSESSMENT

The first step is to assess and identify pain etiology and treat reversible causes when possible. A pain assessment should include a description of the location, radiation, duration, quality of the pain, and any factors that alleviate or aggravate the pain. In addition, information about the impact of pain on the patient's daily living, such as function and sleep, is critical to understand the pain patterns and trajectory. Clinicians should be familiar with the terms used to describe pain and know how to effectively assess the temporality and type of cancer-related pain (Table 8-2; Fig. 8-1).[14]

Table 8-2 Pain Terminology[15]

Term	Definition
Acute pain	Pain occurring over hours up to weeks, characterized by a well-defined temporal pattern of onset with subjective and objective physical signs and hyperactivity of the autonomic nervous system
Subacute pain	Pain present for between 6 weeks and 3 months
Chronic pain	Pain present more than 3 months, cause often not easily identified, usually multifactorial, may be nociceptive and/or neuropathic; characterized by vegetative signs (eg, anorexia, anhedonia, sleep disturbance) as well as physical and mental withdrawal

Term	Definition
Nociceptive pain	Somatic or visceral pain associated with actual or potential tissue damage caused by ongoing activation of intact nociceptors
Neuropathic pain	Pain resulting from injury to the peripheral or central nervous system, causing pain described as burning, shooting, tingling, stabbing, scalding, crawling, or painful numbness
Somatic pain	Localized pain causing activation of the μ-receptors and described as aching, stabbing, or throbbing
Visceral pain	Poorly localized pain resulting from activation of nociceptors in the viscera by obstruction, infiltration, ischemia, stretching, compression, and/or inflammation
Baseline pain	Average pain intensity experienced for 12 hours during a 24-hour period
Breakthrough pain	Transient increase in pain to greater than moderate intensity, occurring in addition to baseline pain
Incident pain	Specific experience of pain associated with an event or movement (eg, wound care)
Episodic pain	Transient exacerbation or recurrence of pain
Allodynia	Pain from light touch or mild pressure
Hyperalgesia	Increased pain response to a noxious stimulus
Dysesthesia	Unpleasant, abnormal sense of touch
Paresthesia	Abnormal dermal sensation (eg, tingling, pricking, chilling, burning, or numb sensation on the skin) with no apparent physical cause
Opiates	Natural substances that come from opium, including morphine and codeine
Opioid	Semisynthetic or synthetic products that bind to the same receptors as opiates but do not occur naturally; used broadly to include both natural or synthetic (or semisynthetic) substances acting on one of the three main opioid receptor systems (μ, κ, δ)
Adjuvant	Non-opioid medications used to enhance analgesia and minimize adverse effects, including anticonvulsants and antidepressants
End-of-dose failure	Predictable return of pain before the next scheduled dose of medication
Incomplete cross tolerance	Different levels of tolerance to an opioid of a different class

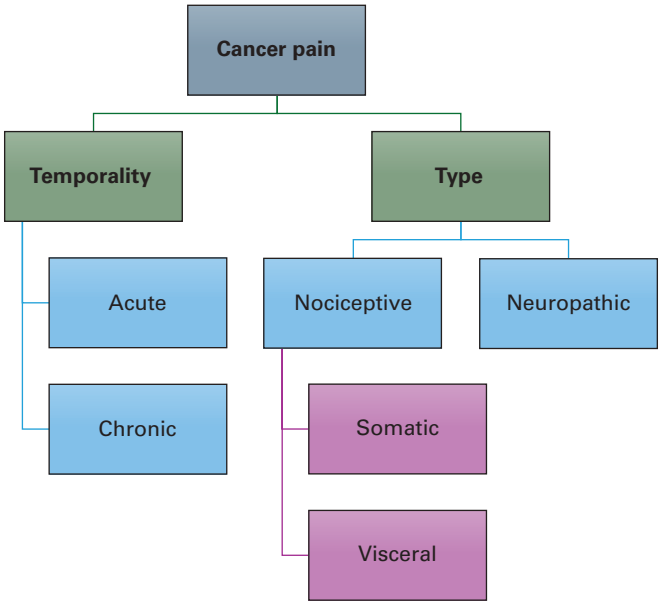
Figure 8-1 Characterization of Pain by Temporality and Type



Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Temporality

Typically, we categorize pain temporality as acute or chronic. Acute pain occurs for hours up to weeks, with a well-defined pattern of onset, subjective and objective physical signs, and hyperactivity of the autonomic nervous system. This hyperactivity manifests as tachycardia, sweating, and hypertension. Usually self-limited, acute pain responds to treatment of its precipitating cause in combination with analgesics.

By contrast, chronic pain persists for longer than 3 months, with a less well-defined temporal onset and without the signs common to acute pain (eg, tachycardia, facial grimace). Chronic pain, rather, causes objective impairment in function (physical, psychological, social, or spiritual). Treatment of chronic pain in patients who have cancer requires a careful assessment of pain intensity and its multidimensional aspects, including psychosocial factors. Examples of psychosocial factors may include anxiety, maladaptive coping, history of substance use disorder, limited social support, cultural barriers to reporting pain, limited English proficiency, limited understanding of illness, or restricted access to medications.[16]

The temporal assessment should also include key features such as onset, duration, and course. Patients describe temporality in terms of their daily experience with pain. Constant pain is described as pain experienced for at least 12 hours per day; breakthrough pain is characterized as a transient increase in pain to greater than moderate intensity; incident pain is described as a specific experience of pain associated with an event or movement (eg, changing position, walking).

Pain Type

To understand the etiology of, and potential therapies for, pain in cancer patients, we characterize cancer-related pain as nociceptive, neuropathic, visceral, or mixed type. Nociceptive pain may be somatic or visceral and is often associated with actual or potential tissue damage caused by ongoing activation of intact nociceptors. Injury to the skin, soft tissue, bones, or joints causes somatic pain. Patients who have somatic pain can typically localize the pain and describe it as aching, stabbing, or throbbing. Visceral pain results from activation of nociceptors in the viscera by obstruction, infiltration, ischemia, stretching, compression, or inflammation. Patients may have difficulty localizing the pain and frequently experience referred pain, such as the left arm pain reported by patients who have myocardial ischemia. Patients describe visceral pain as cramping, pressure, gnawing, or squeezing. Injury to the peripheral or central nervous system (CNS) causes neuropathic pain. Neuropathic pain may share similar descriptors with nociceptive pain. Patients describe neuropathic pain as burning, shooting, tingling, stabbing, scalding, crawling, or painful numbness. It is also common to observe allodynia (pain from light touch or mild pressure) and hyperalgesia (abnormal sensitivity to sensory stimuli) with neuropathic pain. Examples of neuropathic syndromes include post-herpetic neuralgia, phantom pain syndrome, tumor infiltration into a nerve plexus, and CIPN.

Pain Trajectory

Developing an effective treatment plan requires a clear understanding of the pain diagnosis and its expected trajectory. For instance, medication selection, the balance between short- and long-acting opioids, and the frequency of pain reassessment will differ significantly between a patient experiencing severe post-radiation pain after curative therapy for head and neck cancer and another with progressive pain from advanced pancreatic cancer.

TREATMENT OF PATIENTS WITH CANCER EXPERIENCING PAIN

The goals of pain management are to optimize patient outcomes across these five dimensions:

- Analgesia: optimal pain relief
- Activities: improved function, including psychosocial and spiritual function
- Adverse effects: minimal adverse effects
- Aberrant drug use: prevention and recognition of substance use disorder
- Affect: the relationship between pain and mood

In addition to pharmacological approaches explored here, clinicians should consider non-pharmacological strategies when appropriate. These strategies are outlined in Table 8-3 and explored further across several recent ASCO guidelines, including (1) use of opioids for adults with pain from cancer or treatment, (2) the joint guideline with the Society for Integrative Oncology (SIO) on integrative medicine guidelines, and new ASCO guidelines for (3) anxiety and depression in patients with advanced cancer and (4) cannabis and cannabinoids in cancer care.[2]

PHARMACOLOGICAL APPROACHES TO CANCER PAIN: OPIOIDS AND ADJUVANTS

The World Health Organization ladder of pain management describes three levels of patient-reported pain corresponding to the selection of analgesic type: non-steroidal anti-inflammatory drugs (NSAIDs) and acetaminophen for mild pain (step 1), a fixed combination of low-dose opioids and acetaminophen or NSAIDs for moderate pain or pain refractory to step 1 agents (step 2),

Table 8-3 **Non-Pharmacological Approaches to Treating Cancer Pain**[8]	
Category	**Treatment Type**
Alternative, complementary, or integrative strategies	Acupuncture, art therapy, massage, music therapy, physical/movement, aromatherapy
Interventional	Injection therapies, implant therapy, neural blockade, surgical neuroablation, orthopedic procedures
Rehabilitative	Hydrotherapy, occupational therapy, physical modalities such as ultrasound, therapeutic exercise, and therapy for specific disorders such as lymphedema
Psychological	Hypnotherapy, cognitive behavioral therapy, guided imagery, other forms of psychotherapy, psychoeducational interventions, relaxation therapy, stress management
Neurostimulation	Dorsal column stimulation, intrathecal drug delivery

The IMPACT trial recently showed that both acupuncture and massage improved pain, fatigue, insomnia, and quality of life over 26 weeks in advanced cancer patients, highlighting the importance of integrating non-pharmacological approaches to pain and symptom management when possible.[17]

and higher doses of opioids for severe pain or pain refractory to step 2 agents (step 3). It is intended to be used bidirectionally in patients with cancer.

While the ladder suggests the use of NSAIDs and acetaminophen for mild pain, there are some studies that suggest that some NSAIDs, as well as the antidepressant imipramine, may be as good or better than opioids at controlling moderate to severe background cancer pain.[18] Conversely, evidence is inconclusive regarding the benefit of acetaminophen alone or in combination with

Table 8-4 **Non-Opioid Pharmacological Agents Targeting Neuropathic Pain**			
Pharmacological Agent Targeting Neuropathic Pain	**Mode of Action**	**Starting Dose/Max Dose**	**Adverse Effect**
Anticonvulsants	Decreased release of glutamate, norepinephrine, and substance P affects calcium channels		Sedation and dizziness should not be abruptly stopped
Gabapentin		100-300 mg 1-3× per day/1,200 mg 3× per day[a]	
Pregabalin		50 mg 3× per day/200 mg 3× per day	
Antidepressants			
TCAs: nortriptyline, desipramine	Inhibition of serotonin/norepinephrine reuptake, sodium channel blocking, and anticholinergic	25 mg/150 mg daily	Sedation, anticholinergic effect, cardiac arrhythmias, and nausea
SNRISs: duloxetine, venlafaxine	Inhibition of serotonin/norepinephrine reuptake	Duloxetine: 30 mg daily/60 mg 2× daily; venlafaxine: 37.5 mg daily or twice daily/225 mg daily	Nausea, insomnia, appetite loss, weight gain
Topical agents			
5% Lidocaine patch	Sodium channel blocking	1-3 patches/3 patches daily	Rash, local erythema
Capsaicin: cream, 8% patch	Highly selective agonist for TRPV1 receptors expressed in afferent neuronal C fibers and some Aδ fibers	Cream: 0.025%, 0.075%, and 0.1% creams; apply 3-4 times per day; 8% patch: 1 patch/4 patches applied for 60 minutes every 3 months[b]	Erythema and uncomfortable burning, stinging, or itching

Abbreviations: SNRIS, serotonin and norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant.
[a]Need to adjust in those with renal insufficiency, especially those on renal replacement therapy.
[b]8% patch is applied by a medical provider only. Consideration of cost.

opioids for cancer patients with moderate to severe pain. In addition, there is growing evidence that the use of acetaminophen in combination with immunotherapy for cancer treatment may negatively impact the effect of the immunotherapy, and caution is advised.[19-21]

This ladder also includes adjuvant therapies.[22] Adjuvant medications that are non-opioid medications with evidence for pain improvement include anticonvulsants and antidepressants; adjuvants can be used at each step, particularly for patients with neuropathic pain (Table 8-4). Because of extensive feedback, the World Health Organization is in the process of revising the guideline and ladder. Many experts have suggested the addition of invasive and minimally invasive interventions, as well as an approach that includes the physical, psychological, and emotional causes of pain, to the guideline (Fig. 8-2).[23]

Figure 8-2 The Revised World Health Organization Analgesic Ladder

The choice of opioid agent depends on pharmacokinetics, route of delivery, availability, cost, clinician experience, and patient factors such as age, renal function, comorbidities, and concomitant drugs (Table 8-5).[24] Generally, patients experiencing constant pain should receive a scheduled opioid. Sustained-release preparation of a short-acting agent or a transdermal fentanyl (TDF) or buprenorphine patch is indicated for constant pain that is likely to continue to be present, but this should be reserved for patients who have developed some tolerance to the common adverse effects of opioids. In patients who are opioid-naive and who are experiencing constant pain, a standing dose of a short-acting opioid (eg, morphine every 4 hours) should be initiated. Interval of opioid doses should be based on their specific half-life, to allow achieving steady-state levels of the drug after four to five half-lives. Once the effective 24-hour dose of opioid is determined, patients with constant pain should have a sustained-release or transdermal patch added to the regimen to provide longer-lasting pain relief. The short-acting opioid should be continued to relieve breakthrough or incident pain episodes. For example, a patient with constant pain from pancreatic cancer who experiences relief from 15 mg of oral morphine every 4 hours "around the clock" could be started on 30 mg of oral sustained-release morphine q8h. Alternatively, since the patient took 90 mg of oral morphine in 24 hours, a fentanyl patch of 37 mcg/h or, if the pain is still severe, 50 mcg/h could be initiated.

Some patients with complex mixed-pain syndromes, especially neuropathic pain, can benefit from methadone, which is an intermediate- to long-acting opioid. It is highly recommended to seek expert palliative/supportive care or anesthesia pain management consultation when initiating methadone because titration can be complex, and close monitoring is required.

Patients who have cancer often also experience breakthrough or incident pain; they can concomitantly use short-acting opioids for these episodes. Breakthrough doses can be safely administered at a frequency based on the time to maximum concentration (eg, 1 hour for oral morphine). Generally, the breakthrough dose is 10% to 20% of the total daily sustained-release dose

Table 8-5 **Opioids, Active Metabolites, and Pharmacokinetics**[25-27]

Opioid	Active Metabolites	Half-Life (Hours)	Equianalgesic	
			Parental	Oral
Morphine	Yes	2-4	10	30
Oxycodone	Yes	3-4	Not available in the United States	20
Hydrocodone	No	3-4	NA	30
Hydromorphone	Yes	2-3	1.5	7.5
Fentanyl	No	Transmucosal: 1-2 Transdermal: 48-72	Variable conversion methods available; may consider using ratio of 2.5-1 (oral morphine per day: TDF per hour); should not initiate in opioid-naive patients or patients receiving less than 60 mg MEDD	
Methadone	No	2-3 (distribution phase); 15-60 (elimination phase)	[a]	

Abbreviations: MEDD, morphine equivalent daily dose; NA, not applicable; TDF, transdermal fentanyl.
There is no clear consensus on opioid conversions; these serve as guidelines only.
[a]Methadone conversions should be supervised by a pain expert (palliative care specialist or acute/chronic pain management specialist).

(except for methadone and short-acting fentanyl products). For example, a patient taking 15 mg of sustained-release morphine three times a day (ie, 45 mg in 24 hours) would take 5 to 10 mg of short-acting oral morphine for breakthrough or incident pain. For patients using a fentanyl patch, calculate the oral morphine equivalent and use 10% to 20% of that for the breakthrough dose. For example, for a patient using a 50 mcg/h patch, the oral morphine equivalent is approximately 100 mg, and the breakthrough dose would be 10 to 20 mg of liquid morphine or a 15-mg tablet.

NEUROPATHIC PAIN

Although opioids are effective for the management of acute and severe cancer pain of all types (nociceptive and neuropathic), when neuropathic pain is identified, additional agents are needed. Pharmacotherapies that target neuropathic pain will yield the highest effect. Common classes of drugs targeting neuropathic pain include antidepressants, anticonvulsants, and topical agents. To avoid sedation, these often require gradual titration over several weeks to achieve maximal effect. It is important to counsel patients about options and common adverse effects and set realistic expectations for symptom management. Monitoring patients closely for adverse effects is important because many of these pharmacotherapies can have multiple adverse effects and may interact with many other commonly used medications.

RENAL AND HEPATIC CONSIDERATIONS

With careful monitoring and appropriate dosing, opioids are safe and effective in patients with renal or hepatic dysfunction. For opioids other than fentanyl, buprenorphine, and methadone, the active drug half-life and drug metabolites increase in renal dysfunction. For example, the liver metabolizes morphine into its active metabolites of morphine-3-glucuronide and morphine-6-glucuronide. Renal dysfunction leads to the accumulation of morphine-6-glucuronide, manifesting as myoclonus or, rarely, seizures. Therefore, in the setting of severe renal dysfunction, morphine and codeine should be avoided, and hydromorphone or oxycodone should be used instead, with caution and close monitoring; methadone, fentanyl, and buprenorphine are the preferred long-acting options.

Cautious use of opioids is also necessary in severe liver dysfunction, because opioids can contribute to sedation, constipation, and encephalopathy if inappropriately dosed or not monitored carefully. Because patients who have hepatic insufficiency experience decreased opioid clearance, initial dose reductions and increased dosing intervals should be considered.[28] Oxycodone, tramadol, and hydromorphone should be avoided, but morphine and buprenorphine can be used with caution in the setting of severe hepatic dysfunction. Fentanyl and methadone can be used, but these are generally given at longer intervals than typical patients who have normal hepatic function. However, if patients who have cancer have mild or transient liver function changes, most opioids are safe and equally effective.

OPIOID TITRATION AND ROTATION

Unfortunately, we cannot predict the most effective and tolerable opioid for each patient. In clinical practice, opioid selection usually depends on availability, cost, and prior patient experience. If a patient experiences an intolerable adverse effect from one opioid, rotation to another opioid may be required. Of note, clinicians must differentiate anticipated adverse effects from an opioid (eg, transient nausea, pruritus) versus true allergic reactions (eg, hives, shortness of breath). Avoid labeling of anticipated adverse effects as true allergies, which occurs most commonly with morphine and codeine.[29]

Despite misconceptions about the drug morphine, it continues to be the most studied, evidence-based, cost-efficient opioid for treating cancer patients with pain. Equianalgesic tables and dosing charts are available to convert to a different route of administration or to rotate to a different opioid, but it should be noted that these guidelines originated from single-dose studies in healthy volunteers. Consequently, these conversions should be used with caution, because they serve as rough approximations and do not replace clinical judgment.

The indications to rotate opioids may include insufficient analgesic efficacy, intolerable adverse effects, ineffective administration route, drug interactions, development of tolerance, and financial constraints. To initiate an opioid rotation, the clinician should convert the daily opioid consumption to an oral morphine equivalent (or morphine equivalent daily dose) using an equianalgesic table, which a colleague should independently check. Although opioid conversion calculators can be found online, they should be used cautiously and should never replace clinical judgment.

Unless the patient is in severe pain, incomplete cross tolerance requires a dose reduction of 25% to 50% of the calculated equianalgesic dose of the new opioid. The difference between tolerance and incomplete cross-tolerance is that tolerance refers to the reduced analgesia that may occur with repeated opioid use, whereas incomplete cross-tolerance refers to a differential ability to tolerate an adverse effect, such as respiratory depression, between one opioid and another. It is, therefore, important to account for incomplete cross-tolerance when rotating a patient from one opioid to another. During opioid rotations, patients require careful monitoring and ready access to breakthrough doses of short-acting opioids. Converting other opioids to methadone requires additional care because of its unique pharmacokinetic profile and is best done in consultation with clinicians experienced with its use, such as palliative/supportive care clinicians.

Most Common Reasons for Opioid Rotation

- Severe, intractable, or refractory adverse effects
- Decrease in liver or renal function (expected to decrease opioid metabolism or elimination, causing accumulation of an opioid and its active metabolites)
- Possible or actual drug interactions, including prolongation of the heart rate-corrected QT interval (QTc; including with a clinical trial's investigational study drug [commonly seen with methadone])
- Access barriers including insurance limitations, stock availability at pharmacies, high out-of-pocket costs, and low health literacy
- Patient preference, high pill count, or barriers to administration (eg, loss of oral or enteral access)

Reasons Not to Rotate

- Patient tolerates the current pain regimen with minimal adverse effects and good analgesia.
- Patient declines recommended opioid. (Take this as an opportunity to explore their reasons further before changing the approach. For example, the patient may have heard about bad experiences with that opioid in the past. If the patient reports a personal experience of a serious adverse effect, consider using a different opioid.)

PARAMETERS FOR AVOIDING OR CHOOSING CERTAIN OPIOIDS

- Urinary retention: rotate to another opioid.
- Pruritus: consider opioids from a different class (eg, fentanyl ormethadone for patients on morphine, oxycodone, or hydromorphone).
- Renal failure: consider rotating to fentanyl, buprenorphine, or methadone for long-acting opioids. For short-acting or breakthrough opioids, consider oxycodone or hydromorphone over morphine.
- Liver failure: use opioids with an expectation to see increased half-life of both immediate (short-acting) and extended-release (long-acting) formulations; may need to use short-acting opioids for a few days until a new, effective, and tolerated dose is established at the new steady state.
- Respiratory insufficiency: use buprenorphine or scheduled doses of short-acting opioids until the patient develops tolerance.
- Sedation with good analgesia: may add methylphenidate. If sedation continues, decrease opioid dose by 25% to 50% and monitor; if sedation persists and analgesia is still adequate, further decrease dose or rotate opioid; if pain increases, obtain a palliative/supportive care consult.
- Altered mental status: decrease dose by 25% to 50%; if no improvement, rotate opioid.

- Constipation: increase laxative regimen and continue opioids. Ensure patients receive senna with or without polyethylene glycol (PEG); may need additional laxatives if constipation does not resolve. See the section below for management of constipation.
- Myoclonus: avoid morphine and hydromorphone. Consider the decrease in the gabapentin dose first.
- Prolonged QTc: correct contributing metabolic abnormalities (eg, hypokalemia, hypomagnesemia, hypocalcemia); avoid methadone for QTc greater than 500 milliseconds.

REASONS TO AVOID MORPHINE

- History of altered mental status or intolerable adverse effects (eg, visual hallucinations, myoclonus, severe nausea)
- Renal failure

METHADONE

Previously considered a late-line pain management option, clinicians experienced in its use can use methadone as first- or second-line treatment for patients with cancer-related pain. Methadone is a synthetic opioid with a chemical structure unrelated to opium derivatives. It is a unique opioid given its actions as a mu agonist and an *N*-methyl-D-aspartate receptor antagonist, making it particularly useful for treating patients with neuropathic cancer pain. It may be the only agent effective for patients with pain syndromes caused by invasion of a nerve plexus (eg, from invasion of the brachial, lumbosacral, or perineal plexus). Unlike other opioids, methadone has the advantage of lacking active metabolites, making it potentially safer in patients with renal and hepatic insufficiency. Unlike daily dosing for methadone maintenance therapy in patients recovering from opioid addiction, pain management and palliative/supportive care experts dose methadone every 8 to 12 hours for patients with cancer-related pain.

However, methadone is a complicated drug requiring expert oversight in its prescribing and monitoring. The complexities of methadone include oral bioavailability ranging from 40% to 99% and biphasic elimination-excretion coinciding with tissue distribution. A rapid and extensive distribution phase occurs at 2 to 3 hours, and a slow elimination phase occurs at 15 to 60 hours. Consequently, in the setting of a methadone overdose, patients must receive continuous naloxone rather than single or intermittent doses. The prescribing information states that although respiratory depression can happen at any point during the use of methadone, the risk is greatest at initiation of therapy and after an increase in the dose; therefore, patients need to be monitored very closely. In addition, the liver extensively metabolizes methadone with major CYP3A4, CYP2B6, CYP2D6, and CYP2C19 interactions, causing multiple drug-drug interactions. These drug interactions are a particular concern in patients who take concurrent medications prone to interactions, such as antiretroviral drugs metabolized through the CYP450 system, thereby evaluating all concomitant medications essential. Additional common interactions include hypoglycemia with high doses or rapid dose increase of methadone and QTc prolongation from methadone, requiring close monitoring, especially with concomitant medications also associated with QTc interval prolongation or electrolyte disturbances, such as hypokalemia, hypomagnesemia, or hypocalcemia, all of which also prolong the QTc.[30,31] In patients with end-stage cancer, the intensity of QTc monitoring should align with patient goals and preferences.[32]

For more information on common interactions, please see online resources, such as STATPearls.[33] Finally, converting routes of administration and equianalgesic dosing varies dramatically depending on the extent of previous exposure to opioids.[31] Clinicians should consider collaborating with a palliative/supportive care or anesthesia pain expert when converting a patient from another opioid to methadone.[30,33]

TRANSDERMAL OPIOIDS

Transdermal opioid patches (fentanyl and buprenorphine) offer an alternative long-acting formulation for cancer-related pain control, particularly if there are barriers to oral administration of drugs. By maintaining constant plasma drug levels, the transdermal route provides sustained pain relief and may reduce adverse effects. A TDF patch is applied to the skin over an area of adequate subcutaneous fat (and not over a tattoo or edema); a subcutaneous drug reservoir develops over approximately 12 to 18 hours. They are changed every 48 to 72 hours. A retrospective 2019 study suggested that there is no basis for avoiding TDF or modifying its dose in patients with cancer with low body mass index (BMI) and cachexia.[34] It is important to note that TDF is approved for opioid-tolerant patients; therefore, it is not recommended as a first-line opioid. Opioid-tolerant patients are those taking, for 1 week or longer, at least 60 mg of oral morphine equivalent daily. In addition, buprenorphine is an alternative option for those with advanced cancer, especially those with a concern for respiratory insufficiency or concurrent opioid use disorder (OUD).[34,35] Buprenorphine is a μ-opioid partial agonist, with higher affinity to μ-opioid receptors compared with other opioids. Buprenorphine patches do not need to be placed over a fatty area. They are changed every 7 days. It is important to note that the prescribing information advises that buprenorphine can potentially precipitate withdrawal in patients who are already on opioids. Furthermore, the prescribing information recommends avoiding buprenorphine in opioid-tolerant patients receiving more than 80 mg per day of morphine or its equivalent, because the highest formulation available in the United States (20 mcg/h) will not provide adequate analgesia for patients receiving these higher doses of opioids. See STATPearls for additional guidelines for

prescribing buprenorphine.[25,36] Oncology clinicians should collaborate with palliative care, anesthesia, pain, or addiction medicine specialists when caring for patients who may benefit from buprenorphine.

MANAGING OPIOID ADVERSE EFFECTS

When prescribing opioids for patients with cancer, prescribers must be informed about expected adverse effects and attempt to prevent them. All adverse effects associated with opioid use are transient except for opioid-induced constipation (OIC). Consequently, clinicians should consider appropriate education and prophylaxis in opioid-naive patients to prevent the attribution of expected adverse effects, such as constipation, to allergies.[29] Patient or family misunderstandings can prevent future use. If the medical chart notes an opioid as an allergy, the clinician should explore what specific reactions have occurred with its use and update the medical record accordingly.

Common adverse effects include nausea, pruritus, sedation, and constipation (see following section). Effective treatment of opioid-induced nausea includes antiemetics targeting dopaminergic receptors (eg, prochlorperazine, metoclopramide) rather than 5-hydroxytryptamine type 3 ($5HT_3$) receptor antagonists to avoid constipation associated with $5HT_3$ receptor antagonists. Non-sedating antihistamines (eg, cetirizine) can be used to prevent or treat pruritus. Diphenhydramine should be avoided, given the additive sedation it produces when administered with opioids, especially in patients with acute illness or who are elderly. Instead, change the opioid to a synthetic opioid or consider using a second-generation non-sedating antihistamine, such as cetirizine.[37]

Opioid-Induced Constipation

OIC is a particularly troublesome adverse effect that can lead patients to experience nausea, vomiting, and anorexia, and even discontinue their opioid medication. Opioids cause constipation by binding to μ receptors on enteric neurons, disrupting the neural coordination necessary for peristalsis and slowing bowel motility. They also increase the tolerance of the anal sphincter, already increased in elderly patients. The approach to OIC includes stimulant laxatives, such as senna (one to eight tablets daily) or bisacodyl (5-10 mg twice daily). Evidence has demonstrated no added benefit of a softener used along with sennosides for OIC.[38] A recent double-blind randomized controlled trial (RCT) of PEG versus sennosides in patients with cancer and OIC did not show a convincingly favorable efficacy for either agent.[39]

OIC prophylaxis with sennosides (senna) or PEG begins at the initiation of an opioid regimen and is done in a stepwise, additive fashion. Insoluble fiber (eg, psyllium) or other bulk-forming laxatives can worsen OIC in patients who cannot maintain adequate hydration. Patients should discontinue fiber or replace the insoluble fiber with a soluble fiber product.[40]

Lubiprostone is a drug that activates chloride channels to increase fluid in the intestines and is approved by the Food and Drug Administration (FDA) for use in opoid-induced constipation in non-cancer patients. Current NCCN guidelines recommend the use of lubiprostone in patients with cancer only in clinical trials. A retrospective cohort study of the use of the agent in cancer versus non-cancer patients showed that while it was equally effective in treating constipation, there was significantly more nausea and diarrhea experienced by cancer patients using lubiprostone, and more frequent discontinuation due to the adverse effects.

Peripheral-acting μ receptor antagonists (PAMORAs) are the latest class of constipation medications that block the peripheral effects of opioids on the gut. PAMORAs do not cross the blood-brain barrier and consequently do not reduce an opioid's central analgesic effects.[41] PAMORAs (eg, methylnaltrexone) are the best second-line therapy option for OIC, effective in up to three-fourths of patients who take opioids for cancer pain.[42,43]

Methylnaltrexone was the first US FDA-approved subcutaneous or intravenous injection to treat OIC. In the 2008 RCT, 48% of patients in the methylnaltrexone arm had a bowel movement within 4 hours of the first dose compared with 15% in the placebo arm; the treatment arm patients also had significantly lower rates of rescue laxative use; only 8% of the placebo arm had a bowel movement without rescue laxatives compared with 52% in the methylnaltrexone arm.[44] Methylnaltrexone, like other PAMORAs, should only be used after other measures have been ineffective, and the lower bowel has been emptied of stool. If a lower bowel impaction is present, methylnaltrexone can cause perforation of the upstream bowel. Methylnaltrexone causes abdominal cramping and diarrhea and is expensive. Additional oral PAMORAs (also expensive) include alvimopan, naloxegol, and naldemedine; naldemedine was recently shown to be effective for patients with cancer with OIC[45]; however, regulatory agencies have not approved these agents in the cancer setting.[46-48]

Opioid-Induced Hyperalgesia

Opioid-induced hyperalgesia is a state of nociceptive sensitization from exposure to high-dose opioids, causing pain exacerbation. The type of pain experienced might be different or the same as the underlying pain. Opioid-induced hyperalgesia is a distinct, definable, and characteristic phenomenon that may explain the loss of opioid efficacy in some patients. The most likely cause of opioid-induced hyperalgesia involves the central glutaminergic system, but the precise molecular mechanism is not yet understood.[49]

Clinicians should suspect opioid-induced hyperalgesia when escalating opioid doses to increase pain paradoxically without evidence of disease progression. Tremulousness, myoclonus, confusion, or allodynia, causing reports of pain wherever the patient is touched, may also accompany this increase in pain. Myoclonus may be masked, however, by concomitant use of benzodiazepines for anxiety or nausea. Concerns about opioid-induced hyperalgesia should not justify withholding or limiting opioid therapy, but when hyperalgesia is suspected, it is important to consider dose reduction, opioid rotation, or dose reduction combined with non-opioid interventions to prevent seizures, the most serious consequence of the toxicity. Nonetheless, concerns about opioid-induced hyperalgesia should not justify withholding or limiting opioid therapy. It is essential to differentiate between opioid-induced hyperalgesia and uncontrolled pain.

MANAGING OPIOID RISK

Over the last two decades, clinicians have witnessed a growing trend in the aberrant use of opioids. Clinicians should always advocate for ready access to opioids for medically indicated purposes, including cancer-related pain.[24] However, clinicians must also advocate for and attempt to ensure safe opioid use, storage, and disposal through close monitoring and patient and caregiver education.

OUD and Addiction

Clinicians must be clear about the phenomena and the terminology used to describe aberrant opioid use, because these terms continue to evolve and carry strong social meaning (Table 8-6). Most recently, to describe what was previously referred to as opioid addiction, the *Diagnostic and Statistical Manual for Psychological Disorders, Fifth Edition*,[50] introduced the term OUD. OUD is a problematic pattern of opioid use that leads to clinically significant impairment or distress, as manifested by at least 2 of 11 symptoms or behaviors. In short, OUD is an inability to take opioids as prescribed because of impaired control over drug use, compulsive use, continued use despite harm, and craving.

Table 8-6 Opioid Aberrancy Terminology[33,50-53]

Term	Definition
Aberrant	Actions departing from accepted, medically appropriate drug-taking behaviors
Abuse	A maladaptive pattern of prescription opioid use leading to clinically significant impairment and distress
Addiction	A primary, chronic, and neurobiological disease with manifestations influenced by genetic, psychosocial, and environmental factors, characterized by impaired control over drug use, compulsive use, continued use despite harm, and craving
Chemical coping	Behaviors focused on obtaining opioids to relieve psychosocial distress rather than pain
Dependence	A state of adaptation indicated by a medication class-specific withdrawal syndrome produced by abrupt cessation, rapid dosage reduction, decreasing blood level of the drug, or administration of an antagonist
Misuse	The inappropriate use of a prescription opioid agent, whether intentional or unintentional, and regardless of motivation
Pseudo-addiction	An iatrogenic syndrome with behaviors that mimic addiction, driven by unrelieved pain
Substance abuse	Use of a substance in a manner outside of sociocultural conventions
Tolerance	Diminution of one or more drug effects caused by exposure to the drug that may require higher doses for effect
Withdrawal	An uncomfortable but non–life-threatening reaction that occurs after the abrupt cessation of opioids or use of naloxone, characterized by the presence of one or more of a variable group of symptoms and signs, including tremulousness, anxiety, insomnia, tachycardia, tachypnea, hypertension, nausea and vomiting, diarrhea, piloerection, and sweating

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

The most accepted risk factors for OUD include a personal history of alcohol use disorder, drug abuse, tobacco dependency, major psychiatric disorder, or family history of alcoholism or drug abuse.[54] Other factors include youth, length of exposure to opioids, and history of preadolescent sexual abuse. Pseudo-addiction is a term for an iatrogenic condition that manifests as apparent drug-seeking behavior but is caused by incorrect frequency of opioid dosing for a patient requiring opioids for pain relief (eg, dosing oxycodone every 6 hours when the pain relief lasts at most 4 hours). Pseudo-addiction should be ruled out and assessments documented when treating a patient with apparent drug-seeking behaviors.[55,56]

Although patients who have cancer pain are appropriately excluded from most guidelines aiming to decrease prescriptions of opioids for patients who have other causes of pain, it is not uncommon to need to prescribe opioids for patients who have both severe cancer pain and a history of OUD. Management of cancer pain in these patients is complicated by the need to manage both the patient's pain and OUD at the same time.

It is essential to continue addressing and treating the OUD when treating pain in a patient with cancer. Having OUD may impair relationships with the clinical team and personal support systems and put patients at risk for undertreatment of pain and cancer.[57] Because most cancer hospitals do not offer treatment of patients with OUD, clinicians treating pain in patients with cancer should collaborate and coordinate care with local methadone or buprenorphine prescribers, especially if already involved in the patient's care.[58] If a patient with OUD comes to a cancer center on buprenorphine, the prescriber should be asked to continue prescribing buprenorphine for the OUD and to continue mental health counseling and support for the patient. If a local buprenorphine prescriber is not available, collaboration with the institution's pain, palliative/supportive care, or mental health clinicians certified to prescribe buprenorphine for OUD is indicated. If an addiction specialist is not available, an outside referral is strongly recommended for medication-assisted treatment of OUD. Stopping medication for treatment of OUD is not an acceptable option, because it has been found to lead to 50% of patients experiencing OUD relapse.[59]

Clinical Practice Safeguards When Managing Cancer Pain

Clinicians recognize the serious nature of OUD and their role in mitigating its negative effects. Prescribing clinicians should take a balanced approach, which includes taking universal precautions. To do this, clinicians prescribing opioids assess all patients for a history or risk of opioid misuse independent of demographic, social, or disease-related variables. Most of the data to support universal precautions in opioid prescribing originate from the non-cancer pain and cancer survivorship literature; nevertheless, this approach has clear applications for patients being actively treated for cancer or those patients with advanced disease not currently receiving treatment.[56] Instituting universal precautions in clinical practice requires outlining opioid-prescribing procedures and obtaining support from institutional leadership and colleagues. Once a clinical practice adopts an opioid-prescribing process, all clinicians must routinely use this process before prescribing opioids to any patient. Consultation and collaboration with a pain and addiction medicine specialist or a palliative/supportive care specialist should be considered when managing cancer pain in a patient with OUD.

The following approaches should be considered as part of universal precautions: prescription drug monitoring program reports, electronic prescribing, education, pain contracts/agreements, opioid aberrancy risk assessment, urine drug screens, safe storage, and disposal.

Prescription Drug Monitoring Plans

Nearly all states now provide prescription drug monitoring plans, which digitally store controlled substance dispensing information and make these data accessible to prescribers and pharmacies. Some states now require that clinicians review and document that they have reviewed an online prescription drug monitoring plan report before prescribing an opioid. The prescription drug monitoring plan is a vital tool to review current opioids, doses, names of prescribing clinicians, and names of pharmacies that dispensed the opioids. Furthermore, electronic prescribing of opioids is now available in most states and has many benefits. Overall, this provides a convenient, safe, and patient-centered approach to prescribing opioids and has become the new standard in opioid prescribing.[60]

Pain Agreements

Clinicians should also consider the routine use of pain agreements (or contracts) with patients receiving opioids. The primary aim of opioid agreements is to communicate clearly and document expectations of prescribing clinicians and patients.[61] Clinician expectations should outline the clinical team members involved, hours of operation, and policies around lost or stolen medications, and state that clinicians cannot prescribe opioids if not used for their intended medical purpose. Patient expectations may include clarity regarding participation at scheduled appointments and referrals, consent to tests such as pill counts and urine drug screens, abstinence from alcohol and other illicit drugs, and limiting the patient's opioid consumption. Published guidelines recommend written opioid agreements for all patients initiating therapy or patients at higher risk of aberrant drug-related behaviors.[62,63]

Assessment of Opioid Aberrancy Risk

In addition to personal and family risk factors, screening tools can be used to assess risks of OUD and monitor safety. Unfortunately, tools often used for risk stratification have not been validated in patients who have cancer pain. Some of the common screening and monitoring tools include the following:

- Opioid Risk Tool[64,65]
- Screener and Opioid Assessment Measure for Patients with Pain–Revised[66] or Screener and Opioid Assessment Measure for Patients with Pain Short Form[66]
- Cut Down, Annoyed, Guilty, and Eye-Opener Adapted to include Drugs Questionnaire
- Current Opioid Misuse Measure[51,67]

Based on the assessed risk for OUD, clinicians can inform patients about their potential risk for OUD, modify clinical assessment and opioid refill intervals, and use urine drug screens.[56] At initiation and periodically throughout opioid therapy, clinicians can use urine drug screens to enhance objective data regarding patient behaviors. Understanding of the methodological practices of testing (eg, immunoassays, gas chromatography–mass spectrometry) at each institution, including limitations, such as false-positive and false-negative rates, is required to interpret the screen results correctly. Before ordering a drug screen, the clinician should consider how this information will change the clinical management of the patient's pain.

Nasal Naloxone

There is an increasing number of states in which naloxone prescribing is recommended or required when prescribing opioids in excess of certain doses or in combination with other sedating medications.[68] Naloxone is also increasingly available at pharmacies without a prescription. Clinicians must educate caregivers on how and when to administer naloxone and should advise caregivers to call 911 if they use it. Not calling for help could result in the patient's death, especially when the overdose was caused by taking a long-acting opioid, such as methadone.

Opioid Storage and Disposal

Improperly stored opioids can lead to diversion or accidental poisoning. Patients and caregivers should remove expired or unused medicines from their homes when they are no longer needed by attending opioid take-back events, using mail-back envelope programs, or permanent collection sites.[69,70] Patients should be encouraged to consult with their local government about best practices for opioid disposal.

INTERVENTIONAL CANCER PAIN TREATMENTS

A vast majority of oncology patients will be able to achieve adequate pain control with aggressive management using systemic analgesics, adjuvants, and cognitive behavioral techniques. However, 5% to 10% of patients require interventional strategies to manage their pain. Interventional options should be integrated into an interdisciplinary approach toward effective oncological pain management along with medical management, supportive care, rehabilitative measures, and psychological management. Improved access to and knowledge of interventional options will allow for early diagnosis and access to effective analgesic treatments before advanced stages of disease. If pain is refractory or there is clinical suspicion that the patient may benefit from interventional pain approaches, consider consulting pain experts for further evaluation.

BONE PAIN

Painful bone lesions and spine fractures may be amenable to treatment with NSAIDs, bisphosphonates, receptor activator of nuclear factor κ-B ligand inhibitors, kyphoplasty, radiofrequency ablation, or single-fraction radiotherapy.[26] Patients who have diffuse bony metastases, such as those occurring in metastatic prostate cancer, who are refractory to androgen-deprivation treatments and do not have additional cytotoxic therapies planned may benefit from infusion of a radiopharmaceutical, such as the β emitter ^{153}Sm-SM lexidronam, the α emitter radium-223, or ^{177}Lu, targets prostate-specific antigen.[71,72] The limitation of these agents is the localization to metastases in major marrow areas, resulting in cytopenias.

A systematic review from 2019 of the effectiveness and safety of vertebral augmentation for malignant vertebral compression fracture showed clinically relevant improvements in pain, Oswestry Disability Index, and Karnofsky Performance Status in patients with malignancy treated with percutaneous vertebroplasty and kyphoplasty.[73]

PRESENTING CASE STUDY

A 65-year-old woman presents with worsening back pain due to progression of breast cancer metastases in the vertebrae. Previously, her bone pain was well-controlled with extended-release oral morphine sulfate (30 mg every 12 hours) and immediate-release oral morphine (7.5 mg every 4 hours as needed) for breakthrough pain; at baseline, she required two to three doses of immediate-release morphine per day. In the past week, her pain has been increasingly worse, and today she rates her pain severity as 10 out of 10. She describes her pain as aching and stabbing at times, and it is well localized to her mid- and lower back. She appears acutely distressed, tearful, and diaphoretic on physical examination. There are no changes in her strength or sensation. Vital signs include a temperature of 99.1°F (37.3°C), heart rate of 115 beats per minute, respiratory rate of 20 breaths per minute, and blood pressure of 150/95 mm Hg. Cervical, thoracic, and lumbar spinal MRI identifies multiple new lesions in her spine, but no impending fracture or spinal cord compression. She is admitted for pain control with intravenous (IV) morphine. Laboratory studies show renal function, hepatic function, vitamin D, and calcium levels were within reference limits.

Given the patient's acute and severe exacerbation of bone pain, requiring immediate inpatient management, why is the transition from oral to IV morphine the most appropriate initial step?

The primary goal in this scenario is to achieve rapid and effective pain relief. The patient's severe pain (10/10) and acute distress necessitate prompt intervention. IV opioid administration is the most appropriate initial step, as IV opioids provide a rapid onset of action, with peak effects occurring within approximately 10 minutes. This approach allows for immediate titration and precise dosing to achieve adequate analgesia. Since her renal and hepatic function are normal, IV morphine is a safe and reasonable option.

To provide adequate pain relief, convert her oral rescue dose to IV and consider doubling that dose because she is in severe pain (oral dose doubled = 15 mg; converted to IV = 5 mg IV). Consider ordering 3- to 5-mg IV morphine every 3 hours as needed in addition to continuing her oral extended-release morphine.

Alternatively, to provide continuous pain control and relieve her breakthrough pain, consider converting all oral opioids to an IV infusion either with a patient-controlled analgesia (PCA) or nursing boluses (60 mg oral morphine/24 hours = 20 mg IV morphine/24 hours). Because she has taken multiple breakthrough doses, it would be reasonable to start the morphine infusion at 1 mg/h. Nursing doses when required should be 10% to 20% of the 24-hour dose or 3- to 5-mg IV morphine every 3 hours. PCA bolus doses could be 0.5 mg IV every 15 minutes.

What are the potential drawbacks of alternative options?

Alternative management options that may be considered could include increasing oral opioids, changing oral opioids, or introducing a fentanyl patch, but none of these are preferred. Increasing either short-acting or long-acting oral opioids would be insufficient for rapid pain relief. Oral opioids have a longer time to peak effect (approximately 1 hour). Switching to oral hydromorphone, while a more potent opioid, would still result in a delayed onset of action like with other oral medications; as such, this option is not ideal for acute pain. This delay in effective pain control could lead to prolonged suffering and increased distress. Finally, fentanyl patches are designed for chronic pain management and have a very slow onset of action. They are not suitable for acute pain exacerbations requiring rapid titration.

- **Additional considerations.** In addition to IV opioids, adjunctive therapies should be considered. Nonsteroidal anti-inflammatory drugs can be effective for bone pain, provided there are no contraindications. Acetaminophen can be considered a co-analgesic, though studies showing additional benefit have had conflicting results. Administration of a bisphosphonate (eg, zoledronic acid) or a RANK-L inhibitor should be considered as a component of pain control; RANK-L inhibitors have modest benefit over bisphosphonates.

Once her acute pain is controlled, a comprehensive plan for pain management should include a transition strategy for oral or transdermal medications, if feasible, along with a plan for managing breakthrough pain. Further evaluation of the treatment of the new spinal lesions by radiation oncology, interventional radiologist (Kyphoplasty, nerve block) should be considered. Finally, it is important to address the patient's emotional and spiritual/existential distress and provide supportive care to help her cope with the progression of her disease.

By prioritizing rapid pain control with IV opioids and considering adjunctive therapies, clinicians can effectively manage acute exacerbations of cancer-related bone pain and improve patient comfort.

NEUROPATHIC PAIN

Sympathetic Blockade

The sympathetic chain is a known target for anesthetic interventions, and the sympathetic neural blockade is commonly used for visceral pain treatment. Pain in the midback related to upper abdominal malignancies can be debilitating and is often responsive to a celiac plexus block. A meta-analysis showed that 90% of patients achieve pain relief within 2 weeks, and 70% to 90% of patients achieve partial to complete relief until death or after 3 months or more. Common adverse effects include orthostatic hypotension and diarrhea. Less common complications include pneumothorax, back pain, and, rarely, paraplegia.[74]

Superior and inferior hypogastric blocks can be used effectively to treat advanced pelvic pain, with a retrospective study of 180 patients showing sustained visual analog scale reduction of 49.55% at 3 months.[75] The ganglion of impar has been successfully targeted for treatment of rectal and anal cancer pain, and a retrospective review has shown a reduction in morphine consumption at 3 months.[76]

SPINAL DRUG DELIVERY/NEUROLYSIS

Patients who have diffuse neuropathic pain syndromes, who have pain refractory to aggressive analgesic titration, or who are experiencing intolerable adverse effects should be referred for consideration of epidural or intrathecal drug delivery or destructive neurolytic procedures.[77] After successful treatment, a patient may require a significant reduction of systemic pain medications. Intrathecal drug delivery allows for lower doses of medications to be continuously delivered to the CNS to improve analgesia and reduce adverse effects.[78] Opioids, local anesthetics, clonidine, and ziconotide have all been used to effectively treat cancer-related pain. A 2002 RCT comparing an implantable drug delivery system and comprehensive medical management of pain in patients with advanced cancer showed that the implantable drug delivery system led to clinical success in pain control, reduced pain, and significant relief from common drug toxicities compared with medical management.

Spinal cord stimulation is a common pain treatment most often used for neuropathic pain and the treatment of complex regional pain syndrome in patients without cancer. However, current evidence is generally insufficient to support routine use for cancer-related pain.[79]

ANALGESIC AGENTS THAT ARE NOT RECOMMENDED

Mixed agonist-antagonists (ie, butorphanol, pentazocine) should not be used in combination with opioid agonist drugs for cancer pain management. Converting from an agonist to an agonist-antagonist could precipitate abstinence syndrome (withdrawal crisis).

Meperidine and placebos should not be used for patients with cancer pain. Meperidine is contraindicated for chronic pain, especially in patients with impaired renal function or dehydration, because accumulation of metabolites that are renally cleared may result in neurotoxicity (seizures) or cardiac arrhythmias. The use of a placebo in the treatment of pain is unethical.

Combination formulations of short-acting opioids with non-opioid medications, such as acetaminophen, are often used to treat cancer pain (eg, Percocet, Vicodin), although evidence of their efficacy is limited in moderate and severe cancer pain. These combined opioid/acetaminophen formulations are recommended to be prescribed for very short courses (<3 days) for moderate pain that is predicted to resolve because of the risk of liver toxicity from acetaminophen (amounts greater than 4 g in 24 hours) and potential for masking fevers in patients with cancer.

KEY POINTS

- A multimodal approach to managing the pain of cancer patients that includes pharmacological and non-pharmacological interventions is strongly recommended.
- Non-steroidal anti-inflammatory agents are first-line therapies for mild pain and can minimize the need for opioids in patients with somatic pain, including pain from bone metastases.
- Morphine is the most studied, evidence-based, cost-efficient opioid for the treatment of patients with cancer who have pain.
- Methadone is a mu agonist and *N*-methyl-D-aspartate receptor antagonist effective in treating neuropathic pain. Methadone is a complex drug that requires expert oversight in its prescribing and monitoring.
- TDF and buprenorphine patches are approved for opioid-tolerant patients.
- Methadone, buprenorphine, and fentanyl are the safest opioids in the setting of renal failure; however, they are not intended to be first-line options in those for whom other opioids can be considered or used.
- Avoid defining anticipated and transient opioid-associated adverse effects (eg, nausea, pruritus) as true allergies (eg, hives, shortness of breath).
- When prescribing opioids to patients who have cancer, it is important to anticipate expected adverse effects and develop strategies to prevent them.
- Stimulant laxatives (eg, senna, bisacodyl), not stool softeners, are the most effective approach to prevent and treat OIC. Polyethylene glycol is also effective.
- Consideration of interventional approaches for cancer pain should be discussed.
- Oncologists must use accurate terminology to describe OUD.
- Universal precautions describe an opioid-prescribing practice in which clinicians assess all patients for history or risk of opioid misuse regardless of demographic, social, or disease-related variables.
- Effective use of adjuvant agents for bone and neuropathic pain can provide more effective pain control with fewer adverse effects than opioids alone.

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

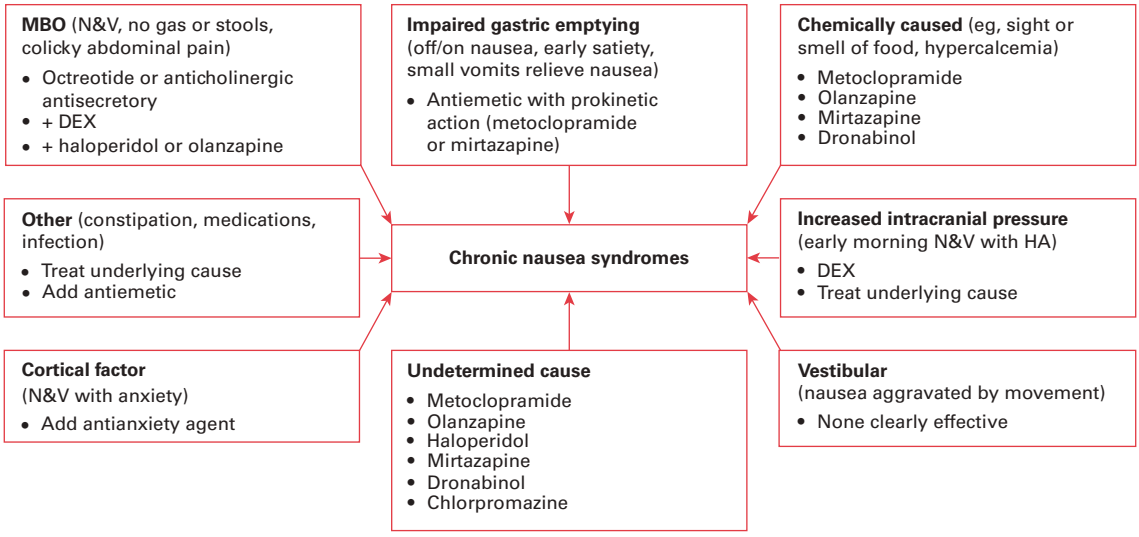
Nausea and vomiting in patients undergoing cancer treatment may significantly reduce their QoL and affect therapy adherence.[80] A summary of the causes of nausea and vomiting unrelated to cancer therapy and how to manage them is included in Figure 8-3.

The principal strategy for developing effective antiemetic agents for chemotherapy-induced nausea and vomiting (CINV) requires identifying and blocking key neurotransmitter receptors in the Chemoreceptor Trigger Zone: dopamine, serotonin, and substance P (Table 8-7). Blocking receptors for endocannabinoids, histamine, and acetylcholine may provide additional protection, as does dexamethasone, in some situations.

Choice of antiemetic regimen for CINV involves assessing the emetic risk of the chemotherapy itself and the neurotransmitters involved, along with individual patient risk factors. Chemotherapy falls into four emetic risk categories[81-83]:

- High (>90%)
- Moderately emetogenic chemotherapy (30%-90% risk)
- Low emetogenic chemotherapy (10%-30% risk)
- Minimal (<10%)

Figure 8-3 Nausea Management Options



Abbreviations: DEX, dexamethasone; HA, headache; MBO, malignant bowel obstruction; N&V, nausea and vomiting.
Adapted under Creative Commons license. Source: Wickham R. Nausea and vomiting not related to cancer therapy: intractable problem or clinical challenge? *J Adv Pract Oncol*. 2020;11(5):476-488. doi:10.6004/jadpro.2020.11.5.4

Individual patient risk factors also increase the risk of developing nausea and vomiting, including previous CINV, female sex, age younger than 50 years, low alcohol intake, motion sickness history, an expectation of experiencing nausea and vomiting, and a history of hyperemesis gravidarum.[61,85] Notably, patients who experience CINV during their first cycle of chemotherapy are up to five times more likely to experience nausea in subsequent cycles.[85] When patients have at least one of these risk factors, aggressive antiemetic use should be considered, especially before the first cycle of chemotherapy, to improve future treatment dose tolerance.

TYPES OF CINV

There are four types of CINV: acute, delayed, breakthrough, and anticipatory (Table 8-8). Acute CINV occurs no more than 24 hours after administration of chemotherapy. By contrast, delayed CINV occurs 2 to 5 days after the administration of chemotherapy and is most commonly associated with platinum chemotherapy. This delayed emesis is often of lesser intensity, but it can last longer. The antiemetic agents that effectively manage acute CINV differ from those used for delayed CINV; this difference suggests unique neurotransmitter mechanisms, if not different physical sites, involved in these two forms of CINV. Breakthrough CINV occurs despite receiving guideline-based antiemetic prophylaxis. Clinicians can use as-needed medications to treat breakthrough nausea, which have different mechanisms of action than the antiemetics used for prophylaxis. Finally, anticipatory nausea is a conditioned reflex that occurs after inadequate antiemetic protection during an earlier chemotherapy course.[86] Numerous stimuli trigger chemotherapy-associated anticipatory nausea (eg, proximity to the infusion center and smells), and symptoms can occur at any time. Clinicians can use non-pharmacological measures (eg, hypnosis) and benzodiazepines to treat the subsequent anxiety and decrease anticipatory nausea.

Table 8-7 **Selection of Antiemetics Based on Neurotransmitters Involved**[84]		
Anatomic Location	**Neurotransmitter Involved**	**Drug Class**
Cortex	Unknown	Dexamethasone
		Lorazepam
		Cannabinoids
	Dopamine	Haloperidol
Chemoreceptor trigger zone	Serotonin	Metoclopramide
		Prochlorperazine
		Ondansetron
		Oral granisetron
		Transdermal granisetron
	Dopamine	Metoclopramide
		Prochlorperazine
	Endocannabinoid	Cannabinoids
	Substance P inhibitors	Aprepitant
		Fosaprepitant
		Netupitant
		Rolapitant
Vomiting center/vestibular apparatus	Histamine	Cetirizine (preferred)
		Diphenhydramine
		Meclizine
		Hydroxyzine
	Acetylcholine	Scopolamine

CINV PROPHYLAXIS

Adherence to evidence-based CINV prophylaxis guidelines significantly improves patient-centered outcomes.[61,87-89] One effective method to ensure adherence to antiemetic guidelines is to incorporate guideline-based antiemetic ordering as part of all chemotherapy regimen plans.[90] In 2020, ASCO convened a multidisciplinary panel to update antiemesis guidelines.[91] Highly emetogenic chemotherapy prophylaxis includes a neurokinin-1 receptor antagonist, a $5HT_3$ receptor antagonist, dexamethasone, and olanzapine; moderately emetogenic chemotherapy requires a $5HT_3$ receptor antagonist and dexamethasone; low emetogenic chemotherapy requires a single dose of a $5HT_3$ receptor antagonist or dexamethasone; and minimally emetogenic chemotherapy does not require routine antiemetic prophylaxis.[91] In patients receiving combination chemotherapy, the chemotherapeutic agent with the highest emetic risk determines the CINV prophylactic strategy. Patients receiving radiation based on risk category should receive evidence-based CINV prophylaxis (Table 8-9).

Olanzapine is an atypical antipsychotic drug initially developed for the treatment of schizophrenia and bipolar disorder. It affects multiple dopamine and serotonin receptors associated with nausea and vomiting (ie, dopamine 2 receptor, $5HT_{2A}$, $5HT_{2C}$, and $5HT_3$).[92-94]

At 5- and 10-mg doses, olanzapine is an effective agent that prevents and treats acute, delayed, breakthrough, and overall CINV and other chronic nausea and vomiting from highly emetogenic agents.[85,90,92,95] There is recent phase 3 RCT evidence for using olanzapine along with triple therapy for prevention of CINV in patients receiving moderately emetogenic chemotherapy.[96,97]

Table 8-9 **CINV Prophylaxis Based on Emetic Risk**	
Risk	**Recommended Prophylaxis**
High	NK-1 + $5HT_3$ + dexamethasone + olanzapine
Moderate	$5HT_3$ + dexamethasone
Low	$5HT_3$ or dexamethasone
Minimal	None

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

In patients with cancer receiving highly emetogenic chemotherapy, 10 mg of olanzapine for 4 days and standard guideline-based prophylaxis antiemetics significantly improved acute CINV (74% vs. 45%; $P = .002$), delayed CINV (37% vs. 22%; $P = .002$), and overall CINV (37% vs. 22%; $P = .002$).[15] Taking olanzapine can cause sedation, but overall, it is well tolerated.[93] A phase 3 study in Japanese breast cancer patients compared olanzapine 5 mg versus placebo; patients who received olanzapine, given within 5 hours after chemotherapy completion, had excellent responses with less sedation.[98] Similarly, another phase 3 study from India comparing olanzapine 2.5 mg versus 10 mg showed non-inferiority in overall control of N/V while significantly reducing daytime somnolence (any grade; 65% vs. 90%, $P < .0001$).[99] Olanzapine has improved efficacy over metoclopramide in treating breakthrough CINV.[100] In patients who received highly emetogenic chemotherapy and evidence-based CINV prophylaxis, those who received olanzapine compared with metoclopramide experienced less vomiting (70% vs. 31%; $P < .01$) and nausea (68% vs. 23%; $P < .01$) over 72 hours.

MULTIPLE-DAY AND HIGH-DOSE CHEMOTHERAPY

In patients receiving chemotherapy over multiple days, including those with hematological malignancies, ASCO guidelines recommend CINV prophylaxis based on the chemotherapeutic agent with the greatest emetic risk; prophylaxis should be given each day of chemotherapy and continue for 2 days after completion. Specifically, for cisplatin-containing multiple-day regimens, ASCO guidelines support the use of a neurokinin-1 receptor antagonist, a $5HT_3$ receptor antagonist, and dexamethasone. An RCT in patients with germ cell tumors similarly supported using a combination of a neurokinin-1 receptor antagonist, a $5HT_3$ receptor antagonist, and dexamethasone to prevent both acute and delayed emesis.[101,102]

In patients receiving high-dose chemotherapy preparation for hematopoietic cell transplantation, data support a combination of a neurokinin-1 receptor antagonist, a $5HT_3$ receptor antagonist, and dexamethasone with or without olanzapine.[91,95,103-105]

RADIATION-INDUCED NAUSEA AND VOMITING

As with chemotherapy, radiotherapy can cause nausea and vomiting because 80% of the body's serotonin is located in the gastrointestinal tract, and gut serotonin is released by gut injury, such as that induced by radiation. Determinants of risk include the treatment field, dose of radiation, and fractionation pattern (Table 8-10).

Table 8-10 **Emetic Risk in Adults by Site of Radiation Therapy**		
Risk Level	**Site**	**Therapy Options**
High (>90%)	Total body irradiation	5-HT_3 antagonist with dexamethasone
Moderate (30%-90%)	Upper abdomen, craniospinal irradiation	5-HT_3 antagonist with or without dexamethasone
Low (10%-30%)	Brain, head and neck, thorax, pelvis	Brain: dexamethasone; head and neck, thorax, pelvis: $5HT_3$ antagonist or dexamethasone or dopamine receptor antagonist (use as rescue)
Minimal (<10%)	Extremities, breast	$5HT_3$ antagonist, dexamethasone, or dopamine receptor antagonist (use as rescue)

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Approximately 50% to 80% of patients undergoing radiotherapy will experience nausea and vomiting if they do not receive appropriate prophylaxis.[106] Guidelines state that total-body irradiation is associated with the highest risk (>90%), and radiation to the upper abdomen is associated with a moderate risk (30%-90%) of nausea and vomiting.[80,91] A meta-analysis suggests that $5HT_3$ receptor (ie, serotonin) antagonists are the preferred prophylaxis for radiotherapy-induced nausea and vomiting.[107] For those treated with highly emetogenic radiotherapy, recommendations include a $5HT_3$ receptor antagonist and dexamethasone.

Guidelines recommend a $5HT_3$ receptor antagonist and an optional 5-day dexamethasone course for patients receiving moderately emetogenic radiotherapy.[80]

In patients receiving combination chemotherapy and radiotherapy, clinicians should provide antiemetics based on the highest emetic risk of either the chemotherapy or the radiotherapy.[61,89-91]

DEXAMETHASONE-SPARING CINV PROPHYLAXIS STRATEGIES

Dexamethasone has been a central component of CINV prophylaxis for a long time. However, the multiple adverse effects of dexamethasone may limit its use (eg, hyperglycemia, insomnia, anxiety, gastric ulcers, poor wound healing). Four placebo-controlled RCTs and two meta-analyses have evaluated dexamethasone-sparing strategies comparing CINV outcomes for patients receiving highly emetogenic chemotherapy or moderately emetogenic chemotherapy.[108-112] These data support limiting the administration of dexamethasone to the first day of chemotherapy administration in patients intolerant of dexamethasone or those with few individual risk factors for CINV. Replacing dexamethasone with olanzapine should be considered for patients unable to tolerate dexamethasone.[61,91]

REFRACTORY CINV

Refractory CINV refers to nausea and/or vomiting that occurs during subsequent treatment cycles when adequate antiemetic prophylaxis and/or rescue has not been effective in earlier cycles. Different strategies can be used to control refractory CINV.

- Consideration for a change in the prophylactic antiemetic regimen. This may include escalation to the next higher category for CINV prophylaxis or using drugs with alternative mechanisms.
- For patients with anticipatory nausea or anxiety, the addition of a benzodiazepine could be considered.
- Cannabinoids: Dronabinol has been approved by the FDA for refractory CINV. Recommended starting doses are dronabinol oral solution at 4.2 mg/m^2 or dronabinol capsules at 5 mg/m^2 given three to four times a day.
- Dopamine receptor antagonists, such as metoclopramide or prochlorperazine, although not preferred secondary to the risk of extrapyramidal adverse effects, can be used rarely.
- In a retrospective study involving patients with refractory CINV, the addition of olanzapine at 5 to 10 mg to the nausea regimen in subsequent cycles demonstrated an overall success rate of 70%.[113]

KEY POINTS

- There are four types of CINV: acute, delayed, breakthrough, and anticipatory.
- Chemotherapy is classified into four emetic risk categories: highly emetogenic (>90% risk), moderately emetogenic (30%-90% risk), low emetogenic (10%-30% risk), and minimally emetogenic (<10% risk).
- Prevention of CINV is key because patients who experience CINV during the first cycle of chemotherapy are up to five times more likely to experience CINV in subsequent cycles.
- Olanzapine significantly reduces nausea and emesis in highly emetogenic chemotherapy regimens when combined with neurokinin-1 receptor antagonists, $5HT_3$ receptor antagonists, and dexamethasone.

CANCER-RELATED FATIGUE

Cancer-related fatigue is a multifactorial symptom defined as a distressing, persistent, subjective sense of physical, emotional, and cognitive exhaustion related to cancer or its treatment.[114] Cancer-related fatigue results in a decreased capacity for physical or mental activity and occurs in up to 80% of patients receiving chemotherapy and/or radiotherapy. Fatigue affects QoL by interfering with patients' abilities to fulfill their roles and participate in meaningful activities. The causes of cancer-related fatigue are multifactorial, and an in-depth assessment should first focus on identifying possible reversible underlying causes: medications causing fatigue, such as β-blockers, hypothyroidism, anemia, adrenal insufficiency, hypoglycemia, dehydration, hypercalcemia, hypogonadism, poorly controlled pain, depression, sleep disturbances, and deconditioning. A recent comprehensive study divided the experience of the patient coping with fatigue into five interrelated themes:

1. Discovering physical and emotional boundaries
2. Communicating support needs
3. Reorganizing and planning activities and rest
4. Letting go of one's habitual identity
5. Recognizing and accepting chronic cancer-related fatigue

Unpacking the physical, psychological, social, emotional, and spiritual/existential aspects of fatigue into these distinct categories can facilitate communication among patients, their families, and clinicians and help to make a shared decision about the

preferred treatments. Health professionals should make patients aware of the different options and refer them to their preferred treatment(s).[115] Identification and treatment of fatigue might include referral to appropriate specialties, such as endocrinology, physical therapy, psychology, and palliative care. In addition to treating the underlying contributing factors, there are non-pharmacological and pharmacological interventions for addressing cancer-related fatigue.

NON-PHARMACOLOGICAL APPROACHES

Cancer-related fatigue is unlikely to respond to increased rest; paradoxically, increased activity may benefit select patients.[114] Non-pharmacological therapies for cancer-related fatigue include physical exercise and psychological interventions. ASCO-SIO guidelines provide multiple options to help reduce fatigue during treatment, including the following[5]:

1. Exercise (aerobic and/or resistance; tailored to patient tolerance and ability), either in a supervised or non-supervised setting
2. Cognitive behavior therapy, with or without hypnosis
3. Mindfulness-based programs, including stress management
4. Low- to moderate-intensity tai chi or qigong
5. Psychoeducation

A meta-analysis of 113 studies and more than 11,000 patients found that exercise, psychological interventions, and the combination of both reduced cancer-related fatigue during and after primary treatment.[116]

Patients should be encouraged to engage in moderate-level physical activity (eg, brisk walking, stationary biking) as tolerated, encouraging 150 minutes per week of aerobic exercise, 2 days per week of strength training, and flexibility exercises on the remaining days of the week.[117] Patients should use any necessary walking aids to ensure safety and decrease the risk of falls.

In addition, there is insufficient evidence to make recommendations for or against acupressure, brain wave vibration meditation, music or music therapy, progressive muscle relaxation, reflexology, solution-focused therapy, biofeedback, social support, or yoga to reduce the severity of cancer-related fatigue in adults undergoing cancer treatment. However, such strategies can be explored based on the patient's preferences, provider experience, and resource availability.

PHARMACOLOGICAL INTERVENTIONS

The most widely used pharmacological management includes psychostimulants (eg, methylphenidate, modafinil), ginseng, or corticosteroids.[5] However, current ASCO-SIO guidelines recommend against the use of modafinil or armodafinil, methyphenidate, L-carnitine, or paroxitene. Investigators have also evaluated ginseng to treat cancer-related fatigue. In a phase 3 study, 8 weeks of American ginseng (*Panax quinquefolius*) improved fatigue compared with placebo, especially for patients actively receiving cancer-directed therapies.[118] A double-blind, randomized, placebo-controlled trial of Korean red ginseng (*Panaxginseng*) also demonstrated reduced fatigue in patients with colorectal cancer receiving combination chemotherapy (ie, modified fluorouracil, leucovorin, and oxaliplatin) over 4 months.[119] Current guidelines only conditionally recommend the use of American ginseng based on low-quality evidence. Finally, corticosteroids may show immediate benefit in mood and energy, but the duration of benefit is usually limited to days to 2 weeks, and patients experience associated adverse effects.

KEY POINTS

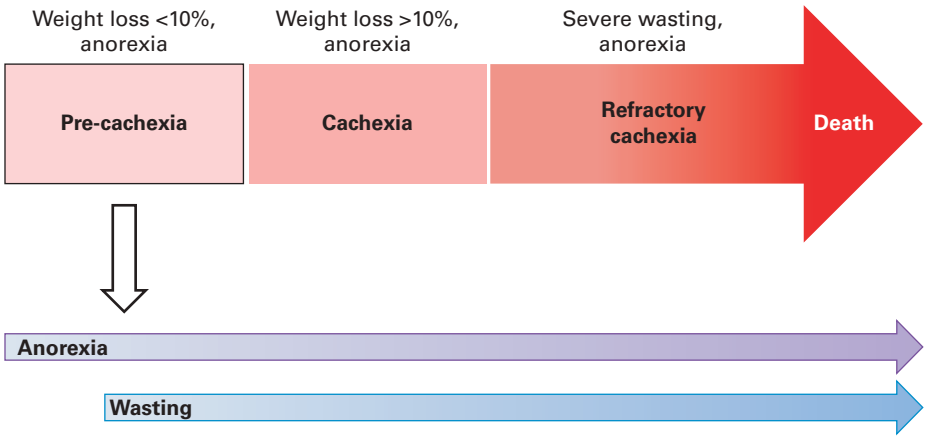
- Cancer fatigue is widespread and often multifactorial.
- In patients experiencing cancer-related fatigue, clinicians should evaluate and treat coexisting conditions, such as depression, anemia, thyroid dysfunction, and electrolyte disorders, and discontinue fatigue-inducing medications when possible.
- In patients who have cancer fatigue, moderate-intensity exercise, psychological interventions, and Tai Chi–based interventions can improve symptoms.
- National guidelines do not support the use of psychostimulants, antidepressants, or wakefulness agents to treat cancer-related fatigue.
- Two phase 3 studies demonstrated improved cancer-related fatigue with ginseng compared with placebo for patients undergoing cancer treatment.

ANOREXIA AND CACHEXIA

Cachexia is a hypermetabolic syndrome characterized by loss of appetite, weight, and skeletal muscle, leading to fatigue, functional impairment, increased treatment-related toxicity, poor QoL, and reduced survival.[120-123] According to international guidelines, cachexia can be categorized into three phases: precachexia, cachexia, and refractory cachexia (Fig. 8-4).[124] Multiple factors

contribute to cachexia, including metabolic dysregulation, increased fat and protein breakdown, decreased nutrient intake, and neurohormonal dysregulation of compensatory feeding stimuli. Consequently, these factors result in an energy imbalance and skeletal muscle loss.[124,125] Cancer cachexia is associated with increased toxicity of cancer treatment and predicts poor survival.[126] In a large population-based data set, the degree of weight loss and change in BMI predicted decreased survival. For example, a patient with a BMI of 28 kg/m^2 losing 2.5%, 2.5% to 6%, 6% to 11%, >11% expected median survival is 20.9, 14.6, 10.8, and 7.6 months.[126]

Figure 8-4 Stages of Cachexia: Precachexia, Cachexia, and Refractory Cachexia



Reprinted under Creative Commons license. Source: Yeom E and Yu K. Understanding the molecular basis of anorexia and tissue wasting in cancer cachexia. *Exp Mol Med*. 2022;54:426-432. doi:10.1038/s12276-022-00752-w

Anorexia (ie, loss of appetite) is a prominent feature of cancer cachexia. Potential causes of anorexia include constipation, emesis, mucositis, depression, decreased gastric emptying, dysphagia, food aversions, and fat malabsorption.

The intensity of symptoms of anorexia varies among patients. The lack of eating is often a bigger challenge for caregivers than for patients because a lack of appetite often does not cause patient distress. When patients abstain from eating, caregivers may believe that they have lost an important way to nurture their loved ones, or that their loved one is "giving up." Teaching caregivers that anorexia is a normal part of the advancing cancer and that they can substitute other nurturing activities (eg, help with bathing or massage) for preparing food may help assuage their concerns. Clinicians should provide support for the distress of caregivers as they witness their loved ones with anorexia develop weight loss, weakness, and decreased QoL.

The 2020 ASCO cachexia guideline and the 2023 ASCO rapid guideline cachexia update summarize available evidence in managing this distressing syndrome in patients who have advanced cancer. An informal consensus recommended that clinicians refer patients who have advanced cancer and loss of appetite and body weight to registered dieticians for assessment and counseling regarding nutritional interventions. Registered dieticians provide patients and caregivers with practical and safe advice for feeding (eg, high-protein, high-calorie, nutrient-dense food), cautioning about fad diets and other dietary habits that may be advocated in popular culture without the associated evidence.[120] A study of more than 400 patients who had esophagogastric cancer demonstrated a marginally lower incidence of weight loss at 3 months in the group of patients referred to a dietician at diagnosis (0% vs. 2%; P = .047).[127] In addition, a 2021 open-label phase 3 RCT of patients who had metastatic esophagogastric cancer compared interdisciplinary supportive care integrated early into standard oncological care versus standard care.[128] The early interdisciplinary supportive care included a team of gastrointestinal medical oncologists, oncology nurse specialists, dietitians, and psychologists. Patients who received early interdisciplinary supportive care within 8 weeks of diagnosis experienced improved survival (14.8 months vs. 11.9 months; hazard ratio, 0.68; 95% CI, 0.51-0.9; P = .021) along with less weight loss and improved emotional and cognitive functioning.[128]

NUTRITIONAL INTERVENTIONS

Clinicians should not routinely offer enteral tube feeding or parenteral nutrition to manage cachexia in patients who have advanced cancer. A time-limited trial of enteral or parenteral nutrition may be considered in highly selected, fit patients, including those with reversible bowel obstruction, short-gut syndrome, or malabsorption.[120] The most serious complication associated with enteral nutrition is aspiration, the incidence of which increases in patients who have delayed gastric emptying and advanced age. Other adverse effects of enteral nutrition include diarrhea, nausea, vomiting, abdominal cramping, bloating, and distention. Parenteral nutrition is hyperosmolar, calorie-dense nutrition administered via a central catheter. In general, when clinicians

must use parenteral nutrition, it should be limited to the preoperative setting of potentially resectable obstructing tumors over a period of less than 10 days. Risks of parenteral nutrition are primarily infectious (ie, catheter-associated sepsis and bacteremia) and metabolic (ie, hyperglycemia, electrolyte abnormalities, abnormalities in liver enzymes, essential fatty acid deficiency, and hypertriglyceridemia). Overall, studies demonstrate net harm when parenteral nutrition is routinely provided to patients who have cancer.[120] Evidence also suggests a decreased tumor response to chemotherapy, increased infections, and inferior survival when patients with cancer receive parenteral nutrition.

If nutritional support is required, enteral nutrition offers several advantages over parenteral nutrition, including fewer risks and complications, delivery of nutrients in a physiological manner, convenience for home use, and decreased cost.

POTENTIAL PHARMACOLOGICAL AGENTS FOR THE MANAGEMENT OF CANCER CACHEXIA

Multiple clinical trials have investigated drugs for the treatment of cancer cachexia, but the FDA has not approved any agent to date.[125] However, several recent high-quality trials have shown a notable effect on cachexia-related outcomes and now give oncology clinicians additional evidence-based pharmacological options.

Olanzapine

The 2023 ASCO rapid guideline update for cancer cachexia highlights the 2023 double-blind, placebo-controlled RCT of olanzapine for chemotherapy-related anorexia in patients who have locally advanced or metastatic gastric, hepatopancreaticobiliary, or lung cancer.[3,129] After starting chemotherapy, patients were randomly assigned to receive 2.5 mg of olanzapine once daily or a placebo for a total of 12 weeks. The study found that 60% of patients receiving olanzapine experienced a weight gain of more than 5% compared with 9% in those receiving the placebo ($P < .001$). Furthermore, patients in the olanzapine arm also reported improved appetite and a lower incidence of high-grade (grade 3 or higher) therapy-related toxicity (12% in the olanzapine arm compared with 37% in the placebo arm; $P = .002$). Olanzapine-related adverse events were not significantly different from those in the placebo arm. This study, taken together with past studies of olanzapine and weight gain and appetite, among other symptoms, led to the ASCO Guidelines Panel recommendation that clinicians consider a low dose (2.5 mg) of olanzapine once daily to improve weight gain and appetite in adults who have advanced cancer.[3,129]

Mirtazapine

Clinicians use mirtazapine (7.5-45 mg daily), a tetracyclic antidepressant, to treat cancer-related cachexia and anorexia. Until recently, one open-label pilot study and a single open-label phase 2 trial comprised all available data. However, a 2024 single-center, phase 3, double-blind, placebo-controlled trial randomly assigned 86 patients who had advanced non–small cell lung cancer to receive 15 mg of mirtazapine orally daily or placebo for 2 weeks, then increasing to 30 mg or placebo for 6 more weeks.[130] The outcomes of interest were appetite, as scored on the Anorexia Cachexia Scale, along with patient-reported caloric intake. The study found no significant difference in appetite scores between the two arms after both 4 and 8 weeks. However, after 4 weeks, patients in the mirtazapine arm had significantly greater intake of overall calories as well as proteins, carbohydrates, and fats; in fact, at 8 weeks, the fat intake in the mirtazapine cohort was 14.5 g compared with 0.7 g in the placebo group ($P = .02$). In addition, at 8 weeks, the mirtazapine arm had a significantly lower proportion of patients who had sarcopenia (57.1% compared with 82.8% in the placebo arm; $P = .03$). Although intriguing, these findings need further evaluation in a larger study before mirtazapine can be recommended for management of certain cancer-related wasting syndromes.

Steroid-Based Regimen

Clinicians may consider a short-term trial of a corticosteroid in patients experiencing loss of appetite and body weight but must balance risks and benefits.[120] The corticosteroid dexamethasone may transiently improve anorexia but does not enhance skeletal muscle mass. Dexamethasone is associated with multiple adverse effects (eg, Cushing syndrome, hyperglycemia, adrenal insufficiency, myopathy, infection risk, osteoporosis) related to duration and cumulative dose of dexamethasone.

Megestrol acetate, a synthetic derivative of the naturally occurring corticosteroid hormone progesterone, provides benefits for appetite, caloric intake, and weight gain that seem to plateau at 800 mg. However, the weight gained using megestrol is predominantly adipose tissue and not skeletal muscle. Serious adverse effects associated with megestrol use include increased risks of death (relative risk, 1.42; 95% CI, 1.04-1.94), thromboembolic events (relative risk, 1.84; 95% CI, 1.07-3.18), and edema (relative risk, 1.36; 95% CI, 1.07-1.72).[131] Studies have also demonstrated that megestrol can cause diarrhea, rash, impotence, and, if stopped abruptly, adrenal insufficiency. Most recently, Currow et al[132] completed a multisite RCT comparing megestrol acetate at 480 mg daily, dexamethasone at 4 mg daily, and placebo to evaluate their effect on appetite in patients with advanced cancer and anorexia (2 weeks or longer; 0-4 patient-reported anorexia score). In nearly 200 patients, there was no difference in anorexia (25% or greater improvement over baseline) observed among the three arms at 1 week. The 2023 ASCO rapid guideline update for cancer cachexia does suggest that clinicians may offer a short-term trial of a progesterone analog or a corticosteroid for weight loss and/or decreased appetite for patients who have advanced cancer who are unable to tolerate a low dose (2.5 mg) of olanzapine.[3]

Limited data support the combination of olanzapine plus megestrol acetate to treat cancer-related anorexia. Patients who have advanced gastrointestinal or lung cancer with anorexia and at least 5% weight loss from previous weight who took 5 mg

of olanzapine per day plus 800 mg of megestrol acetate per day (compared with those taking megestrol acetate alone) reported improved appetite and at least 5% weight gain at 8 weeks.[133] However, since olanzapine alone can produce these effects, the role of the additional megestrol acetate in producing these outcomes is unclear.

Newer Agents

Ponsegromab, a monoclonal antibody targeting growth differentiation factor 15 (GDF-15), increased weight gain among patients with cancer cachexia. A recent phase 2 double-blind study compared the GDF-15 inhibitor ponsegromab with placebo at three different doses. The study enrolled 187 adults with elevated serum GDF-15 with various cancer types and cancer cachexia to receive three doses of 100, 200, or 400 mg of ponsegromab subcutaneously or placebo every 4 weeks.[134] Patients had weight gain at all ponsegromab doses, and the drug showed increased overall activity at the highest dose.

Agents Without Evidence of Efficacy

Multiple pharmacological agents, including cannabinoids, androgens, and cyproheptadine, have been studied for the treatment of cancer cachexia but all show limited efficacy.[134,135] A phase 3 RCT of 243 patients with advanced cancer and weight loss (5% or greater over 6 months) evaluated the effect of cannabis extract (2.5 mg of *d*-9-tetrahydrocannabinol and 1 mg of cannabidiol), 2.5 mg of *d*-9-tetrahydrocannabinol, or placebo on appetite and QoL. Researchers found no difference in patient appetite or QoL among treatment arms over 6 weeks. Another commonly used cannabinoid is dronabinol, a synthetic *d*-9-tetrahydrocannabinol. Dronabinol is also less effective than megestrol acetate in producing weight gain, appetite, or improved QoL. Like megestrol acetate, dronabinol primarily increases adipose tissue and body fluid, and not lean muscle mass. Cannabinoids should be used with caution, especially in elderly and seriously ill patients because of their multiple adverse effects, including drowsiness, dizziness, dysphoria, euphoria, impaired cognition, and fall risk.[135]

Three RCTs evaluated androgens or selective androgen receptor modulators. One study comparing megestrol acetate, dexamethasone, and fluoxymesterone to treat patients with cancer cachexia and anorexia found no difference in weight gain across the three arms and showed that megestrol acetate improved appetite better than fluoxymesterone. Nandrolone decanoate (200 mg intramuscularly) administered weekly over 4 weeks to patients with incurable lung cancer receiving chemotherapy showed no difference over usual care.[136] In a double-blind, placebo-controlled, phase 2 trial evaluation of weekly injections of testosterone enanthate in 21 patients with advanced cancer receiving chemotherapy. Testosterone improved lean body mass and increased QoL and physical activity compared with placebo.[137,138] No phase 3 trials have been reported. Investigators compared placebo with two different doses of enobosarm (1 or 3 mg), an investigational selective androgen receptor modulator, in a phase 2 RCT.[34] Patients receiving enobosarm experienced greater increases in lean body mass than patients in the placebo arm, but no follow-up phase 3 trials have been reported.[139] Anamorelin, a ghrelin receptor agonist, showed significantly increased lean body mass but not handgrip strength in two randomized, placebo-controlled trials in 900 patients who had advanced non–small cell lung cancer and cachexia.[140] Anamorelin has not received FDA approval to date.

Cyproheptadine, a serotonin antagonist, produced only a mild increase in appetite and food intake and did not affect progressive weight loss in a large randomized controlled study using oral cyproheptadine at 8 mg three times daily. Cyproheptadine should be avoided, given its adverse effects, most notably sedation, and limited efficacy for patients who have cancer-related cachexia.

FAT MALABSORPTION

Fat malabsorption may occur in multiple cancer settings: pancreatic cancer and exocrine insufficiency, gastric resection, hematopoietic cell transplantation, short-gut syndrome, and chronic radiation enteritis. Vague abdominal pain, increased gas, steatorrhea, and increased stool odor characterize fat malabsorption. Exogenous oral pancreatic enzymes can minimize fat malabsorption. Enteric-coated pancreatic enzymes resist destruction or inactivation in gastric acid and release the enzymes in vivo in the duodenum at a pH greater than 5.5. In the duodenum and proximal small intestine, these exogenous enzymes replace physiological digestive enzymes secreted by the pancreas, catalyzing the hydrolysis of fats into monoglycerol and fatty acids, protein into peptides and amino acids, and starch into dextrans and short-chain sugars.

Pancreatic enzymes should be taken with food, initiated at the lowest recommended dose, and gradually increased based on clinical symptoms, degree of steatorrhea, and fat content in the diet. Prescribers base enzyme doses on lipase units. Initially, adults start at 500 lipase units/kg per meal, with titration to a maximum of 2,500 lipase units/kg per meal. Half of the prescribed dose should be given with snacks between meals. The degree of abdominal pain and steatorrhea reflects adherence and adequacy of enzyme doses and should be monitored.

KEY POINTS

- Categories of cachexia include precachexia, cachexia, and refractory cachexia.
- Cachexia is associated with increased treatment-related toxicity, decreased QoL, and poor survival.
- Overall, studies demonstrate a net harm when providing parenteral nutrition to patients who have cancer.

- There are no FDA-approved pharmacological treatments for weight loss associated with cancer cachexia.
- The weight gain associated with the use of megestrol acetate, dronabinol, and dexamethasone is primarily adipose tissue and fluid, not skeletal muscle.
- Deep vein thrombosis and adrenal suppression are two notable adverse effects of megestrol acetate.
- Clinicians must support caregivers given the paucity of effective treatment options and the distress cachexia causes when caregivers witness anorexia, weight loss, weakness, and decreased QoL in their loved ones.
- Pancreatic exocrine insufficiency is common in patients who have pancreatic cancer. Clinicians should treat patients with exogenous enzyme replacement and titrate to control abdominal symptoms and steatorrhea.

DIARRHEA

Diarrhea is characterized by frequent loose or liquid bowel movements. In patients who have cancer, diarrhea can result from cancer itself or its treatment. Examples include osmotic diarrhea associated with pancreatic cancer exocrine insufficiency (as described in the "Fat Malabsorption" section of this chapter) or secretory diarrhea associated with medullary thyroid cancer, carcinoid syndrome, and pancreatic islet cell cancer. Cancer treatments, such as chemotherapy, radiation to the abdomen, targeted therapy, immunotherapy, and graft-versus-host disease, can also cause diarrhea. The incidence of chemotherapy-induced diarrhea is approximately 50% to 80%.[140]

A careful history and physical examination are necessary to determine etiology. The history should include onset, frequency, approximate volume, presence or absence of blood, and other stool characteristics. Clinicians can classify diarrhea as acute (less than 2 weeks), persistent (2-4 weeks), or chronic (longer than 4 weeks). Complete abdominal examination, digital rectal examination, temperature, and assessment of hydration status are helpful. History and examination will guide potential diagnostic evaluations, which might include stool studies. Blood work may help in evaluating hydration status, and evidence of leukocytosis may suggest an infectious etiology. Acute diarrhea unrelated temporally to treatment (see "Chemotherapy-Induced Diarrhea" section) is often infectious (ie, viral, bacterial). Within a population of patients who have advanced chronic illness, *Clostridium difficile* infection should be considered if the patient has a history of *C. difficile* infection, recent hospitalization, or recent antibiotic use.

CHEMOTHERAPY-INDUCED DIARRHEA

In general, diarrhea is most common in patients receiving chemotherapy regimens that include antimetabolites. The most studied of these agents is 5-fluorouracil (FU). The risk of diarrhea from FU increases when leucovorin is administered as a modulating agent or with protracted infusions. As with infusions, daily oral capecitabine provides long-term exposure to FU and has toxicities similar to infusional FU. Patients who have severe or uncontrolled diarrhea with 5FU or capecitabine therapy should undergo dihydropyrimidine dehydrogenase (DPD) testing.[140] There has been an increasing uptake among US institutions regarding pre-treatment testing for DPD.

Other antimetabolites associated with diarrhea include the topoisomerase I inhibitors irinotecan and topotecan. The cholinergic adverse effects of irinotecan cause an acute onset of diarrhea accompanied by abdominal cramping, rhinitis, lacrimation, and salivation. The routine use of atropine effectively prevents this cholinergic reaction. After 24 hours, a more severe form of diarrhea occurs, correlating with peak plasma levels of the irinotecan metabolite SN38. The variant of UGT1A1 in approximately 10% of White individuals leads to poor metabolism of SN38 and predicts irinotecan toxicity. Patients receiving irinotecan should, therefore, be educated about the potentially life-threatening adverse effect of severe colitis and the need to report symptoms promptly.

For uncomplicated, non-infectious, mild-to-moderate diarrhea, management includes dietary counseling (discontinuing lactose- and caffeine-containing products, alcohol, high osmolar supplements [eg, Ensure]), hydration, and antidiarrheal medications). The antidiarrheal agents loperamide and combination diphenoxylate/atropine are used most often to treat acute diarrhea. Oral loperamide should be administered at 4 mg for the first dose and 2 mg every 4 hours (maximum, 16 mg/d) or after an unformed stool. Loperamide decreases intestinal motility and has minimal systemic effects because there is little to no absorption. Diphenoxylate/atropine combination is administered as two 5-mg tablets every 6 hours for the first day (maximum, 40 mg/d) and then one 5-mg tablet daily.

If diarrhea persists for more than 48 hours during loperamide therapy, diphenoxylate and atropine or other second-line agents, including deodorized tincture of opium, bulk-forming agents, or octreotide, should be considered. Deodorized tincture of opium is concentrated morphine (10 mg/mL) administered at 10 to 15 drops in water every 4 hours. A bulk-forming agent, such as psyllium, or a bile acid sequestrant, such as cholestyramine, should be considered for patients who have adequate hydration. However, in the setting of low performance status or inadequate hydration, these agents may cause more harm than benefit and are not recommended. Octreotide is a somatostatin analog that decreases the secretion of several gastrointestinal hormones and prolongs intestinal transit time. The recommended octreotide dose for diarrhea management is 100 to 150 mcg subcutaneously three times a day.[141] Studies have demonstrated improved control of diarrhea with the use of octreotide versus loperamide. However, given its short half-life, octreotide must be administered subcutaneously, or via continuous infusion.

TARGETED THERAPY–ASSOCIATED DIARRHEA

Studies of small-molecule inhibitors of epidermal growth factor receptor (EGFR; eg, erlotinib, gefitinib, afatinib) reported a diarrhea incidence of up to 90%, but only 15% of cases were severe. The human EGFR2-directed drugs lapatinib, neratinib, and pertuzumab cause diarrhea in up to 80% of patients.[142,143] The dose-limiting toxicity of neratinib, an inhibitor of human Her-2, Her-4, and EGFR, is severe diarrhea in 40% of patients, even with loperamide prophylaxis.[142,144] The monoclonal antibodies directed against EGFR (eg, cetuximab, panitumumab) cause diarrhea rates in the 20% range, but severe diarrhea incidence is minimal.[145]

Drugs that inhibit the vascular endothelial growth factor pathway (eg, sorafenib, sunitinib, axitinib, pazopanib, cabozantinib, lenvatinib, bevacizumab, and regorafenib) cause diarrhea in 30% to 80% of patients, with few experiencing grade 3 or 4 symptoms.[146,147]

Guideline-based recommendations should be followed to treat targeted therapy–induced diarrhea.[141] Treatment is generally supportive, including dietary counseling (discontinuing lactose- and caffeine-containing products, alcohol, high-osmolar supplements [eg, Ensure]), hydration, antimotility agents (as described in the "Chemotherapy-Induced Diarrhea" section of this chapter), and withdrawal of the offending drug until symptoms resolve.

IMMUNOTHERAPY-INDUCED DIARRHEA

Diarrhea associated with ipilimumab occurs in approximately 30% of patients, whereas PD-1 blockade produces diarrhea less frequently.[148,149] Patients receiving immunotherapy should be educated about the potentially life-threatening adverse effects of severe colitis and the need to report symptoms promptly.

Checkpoint inhibitor–induced diarrhea is managed differently than most other types of diarrhea, often requiring corticosteroids.[150] Antidiarrheal agents such as loperamide should be used with caution, because they can mask the underlying autoimmune pathology. In severe cases, high-dose intravenous corticosteroids (prednisone or methylprednisolone at 1-2 mg/kg per day) and infliximab at 5 mg/kg every 2 weeks should be administered.[140,151-154] For patients refractory to steroids, infliximab, vedolizumab, or ustekinumab can be considered.[155,156]

RADIATION-INDUCED DIARRHEA

Diarrhea is the most common adverse effect of abdominal and pelvic irradiation. Radiation damages the mucosa of the small and large intestines and, thus, can produce secretory diarrhea. The incidence and severity of diarrhea increase with the addition of FU. Several placebo-controlled clinical trials have evaluated drugs to prevent diarrhea induced by pelvic irradiation. RCTs have been performed supporting various formulations of probiotics and octreotide (100-150 mg subcutaneously three times a day).[157-159] Sucralfate provided mixed results, glutamine showed no improvement, and sulfasalazine exacerbated symptoms.[157-164]

HEMATOPOIETIC CELL TRANSPLANTATION/GRAFT-VERSUS-HOST DISEASE

Diarrhea in patients who undergo hematopoietic cell transplantation may result from graft-versus-host disease and infections related to immunosuppressive therapy. The epithelial damage caused by high-dose chemotherapy can activate alloreactive cytotoxic T cells, which release a cascade of inflammatory cytokines that contribute to necrosis of gut epithelial crypt cells.

At the first sign of acute gastrointestinal symptoms consistent with graft-versus-host disease, stools should be analyzed for bacterial, fungal, and viral pathogens. Supportive management should be simultaneously initiated, and a gastroenterologist consultation should be considered. If the stool evaluation findings are positive for pathogenic bacteria, appropriate antibiotics should be used for treatment. For patients with biopsy-proven graft-versus-host disease, systemic corticosteroids should be initiated, and prophylactic immunosuppression optimized. A time-limited trial of octreotide for 7 days (500 mg intravenously every 8 hours) may be considered, but if the patient has no response within 4 days, octreotide should be discontinued to avoid ileus. If there is no response to octreotide, second-line therapy with antithymocyte globulin or infliximab should be considered.[165]

KEY POINTS

- FU and topoisomerase I inhibitors (irinotecan, topotecan) commonly cause diarrhea.
- Irinotecan causes acute diarrhea because of a cholinergic mechanism, as well as subsequent, more severe diarrhea because of its active metabolite SN38.
- In addition to supportive measures, loperamide can be used effectively to treat chemotherapy-induced diarrhea. Second-line approaches include diphenoxylate and atropine, deodorized tincture of opium, and octreotide.
- In addition to supportive measures, radiotherapy-induced diarrhea should be treated with octreotide.
- Diarrhea is common with targeted therapy and is best treated with antimotility agents and withdrawal of the offending drug.
- Checkpoint inhibitors can cause life-threatening colitis that is best treated with corticosteroids and, rarely, infliximab.
- Graft-versus-host disease–associated diarrhea should be treated with corticosteroids, optimal immunosuppression, and octreotide.

MUCOSITIS

Oral mucositis and esophagitis are common complications of chemotherapy and radiotherapy. The overall incidence of oral mucositis is approximately 40% for patients who receive standard-dose chemotherapy. Incidence varies with chemotherapy agents used and increases substantially for patients who receive dose-intensified regimens. Mucositis and esophagitis are common in patients receiving radiation to susceptible areas, and concurrent chemotherapy may exacerbate symptoms. Mucositis may occur from direct injury by cytotoxic chemotherapy or radiotherapy, secondary infections from treatment-induced myelosuppression, or graft-versus-host disease. The severity of mucositis is dose and treatment-specific.

Mucositis typically starts 5 to 7 days after the initiation of chemotherapy. It often presents first as erythema on the soft palate, buccal mucosa, ventral surface of the tongue, and floor of the mouth. These symptoms may progress to generalized desquamation. Approximately 90% of ulcerations localize to the non-keratinized mucosa. Mucositis resulting from chemotherapy can resolve within a few days or last up to 3 weeks. Chemotherapy agents frequently associated with mucositis include the antimetabolites FU and methotrexate, and high-dose or prolonged infusions of chemotherapy. Newer targeted agents can also cause mucositis, including many tyrosine kinase inhibitors, such as everolimus, and immune checkpoint inhibitors.

Oral mucositis caused by radiotherapy typically lasts an average of 6 weeks.[166]

PREVENTION OF TARGETED CHEMOTHERAPY– OR RADIOTHERAPY-INDUCED MUCOSITIS

Clinical practice guidelines should be followed to prevent and treat cancer therapy–induced oral and gastrointestinal mucositis secondary to cancer therapy.[166] A dental evaluation is recommended before beginning radiotherapy involving the oral cavity to decrease risks of local and systemic infections. If worn during radiotherapy, fluoride carriers (delivering oral fluoride) maintain tooth integrity and help to prevent radiation scatter from metal dental work.

Preventive and treatment strategies depend on radiation dose and setting (eg, head and neck cancer vs. hematopoietic cell transplantation). Effective preventive strategies include dilute rinses (eg, saline, sodium bicarbonate, benzydamine, dexamethasone, and honey), low-level laser therapy, cryotherapy, and palifermin.[166] In patients with breast cancer receiving everolimus, oral dexamethasone swish-and-spit preparation decreased mucositis markedly compared with placebo.[167] Only institutions familiar with low-level laser therapy should provide this treatment in adults receiving high-dose chemotherapy in preparation for hematopoietic cell transplantation with or without irradiation.[166] Oral cryotherapy (ie, sucking on ice chips during chemotherapy administration) produces temporary vasoconstriction and reduces the delivery of bolus dose FU chemotherapy to the oral mucosa. Data indicate that cryotherapy reduces oral mucositis by approximately 50%. A recent multi-institutional study randomized patients receiving chemotherapy to a reusable self-contained cryotherapy delivery device or best supportive care. The patients on the cryotherapy arm developed less oral pain and had less use of analgesics in the first two cycles.[168] The keratinocyte growth factor palifermin decreases severe mucositis for patients undergoing autologous hematopoietic cell transplantation with total-body irradiation conditioning regimens.[166] Palifermin c was superior to placebo in preventing FU-associated mucositis, but it has not been widely adopted because of cost. A phase 2 study in peripheral T-cell lymphoma and cutaneous T-cell lymphoma patients using oral leucovorin 25 mg three times a day for 48 hours starting 24 hours after pralatrexate reduced rates of grade 2/3 mucositis.[169] Sucralfate, allopurinol, chamomile tea, glutamine, and vitamin E are not more effective than placebo. Sucralfate also does not prevent radiotherapy-associated esophagitis. Although evidence suggests that amifostine, a cytoprotective adjuvant, can mildly decrease radiotherapy-induced esophagitis, inconvenience and expense limit its widespread use.

MUCOSITIS TREATMENT

Effective oral mucositis management includes general measures such as oral hygiene and dietary modification, topical local anesthetics, and systemic analgesics. Empirical clinical practices include gently brushing teeth with a soft-bristled toothbrush and fluoride toothpaste two to three times daily. Gentle flossing daily is encouraged to remove food and bacteria buildup. Dentures should be removed, particularly at night. When patients have mucositis-induced severe pain, adequate pain relief often requires systemic opioids, including parenteral opioids and patient-controlled analgesia.

Investigators have evaluated multiple types of mouthwash in the palliation of mucositis. A mouthwash made of doxepin, a tricyclic antidepressant, has demonstrated improved palliation of radiotherapy-associated oral mucosal pain.[170,171] A randomized study evaluated different mouthwashes consisting of saline, sodium bicarbonate, or chlorhexidine and so-called magic mouthwash (ie, lidocaine, diphenhydramine, aluminum hydroxide, magnesium hydroxide) and found decreased signs and symptoms of mucositis within 12 days without any significant differences among the groups. Given the comparable effectiveness of the mouthwashes, the least costly was the mouthwash containing salt and sodium bicarbonate.[166] Alcohol-based mouthwashes and spicy foods or beverages should be avoided.

XEROSTOMIA

Xerostomia can be seen up to 80% of the head and neck patients receiving RT.[172] Salivary functions can continue to decline for several weeks after completion of radiation therapy more so Xerosotmia can cause QoL impairment and multiple long-term

oral complications.[173] Lack of saliva also cause dyguesia and difficulty in chewing and swallowing foods, speech changes.[174] A retrospective study of 91 patients found grade 2 or higher xerostomia was associated with tumors located in the nasopharynx, oropharynx, floor of mouth, or oral cavity, while grade 3 or higher was associated with age >61 years.[175] ISOO/MASCC/ASCO Guidelines on Xerostomia induced by non-surgical modalities recommend tissue-sparing intensity-modulated radiation therapy (IMRT) to decrease injury to salivary glands. Patients who develop xerotomia can use topical mucosal lubricants or saliva substitutes can be used. Transient relief can be obtained by stimulating the residual gland capacity using sugar-free acidic or non-acidic gums/lozenges or muscarinic agonist, for example, pilocarpine or Cevimeline.[176]

KEY POINTS

- Evidence-based prevention strategies of mucositis include oral rinses, low-dose laser therapy, cryotherapy, and palifermin.
- Dexamethasone rinse improves the prevention of everolimus-induced stomatitis. Doxepin mouthwash improves mucositis-related pain.
- There are no differences in effectiveness for palliation of oral mucositis among mouthwashes consisting of saline, sodium bicarbonate, chlorhexidine, or so-called magic mouthwash.

CHEMOTHERAPY-INDUCED PERIPHERAL NEUROPATHY

CIPN may develop after treatment with platinum analogs (eg, cisplatin, oxaliplatin, carboplatin), taxanes (eg, paclitaxel, docetaxel, nab-paclitaxel), vinca alkaloids (eg, vincristine), proteasome inhibitors (eg, bortezomib), and immunomodulators (eg, thalidomide, lenalidomide). The clinical presentation reflects an axonal peripheral neuropathy with glove-and-stocking distribution sensory loss, combined with features suggestive of nerve hyperexcitability, including paresthesia, dysesthesia, and pain. These symptoms may be disabling, adversely affecting activities of daily living and QoL.

The incidence of CIPN seems to be related to cumulative dose and infusion duration; individual risk factors may also influence the development and severity of neurotoxicity. Substantial work has evaluated genetic predispositions for CIPN, but no genetic

Table 8-11 **Mechanisms of Chemotherapy-Induced Peripheral Neuropathy**

Chemotherapy	Neurotoxicity	Incidence	Cumulative Dose	Recovery
Cisplatin	Long-lasting cumulative distal sensory neuropathy	50%-90% of patients receiving ≥500 mg/m^2	Beginning at 300 mg/m^2	Incomplete
Carboplatin	Mild sensorimotor neurotoxicity	Uncommon; mild in 25% of patients; severe in 5%	More common with high doses: 800-1,600 mg/m^2	Not fully described
Oxaliplatin	Acute cold–associated neurotoxicity and chronic sensory neuropathy	Acute symptoms in 95%; severe chronic toxicity in 10%-20% at 750-850 mg/m^2	Acute symptoms at all doses, severe at >540-700 mg/m^2	May persist for a long time; in 10% of patients at 2 years post-treatment
Paclitaxel	Distal sensory neuropathy with pain and motor symptoms at high doses	Severe dose dependence in 10%-30% of patients	>300 mg/m^2 but can occur at lower doses	May persist, although reversibility is reported
Docetaxel	Distal sensory neuropathy with pain	Less severe neurotoxicity than paclitaxel, severe in 6%-10% of patients	>100 mg/m^2; severe toxicity >600 mg/m^2	Not fully described
Vincristine	Distal sensorimotor painful neuropathy	60% of patients, dose dependent	4-10 mg	≤33% of patients report persistent symptoms
Bortezomib	Sensory axonal neuropathy, occasionally demyelinating	≥35%-50% of patients	1.3 mg/m^2	Resolution in 3 months; may persist
Thalidomide	Sensorimotor painful neuropathy	25%-75% of patients	At dose ≥20 g	Not fully described

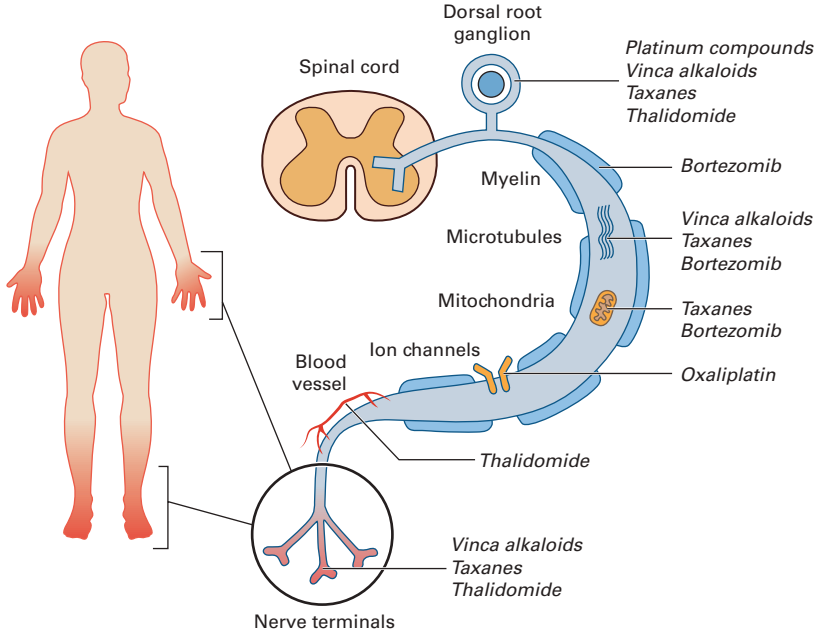
tests have been established for use in clinical practice. However, patients who have family members with Charcot-Marie-Tooth–associated neuropathies may be predisposed to CIPN from neurotoxic chemotherapy.[177] CIPN develops more often in patients who have obesity, diabetes, or a history of alcoholism. Exercise and increased blood to the peripheral nerves might mitigate this toxicity.[178-180]

Differences in structural properties between chemotherapies further contribute to variations in clinical presentation. The mechanisms underlying CIPN are diverse and, when present in combination, additive (Table 8-11). Different chemotherapy classes target different components of the peripheral nervous system, including dorsal root ganglia neuronal cell bodies, axonal transport pathways, mitochondrial operation, calcium ion regulation systems, and axonal membrane ion channels (Fig. 8-5). In addition, data strongly support that the acute pain syndrome caused by paclitaxel, which classically has been identified as arthralgias and myalgias, is not from an injury to muscles or joints; rather, it seems to be a manifestation of an acute neuropathy.[181]

Figure 8-5 Mechanisms of CIPN



Abbreviation: CIPN, chemotherapy-induced neurotoxicity.
Proposed targets of CIPN in the peripheral nervous system include damage to dorsal root ganglion neuronal cell bodies (platinum compounds, vinca alkaloids, taxanes, thalidomide), demyelination (bortezomib), microtubule-associated toxicity (vinca alkaloids, taxanes, bortezomib), mitochondrial dysfunction (taxanes, bortezomib), axonal membrane ion channelopathy (oxaliplatin), peripheral vasculature impairment (thalidomide), and distal axonal injury (vinca alkaloids, taxanes, thalidomide).
Adapted from Park SB, Goldstein D, Krishnan AV, et al. Chemotherapy-induced peripheral neurotoxicity: a critical analysis. *CA Cancer J Clin*. 2013;63:419-437. doi:10.3322/caac.21204

The 2020 ASCO CIPN guideline reviewed the value of strategies for preventing CIPN and treating patients with it.[182] Amifostine, amitriptyline, calcium and magnesium, glutathione, and vitamin E were all found to be ineffective in preventing CIPN. Per this guideline, no agents are recommended for preventing CIPN. However, there is one preventive strategy specific to the administration of bortezomib. Patients with multiple myeloma treated with subcutaneous versus intravenous bortezomib experienced less CIPN and had similar overall response rates.[183] Consequently, subcutaneous administration of bortezomib to patients with multiple myeloma is now the standard of care.[184,185] Cryotherapy is also emerging as an option to help prevent taxane-induced peripheral neuropathy and is supported by recent meta-analyses, given its relative safety.[184] Duloxetine is the only agent with proven efficacy for treating established CIPN.[139,186] Gabapentinoids (gabapentin and pregabalin), helpful for many peripheral neuropathies of other etiologies, are not effective for CIPN. Limited data do not support the use of acetyl-L-carnitine, tricyclic antidepressants, or topical treatments (eg, baclofen, amitriptyline hydrochloride, ketamine) to treat patients with CIPN.[182] A recent observational study in breast cancer patients with painful CIPN showed that a high-concentration topical capsaicin patch caused a significant reduction in neuropathic pain and improvement in CIPN-related QoL.[187] This agent will need further validation in large-scale studies. In addition, meta-analysis suggests exercise interventions are associated with improved patient CIPN symptoms and QoL, though higher-quality trials are needed.[188]

KEY POINTS

- There are no established methods to prevent CIPN other than limiting exposure to the offending drugs.
- Patients at higher risk for developing CIPN include those with a history of inherited neuropathy, obesity, diabetes, and alcoholism.
- The best-established drug for treating painful CIPN is duloxetine, but its efficacy is limited.

DYSPNEA

Dyspnea is the subjective experience of breathlessness. In patients who have advanced cancer, the prevalence is 21% to 79%, with moderate to severe dyspnea in 10% to 63% of patients. The respiratory center, located in the medulla oblongata and pons of the brainstem, controls breathing homeostasis. Chemoreceptors detect blood oxygenation, and mechanoreceptors detect stretching and congestion. Alterations in blood pH and blood gases increase the demand for respiratory signaling by the brain through activation of chemoreceptors and mechanoreceptors, resulting in dyspnea.

Dyspnea is a subjectively measured outcome. Objective measurements of compromised respiratory status (eg, respiratory rate, peripheral oxygen saturation) may or may not correlate with a patient's subjective report.[189] In appropriate patients, a short walking test with or without oxygen monitoring should be considered. Although there can be many unrelated cancer etiologies and comorbid disease states causing dyspnea (eg, chronic obstructive pulmonary disease, asthma, congestive heart failure), common causes in patients who have advanced cancer are pleural effusions, lymphangitic tumor spread, and pulmonary embolism. Treatment-related causes include infectious pneumonitis and pneumonitis caused by molecularly targeted agents, checkpoint inhibitors, cytotoxic chemotherapy, and radiotherapy.

NON-PHARMACOLOGICAL APPROACHES

ASCO published guidelines on the management of dyspnea in patients with advanced cancer in 2021.[189] Limited evidence exists on the effectiveness of non-pharmacological management of dyspnea in patients who have cancer, but clinicians may offer supplemental oxygen for patients who have hypoxemia and psychoeducational self-management, a room air fan, or room air delivered by nasal cannula.[190,191] A room air fan positioned to target the patient's maxillary ridge is often effective.[189,192] The proposed mechanism is facial cooling of the trigeminal cranial nerve branches. In a phase 3 trial of nasal cannula oxygen versus room air in patients who did not have hypoxia, oxygen provided no additional symptomatic benefit for the relief of refractory dyspnea compared with room air.[191] The flow of either oxygen or room air activates nasal mechanoreceptors and decreases dyspne.

PHARMACOLOGICAL APPROACHES

For patients who have dyspnea for whom non-pharmacological interventions do not provide relief, clinicians may offer systemic opioids and consider corticosteroids and benzodiazepines.[193] Opioids may relieve dyspnea by reducing ventilation and the central-mediated perception of dyspnea through the same receptors that relieve pain. For opioid-naive patients, low-dose oral morphine at 5 to 10 mg every 3 to 4 hours or intravenous morphine at 2 to 5 mg (or equivalent) every 2 hours typically provides relief. Patients receiving long-term opioid treatment should be given the same rescue opioid dose (ie, 10%-20% of the total 24-hour opioid dose) that is given for intermittent pain relief. Evidence does not support nebulized morphine use.[193] Given the interrelatedness of dyspnea and anxiety, limited evidence supports short-acting benzodiazepines for patients who experience dyspnea-related anxiety refractory to opioids and non-pharmacological measures. If airway obstruction or inflammation is a likely contributor to dyspnea, systemic corticosteroids should be considered. Bronchodilator use should be limited to patients with dyspnea resulting from obstructive pulmonary disorder or bronchospasm. Evidence does not support the use of antidepressants, neuroleptics, or inhaled furosemide for the palliation of dyspnea. For patients with a life expectancy of days and refractory dyspnea, continuous palliative sedation, ideally in collaboration with hospice clinicians or palliative care specialists, will provide relief.[193]

KEY POINTS

- Dyspnea is a subjective experience that may or may not correlate with objective findings.
- Any reversible causes of dyspnea should be identified and treated when possible.
- In the absence of hypoxemia, oxygen provides no additional symptomatic benefit for dyspnea compared with room air.
- Limited evidence supports the use of systemic opioids to palliate dyspnea.

CUTANEOUS TOXICITIES OF CANCER THERAPIES

EGFR INHIBITORS

Up to 50% of patients with cancer who receive EGFR inhibitors experience a prominent skin rash.[194,195] This rash has acne-like characteristics but is not considered acne. Other targeted drugs associated with a similar rash include mammalian target of rapamycin (eg, everolimus and temsirolimus) and multikinase inhibitors (eg, sorafenib and sunitinib). Prophylactic and treatment

guidelines describe the prevention and treatment of patients with EGFR inhibitor–associated rash (Table 8-12).[85] EGFR inhibitor rash prevention includes topical corticosteroids and moisturizers or oral minocycline or doxycycline. EGFR inhibitor rash treatment includes topical corticosteroids, clindamycin, oral minocycline, doxycycline, or low-dose isotretinoin. Patients with moderate to severe rash may benefit from a consultation with a dermatologist. In addition to the acneiform rash, these drugs can also cause many other dermatological problems, including periungual disease, photosensitivity, pruritus, xerosis, Stevens-Johnson syndrome, and skin cancer. Of note, data support the development of an EGFR inhibitor–induced rash as a pharmacodynamic marker of antitumor activity.[153,196,197]

Table 8-12 Strategies for EGFR-Associated Acneiform Rash

Strategy	Recommended	Not Recommended
Topical preventive	Hydrocortisone	Pimecrolimus
		Tazarotene
		Sunscreen as a single agent
Systemic preventive	Minocycline	Tetracycline
	Doxycycline	
Topical treatment	Alclometasone	
	Fluocinonide	
	Clindamycin	
Systemic treatment	Doxycycline, 100 mg twice daily	Photosensitizing agents
	Minocycline, 100 mg daily	
	Low-dose isotretinoin, 20-30 mg daily	

Abbreviation: EGFR, epidermal growth factor receptor.
Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

HAND-FOOT SYNDROME

One of the dose-limiting toxicities of capecitabine is a prominent rash called palmar-plantar erythrodysesthesia, also known as hand-foot syndrome.[198] Patient symptoms usually begin with erythema and proceed to pain, swelling, desquamation, and rarely ulceration. With prolonged capecitabine use, hand-foot syndrome can lead to substantial morbidity to the point that patients may be unable to use their hands and feet. Predictors of hand-foot syndrome include increased serum folate and red blood cell folate levels as well as genomic variants linked to wound healing and cytoskeletal anchoring.[52]

Celecoxib prevented moderate to severe and all-grade hand-foot syndrome in RCTs.[53,199,200] A single-center, double-blind, placebo-controlled trial using topical diclofenac gel for hand-foot syndrome prevention in patients with breast and gastrointestinal cancers treated with capecitabine showed a reduction in grade 2/3 hand-foot syndrome from 18.1% to 6.1%. In the same study, the rates of capecitabine dose reduction because of hand-foot syndrome were 13.5% (placebo) versus 3.8% (topical diclofenac).[200] The current mainstay of treatment is interruption of therapy and, if necessary, dose reduction. Placebo-controlled studies demonstrated no benefit from vitamin B6, urea–lactic acid cream, topical emollients or creams, systemic or topical corticosteroids, nicotine patches, or vitamin E.[52,85,201]

ALOPECIA

Chemotherapy-induced alopecia is a common concern for patients undergoing cancer-directed therapies and is such a feared complication that nearly 10% of women would consider refusing chemotherapy to avoid it.[202] Thinning of the hair shaft, leading to breakage, and inhibition of dividing hair matrix cells, resulting in hair separation from the bulb, are likely responsible. Risks for alopecia include the type of chemotherapy, higher chemotherapy doses, shorter infusion times, certain non-Western European hair, female sex, and older age. Hair loss generally occurs 2 to 4 weeks after chemotherapy initiation, and regrowth occurs 3 to 6 months after cessation of therapy, although, rarely, irreversible hair loss occurs. Available evidence suggests that regional hypothermia decreases alopecia without increasing the incidence of scalp metastasis in patients with solid tumors.[202-207] However, there are no data to suggest the safety of regional hypothermia for patients with hematological malignancies.[85]

KEY POINTS

- Prevention of patients with EGFR inhibitor–associated rash includes topical corticosteroids and moisturizers, or oral minocycline or doxycycline.

- Treatment of patients with EGFR inhibitor–associated rash includes topical corticosteroids, clindamycin, oral minocycline, doxycycline, or low-dose isotretinoin.
- No evidence supports the use of vitamin B6 supplementation, urea–lactic acid cream, topical emollients or creams, systemic or topical corticosteroids, nicotine patches, or vitamin E to prevent or treat hand-foot syndrome.
- Scalp cryotherapy is effective for select patients with solid tumors, but safety data are lacking for patients with hematological malignancies.

HORMONE-DEPRIVATION SYMPTOMS

Androgen-deprivation treatment is often used to treat patients with prostate cancer but is associated with multiple adverse effects, including weight gain, osteoporosis and bone fractures, and hot flashes (see "Hot Flashes" section). Although a recent prospective study showed that androgen-deprivation treatment was not associated with a cognitive decline, after 1 year of treatment, androgen-deprivation treatment was associated with increased depressive symptoms, fatigue, and more sleep disturbances. Increased insomnia symptoms explained the relationship between taking androgen-deprivation treatment and perceived cognitive function and satisfaction with cognition.[208-210]

HOT FLASHES

Hot flashes are highly prevalent among patients with breast cancer and other premenopausal women who undergo ovarian function suppression. In addition, approximately 75% of men undergoing androgen-deprivation treatment will have substantial discomfort because of hot flashes. Non-pharmacological approaches to prevent hot flashes in healthy postmenopausal women include electroacupuncture, paced respiration, cognitive behavioral therapy, and hypnosis.[211]

Estrogens and androgens can alleviate hot flashes for women and men, respectively; however, there is concern about administering exogenous hormones to patients with hormonally driven cancers. Alternative agents, therefore, should be used to control hot flashes for patients who are refractory to non-pharmacological approaches.

Evidence supports the use of antidepressants to treat hot flashes. Use venlafaxine, citalopram, or escitalopram for patients receiving tamoxifen, because these agents do not alter tamoxifen metabolism. Paroxetine, fluoxetine, and sertraline, however, should be avoided in patients taking tamoxifen, because they can decrease the metabolism of tamoxifen to its active metabolite endoxifen by the enzyme CYP2D6.

The results from placebo-controlled RCTs indicate that clonidine inhibits hot flashes more than placebo but carries a higher risk of anticholinergic adverse effects.[212] Gabapentin is also effective in controlling hot flashes at a dose of 900 mg per day, but not at a dose of 300 mg per day. Randomized placebo-controlled trials demonstrated that oxybutynin decreased hot flashes in men, with mouth dryness being the most common adverse effect.[212]

A recent phase 3 study demonstrated that elinzanetant (dual NK-1/NK-3 antagonist) caused a significant decrease in hot flash frequency, severity, and sleep disturbance, along with improved QoL in patients with breast cancer on endocrine therapy.[213]

Oxybutnin has shown promising results in the management of hot flashes in men on androgen deprivation therapy (ADT) for prostate cancer. A phase 2 study using high-, low-dose oxybutynin, and placebo showed daily hot flash score reduction of 13.95, 9.94, and 4.85, respectively, from an average daily hot flash of 18.23.[214]

Results from large placebo-controlled clinical trials do not demonstrate any benefit from a phytoestrogen product for breast cancer survivors.[215] Black cohosh, flaxseed, magnesium oxide, and vitamin E were similarly ineffective.[216-218]

VAGINAL DRYNESS, DYSPAREUNIA, AND LOW LIBIDO

More than 60% of people treated for cancer have long-term sexual dysfunction. However, fewer than 25% of those with sexual problems get professional help.[219] Although cancer-related sexual problems usually begin with physiological damage from cancer treatment, a patient's coping skills and the quality of the sexual relationship are crucial in sexual rehabilitation. Barriers to care for patients with cancer with sexual dysfunction include a lack of discussion of this problem with the oncology team.

Vaginal dryness from urogenital atrophy is a major symptom of estrogen depletion for some women. It can contribute to pain during intercourse as well as itching and irritation. Aqueous lidocaine preparation, used topically at the introitus before sexual activity, can decrease dyspareunia. Non–estrogen-containing vaginal lubricants help to alleviate symptoms.[220] These products, however, are less efficacious than topical estrogen therapy.[221]

Despite evidence showing rare persistent estradiol elevation among patients who have breast cancer receiving aromatase inhibitors,[222] clinicians continue to report concern about the systemic absorption of topical estrogens and testosterone. However, data presented at ASCO 2025 demonstrated no increased risk from vaginal estrogen tablets in breast cancer survivors,[223] and their use decreases the incidence of urinary tract infections.

Data in women who do not have cancer show that vaginal dehydroepiandrosterone can decrease vaginal dryness and reduce discomfort during sexual activity without increasing systemic estrogen levels. RCTs involving patients who have a history of cancer support the safe use of dehydroepiandrosterone, an estradiol-releasing vaginal ring, and intravaginal testosterone cream

for dyspareunia.[224] A double-blind, randomized, placebo-controlled trial of transdermal testosterone in women with cancer, however, did not show any improvement in libido.[13] A potential explanation for the negative results in patients with cancer is that the women involved in this trial were postmenopausal and did not receive supplemental estrogen. In most previous trials in other patient groups, women were premenopausal and had also been receiving estrogen-replacement therapy (Table 8-13).

Table 8-13 Approaches to Hormone-Related Symptoms in Patients With Cancer

Symptom	Evidence-Based Therapy	Non-Evidence-Based Therapy
Hot flashes	Antidepressants	Phytoestrogen product (soy)
	Clonidine	Black cohosh
	Gabapentin	Flaxseed
	Oxybutynin	Magnesium oxide
	Cognitive behavioral therapy	
	Hypnosis	
	Elinzanetant (dual NK-1/NK-3 antagonist)	
Vaginal dryness	Dehydroepiandrosterone	
	Vaginal estrogen tablets	
Dyspareunia	Lidocaine	
	Vaginal estrogen tablets	
Low libido		Transdermal testosterone

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

KEY POINTS

- Sexual health concerns are common in patients who have cancer, but oncologists do not commonly discuss them with patients.
- Non-hormonal therapies to decrease hot flashes include antidepressants, gabapentin, clonidine, oxybutynin, and elinzanetant.
- For patients receiving tamoxifen, paroxetine, fluoxetine, and sertraline should be avoided, because they can decrease the metabolism of tamoxifen by CYP2D6 to its active metabolite.
- Hormonal therapy for hot flashes can include the use of progesterone analogs.
- Dehydroepiandrosterone, vaginal laser therapy, and vaginal estrogen tablets can help to alleviate vaginal dryness.
- Topical dehydroepiandrosterone, an estradiol-releasing vaginal ring, intravaginal testosterone cream, vaginal estrogen tablets, and topical lidocaine can ease dyspareunia.
- Testosterone, without the addition of estrogen-replacement therapy, does not seem to help increase libido in postmenopausal women who have cancer.

HIGH-YIELD TAKEAWAYS

- No pharmacological intervention is supported by evidence to treat cancer-related fatigue.
- Low-dose olanzapine can be used to improve weight and appetite in patients with advanced cancer.
- Opioids can be considered for patients with advanced cancer to relieve dyspnea.
- In patients with painful chemotherapy-induced peripheral neuropathy, duloxetine should be considered.

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

PAIN AND SYMPTOM MANAGEMENT

8

CHAPTER SUMMARY GUIDE

KEY POINTS

- Clinicians may inadvertently miss or underestimate the severity of patient symptoms.
- Symptom monitoring using PROs improves QoL and overall survival for patients who have advanced cancer.
- Daily patient-reported global symptom monitoring is feasible in hospitalized patients and outpatient settings who have advanced cancer.
- A multimodal approach to managing the pain of cancer patients that includes pharmacological and non-pharmacological interventions is strongly recommended.
- Non-steroidal anti-inflammatory agents are first-line therapies for mild pain and can minimize the need for opioids in patients with somatic pain, including pain from bone metastases.
- Morphine is the most studied, evidence-based, cost-efficient opioid for the treatment of patients with cancer who have pain.
- Methadone is a mu agonist and *N*-methyl-D-aspartate receptor antagonist effective in treating neuropathic pain. Methadone is a complex drug that requires expert oversight in its prescribing and monitoring.
- TDF and buprenorphine patches are approved for opioid-tolerant patients.
- Methadone, buprenorphine, and fentanyl are the safest opioids in the setting of renal failure; however, they are not intended to be first-line options in those for whom other opioids can be considered or used.
- Avoid defining anticipated and transient opioid-associated adverse effects (eg, nausea, pruritus) as true allergies (eg, hives, shortness of breath).
- When prescribing opioids to patients who have cancer, it is important to anticipate expected adverse effects and develop strategies to prevent them.
- Stimulant laxatives (eg, senna, bisacodyl), not stool softeners, are the most effective approach to prevent and treat OIC. Polyethylene glycol is also effective.
- Consideration of interventional approaches for cancer pain should be discussed.
- Oncologists must use accurate terminology to describe OUD.
- Universal precautions describe an opioid-prescribing practice in which clinicians assess all patients for history or risk of opioid misuse regardless of demographic, social, or disease-related variables.
- Effective use of adjuvant agents for bone and neuropathic pain can provide more effective pain control with fewer adverse effects than opioids alone.
- There are four types of CINV: acute, delayed, breakthrough, and anticipatory.
- Chemotherapy is classified into four emetic risk categories: highly emetogenic (>90% risk), moderately emetogenic (30%-90% risk), low emetogenic (10%-30% risk), and minimally emetogenic (<10% risk).
- Prevention of CINV is key because patients who experience CINV during the first cycle of chemotherapy are up to five times more likely to experience CINV in subsequent cycles.
- Olanzapine significantly reduces nausea and emesis in highly emetogenic chemotherapy regimens when combined with neurokinin-1 receptor antagonists, $5HT_3$ receptor antagonists, and dexamethasone.
- Cancer fatigue is widespread and often multifactorial.
- In patients experiencing cancer-related fatigue, clinicians should evaluate and treat coexisting conditions, such as depression, anemia, thyroid dysfunction, and electrolyte disorders, and discontinue fatigue-inducing medications when possible.
- In patients who have cancer fatigue, moderate-intensity exercise, psychological interventions, and Tai Chi–based interventions can improve symptoms.
- National guidelines do not support the use of psychostimulants, antidepressants, or wakefulness agents to treat cancer-related fatigue.
- Two phase 3 studies demonstrated improved cancer-related fatigue with ginseng compared with placebo for patients undergoing cancer treatment.

- Categories of cachexia include precachexia, cachexia, and refractory cachexia.
- Cachexia is associated with increased treatment-related toxicity, decreased QoL, and poor survival.
- Overall, studies demonstrate a net harm when providing parenteral nutrition to patients who have cancer.
- There are no FDA-approved pharmacological treatments for weight loss associated with cancer cachexia.
- The weight gain associated with the use of megestrol acetate, dronabinol, and dexamethasone is primarily adipose tissue and fluid, not skeletal muscle.
- Deep vein thrombosis and adrenal suppression are two notable adverse effects of megestrol acetate.
- Clinicians must support caregivers given the paucity of effective treatment options and the distress cachexia causes when caregivers witness anorexia, weight loss, weakness, and decreased QoL in their loved ones.
- Pancreatic exocrine insufficiency is common in patients who have pancreatic cancer. Clinicians should treat patients with exogenous enzyme replacement and titrate to control abdominal symptoms and steatorrhea.
- FU and topoisomerase I inhibitors (irinotecan, topotecan) commonly cause diarrhea.
- Irinotecan causes acute diarrhea because of a cholinergic mechanism, as well as subsequent, more severe diarrhea because of its active metabolite SN38.
- In addition to supportive measures, loperamide can be used effectively to treat chemotherapy-induced diarrhea. Second-line approaches include diphenoxylate and atropine, deodorized tincture of opium, and octreotide.
- In addition to supportive measures, radiotherapy-induced diarrhea should be treated with octreotide.
- Diarrhea is common with targeted therapy and is best treated with antimotility agents and withdrawal of the offending drug.
- Checkpoint inhibitors can cause life-threatening colitis that is best treated with corticosteroids and, rarely, infliximab.
- Graft-versus-host disease–associated diarrhea should be treated with corticosteroids, optimal immunosuppression, and octreotide.
- Evidence-based prevention strategies of mucositis include oral rinses, low-dose laser therapy, cryotherapy, and palifermin.
- Dexamethasone rinse improves the prevention of everolimus-induced stomatitis. Doxepin mouthwash improves mucositis-related pain.
- There are no differences in effectiveness for palliation of oral mucositis among mouthwashes consisting of saline, sodium bicarbonate, chlorhexidine, or so-called magic mouthwash.
- There are no established methods to prevent CIPN other than limiting exposure to the offending drugs.
- Patients at higher risk for developing CIPN include those with a history of inherited neuropathy, obesity, diabetes, and alcoholism.
- The best-established drug for treating painful CIPN is duloxetine, but its efficacy is limited.
- Dyspnea is a subjective experience that may or may not correlate with objective findings.
- Any reversible causes of dyspnea should be identified and treated when possible.
- In the absence of hypoxemia, oxygen provides no additional symptomatic benefit for dyspnea compared with room air.
- Limited evidence supports the use of systemic opioids to palliate dyspnea.
- Prevention of patients with EGFR inhibitor–associated rash includes topical corticosteroids and moisturizers, or oral minocycline or doxycycline.
- Treatment of patients with EGFR inhibitor–associated rash includes topical corticosteroids, clindamycin, oral minocycline, doxycycline, or low-dose isotretinoin.
- No evidence supports the use of vitamin B6 supplementation, urea–lactic acid cream, topical emollients or creams, systemic or topical corticosteroids, nicotine patches, or vitamin E to prevent or treat hand-foot syndrome.
- Scalp cryotherapy is effective for select patients with solid tumors, but safety data are lacking for patients with hematological malignancies.
- Sexual health concerns are common in patients who have cancer, but oncologists do not commonly discuss them with patients.
- Non-hormonal therapies to decrease hot flashes include antidepressants, gabapentin, clonidine, oxybutynin, and elinzanetant.
- For patients receiving tamoxifen, paroxetine, fluoxetine, and sertraline should be avoided, because they can decrease the metabolism of tamoxifen by CYP2D6 to its active metabolite.
- Hormonal therapy for hot flashes can include the use of progesterone analogs.
- Dehydroepiandrosterone, vaginal laser therapy, and vaginal estrogen tablets can help to alleviate vaginal dryness.
- Topical dehydroepiandrosterone, an estradiol-releasing vaginal ring, intravaginal testosterone cream, vaginal estrogen tablets, and topical lidocaine can ease dyspareunia.
- Testosterone, without the addition of estrogen-replacement therapy, does not seem to help increase libido in postmenopausal women who have cancer.

CHAPTER TABLES AND IMAGES

Table 8-1 Examples of Validated Pain Instruments in Cancer Patients[12]

Instrument Name	Constructs Measured	Estimated Completion Time
Brief Pain Inventory Short Form	Pain severity, pain interference with physical and affective functioning, pain location	5 minutes
Edmonton Symptom Assessment System–Revised	Current pain severity, pain location	1 minute
Short-Form McGill Pain Questionnaire	Pain quality, pain location, pain severity	5-10 minutes
Verbal analog scales	Pain level	1 minute
Verbal rating scales	Pain level	1 minute
Wong-Baker FACES Pain Rating Scale[a]	Pain level	1 minute

[a]Validated in pediatric care; age 3 years or older.

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 8-2 **Pain Terminology**[15]	
Term	**Definition**
Acute pain	Pain occurring over hours up to weeks, characterized by a well-defined temporal pattern of onset with subjective and objective physical signs and hyperactivity of the autonomic nervous system
Subacute pain	Pain present for between 6 weeks and 3 months
Chronic pain	Pain present more than 3 months, cause often not easily identified, usually multifactorial, may be nociceptive and/or neuropathic; characterized by vegetative signs (eg, anorexia, anhedonia, sleep disturbance) as well as physical and mental withdrawal
Nociceptive pain	Somatic or visceral pain associated with actual or potential tissue damage caused by ongoing activation of intact nociceptors
Neuropathic pain	Pain resulting from injury to the peripheral or central nervous system, causing pain described as burning, shooting, tingling, stabbing, scalding, crawling, or painful numbness
Somatic pain	Localized pain causing activation of the μ-receptors and described as aching, stabbing, or throbbing
Visceral pain	Poorly localized pain resulting from activation of nociceptors in the viscera by obstruction, infiltration, ischemia, stretching, compression, and/or inflammation
Baseline pain	Average pain intensity experienced for 12 hours during a 24-hour period
Breakthrough pain	Transient increase in pain to greater than moderate intensity, occurring in addition to baseline pain
Incident pain	Specific experience of pain associated with an event or movement (eg, wound care)
Episodic pain	Transient exacerbation or recurrence of pain
Allodynia	Pain from light touch or mild pressure
Hyperalgesia	Increased pain response to a noxious stimulus
Dysesthesia	Unpleasant, abnormal sense of touch
Paresthesia	Abnormal dermal sensation (eg, tingling, pricking, chilling, burning, or numb sensation on the skin) with no apparent physical cause
Opiates	Natural substances that come from opium, including morphine and codeine
Opioid	Semisynthetic or synthetic products that bind to the same receptors as opiates but do not occur naturally; used broadly to include both natural or synthetic (or semisynthetic) substances acting on one of the three main opioid receptor systems (μ, κ, δ)
Adjuvant	Non-opioid medications used to enhance analgesia and minimize adverse effects, including anticonvulsants and antidepressants
End-of-dose failure	Predictable return of pain before the next scheduled dose of medication
Incomplete cross tolerance	Different levels of tolerance to an opioid of a different class

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 8-3 **Non-Pharmacological Approaches to Treating Cancer Pain**[8]

Category	Treatment Type
Alternative, complementary, or integrative strategies	Acupuncture, art therapy, massage, music therapy, physical/movement, aromatherapy
Interventional	Injection therapies, implant therapy, neural blockade, surgical neuroablation, orthopedic procedures
Rehabilitative	Hydrotherapy, occupational therapy, physical modalities such as ultrasound, therapeutic exercise, and therapy for specific disorders such as lymphedema
Psychological	Hypnotherapy, cognitive behavioral therapy, guided imagery, other forms of psychotherapy, psychoeducational interventions, relaxation therapy, stress management
Neurostimulation	Dorsal column stimulation, intrathecal drug delivery

The IMPACT trial recently showed that both acupuncture and massage improved pain, fatigue, insomnia, and quality of life over 26 weeks in advanced cancer patients, highlighting the importance of integrating non-pharmacological approaches to pain and symptom management when possible.[17]

Table 8-4 **Non-Opioid Pharmacological Agents Targeting Neuropathic Pain**

Pharmacological Agent Targeting Neuropathic Pain	Mode of Action	Starting Dose/Max Dose	Adverse Effect
Anticonvulsants	Decreased release of glutamate, norepinephrine, and substance P affects calcium channels		Sedation and dizziness should not be abruptly stopped
Gabapentin		100-300 mg 1-3× per day/1,200 mg 3× per day[a]	
Pregabalin		50 mg 3× per day/200 mg 3× per day	
Antidepressants			
TCAs: nortriptyline, desipramine	Inhibition of serotonin/norepinephrine reuptake, sodium channel blocking, and anticholinergic	25 mg/150 mg daily	Sedation, anticholinergic effect, cardiac arrhythmias, and nausea
SNRISs: duloxetine, venlafaxine	Inhibition of serotonin/norepinephrine reuptake	Duloxetine: 30 mg daily/60 mg 2× daily; venlafaxine: 37.5 mg daily or twice daily/225 mg daily	Nausea, insomnia, appetite loss, weight gain
Topical agents			
5% Lidocaine patch	Sodium channel blocking	1-3 patches/3 patches daily	Rash, local erythema
Capsaicin: cream, 8% patch	Highly selective agonist for TRPV1 receptors expressed in afferent neuronal C fibers and some Aδ fibers	Cream: 0.025%, 0.075%, and 0.1% creams; apply 3-4 times per day; 8% patch: 1 patch/4 patches applied for 60 minutes every 3 months[b]	Erythema and uncomfortable burning, stinging, or itching

Abbreviations: SNRIS, serotonin and norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant.
[a]Need to adjust in those with renal insufficiency, especially those on renal replacement therapy.
[b]8% patch is applied by a medical provider only. Consideration of cost.

Table 8-5 **Opioids, Active Metabolites, and Pharmacokinetics**[25-27]

Opioid	Active Metabolites	Half-Life (Hours)	Equianalgesic	
			Parental	Oral
Morphine	Yes	2-4	10	30
Oxycodone	Yes	3-4	Not available in the United States	20
Hydrocodone	No	3-4	NA	30
Hydromorphone	Yes	2-3	1.5	7.5
Fentanyl	No	Transmucosal: 1-2 Transdermal: 48-72	Variable conversion methods available; may consider using ratio of 2.5-1 (oral morphine per day: TDF per hour); should not initiate in opioid-naive patients or patients receiving less than 60 mg MEDD	
Methadone	No	2-3 (distribution phase); 15-60 (elimination phase)	[a]	

Abbreviations: MEDD, morphine equivalent daily dose; NA, not applicable; TDF, transdermal fentanyl.
There is no clear consensus on opioid conversions; these serve as guidelines only.
[a]Methadone conversions should be supervised by a pain expert (palliative care specialist or acute/chronic pain management specialist).

Table 8-6 **Opioid Aberrancy Terminology**[33,50-53]

Term	Definition
Aberrant	Actions departing from accepted, medically appropriate drug-taking behaviors
Abuse	A maladaptive pattern of prescription opioid use leading to clinically significant impairment and distress
Addiction	A primary, chronic, and neurobiological disease with manifestations influenced by genetic, psychosocial, and environmental factors, characterized by impaired control over drug use, compulsive use, continued use despite harm, and craving
Chemical coping	Behaviors focused on obtaining opioids to relieve psychosocial distress rather than pain
Dependence	A state of adaptation indicated by a medication class-specific withdrawal syndrome produced by abrupt cessation, rapid dosage reduction, decreasing blood level of the drug, or administration of an antagonist
Misuse	The inappropriate use of a prescription opioid agent, whether intentional or unintentional, and regardless of motivation
Pseudo-addiction	An iatrogenic syndrome with behaviors that mimic addiction, driven by unrelieved pain
Substance abuse	Use of a substance in a manner outside of sociocultural conventions
Tolerance	Diminution of one or more drug effects caused by exposure to the drug that may require higher doses for effect
Withdrawal	An uncomfortable but non–life-threatening reaction that occurs after the abrupt cessation of opioids or use of naloxone, characterized by the presence of one or more of a variable group of symptoms and signs, including tremulousness, anxiety, insomnia, tachycardia, tachypnea, hypertension, nausea and vomiting, diarrhea, piloerection, and sweating

Table 8-7 **Selection of Antiemetics Based on Neurotransmitters Involved**[84]

Anatomic Location	Neurotransmitter Involved	Drug Class
Cortex	Unknown	Dexamethasone
		Lorazepam
		Cannabinoids
	Dopamine	Haloperidol
Chemoreceptor trigger zone	Serotonin	Metoclopramide
		Prochlorperazine
		Ondansetron
		Oral granisetron
		Transdermal granisetron
	Dopamine	Metoclopramide
		Prochlorperazine
	Endocannabinoid	Cannabinoids
	Substance P inhibitors	Aprepitant
		Fosaprepitant
		Netupitant
		Rolapitant
Vomiting center/vestibular apparatus	Histamine	Cetirizine (preferred)
		Diphenhydramine
		Meclizine
		Hydroxyzine
	Acetylcholine	Scopolamine

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 8-8 **CINV Types**

Types of CINV	Time Frame
Acute	Within 24 hours of chemotherapy administration
Delayed	2-5 days after chemotherapy administration
Breakthrough	Anytime, despite adequate prophylaxis
Anticipatory	Before the next treatment

Abbreviation: CINV, chemotherapy-induced nausea and vomiting.
Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 8-9 **CINV Prophylaxis Based on Emetic Risk**	
Risk	**Recommended Prophylaxis**
High	NK-1 + $5HT_3$ + dexamethasone + olanzapine
Moderate	$5HT_3$ + dexamethasone
Low	$5HT_3$ or dexamethasone
Minimal	None

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 8-10 **Emetic Risk in Adults by Site of Radiation Therapy**		
Risk Level	**Site**	**Therapy Options**
High (>90%)	Total body irradiation	5-HT_3 antagonist with dexamethasone
Moderate (30%-90%)	Upper abdomen, craniospinal irradiation	5-HT_3 antagonist with or without dexamethasone
Low (10%-30%)	Brain, head and neck, thorax, pelvis	Brain: dexamethasone; head and neck, thorax, pelvis: $5HT_3$ antagonist or dexamethasone or dopamine receptor antagonist (use as rescue)
Minimal (<10%)	Extremities, breast	$5HT_3$ antagonist, dexamethasone, or dopamine receptor antagonist (use as rescue)

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 8-11 **Mechanisms of Chemotherapy-Induced Peripheral Neuropathy**

Chemotherapy	Neurotoxicity	Incidence	Cumulative Dose	Recovery
Cisplatin	Long-lasting cumulative distal sensory neuropathy	50%-90% of patients receiving ≥500 mg/m^2	Beginning at 300 mg/m^2	Incomplete
Carboplatin	Mild sensorimotor neurotoxicity	Uncommon; mild in 25% of patients; severe in 5%	More common with high doses: 800-1,600 mg/m^2	Not fully described
Oxaliplatin	Acute cold–associated neurotoxicity and chronic sensory neuropathy	Acute symptoms in 95%; severe chronic toxicity in 10%-20% at 750-850 mg/m^2	Acute symptoms at all doses, severe at >540-700 mg/m^2	May persist for a long time; in 10% of patients at 2 years post-treatment
Paclitaxel	Distal sensory neuropathy with pain and motor symptoms at high doses	Severe dose dependence in 10%-30% of patients	>300 mg/m^2 but can occur at lower doses	May persist, although reversibility is reported
Docetaxel	Distal sensory neuropathy with pain	Less severe neurotoxicity than paclitaxel, severe in 6%-10% of patients	>100 mg/m^2; severe toxicity >600 mg/m^2	Not fully described
Vincristine	Distal sensorimotor painful neuropathy	60% of patients, dose dependent	4-10 mg	≤33% of patients report persistent symptoms
Bortezomib	Sensory axonal neuropathy, occasionally demyelinating	≥35%-50% of patients	1.3 mg/m^2	Resolution in 3 months; may persist
Thalidomide	Sensorimotor painful neuropathy	25%-75% of patients	At dose ≥20 g	Not fully described

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 8-12 **Strategies for EGFR-Associated Acneiform Rash**

Strategy	Recommended	Not Recommended
Topical preventive	Hydrocortisone	Pimecrolimus
		Tazarotene
		Sunscreen as a single agent
Systemic preventive	Minocycline	Tetracycline
	Doxycycline	
Topical treatment	Alclometasone	
	Fluocinonide	
	Clindamycin	
Systemic treatment	Doxycycline, 100 mg twice daily	Photosensitizing agents
	Minocycline, 100 mg daily	
	Low-dose isotretinoin, 20-30 mg daily	

Abbreviation: EGFR, epidermal growth factor receptor.
Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

Table 8-13 **Approaches to Hormone-Related Symptoms in Patients With Cancer**

Symptom	Evidence-Based Therapy	Non-Evidence-Based Therapy
Hot flashes	Antidepressants	Phytoestrogen product (soy)
	Clonidine	Black cohosh
	Gabapentin	Flaxseed
	Oxybutynin	Magnesium oxide
	Cognitive behavioral therapy	
	Hypnosis	
	Elinzanetant (dual NK-1/NK-3 antagonist)	
Vaginal dryness	Dehydroepiandrosterone	
	Vaginal estrogen tablets	
Dyspareunia	Lidocaine	
	Vaginal estrogen tablets	
Low libido		Transdermal testosterone

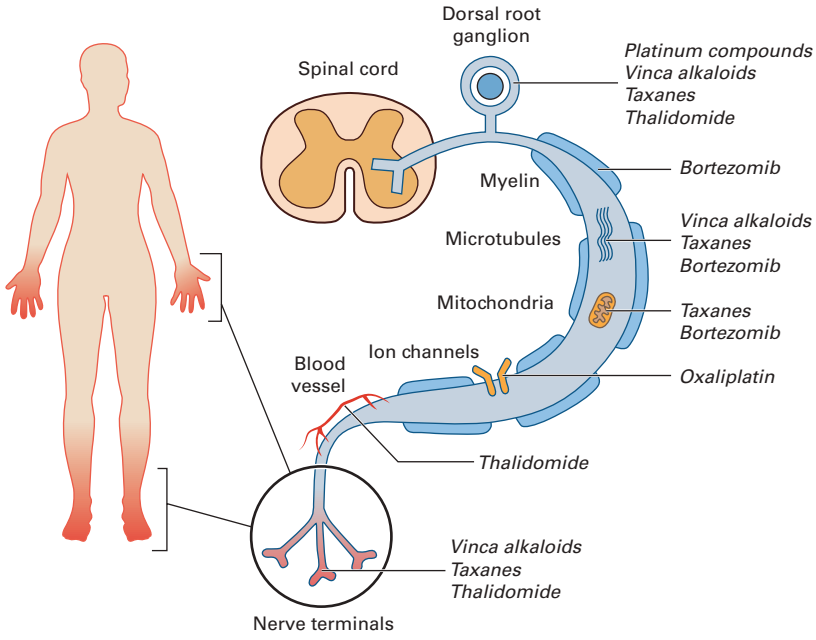
Figure 8-5 Mechanisms of CIPN



Abbreviation: CIPN, chemotherapy-induced neurotoxicity.
Proposed targets of CIPN in the peripheral nervous system include damage to dorsal root ganglion neuronal cell bodies (platinum compounds, vinca alkaloids, taxanes, thalidomide), demyelination (bortezomib), microtubule-associated toxicity (vinca alkaloids, taxanes, bortezomib), mitochondrial dysfunction (taxanes, bortezomib), axonal membrane ion channelopathy (oxaliplatin), peripheral vasculature impairment (thalidomide), and distal axonal injury (vinca alkaloids, taxanes, thalidomide).
Adapted from Park SB, Goldstein D, Krishnan AV, et al. Chemotherapy-induced peripheral neurotoxicity: a critical analysis. *CA Cancer J Clin*. 2013;63:419-437. doi:10.3322/caac.21204

PALLIATIVE CARE AND CARE AT THE END OF LIFE

9

Kathryn DeCarli, MD, MBE, and Frederick J. Meyers, MD, MACP

RECENT UPDATES

- Inpatient palliative care for patients hospitalized for intensive chemotherapy treatment of acute myeloid leukemia or for hematopoietic stem cell transplantation led to better quality of life and less psychological distress than for patients receiving standard oncology care.[1-3]
- Delivery of early palliative care follow-up visits virtually versus in person demonstrated equivalent effects on quality of life in patients with advanced non–small cell lung cancer, underscoring the potential to improve access to timely palliative care through telehealth delivery.[4]
- A stepped-care model resulted in fewer palliative care visits without diminishing the benefits for patients' quality of life.[5] In this model, palliative care follow-up visits occur only at key disease transitions or acute episodes during patients' cancer trajectories, with the recognition that a decrement in quality of life should trigger more intensive palliative care exposure.

OVERVIEW

Palliative care is an interdisciplinary medical specialty centered around preventing or relieving suffering and improving quality of life (QoL) for patients with serious illness and their caregivers. Palliative care is an essential component of high-quality cancer care throughout the cancer journey. The 2024 ASCO Guideline Update states that oncologists should refer patients with advanced cancer to specialized interdisciplinary palliative care teams early in the course of the disease, alongside active treatment of their cancer.[6] As outlined in the National Consensus Project clinical practice guidelines for quality palliative care,[7] high-quality palliative care includes eight domains:

1. Structures and processes of care (eg, the nature of palliative care services available, such as the presence of a truly interdisciplinary team or the availability of a bereavement program)
2. Physical aspects of care (eg, regular symptom assessment and appropriate management)
3. Psychological (emotional) and psychiatric aspects of care (eg, screening and management of mood disorders, distress, and grief)
4. Social aspects of care (eg, comprehensive interdisciplinary assessment of patient and family social needs and development of a care plan to address them)
5. Spiritual, religious, and existential aspects of care (eg, attention to issues such as faith, meaning, identity, and control)
6. Cultural aspects of care (eg, attention to cultural values, beliefs, and preferences)
7. Care of the patient nearing the end of life (eg, attention to issues specific to end-of-life care)
8. Ethical and legal aspects of care (eg, methods to assess values and preferences and implement goal-concordant care, including but not limited to advance directives)

Some cancer centers in the United States have rebranded specialist palliative care as the "Supportive Care" team. Studies show that clinicians and patients are more likely to engage with a supportive care team due to misperceptions about the name "Palliative Care" and conflation with hospice or end-of-life care.[8-10] Indeed, even this chapter treats palliative care and hospice together. While palliative care and hospice share a focus on comfort, they are distinct and distinguished by the goals of care. Hospice care is appropriate for patients who are not receiving cancer-directed care and have a prognosis of <6 months. On the other hand, palliative or supportive care can be given to any patient with a serious illness, concurrently with cancer-directed care. This includes patients undergoing curative-intent treatment and patients with long life expectancy. For this chapter, we will use

the nomenclature "Palliative Care," but acknowledge the benefits of using "Supportive Care" to name the services provided by specialist palliative care clinicians.

This chapter focuses on the timely delivery and implementation of specialist palliative care, topics in communication, patient and caregiver distress, and an overview of hospice and end-of-life (EOL) care. Pain and symptom management, which are key components of high-quality palliative care, are covered separately in Chapter 8. Symptoms that can be particularly impactful at EOL are discussed in the last portion of this chapter. This chapter aims to outline the scope of palliative care for patients with cancer and their caregivers and to prepare the oncologist to effectively collaborate with palliative care specialists.

SCOPE OF PALLIATIVE CARE IN ONCOLOGY

Simply stated, palliative care aims to help patients and their loved ones live life to the fullest when faced with serious or life-threatening illness. Palliative care is ideally integrated at diagnosis, extending throughout the course of cancer care regardless of prognosis. This is consistent with the American Society of Clinical Oncology (ASCO) position, as outlined in a 2024 guideline update on integrating palliative care into standard oncology care.[6,11]

To understand the role of palliative care specialists, it is helpful to differentiate primary or generalist palliative care from secondary or specialist palliative care. Primary or generalist palliative care encompasses the basic skills and competencies to support patients' QoL that all oncology clinicians should possess, whereas secondary or specialist palliative care refers to the complex skills and services provided by specialists with additional palliative care training. Specialist palliative care is provided by an interdisciplinary team that includes physicians, advanced practitioners, nurses, chaplains, social workers, and others (Table 9-1). The provision of specialist palliative care in dedicated inpatient palliative care units and academic medical centers, where research and education focus on patients with more complex needs, is sometimes also referred to as tertiary palliative care.

Oncologists and other cancer care clinicians provide most of the primary palliative care for their patients, including assessment and management of symptoms, leading and coordinating patient family conferences on discussions about prognosis and goals of care, and support for the patient and caregiver(s) in coping with serious illness. Referral to or consultation with a palliative care specialist can help provide additional expertise regarding management of difficult-to-control symptoms, existential distress, or complex medical decision-making.

It is important to recognize that specialist palliative care does not duplicate or replace care by the cancer care team; instead, it augments that care in areas of complex patient and caregiver needs. Specialist palliative care enhances the care delivered by the primary oncology team, providing an added layer of support not only to the patient and family but also to the cancer care team.[12] Lack of access to on-site palliative care was associated with lower job satisfaction among chemotherapy-prescribing physicians globally.[12]

In one study, oncologists were more likely to endorse certain palliative care skills than others as fundamental to routine oncology, including communication, shared decision-making, advance care planning, and end-of-life care.[13] Spiritual and cultural assessment, psychosocial assessment, and second-line management of pain, depression, and anxiety were least endorsed by oncologists, and therefore conferred the highest potential for referral to specialty palliative care.

Table 9-1 Primary Versus Secondary Palliative Care

Primary	Management of cancer-related pain, including basic opioid regimens
	Basic non-pain symptom management, including nausea, constipation, and mood
	Advance care planning, eliciting patient values to provide goal-concordant care
	Ongoing prognostic awareness assessment
Secondary	Management of cancer-related pain, including complex opioid regimens
	High-touch and refractory non-pain symptom management
	Advanced communication strategies to augment advanced care planning and serious illness conversations with complex dynamics
	Enhanced prognostic awareness assessment and discussions with key stakeholders (eg, patient, treating team, family members)

Created for ASCO. Copyright © 2026 American Society of Clinical Oncology.

These findings mirror those from randomized trials of integrated palliative care in patients with advanced solid tumors and acute leukemia, wherein palliative care specialists were noted to focus more on coping and psychosocial care during consultations than the oncologists seeing those same patients.[2,14]

IMPLEMENTING EARLY PALLIATIVE CARE

EVIDENCE SUPPORTING EARLY INTEGRATION OF SPECIALIST PALLIATIVE CARE

Palliative care should be delivered concurrently with cancer-directed therapy and integrated early in the disease course.[15,16] Randomized trials have shown that, compared with primary palliative care provided by oncologists, early integrated specialist palliative care improves QoL, symptom intensity, patient and caregiver satisfaction, mood, illness understanding, quality of end-of-life care, and survival.[14,16-19] Importantly, no study to date has shown any harm caused by integrating palliative care into standard oncology care.[19]

Given the rapidly expanding evidence base, ASCO released a provisional clinical opinion in March 2012[20] that was updated and published as a clinical practice guideline update in 2016,[11] and again in 2024.[6] The guideline recommends that "[o]ncology clinicians should refer patients with advanced solid tumors and hematologic malignancies to specialized interdisciplinary palliative care teams that provide outpatient and inpatient care beginning early in the course of the disease, alongside active treatment of their cancer."[2,3,21] Other national and international professional societies also now endorse integrated palliative care as a routine practice, including the American College of Surgeons Commission on Cancer,[22] the Oncology Nursing Society,[23] the National Comprehensive Cancer Network (NCCN),[24] and the European Society for Medical Oncology (ESMO).[25]

Evidence from several new trials in solid tumors demonstrated that early referral to specialized palliative care of patients with advanced cancer led to improved QoL, mood, and a higher likelihood of discussing or documenting end-of-life preferences. In addition, there were two trials of early palliative care for inpatients with hematological malignancies, specifically for patients admitted for treatment of acute myelogenous leukemia and those receiving hematopoietic stem cell (HSC) transplantation, which reported benefits of early palliative care for outcomes of QoL, depression, anxiety, and posttraumatic stress disorder (PTSD).[2,3,26] The same authors recently reported a multi-institutional randomized study of the benefits of palliative care in patients undergoing HSC transplantation. Significant benefit was seen in QoL, depression symptoms, and PTSD, underscoring the need to integrate routine palliative or supportive care in these patients. One note of interpretation, in this study and others, the "improvement in QoL" is often a reduction in the decline in QoL, understandable as many of the QoL instruments include the physical domains, which will decline in patients receiving intensive therapy.

CHALLENGES IN IMPLEMENTING EARLY PALLIATIVE CARE

Despite the abundance of data supporting the benefits of palliative care early in the patient's cancer journey, its incorporation remains markedly underutilized.[27,28] Studies suggest that this is not a uniquely American concern but rather seen in other countries with more robust systems of universal health coverage, including the UK, Australia, and Canada. Over the last decade, there have been many studies documenting this phenomenon as well as the challenges that contribute to the underutilization of palliative care involvement. These include healthcare team factors such as limited time and competing priorities at work, gaps in clinician knowledge and education, lack of access to services, and personal discomfort; as well as patient factors including negative perceptions of palliative care, family and cultural values, and communication barriers. These are summarized in Table 9-2. Even in a research setting at academic sites that met the requirements for integrated palliative care, 14% of patients randomized to receive monthly early palliative care in one study had not received any palliative care by 24 weeks.[28] This discrepancy highlights the challenges of providing early integrated palliative care even in highly resourced settings. The bulk of cancer care in the United States is provided at community sites, many of which lack access to specialty palliative care. Telehealth and policy changes may offer opportunities to enhance palliative care delivery in low-resource settings.[29]

Table 9-2 Barriers and Facilitators to Early Integration of Palliative Care

Factors Impacting Delayed Referral to Palliative Care	Potential Solutions to Improve Early Palliative Care Engagement[30]
• Patient's negative perceptions of palliative care • Family's negative perceptions of palliative care • Physician reluctance to discuss prognosis/EOL issues, including loss of hope • Physician perception of overlapping skill sets with palliative care • Lack of the medical team's recognition of the terminal phase of disease	• Education regarding the benefits of early palliative care for patients and caregivers as part of public health policy strategy • Using the term Supportive Care to name the services offered by the palliative care team • Adequate staffing, training, and resources to accommodate early palliative care referrals • Screening mechanism to help prioritize early palliative care referrals • Effective communication and collaboration among palliative care and oncology teams

Factors Impacting Delayed Referral to Palliative Care	Potential Solutions to Improve Early Palliative Care Engagement[30]
• Lack of integration between oncology and palliative care, including perceived conflict in goals of care that is, disease-directed therapy versus palliative care • Lack of clearly defined responsibilities between oncology and palliative care • Limited palliative care resources and a lack of clearly defined consensus referral criteria • Inadequate systems support and timely actionable data	• Clarifying the roles and responsibilities of oncology and palliative care teams in a collaborative delivery model • Concurrent or simultaneous care models of integration • Bridge programs • Health system support for leadership, access to actionable data, financial support for multidisciplinary team organization, and care delivery • Regulatory amendments that support palliative care services billing separately from disease-directed therapy • Follow-up palliative care visits via virtual care and/or using a stepped-care model, with palliative care visits occurring only at key points in patients' cancer trajectories[4,5]

Abbreviation: EOL, end of life.

Another well-recognized challenge is the integration of palliative care for patients enrolled on early-phase clinical trials. The rapid development of new cancer-directed therapies offers great promise at the population level. However, in a phase 1 trial setting, by definition, there is no guarantee that a particular drug will help a particular patient.[31,32] Patients with advanced cancer who have exhausted standard therapies and are enrolled on phase 1 clinical trials demonstrate high levels of psychological distress.[33] This warrants even more integration between oncology and palliative care. A growing body of literature supports structured specialty palliative care intervention for patients with advanced cancer on phase 1 clinical trials.[34-37]

SOLUTIONS TO THE CHALLENGES OF EARLY INTEGRATION OF PALLIATIVE CARE

Recently reported strategies address some of these challenges (Table 9-2). The experience of an inpatient specialized palliative care team for HSC transplantation noted above is emphasized.

- A recent randomized controlled trial showed that a stepped-care model, with palliative care follow-up visits occurring only at key points in patients' cancer trajectories and using a decrement in QoL to trigger more intensive palliative care exposure, resulted in fewer palliative care visits without diminishing the benefits for patients' QoL.[5]
- Another recently developed model, Symptom Screening with Targeted Early Palliative care (STEP), includes routine symptom monitoring at each oncology visit with referral to palliative care upon reaching a prespecified threshold score.[38] This model, which showed promise in a phase 2 trial, depends on the routine collection and availability of patient-reported outcomes (PROs) with infrastructure that allows the scores to become actionable. This risk-stratified approach to early palliative care referral is especially important in resource-constrained settings. Recognition and agreement between palliative care and oncology teams as to the time frame considered early is important, as it will vary with the disease. When possible, it is important to integrate palliative care and oncology clinical teams in the same space to facilitate communication and patient care. There may also be opportunities in leveraging telehealth to improve access to palliative care consultations, especially considering emerging data showing comparable efficacy. Delivery of early palliative care follow-up visits virtually versus in person demonstrated equivalent effects on QoL in patients with advanced non–small cell lung cancer.[4] This will need to be coupled with regulations supporting telehealth services in palliative care.[4]
- Oncologists can apply lessons from trials of early palliative care when providing primary palliative care for their patients. The TEAM approach (Time, Education, Assessment, and Management) is helpful in this regard[21] (Table 9-3).
- Quality improvement plays an important role in enhancing palliative care delivery. An excellent example is embedded palliative care consultation services. Palliative care consultation teams have expanded rapidly into cancer hospitals and clinics, with 90% of National Cancer Institute–designated cancer centers having both inpatient and outpatient specialty palliative care services.[39] However, despite clinical guidelines recommending that all patients with advanced cancer or high-risk hematological malignancies receive dedicated palliative care services within 8 weeks of diagnosis, referral to specialty palliative care teams typically occurs late in the disease course, if at all. Prognosis-, needs-, and trigger-based models of palliative care integration have been proposed, with trigger-based approaches thought to best capture patients most likely to benefit from consultation.[40] Triggers may include clinical characteristics, symptoms, performance status, prognosis, or a combination of these.[18]

Sustainable improvements in palliative care need systematic and systems-based interventions. Clinical research programs to assess systems and implement and measure change include implementation science and a learning healthcare system (LHCS). The systematic study of how to design and evaluate a set of activities to facilitate the successful uptake of an evidence-based health intervention is implementation science.[41] Implementation science frameworks emphasize multifactorial causes for the successful and sustainable implementation of interventions, such as organizational and patient perspectives, policies, and health system characteristics. A much higher level of training is one aspect of sustainable change that includes teamwork, systems thinking, and a patient/family/community focus, synthesized under the model of an LCHS. LHCS may be seen as one mechanistic approach to not only integrate sustainable change but also to overcome the deficits in workforce and resources cited as foundational to the challenge of palliative care delivery.[42] A frontline oncologist and palliative care specialist might be expected to understand there are many implementation science frameworks and perhaps some of the vocabulary. Behavioral psychologists, sociologists, systems engineers, social workers, and doctoral-trained health outcomes faculty, trained and expert in information system are likely better suited for leadership of such efforts. Oncologists and palliative care clinicians must be present and willing to work in these teams to identify core challenges and promote solutions.

Table 9-3 **The Components of TEAM-Based Palliative Care**

Component	In the Trials	What Is Known
Time	A structured palliative care visit of at least one extra hour per month; repeated at regular intervals (ie, monthly); not once	These assessments can be conducted by a physician or APN with specific training in conducting such assessments.
Education	Structured, prospective, and recurrent discussions about symptoms, goals, and preferences for care, prognosis understanding, advance care planning, and communication with the healthcare team	Education that is done prospectively and regularly, rather than during a crisis, is more effective. Usual topics include, on a recurring basis: • Medically appropriate options for treatment; patients should know they have or have not left any medical stones unturned; this is best done by listing the treatments used and their outcomes, especially with recurrent disease; if appropriate, reinforce patient and family work as advocates • Advance care planning should be started early and revisited along the disease trajectory; documented components may include power of attorney documents, healthcare proxies, living wills or advance directives, and do-not-resuscitate orders • Use of hospice for the best possible care, and arranging a hospice information visit once it is evident the disease is going to take the person's life
Assessment	Formal assessments for: • Symptoms (ESAS, MSAS-C, CAPC rounding tool) • Spirituality (FICA, or "Are you a religious or spiritual person?") • Distress (Distress Thermometer, others) • Psychosocial (PHQ-2) • Caregiver strain It is not sufficient to just ask "How are you?"; patients and families are sometimes reluctant to share their problems for fear that nothing can be done, or that it is not in the clinician's remit, or that the oncologist will stop treating their cancer, or that they will be labeled a complainer.	After these formal symptom assessments, move on to goal setting. Questions may include: • How do you like to get medical information? • What is your understanding of your disease? • What is important to you? • What are you hoping for? • Have you thought about a time when you might become sicker, such that you would need an advance directive or living will? (some motivational interviewing) The authors of the table have incorporated this into a temporary tattoo that gives oncologists a script to start the most difficult discussions (Fig. 9-1). If progressive disease is evident, it is time to revisit goals of care, prognosis understanding, and advance care planning.

Component	In the Trials	What Is Known
Management	By setting protocols and an interdisciplinary team (APNs, social workers, chaplains, doctors)	Interdisciplinary care and referrals were common elements of all studies. Giving people knowledge of their realistic options and a plan of action was shared across all the studies. Establishing ties with social work or chaplaincy is as important as developing ties with surgeons, radiation oncologists, or other medical professionals.

Abbreviations: APN, advance practice nurse; CAPC, Center to Advance Palliative Care; ESAS, Edmonton Symptom Assessment Scale; FICA, Faith and Belief, Importance, Community, Address in Care; MSAS-C, Memorial Symptom Assessment Scale Condensed; PHQ-2, Patient Health Questionnaire-2.

PALLIATIVE CARE SPECIALIST TRAINING AND WORKFORCE

The American Board of Medical Specialties (ABMS) first recognized Hospice and Palliative Medicine (HPM) as a subspecialty in 2006. From 2008 to 2012, physicians could sit for the HPM board examination after fulfilling certain clinical competencies. The first ACGME-approved HPM fellowship was launched in 2012. Since then, ABMS has required candidates to complete a formal fellowship training program (12 months) to be eligible for board certification.[43] There are more than 100 fellowship programs today in the United States. Between 2008 and 2022, 8,328 physicians received subspecialty board certification in HPM through the ABMS; between 2008 and 2018, an additional 419 physicians were certified through the American Osteopathic Association (AOA).[44] Clinicians from 10 different primary fields can train and certify in HPM, including family medicine, anesthesiology, pediatrics, obstetrics and gynecology, emergency medicine, surgery, neurology, psychiatry, internal medicine, radiology, and physical medicine and rehabilitation. Some programs specialize in pediatric palliative care; however, there is only one board certification examination, which includes adult and pediatric content. Dual training has garnered increased interest in recent years, with approximately 630 physicians board-certified in both Hematology/Oncology and HPM as of 2021.[45] In 2023, the inaugural class matriculated to an integrated fellowship in Hematology/Oncology and HPM. This pathway consists of combined ACGME-accredited training over a period of 36 months, resulting in clinical competency and board examination eligibility in both fields. A cohort of dual-trained physicians is projected to effect change in clinical care, palliative care delivery models within cancer centers, and research at the intersection of oncology and palliative care. Fellowship training programs in HPM emphasize the core skills of serious illness care, including comprehensive symptom assessment and management, prognostication and prognostic disclosure, serious illness communication and goals-of-care discussions, conflict management and resolution, advance care planning, psychosocial distress assessment and management, assessment and management of existential distress, family and caregiver support, and end-of-life care. Although these topics are often part of what cancer care clinicians do in caring for their patients with advanced disease, palliative care specialists receive advanced training in these areas and therefore possess expert, high-level skills in these domains. Given that these topics are of central importance to the practicing oncologist as well, they are highlighted briefly in the latter half of this chapter.

Overall, cancer care is facing a looming workforce crisis, with projections forecasting significant shortages of oncologists across the United States. This problem is also affecting the palliative care workforce; there are simply not enough palliative care specialists to see all the patients who would benefit from their services.[46] In this vein, it is important to recognize the important role that advanced practice nurses (APNs) play in providing primary palliative care.[47] Nonphysician clinicians may also train and become certified in palliative care, with various certification programs available through professional societies like the Hospice and Palliative Nurses Association and the National Association of Social Workers, among others. There is also a growing number of fellowship programs available to advanced practitioners and pharmacists providing advanced palliative care training.

Oncologists themselves are also important providers of primary palliative care, which can be provided via the TEAM approach (Table 9-3).[21] Board-certified palliative care specialists with complementary training in leadership, teamwork, and change management lead and participate in the teams responsible for the Implementation Sciences and Learning Health Care System strategies noted above.

PROCESS AND OUTCOME METRICS FOR ASSESSING QUALITY

As oncology practices face mounting financial constraints, quality assessment becomes important to align services with metrics established by healthcare systems and insurers. It is difficult to assess the success of a palliative care program in oncology, as there is limited evidence-based literature on consensus quality metrics to define success. While the benefit of early palliative care is well established in the literature, its widespread adoption and integration nationally lags.[48] Certainly, one of the main goals of palliative care is to improve QoL. However, in practice, improvement in QoL is difficult to benchmark and measure routinely, as assessment generally relies on surveys, which are not routinely administered. QoL questionnaires such as EORTC-QLQ-C30,

McGill QoL questionnaire, and EQ-5D have been validated in the palliative care setting. However, these may not help assess the magnitude of clinically meaningful change. In the United States, surrogate metrics have been used to assess QoL, including some used by the Centers of Medicare and Medicaid Services within the Merit-based Incentive Payment System (MIPS) Quality Measures 2024 for Oncology.[49] These include the following:

- Percentage of patients who died from cancer receiving systemic cancer-directed therapy in the last 14 days of life (lower score—better). A recent report reviewed current outcomes of this metric, a metric previously endorsed by ASCO and the National Quality Forum, NCCN, with similar indicators by ESMO and the Cancer Quality Control Council of Ontario. They reported a rise in the use of systemic therapy at EOL, correlated largely with increased use of immunotherapy.[50]
- Percentage of patients who died from cancer admitted to hospice for less than 3 days (lower score—better).
- Medical and radiation—pain intensity quantified: percentage of patient visits, regardless of patient age, with a diagnosis of cancer currently receiving chemotherapy or radiation therapy, in which pain intensity is quantified.
- Medical and radiation—plan of care for pain.

A study evaluating these metrics in a community academic hospital setting found that among patients referred to and seen by palliative care 30 days before death, the rates of admission to emergency departments (EDs), hospital, and intensive care units (ICUs) in the last 30 days of life were notably lower.[51] Studies such as this can provide a real-world assessment of the impact of palliative care intervention as well as provide areas for growth. A systematic review of the literature on the effectiveness of community-based palliative care programs showed improved outcomes among patients receiving palliative care.[52] Sixty-one studies were included in the review, with half from the United States or Canada and only three from lower-income countries. Hospital utilization was consistently lower in palliative care patients compared with the general population. Patients cared for in a palliative care program also generally have a lower length of stay when admitted to the hospital, and most, but not all, studies reported a decrease in ED visits. Similarly, most studies showed a decrease in healthcare costs for patients enrolled in palliative care programs. The authors note that further research is needed to understand the reasons for mixed results across several metrics. This systematic review emphasizes the importance of creating standard benchmarks for quality and effectiveness in palliative care. Establishing an initial baseline with such metrics and then evaluating the impact of early palliative care can provide tangible improvements in clinical outcomes.

Another study recently synthesized evolving evidence that guides the care of patients with malignant bowel obstruction.[50] Clinical epidemiology and quality outcomes show high rates of perioperative morbidity and mortality for patients who undergo palliative surgery, and improved population-based outcomes in patients who are managed with medical and palliative support. Early identification of patients at risk can be aided by easily available information.[53] The use of intensive at-home palliative care is associated with reduced hospitalizations and days at home, equated with "good days."

These studies support the importance of quality metrics to assess the impact of palliative and supportive care. PROs offer another underutilized avenue for assessing the quality and impact of palliative care interventions among patients with advanced cancer. Patients who are unsheltered or who have insufficient support in the home may need to utilize inpatient palliative care services to achieve similar outcomes.

KEY POINTS

- Oncologists provide primary palliative care—the common and foundational services promoting QoL among patients and families facing cancer—and should refer those with advanced cancer, high-risk hematological malignancies, patients enrolled on phase 1/2 clinical trials, or significant symptom burden to specialists who provide secondary and tertiary palliative care via interdisciplinary teams with specialty training.
- Randomized trials have shown that, compared with primary palliative care provided by oncologists, early integrated specialist palliative care improves QoL, symptom intensity, patient and caregiver satisfaction, mood, illness understanding, quality of end-of-life care, and survival.
- ASCO has released an updated formal guideline recommending that oncology clinicians refer patients with advanced solid tumors and hematological malignancies to specialized interdisciplinary palliative care teams that provide care alongside active cancer treatment beginning early in the disease course.
- Palliative care consultation is the standard of care for patients with advanced cancer and/or significant symptoms, per ASCO guideline recommendations.
- Palliative care specialists are experts in complex symptom management and communication surrounding serious illness.
- Barriers to early palliative care exist but can be addressed through education of oncologists, close collaboration between oncology and palliative care teams, and systems-based research and quality improvement.[4,5]
- APNs play an important role in delivering primary palliative care.[13,21,30,47-49,52,54]

- Stepped palliative care models and virtual palliative care have been demonstrated as being equivalent to routine in-person palliative care follow-up and hold promise for improving palliative care access while reducing resources.
- There is a need for standard metrics for measuring the effectiveness of palliative care programs to identify key interventions.

PALLIATIVE CARE COMMUNICATION IN ONCOLOGY

PROGNOSTIC AWARENESS AND COMMUNICATION

Prognostic awareness is an essential component of informed medical decision-making in oncology and is associated with higher-quality end-of-life care.[55-57] As such, it is critically important for clinicians to routinely assess prognostic understanding throughout the illness course, honestly and empathically convey accurate prognostic information to patients and families, particularly during illness transitions, elicit patient goals and values in the context of this prognosis, and provide clear goal-concordant recommendations.[58]

Many patients with advanced cancer have a poor understanding of their prognosis, estimated survival, or intent of cancer-directed treatment.[59-61] Patients' caregivers similarly often have poor prognostic understanding; in one study of 390 caregivers of adults with incurable cancer, more than half of caregivers had misperceptions about the patients' likelihood of cure, and one-third of patient-caregiver dyads had discordant perceptions.[62]

Relatedly, in a cross-sectional analysis of 236 patients and 38 oncologists, 68% of patients had discordant expectations from their oncologist regarding survival, and only 11% of these patients were aware that their expectations differed from those of their oncologist.[63] Similarly, a secondary analysis of a cluster randomized trial involving patients with incurable solid tumor malignancy or lymphoma and their oncologists found that 60% of patient-oncologist dyads were discordant with respect to cancer curability, and 72% of dyads were discordant with respect to life expectancy estimates.[55,64] Studies show that prognostic misunderstanding is common among patients with hematological malignancies as well.[65,66]

Discussing the intent and potential benefits of cancer-directed therapies should be considered an integral component of the informed consent process, alongside the usual conversations about the risk and potential adverse effects of antineoplastic therapy. In the era of immunotherapies, prognostication is increasingly challenging; although exceptional responders to such therapies remain the exception rather than the rule, robust responses are common enough to raise more uncertainty in discussions about the future with patients who previously would have been said to have clearly incurable metastatic disease with a life expectancy of weeks to months.

Even when accurate prognostic estimates are communicated, patients' interpretations of this information may be affected by the manner in which the information is communicated. For example, a recent study found that the interpretation of estimated survival (25% at 3 years vs 10% at 5 years) was affected more by the chosen timeframe than by the survival probability.[67] Similarly, prognostic estimates that are framed using positive language (eg, survival) are often interpreted differently from the same information framed using negative language (eg, mortality).[68] Furthermore, patients may not believe that the prognosis communicated by their oncologist applies to them because they perceive intrinsic characteristics (eg, fighting spirit or will to live) or faith as having the potential to affect clinical outcomes.[69,70]

Studies show that a vast majority of patients with cancer want to talk about prognosis. Patients desire an honest prognostic disclosure from their oncologist, without sugar-coating. Contrary to oncologists' traditionally held fears, prognostic awareness is not associated with negative outcomes, including sadness, anxiety, or worse patient-physician relationship ratings.[71,72] Rather, prognostic disclosure is associated with maintained hope and increased trust in the oncologist.[73,74] In the setting of serious illness, physicians can help patients redefine hope and establish achievable goals, such as alleviation of distress, improved pain control, and meaningful interactions with loved ones. The challenge is to deliver difficult news with compassion, support, and empathy.[75]

COMMUNICATION PRACTICES AND TECHNIQUES

Serious illness conversations are a critical, challenging, and rewarding aspect of caring for patients with cancer. Communication skills are like physical examination skills in that they can be taught but must be practiced and honed over time. Several educational platforms are successful in improving communication skills in a variety of settings.[76-83] Effective communication in serious illness care should begin not with cancer-related information, but rather with patient-related attributes, including the following:

- Assessment of the patient's capacity for decision-making or need for a surrogate medical decision-maker
- Clarification of the patient's information and communication preferences
- Evaluation of the patient's and family's prognostic awareness
- Discussion of the patient's core values, goals, and priorities that inform medical decision-making, often summarized as "shared goals of care."

This approach emphasizes asking permission before embarking on a difficult discussion or addressing an important topic, an important step in building respect, anchoring rapport, and maintaining open, honest communication. One might conceptualize

this approach as establishing an effective team. It should initiate an ongoing process of clear and consistent discussion with the patient and family regarding treatment, changes in clinical status, prognosis, EOL, and patient and family needs, Timely discussions during disease transitions are associated with less use of acute care and ICU care at the EOL and greater use of hospice, further reinforcing the role of these conversations in optimizing appropriate, patient-centered, advanced cancer care.

A formal ASCO patient-clinician communication guideline[84] outlines best practices for communication in cancer care, including the following:

- Participate in communication skills training programs
- Hold regular discussions of goals of care with patients and their caregivers/families, at the time of diagnosis and at decision points, including a change in clinical status
- Partner with patients actively in their care
- Initiate conversations about goals, values, and end-of-life preferences early in serious illness and often thereafter
- Discuss costs of care
- Discuss with patients all options for their care, including the early initiation of concurrent palliative care
- Endorse the value of and refer patients and families to psychosocial team members (eg, social workers, counselors, psychologists, psychiatrists, and clergy) when appropriate

Figure 9-1 outlines key steps in communicating prognostic information.[85]

Recommended frameworks for communicating difficult news are described elsewhere.[75,84,86] Whenever possible, difficult news should be communicated in a private setting free from distractions, and the oncologist should be seated. Before communicating new clinical information, it is important to first explore the patient's and family's current understanding. Information should be communicated clearly and succinctly, with frequent pauses to listen for and verify understanding, and allow for questions. The use of silence also allows the patient and family to reflect upon and process the new information. Throughout the conversation, the clinician should respond to emotional cues with empathic statements and nonverbal affective communication. At the end of the discussion, the clinician should confirm that the patient and family have a sound understanding, for example, by asking them to summarize the information in their own words. This approach is often termed ask-tell-ask and is rooted in research and teaching about high-quality communication in serious illness care. Finally, next steps should be established, covering what the patient and family will do, what the physician will do, and when the next contact will occur.

CULTURAL HUMILITY ENHANCES COMMUNICATION AND OUTCOMES

Cultural humility is a lifelong process of self-reflection to identify and examine biases. By contrast, cultural competency is the ability to interact with individuals with different belief systems. Clinicians should consider that patients and families hold different views about who should participate in serious illness conversations, what information should be included, the appropriate setting, and who should convey the information. Cross-cultural reviews have helped expand the literature related to communication and are particularly relevant to clinicians treating diverse populations.[87] Cultural norms with respect to medical

decision-making, prognostic disclosure, and withholding of information may affect communication preferences. Taking the time to explain and discuss the communication plan with the patient and family before delivering serious news can help clinicians navigate these potentially challenging conversations. By remaining curious and avoiding assumptions, clinicians can build trust by supporting each patient's specific communication preferences and needs. When a language barrier exists, professional medical interpreters should be used to communicate with the patient and family.

EQUITABLE ACCESS TO PALLIATIVE CARE

Disparities in access to oncology care and cancer outcomes have been well documented.[88-90] There is also an emerging body of evidence showing that there are differences in access to palliative care for underrepresented patients with cancer.[91,92] Disparities in symptom management, including access to medications and symptom relief, exist among non-White/Hispanic patients compared with their White counterparts.[93,94] Improved understanding of patient-level, clinician-level, and structural barriers to the equitable dissemination of palliative care for patients with cancer, coupled with active efforts to address these inequities, is critical. Telemedicine may present an avenue to close the gap in access to specialty palliative care services in rural and underserved areas of the United States.[95]

ADVANCE CARE PLANNING—AN IMPORTANT CHALLENGE IN PALLIATIVE CARE COMMUNICATION

Advance care planning is a process whereby individuals consider their wishes for future care and end-of-life treatment preferences and make them known to loved ones and healthcare professionals in the event of decisional incapacity. Introducing advanced care planning can be a helpful starting point for conversations with patients with advanced and potentially life-limiting diseases. Normalization of the process, that is, routinely raising the issue, can reduce anxiety and negative reactions. Advance care planning should be done in advance—hence the term—and revisited along the clinical trajectory. Documented components of advance care planning may include advance directives for healthcare, healthcare proxies or powers of attorney for healthcare documents, living wills, do-not-resuscitate orders, and forms that communicate a patient's treatment preferences. These documents vary by state in accordance with local policy.

An advance directive is a legal document representing a person's preferences regarding their medical care and appointed durable power of attorney for healthcare. The percentage of individuals with a completed advance directive remains low, even in the setting of serious illness, such as advanced cancer. There are online advance care planning tools available that are effective at increasing rates of advance directive completion by 25% to 35% and are easily completed via free online resources, such as the PREPARE website.[96,97]

There are ICD-10 codes for documented palliative care discussions, for example, Z51.5 and current procedural terminology (CPT) codes for advanced care planning. Documentation of palliative care needs and planning is a quality-of-care outcome. Such documentation by any member of the care team elevates the appropriate referral to hospice at key transitions in illness.

KEY POINTS

- Although often equated with estimated survival, prognosis can refer to a variety of consequences of the disease and its treatment along a patient's clinical trajectory (eg, cognitive decline, functional status, symptom burden).
- Although most patients with advanced cancer desire prognostic disclosure from their oncologists, many patients have a poor understanding of their prognosis, estimated survival, or intent of cancer-directed treatment.
- The ASCO communication guideline outlines principles of good communication in cancer care, including assessment and discussion of prognosis, elicitation of preferences and values, and discussion about the role of early integrated palliative care.
- Coordinated efforts are needed to effectively address disparities in access to specialty palliative care.

PSYCHOLOGICAL DISTRESS, DEPRESSION, SPIRITUAL SUFFERING, AND CAREGIVER DISTRESS

IDENTIFYING AND ADDRESSING PATIENT DISTRESS

Distress is defined as a multifactorial, unpleasant experience of a psychological, social, spiritual, and/or physical nature that may interfere with the ability to cope effectively with cancer, its symptoms, and its treatment.[98] All patients with cancer have some degree of distress related to the cancer diagnosis, its associated symptoms, and its treatment, regardless of the stage of disease. It is estimated that more than 50% of patients with cancer have high levels of psychological distress.[99] Risk factors for distress in patients with cancer include cognitive impairment, communication barriers (eg, language, literacy), history of psychiatric disorder, history of substance use disorder, history of depression or suicidality, psychosocial issues (eg, family conflict, young or dependent children, limited social support, living alone), financial concerns, and uncontrolled symptoms. In addition to leading to poorer QoL, distress is a risk factor for nonadherence to cancer treatment and surveillance and is associated with

increased emergency room visits and longer hospital stays.[98,100] Despite the high prevalence of distress in patients with cancer, it can be difficult to detect or diagnose. Many patients do not tell their oncologist about their distress, and oncologists often do not ask about distress during outpatient visits due to competing priorities and time limitations. Routine screening for distress is therefore important and has been required as an accreditation standard for hospital cancer programs since 2015 (https://www.facs.org/quality-programs/cancer/coc/standards). In Canada, distress screening has been endorsed as the sixth vital sign.[101]

NCCN guidelines recommend routine screening for distress, while ASCO guidelines recommend routine screening specifically for symptoms of depression and anxiety.[98,100] At a minimum, patients should be screened at the initial visit, at appropriate intervals, and as clinically indicated, especially with changes in disease status (eg, remission, recurrence, or progression). Distress can be identified using a simple screening tool, such as the NCCN Distress Thermometer, which asks patients to rate their distress on a 0-to-10 visual scale, from "no distress" (0) to "extreme distress" (10). Although the Distress Thermometer is not a screening tool for psychiatric disorders, it has concordance with the Hospital Anxiety and Depression Scale and the Depression Anxiety and Stress Scale.[98] NCCN also recommends using a 39-item Problem List, which is on the same page as the Distress Thermometer[98]; both are freely available for noncommercial use. The Problem List asks patients to identify their problems in five distinct categories: practical, family, emotional, spiritual/religious, and physical. Problem-based interventions are a validated approach to the reduction of distress in a patient—family-focused strategy. The NCCN patient website includes a patient-friendly description of distress with a copy of the Distress Thermometer.[102]

Moderate to severe distress (Distress Thermometer score of 4 or higher) should prompt referral to a mental health professional, social worker, spiritual counselor, or palliative care team, depending on the problems identified in the Problem List. Such elevated distress scores are not diagnostic but should trigger further evaluation with validated measures for depression and/or anxiety.

Alternatively, screening can occur directly with measures for depression or anxiety. Screening should be done using validated measures that have established cut-offs to ensure that they are clinically meaningful. The Patient Health Questionnaire-9 for depression (cut-off score of 8 or higher for moderate to severe depression) and the Generalized Anxiety Disorder-7 (cut-off score of 10 or higher for moderate to severe anxiety) are in the public domain and recommended for this purpose, but many other validated measures are available.

Studies demonstrate that medical encounters are shorter when the physician explicitly acknowledges the patient's emotions.[103] In addition, emerging data that demonstrate the beneficial effects of specialty-level palliative care suggest this benefit is at least in part mediated through improved coping, a critical skill that oncology clinicians can incorporate into everyday practice.[104] Problem-based assessment and interventions can reduce distress, improve coping, and can be initiated by the primary team, including the oncologist.

DEPRESSION AND ANXIETY

Depression and anxiety are common in patients with cancer, and often co-occur.[105] Using self-reported measures with specific cut-off points, 13% to 27% of patients with cancer have moderate to severe depressive symptoms, with variability depending on cancer diagnosis; prevalence using self-report instruments with specific cut-offs is 4% to 48%, while, in diagnostic interviews, the prevalence is approximately 10%.[106] In one study, 31% of patients with cancer with an anxiety disorder also had major depressive disorder.[107]

ASCO guidelines state that all patients with cancer and their family caregivers should be offered information regarding depression and anxiety, as well as available resources for further evaluation and treatment, within or external to the hospital.[105] All patients with cancer should be re-evaluated for depression and anxiety throughout their course of illness, and both integrative and pharmacological interventions should be implemented when appropriate.[108]

Clinicians should use a stepped-care model, that is, selecting the most effective and least resource-intensive intervention based on symptom severity.

- For patients with mild depression or anxiety, referral to available support services should be offered.
- Patients with moderate to severe depression or anxiety should be offered culturally informed and linguistically appropriate information such as their prevalence among patients with cancer, common associated symptoms, signs of worsening, and indications to call the treatment team. In addition, those with moderate depression or anxiety should be offered individual or group therapy with evidence-based psychosocial interventions (eg, cognitive behavioral therapy, behavioral activation, structured physical activity and exercise, or mindfulness-based stress reduction).
- For a patient with severe symptoms of depression or anxiety, clinicians should offer individual psychotherapy with evidence-based psychosocial interventions (eg, cognitive behavioral therapy, behavioral activation, mindfulness-based stress reduction, or interpersonal therapy). Pharmacological treatment may be offered for those expressing a preference for pharmacotherapy, or those who do not improve following first-line psychological or behavioral management. Pharmacotherapy should also be considered for patients with a history of treatment response to medications, severe symptoms, or depression with accompanying psychotic features.

Differentiating between grief and depression in patients with serious illness can be difficult, even for experienced clinicians.[108] Patients with depression experience sadness, hopelessness, and anhedonia sustained over a period longer than 2 weeks, often accompanied by physical symptoms of decreased appetite and energy. By contrast, patients with normal grief reactions experience improvement in symptoms over time, can maintain a realistic view of themselves, and can modify their healthcare goals to maintain hope. Complicated grief lasts longer than 6 months and impacts normal function, whereas anticipatory grief can affect both the patient and their loved ones as they prepare for the patient's death.

Diagnosing depression in patients with serious illness is of paramount importance. Studies show that untreated depression results in an increase in morbidity and sequelae, including suicide. Depression, as well as hopelessness, loss of meaning in life, and loss of interest in activities, ranks among the risk factors for the desire to hasten death. Patients whose psychosocial needs are acknowledged as less likely to persist in their desire for death. When a patient expresses a desire to hasten death, requests should be addressed explicitly and should prompt a reassessment of symptom control, psychosocial issues such as relationship strain or fear of caregiver burden, spiritual or existential suffering, and psychological issues such as depression. The care plan should be clarified, with renewed attention to how best to relieve physical, psychological, interpersonal, and spiritual suffering. A detailed discussion of Medical Aid in Dying is beyond the scope of this chapter.

Referral should be made to an appropriate clinician, ideally a palliative care expert, psychiatrist, or psychologist with expertise in the management of psychological disorders who can tailor care to the stage of illness. Pharmacological therapies should be considered in the context of a patient's comorbidities and prognosis. For example, a serotonin-norepinephrine reuptake inhibitor may be used to treat depression and chemotherapy-induced peripheral neuropathy, whereas olanzapine may be used to manage both anxiety and chemotherapy-related nausea and vomiting. Notably, for a patient who has a limited life expectancy, selective serotonin reuptake inhibitors may not exert an effect quickly enough; psychostimulants, such as methylphenidate, may offer a more realistic treatment strategy in this setting.

SPIRITUAL OR EXISTENTIAL SUFFERING

Most patients have a spiritual or religious belief system that is important to them and their family, and is an important resource for effective coping with cancer. Attention to a patient's spiritual and existential needs is an essential component of high-quality palliative care and underscores why palliative care teams include chaplaincy members. Up to 50% of patients with cancer and 25% of long-term survivors experience spiritual distress.[109] Existential suffering may arise through questions that include "Why me?," "Why now?," "How did this happen?," "What is the meaning of life?," "Why am I here?," "What have I achieved in my life?," "How do I fit into the universe?," and "What will happen to 'me' after my death?" The spiritual belief systems of all parties concerned, as well as their personal belief systems regarding our spiritual nature, will influence how they react to these broad existential questions. Of note, spirituality and religion are different, and everyone's experience is unique. Although eliciting information about a patient's belief system (eg, religious affiliation) may help oncologists gain understanding of the patient's religious or spiritual framework, it does not determine the interpretations or beliefs that apply. In addition, a patient need not adhere to any system of belief to experience or successfully resolve existential or spiritual issues.

Experiencing a serious illness and confronting mortality can manifest in a variety of emotions, such as anger, fear, or powerlessness. At times, these feelings can be directed toward clinical staff or toward family members. Although physicians typically are not trained to provide spiritual care, patients and families often assume clinicians will be able to adequately introduce and discuss these issues. To help structure an approach to the assessment and care of patients, the NCCN recommends screening for psychosocial distress, including spiritual/existential distress, in all patients with cancer via the NCCN Distress Thermometer and Problem List.[110] Alternatively, semi-structured interviews for spiritual assessment can be used. Common screening questions include the following[111]:

- "Do you have spiritual or religious beliefs?"
- "Have your beliefs been affected by your cancer diagnosis, and if so, how?"
- "Have your spiritual beliefs influenced your healthcare decisions, and if so, how?"

For patients who are experiencing spiritual distress, a more complex tool, such as FICA (Faith, Importance, Community, Address), can guide a comprehensive spiritual assessment by a chaplain or spiritual care provider.[112]

Cancer care at the EOL, perhaps more than in any other phase of the illness, involves multidisciplinary efforts. During spiritual conversations with patients, clinicians should seek to understand the depths and nuances of the patient's orientation toward this potentially complex area of life. This understanding will assist clinicians in identifying needs that other professionals (eg, chaplains, psychotherapists) should address; the oncologist's responsibility is to guide the delivery of compassionate care and incorporate insights about the patient's spiritual or existential status into clinical decisions to best treat the patient as a whole person.

CAREGIVER/FAMILY DISTRESS

Family caregivers are partners, relatives, or friends who provide care that requires substantial time over months to years and involves performing a wide range of physically, socially, emotionally, or financially demanding tasks.[113] Studies show that 32% to 70% of family caregivers of patients with advanced cancer experience a level of distress or depressive symptoms high enough to suggest clinical depression.[114-116] Caregivers often feel unprepared for the various commitments (eg, financial, emotional, physical) that are involved in caring for a loved one.[117] Furthermore, many caregivers lack the medical knowledge and skills necessary to anticipate the needs of the patient. Because of the multiple demands of caregiving, family members often are forced to leave their jobs or work part-time, which adds financial stress at a time that is already emotionally challenging. Moreover, by attending to the needs of their loved ones, caregivers may neglect their own physical or mental health.

Certain characteristics of caregivers are associated with the negative effects of caregiving. These include caregiver age, ethnicity, sex, socioeconomic status, and health and functional status. Younger, non-White, female, and less affluent individuals tend to experience greater negative effects, such as distress or depressive symptoms. Other factors associated with negative effects include the duration and intensity of caregiving, the mood and physical health of the caregiver, a recurrence of the patient's illness, and the caregiver's subjective sense of burden.[113]

Interventions to support caregivers can be categorized into those that target caregivers themselves, those targeting caregiver-patient dyads, and those targeting mainly patients (the latter are mostly palliative care interventions). In a recent meta-analysis, these interventions all led to improvements in QoL, mental well-being, depression, and anxiety.[118] A growing body of evidence suggests that integrated palliative care can yield significant, often underrecognized, benefits in caregiver well-being, particularly regarding mood.[119,120] Care for caregivers in oncology settings can be improved through the CARES framework: Considering caregivers as part of the unit of care; Assessing the caregiver's situation and needs; Referring to appropriate services and resources; Educating about practical aspects of caregiving; and Supporting caregivers through bereavement.[113]

In offering high-quality primary palliative and supportive care, the clinician exerts a powerful therapeutic effect simply by being present. By being available, communicating openly about difficult topics, and addressing symptoms that are causing distress, the physician can provide significant support. Caregivers particularly value the support and respect of clinicians; those who report that physicians listen to their opinions and concerns are less likely to report depressive symptoms. Good communication, which includes anticipatory guidance and clear explanations of what to expect, is an essential therapeutic tool. By providing appropriate referrals to assistance agencies, such as hospice, physicians can greatly support family members. In all cases, effective communication, listening, and availability contribute substantially to alleviating suffering at the EOL.

KEY POINTS

- Most patients who are dying experience psychological distress. Physicians must be prepared to address this via medical and psychosocial support and to encourage patients and families to leverage the expertise of other members of the interdisciplinary oncology team (eg, social work, behavioral health, etc.).
- Oncology practices should systematically screen for psychological and spiritual distress using available validated tools. Patients with moderate to severe distress should be referred to a specialist, while mild distress may be managed by the primary oncology team.
- ASCO guidelines state that all patients with cancer and their family caregivers should be offered information regarding depression and anxiety, as well as internal or external resources for evaluation and treatment.
- Differentiating between illness-related grief and depression is important. Depression is characterized by a persistent set of emotional symptoms, worthlessness, hopelessness, and anhedonia. Identifying and treating depression and its sequelae are essential for reducing end-of-life morbidity as well as the desire for hastened death.
- Caregiver distress is common and can be reduced with simple interventions.

HOSPICE CARE

Hospice is one of the most effective yet underused resources for patients, families, and clinicians as patients with advanced cancer approach the EOL, although use in the United States is increasing annually. Data consistently demonstrate the benefits of hospice for patients and caregivers, including effects on symptom relief and patient goal attainment. In addition, hospice increases quality of care near the EOL, reduces overall healthcare costs, and can directly improve outcomes. Despite the existence and availability of hospice across most of the United States for approximately 35 years, referrals to hospice are underutilized for patients near the EOL, and, when referrals are made, they are often late. In one study, patients spent a median of 10 days in hospice, and 71% (n = 161) of patients were in hospice 30 days or less.[121] Data from the National Hospice and Palliative Care Organization (NHPCO) reveal that 50% of patients were enrolled for 18 days or less, and the median length of stay has been 2.5 to 3 weeks for the last few decades.[122]

Late referrals to hospice stem from both patient factors, oncologist factors, and system barriers. A study of patients with advanced lung cancer revealed that only 53% of patients had discussed hospice with their oncologists 4 to 7 months after

diagnosis; predictors of not having the discussion included patients having overly optimistic assessments of prognosis and lacking moderate to severe pain or dyspnea.[123] In other words, patients with poor understanding of prognosis who feel well often do not bring up hospice with their oncologists, and, likewise, the topic is not broached by their care team, ultimately leading to delayed referrals.

HOSPICE ELIGIBILITY

The key difference between palliative care and hospice care for patients living with cancer is that palliative care can be given concurrently with disease-directed therapy, whereas hospice care typically entails stopping cancer-directed care.

Patients with cancer are eligible for the Medicare hospice benefit if they are determined by a physician to have a terminal diagnosis wherein the average life expectancy is less than 6 months if the disease runs its usual course. The latter part of this statement is important because the usual course of any disease is variable. The patterns of hospice referral noted above dispel any concerns about premature referral to hospice. In addition, given the inherent uncertainty in prognostication, patients may receive hospice services for longer than 6 months if there is clear documentation of the expected trajectory of illness and decline. Of note, hospice enrollment also generally entails the cessation of disease-modifying treatments aimed at extending life, in exchange for a focus on comfort, patient-focused goals equivalent to QoL, and, most often, death at home.[124,125] Regulatory barriers exist for patients who wish to receive hospice care and also participate in early-phase clinical research, or for patients with hematological malignancies who are transfusion-dependent. Encouragingly, Medicare and healthcare delivery systems are increasingly testing models to improve hospice use via concurrent care, offering opportunities to better meet the needs of people living with serious illness and their families.[125]

Up to 90% of hospice participants elect to use the Medicare hospice benefit, an earned benefit as part of Medicare Part A, to pay for hospice services, including pharmacy costs, nurse and social work support, coordination of care, and more. Patients who use their Part A benefit for other purposes, such as acute hospitalization or active rehabilitation within a skilled nursing facility, cannot simultaneously be enrolled in hospice. This leads to quandaries when patients are seeking an approach focused on comfort care near the EOL, but are reliant on 24-hour caregiving services or are interested in the intensive physical rehabilitation provided in skilled nursing facilities.

There remains a common misperception regarding the need for patients to have a do-not-attempt-resuscitation order in place before referral to hospice. In fact, there is no stipulation for this to participate in residential hospice under Medicare, although some hospice care agencies may strongly discourage enrollment of patients without a do-not-attempt-resuscitation order. In fact, the coercion of patients into a particular resuscitation status can lead to significant penalties for individual clinicians and their organizations and can threaten the therapeutic bond between the patient and the clinician. That said, performing cardiopulmonary resuscitation on a patient with terminal disease is highly ineffective[126] and largely incompatible with the philosophy of hospice care and high-quality cancer care, both of which aim at the promotion and maintenance of comfort and QoL rather than treatment of disease. As such, it is critical to understand, to respectfully explore, and to reexamine the issue at intervals, the rationale for maintaining a full-code status in a patient who elects to receive hospice care, to ensure that the patient and family do not harbor significant misconceptions or unrealistic expectations about the likely outcome.

HOSPICE CARE PROVISION

There are more than 6,000 hospices in operation in the United States, covering all 50 states and most territories. Most are independent and free-standing agencies not restricted to serving patients of any particular nursing home, hospital, or home health agency. Hospices are required to provide six foundational services to participate in the Medicare hospice benefit, including a physician medical director, nursing services, social work services, spiritual support, bereavement support, and volunteers. These services are provided along the spectrum of hospice care, often beginning with a comprehensive assessment of needs during the admission process, with frequent reevaluations of needs along the trajectory of care. Integral to this care is the role of the oncology team, whose members are considered partners in the patient's care. As an example of this, with the right billing and coding approach, oncology practices can still be paid for seeing patients in the clinic who are also receiving hospice care, truly reflecting a concurrent care approach. Often, the primary oncologist serves as the hospice physician of record as well, recognizing that many oncologists view care at the EOL as an important aspect of the primary palliative care that they provide to their patients with cancer.

Many patients with cancer hold an incorrect understanding of hospice as a place to go (ie, a physical destination) instead of a type of care optimized to patient and family needs near the EOL. However, recent data from the NHPCO highlight that more than 90% of hospice care is provided at home or in long-term care facilities in which patients reside.

LEVELS OF HOSPICE CARE

Hospice is generally provided within one of four levels of care: routine home care, continuous home care, general inpatient care, and inpatient respite care. As mentioned, most patients receive routine home care, remaining in their usual place of residence with a focus on preventing crises and being in familiar surroundings. Within continuous home care, the hospice team comes

to the residence to provide crisis-directed care, make the patient comfortable, and avoid visits to the ED or hospital. General inpatient care is used when acute symptom crises, often in the last few weeks of life, cannot be managed at home and require admission to a dedicated inpatient hospice facility or through contracted beds in an acute care hospital. This care is focused on acute symptom management with transition back home once symptoms can be managed outside the acute inpatient setting. Last, inpatient respite care is a time-limited admission to an approved facility to allow caregivers some time away and rest from continuous caregiving.

KEY POINTS

- Hospice care is the best mechanism for providing high-quality care near the EOL in the United States and greatly enhances the ability of patients to die at home in comfort, surrounded by family and friends.
- Patients with an expected prognosis of 6 months or less are eligible for hospice.
- More than 90% of hospice care is provided at home or in long-term care facilities in which patients reside.

PRESENTING CASE STUDY

A 48-year-old man is admitted to the hospital for failure to thrive with wild-type *KRAS/NRAS/BRAF*, nonamplified HER2, microsatellite-stable metastatic rectal adenocarcinoma diagnosed 2 years ago. He previously received treatment with 5-fluorouracil, oxaliplatin, irinotecan, bevacizumab, and panitumumab and ultimately progressed. He achieved stable disease with trifluridine and tipiracil hydrochloride (TAS-102), but, after 6 months, repeat imaging indicates progressive disease in his lungs, liver, and peritoneum. Next-generation sequencing does not reveal any actionable mutations. The patient's Eastern Cooperative Oncology Group (ECOG) performance status is 3. He spends most of his time in a chair but is able to walk to the bathroom using a walker, attributing his decreased mobility to fatigue. Liver function tests are two times the upper reference limit, aside from his bilirubin level, which is within the reference range. The patient remains treatment-focused, hoping to gain enough strength to be considered for additional treatment options.

With this patient's advanced, refractory cancer and poor performance status, what treatment approach would you recommend, balancing his wishes with his limited potential for benefit?

The patient's functional status is compromised. While additional treatment options such as regorafenib are available in the United States, Canada, and the European Union, this patient's ECOG status suggests poor tolerance, with studies demonstrating an improvement in mean overall survival of 1.4 months. At this point in the patient's disease course, it is reasonable to discuss alternative options, including best supportive care and hospice. This discussion should include other members of his care team so that the patient's motivation to be considered for treatment can be explored. Most patients will express concerns not directly linked to longevity for example, family concerns, unresolved conflict, financial issues, etc. Despite the longstanding existence and availability of hospice care across most of the United States, hospice referrals are underutilized for patients near the end of life, and, when referrals are made, they are often late. In one study, for example, patients spent a median of 10 days in hospice, and 71% were in hospice for 30 days or less.[121] Data from the NHPCO reveal that approximately 50% of patients are enrolled for 18 days or less, with a median length of stay of 2.5 to 3 weeks.[122]

Late hospice referrals stem from factors related to the patient, their oncologist, and regulatory barriers restricting concurrent hospice care and early-phase clinical research. Initiating a discussion about best supportive care and hospice would allow this patient and his family to consider their options and weigh the risks and benefits of all approaches.

MANAGEMENT OF THE LAST DAYS OF LIFE

SIGNS AND SYMPTOMS OF THE ACTIVE DYING PROCESS

Clinicians should recognize the process of dying as a part of the trajectory of advanced malignancies and sharpen the focus of goals of care to intensive symptom management and family support. The dying process generally manifests in the continued deterioration of a person's overall condition, with increasing lethargy, progressive asthenia, decreasing levels of consciousness, and, at times, increasing confusion, increasing time asleep, less spontaneous movement, decreased urinary output, inability to regulate body temperature, and changes in patterns of respiratory effort (eg, Cheyne-Stokes breathing). For many people, systemic signs

can include progressive hypotension, diminishing oxygenation, and progressive loss of peripheral perfusion, causing mottling of the skin. A large multicenter study determined that 3-day mortality can be predicted in patients with a Palliative Performance Scale (PPS) value of 20 or lower (ie, bedbound, completely dependent) by a simple diagnostic model with three easily evaluable clinical signs (P3did-DT): decreased urine output, decreased response to verbal stimuli, and decreased consciousness.[127]

In contrast to the usual slow decline described above, the terminal phase of cancer may sometimes be signaled by a sudden change in condition: intracerebral bleeding, pulmonary embolus, perforated viscus, or overwhelming sepsis. When this change is superimposed on an already moribund condition, continued symptom control becomes the primary goal. Understanding patients' wishes, often through conversations they have had with their families throughout the course of their illness or life, will help determine the best course of action. Catastrophic decline can be effectively managed with a palliative care team in place, a continued focus on effective communication and symptom goals of care, and well-described patient wishes expressed by a designated caregiver. In this situation, most patients will remain at home or out of the ICU.

Whether the EOL approaches as an expected deterioration or as an unexpected catastrophic decline, the issue of comfort is paramount. Clinicians should ensure that all clinical actions contribute to the comfort of the person who is dying. Given the unfamiliarity of caregivers with the signs and symptoms of the dying process, it is critical to share information and educate them to minimize fear and anxiety. Frequently, hospice programs will have an informational brochure or handout that can be shared with loved ones who are interested. Caregivers can be supported by underscoring that successful care is defining goals of care, and, in this situation, goals of care are focused on comfort and relief of suffering.

BEDSIDE CARE AT THE EOL

Attention to the bedside care of the dying patient is crucial. Regular checking of vital signs should be replaced, at this stage, with regular checking of symptoms. Good bedside care includes the following:

- Mouth care, to ensure that the dying person's mouth is clean and moist, will aid comfort.
- Eyes can also become dry and painful and may require additional supportive measures, such as eye lubricants and/or drops.
- Proper skin care includes regular repositioning of the patient to relieve musculoskeletal pain from inertia and avoid the excruciating (and difficult to control) pain of skin tears and pressure sores. Use of a pressure-relieving mattress is advised. An air mattress will facilitate the shifting of the person's weight.
- The head of the bed can be elevated, or patients can be gently repositioned, to help reduce noisy upper respiratory tract secretions through postural drainage.
- Urinary retention and fecal impaction should be evaluated and treated if present.

TERMINAL SECRETIONS

Noisy ventilation (often referred to as death rattle or terminal secretions), caused by oscillatory movements of accumulated bronchial mucosa and salivary secretions, is common among patients who are dying and are unable to clear secretions by coughing or swallowing.[128] The symptom usually occurs after patients are unconscious, and it may cause considerable distress to families and caregivers. The reported prevalence varies between 12% and 80% in the final 3 days of life.[129]

Intervention to reduce secretions is often instituted to alleviate the distress of attendant family members, even when the patient seems settled. The primary intervention should be to explain the source of this sound to the patient's family or other caregiver(s), with reassurance that it is not associated with any discomfort. Standard nonpharmacological practices for alleviating terminal secretions should be initiated first. These include gentle positioning (reverse Trendelenburg or lateral decubitus), towels placed appropriately to absorb secretions, and reducing parenteral and enteral fluids.

Anticholinergic agents are often used to reduce sputum volume and salivary secretions and alleviate the noise, despite a lack of strong evidence to support their efficacy.[130] These drugs include scopolamine, hyoscyamine, glycopyrrolate, and atropine. The primary difference in these drugs is whether they are tertiary amines that cross the blood-brain barrier (eg, scopolamine, atropine) or quaternary amines, which are less likely to do so (eg, hyoscyamine, glycopyrrolate). However, all these drugs have the potential for central and peripheral anticholinergic adverse effects, including sedation, confusion, delirium, paradoxical excitation, and urinary retention. These medications are especially high risk in older patients, who should be monitored closely for side effects. Atropine, a widely available drug, is frequently used in home care; a common approach is 1% atropine ophthalmic solution, one to two drops sublingually every 4 hours as needed. Scopolamine (hyoscyamine hydrobromide), a muscarinic receptor antagonist, is given transdermally every 72 hours. Glycopyrrolate or hyoscyamine are preferred due to their lower potential for central anticholinergic effects, though use is limited by cost and poor oral absorption.

Best evidence supports prophylactic administration of scopolamine butylbromide in patients close to death, which reduces the number who develop death rattle (13% vs 27% with placebo[131]). Evidence supporting treatment of the death rattle once it has begun is less clear, with no evidence that one antimuscarinic is clearly superior to another.[132] Discussing terminal secretions

with family members to reduce their distress is the most important intervention; these conversations should address the cause, implications, and caregivers' fears and concerns.

DEPRESCRIBING ANCILLARY INTERVENTIONS INCLUDING MEDICATIONS

As the patient nears the EOL, the clinician should review all medications and continue only those that contribute to increased comfort. Long-term medications aimed at reducing late effects, such as statins for cardiovascular risk reduction (primary prevention), should be discontinued in most cases. Deprescribing medications not aimed at comfort and symptom management can significantly reduce pill burden for patients and caregivers.[133] Implanted defibrillators should be deactivated to prevent painful shocks at EOL, though pacemakers may remain active and do not interfere with natural death. Diagnostic tests and functions (eg, transfusions, needle sticks, measurement of intake and output, blood glucose monitoring, oxygen saturation monitoring, suctioning) can and should be discontinued if deemed unnecessary for symptom control and comfort.

In deciding which medications to discontinue, all medications should be reconsidered for their benefit to the patient, not only those that were introduced for symptom control in the palliative phase of the illness. For example, for type 1 diabetes, insulin is necessary to prevent hyperglycemia to spare the patient unquenchable thirst, and it is common to continue such interventions as comfort measures even at the EOL. Essential medications should be obtained in a form that can be administered to someone who may not able to swallow predictably. Alternative formulations include sublingual, subcutaneous, intravenous, transdermal, intranasal, and rectal. Doses of medications retained for symptom management should be increased as necessary to optimize comfort. It is important to discuss deprescribing as a comfort measure near the EOL and individualize this approach with each patient and family, while carefully considering the balance between adverse reactions and benefits and potential withdrawal risk for each medication.[134]

OTHER INTERVENTIONS

Nutrition and Hydration

As patients are actively dying, any nutritional supplements or parenteral hydration should be reviewed. Almost always, parenteral hydration should be stopped, with appropriate advice to the family, because overhydration will worsen respiratory symptoms, and enteral fluids will potentially cause secretions and distention in the gut that may cause vomiting. At worst, ongoing hydration can even prolong or worsen difficult symptoms during the dying process, thus worsening the patient's and family's discomfort.[135] This requires in-depth conversations with and education of the family and caregivers, emphasizing the natural progression of the anorexia-cachexia syndrome at the EOL. It is important to recognize that stopping nutrition and/or hydration can be an emotionally charged issue for loved ones, which may require time to process and extra support from nonmedical colleagues, such as those in social work and chaplaincy, to address cultural, emotional, and existential sources of distress.

Management of Terminal Delirium

Characterized by a disturbance of consciousness, cognition, and perception, delirium is most highly prevalent in the days and hours immediately preceding before death, with rates reported as high as 88%.[136] It often provokes considerable distress among patients, caregivers, and medical providers who are witnessing the patient's transition toward death.[137] Delirium is generally an indirect result of various factors associated with the patient's underlying cancer, such as adverse treatment effects, metabolic disorders, nutritional deficiencies, or infection. Adverse effects of medications are also a common cause of delirium for patients near the EOL.[138]

Terminal delirium (also known as terminal agitation), delirium that occurs in the setting of the active dying process, requires a different approach from that of hyperactive or hypoactive delirium. The clinician should first ensure that this agitation is not a result of pain, urinary retention, or constipation. There is a paucity of studies in this setting, but benzodiazepines are often used. One study suggested that neuroleptics, such as haloperidol and chlorpromazine, can help reduce refractory agitation.[139] When symptoms are severe, sedation may be required through the use of continuous infusion of a benzodiazepine or barbiturate (midazolam or pentobarbital are most commonly used). Sometimes called palliative sedation, this intervention can be controversial and is associated with significant misconceptions about hastening death.[140]

Communication with the Family and/or Caregivers

Communication with the family or other loved ones involved in the last stages of caregiving should be a key focus for health professionals as a patient nears death. What does the family expect? How well do they understand the patient's condition and the dying process? A trusted clinician should clearly, but compassionately, describe the process of dying. The clinician should emphasize that, at this important phase, the sole focus of care is the dying person's comfort and that current medical practice has multiple strategies to optimize comfort.

Many family members have a strong desire to be present at the time of death. This specific time can be difficult to predict. The need to be present varies from family to family and, within families, from one individual to another. If family members have a particular wish to be present at the patient's time of death, the clinician may recommend a vigil roster to ensure that one member of the family is always present during the patient's last days.

Management of Care for the Unconscious Patient

Even when a patient is unconscious, clinical staff should carefully assess him or her to ensure comfort. Evaluation cannot be done from the door of the patient's room. An examination is required, with special attention to the face (is it relaxed?), respiration (is it regular and unlabored?), and positioning (is the patient positioned comfortably?). Available tools to assess nonverbal signs of pain include the following[141]:

- Behavioral Pain Scale (BPS), Checklist of Nonverbal Pain Indicators (CNPI)
- Critical Care Pain Observation Tool (CPOT)
- Faces, Legs, Activity, Cry, Consolability (FLACC) pain tool
- Multidimensional Observational Pain Assessment Tool (MOPAT)
- Nociception Coma Scale (NCS)
- Nonverbal Pain Scale (NVPS)

The clinician should continue to explain to the patient what is happening in the clinical examination, as if he or she were conscious; it is important for family members to understand that people, even when unconscious, may still recognize their voices and their touch. The clinician should also reassure the family that symptom-control medications will be continued to ensure the patient's comfort even though consciousness has been lost. There is no concern that these medications will hasten death, especially if continued at the same dose.

CARE AFTER DEATH

The clinician's role does not end immediately upon the death of the patient. Follow through with the patient's body, logistic considerations, and attention to family members and other caregivers are the crucial last steps in end-of-life care.

Immediately after the patient's death, the clinician should allow the family to spend time with the body, if they so desire. Treatment of the body should be respectful and culturally sensitive. If not addressed previously, plans for eye donation (allowable in many cases of cancer, except some leukemias and eye malignancies) and autopsy are discussed, addressing any family member or caregiver concerns. The clinician files a death certificate, completes any other required forms, and conveys information to the funeral director as needed. In addition, the clinician should inform the patient's other healthcare providers of the death.

Attention should be directed to family members and other caregivers. The normal bereavement process should be described to them; information regarding available bereavement support should be provided, and referral can be made to appropriate services. If the patient and family were receiving support from a hospice team, bereavement support may be obtained through the same agency. Palliative care clinicians can help the oncologist identify family members who may be at risk for complicated bereavement, and they can follow through with requisite care. Formal expressions of condolence on the patient's death, such as a card, phone call, or brief letter, can be immensely meaningful and supportive to family members and caregivers. Amid busy clinical practices, we sometimes forget to pause for a moment to reflect on the privilege of caring for a patient and their family during the patient's last days. Sharing memories, talking with colleagues and staff about the patient, and reflecting on the experience may be helpful in the prevention of burnout, an issue rising in prevalence among oncologists.

KEY POINTS

- At the EOL, the patient's comfort should be the primary focus. Unconscious patients should be treated with the same degree of care, concern, and communication as conscious patients.
- Physical care should address mouth care and musculoskeletal positioning, with attention given to maintaining skin integrity and comfort.
- Terminal secretions can be addressed with the careful administration of anticholinergic agents, as well as with attentive nursing care, positioning, and, most importantly, education of family caregivers.
- As the patient nears the EOL, all medications, medical interventions, nutritional supplements, and hydration efforts should be reviewed to continue only those that directly contribute to comfort.
- Delirium is frequently a source of great distress for the patient, their loved ones, and the care team. The clinician should screen for and treat any underlying reversible causes. If agitation occurs, clinicians should determine the source, if possible, and address it appropriately. Specialist palliative care consultation is recommended in cases of difficult and/or refractory symptoms.
- The wishes of family members with regard to being present at the time of death and aftercare of the patient's body should be respected and facilitated to the greatest degree possible.

HIGH-YIELD TAKEAWAYS

- Hospice referral is often delayed and/or underutilized at the EOL, stemming from patient, physician, and regulatory factors.
- A "Do-Not-Resuscitate" order is not required for enrollment in hospice.
- Clinicians should routinely assess prognostic understanding, honestly and empathically convey accurate prognostic information to patients and families, elicit patient goals and values in the context of this prognosis, and provide clear goal-concordant recommendations.

PALLIATIVE CARE AND CARE AT THE END OF LIFE

9

CHAPTER SUMMARY GUIDE

KEY POINTS

- Oncologists provide primary palliative care—the common and foundational services promoting QoL among patients and families facing cancer—and should refer those with advanced cancer, high-risk hematological malignancies, patients enrolled on phase 1/2 clinical trials, or significant symptom burden to specialists who provide secondary and tertiary palliative care via interdisciplinary teams with specialty training.
- Randomized trials have shown that, compared with primary palliative care provided by oncologists, early integrated specialist palliative care improves QoL, symptom intensity, patient and caregiver satisfaction, mood, illness understanding, quality of end-of-life care, and survival.
- ASCO has released an updated formal guideline recommending that oncology clinicians refer patients with advanced solid tumors and hematological malignancies to specialized interdisciplinary palliative care teams that provide care alongside active cancer treatment beginning early in the disease course.
- Palliative care consultation is the standard of care for patients with advanced cancer and/or significant symptoms, per ASCO guideline recommendations.
- Palliative care specialists are experts in complex symptom management and communication surrounding serious illness.
- Barriers to early palliative care exist but can be addressed through education of oncologists, close collaboration between oncology and palliative care teams, and systems-based research and quality improvement.[4,5]
- APNs play an important role in delivering primary palliative care.[13,21,30,47-49,52,54]
- Stepped palliative care models and virtual palliative care have been demonstrated as being equivalent to routine in-person palliative care follow-up and hold promise for improving palliative care access while reducing resources.
- There is a need for standard metrics for measuring the effectiveness of palliative care programs to identify key interventions.
- Although often equated with estimated survival, prognosis can refer to a variety of consequences of the disease and its treatment along a patient's clinical trajectory (eg, cognitive decline, functional status, symptom burden).
- Although most patients with advanced cancer desire prognostic disclosure from their oncologists, many patients have a poor understanding of their prognosis, estimated survival, or intent of cancer-directed treatment.
- The ASCO communication guideline outlines principles of good communication in cancer care, including assessment and discussion of prognosis, elicitation of preferences and values, and discussion about the role of early integrated palliative care.
- Coordinated efforts are needed to effectively address disparities in access to specialty palliative care.
- Most patients who are dying experience psychological distress. Physicians must be prepared to address this via medical and psychosocial support and to encourage patients and families to leverage the expertise of other members of the interdisciplinary oncology team (eg, social work, behavioral health, etc.).
- Oncology practices should systematically screen for psychological and spiritual distress using available validated tools. Patients with moderate to severe distress should be referred to a specialist, while mild distress may be managed by the primary oncology team.
- ASCO guidelines state that all patients with cancer and their family caregivers should be offered information regarding depression and anxiety, as well as internal or external resources for evaluation and treatment.
- Differentiating between illness-related grief and depression is important. Depression is characterized by a persistent set of emotional symptoms, worthlessness, hopelessness, and anhedonia. Identifying and treating depression and its sequelae are essential for reducing end-of-life morbidity as well as the desire for hastened death.
- Caregiver distress is common and can be reduced with simple interventions.
- Hospice care is the best mechanism for providing high-quality care near the EOL in the United States and greatly enhances the ability of patients to die at home in comfort, surrounded by family and friends.
- Patients with an expected prognosis of 6 months or less are eligible for hospice.
- More than 90% of hospice care is provided at home or in long-term care facilities in which patients reside.

- At the EOL, the patient's comfort should be the primary focus. Unconscious patients should be treated with the same degree of care, concern, and communication as conscious patients.
- Physical care should address mouth care and musculoskeletal positioning, with attention given to maintaining skin integrity and comfort.
- Terminal secretions can be addressed with the careful administration of anticholinergic agents, as well as with attentive nursing care, positioning, and, most importantly, education of family caregivers.
- As the patient nears the EOL, all medications, medical interventions, nutritional supplements, and hydration efforts should be reviewed to continue only those that directly contribute to comfort.
- Delirium is frequently a source of great distress for the patient, their loved ones, and the care team. The clinician should screen for and treat any underlying reversible causes. If agitation occurs, clinicians should determine the source, if possible, and address it appropriately. Specialist palliative care consultation is recommended in cases of difficult and/or refractory symptoms.
- The wishes of family members with regard to being present at the time of death and aftercare of the patient's body should be respected and facilitated to the greatest degree possible.

CHAPTER TABLES AND IMAGES

Table 9-1 **Primary Versus Secondary Palliative Care**	
Primary	Management of cancer-related pain, including basic opioid regimens
	Basic non-pain symptom management, including nausea, constipation, and mood
	Advance care planning, eliciting patient values to provide goal-concordant care
	Ongoing prognostic awareness assessment
Secondary	Management of cancer-related pain, including complex opioid regimens
	High-touch and refractory non-pain symptom management
	Advanced communication strategies to augment advanced care planning and serious illness conversations with complex dynamics
	Enhanced prognostic awareness assessment and discussions with key stakeholders (eg, patient, treating team, family members)

Table 9-2 **Barriers and Facilitators to Early Integration of Palliative Care**

Factors Impacting Delayed Referral to Palliative Care	Potential Solutions to Improve Early Palliative Care Engagement[30]
• Patient's negative perceptions of palliative care • Family's negative perceptions of palliative care • Physician reluctance to discuss prognosis/EOL issues, including loss of hope • Physician perception of overlapping skill sets with palliative care • Lack of the medical team's recognition of the terminal phase of disease • Lack of integration between oncology and palliative care, including perceived conflict in goals of care that is, disease-directed therapy versus palliative care • Lack of clearly defined responsibilities between oncology and palliative care • Limited palliative care resources and a lack of clearly defined consensus referral criteria • Inadequate systems support and timely actionable data	• Education regarding the benefits of early palliative care for patients and caregivers as part of public health policy strategy • Using the term Supportive Care to name the services offered by the palliative care team • Adequate staffing, training, and resources to accommodate early palliative care referrals • Screening mechanism to help prioritize early palliative care referrals • Effective communication and collaboration among palliative care and oncology teams • Clarifying the roles and responsibilities of oncology and palliative care teams in a collaborative delivery model • Concurrent or simultaneous care models of integration • Bridge programs • Health system support for leadership, access to actionable data, financial support for multidisciplinary team organization, and care delivery • Regulatory amendments that support palliative care services billing separately from disease-directed therapy • Follow-up palliative care visits via virtual care and/or using a stepped-care model, with palliative care visits occurring only at key points in patients' cancer trajectories[4,5]

Abbreviation: EOL, end of life.

Table 9-3 **The Components of TEAM-Based Palliative Care**

Component	In the Trials	What Is Known
Time	A structured palliative care visit of at least one extra hour per month; repeated at regular intervals (ie, monthly); not once	These assessments can be conducted by a physician or APN with specific training in conducting such assessments.
Education	Structured, prospective, and recurrent discussions about symptoms, goals, and preferences for care, prognosis understanding, advance care planning, and communication with the healthcare team	Education that is done prospectively and regularly, rather than during a crisis, is more effective. Usual topics include, on a recurring basis: • Medically appropriate options for treatment; patients should know they have or have not left any medical stones unturned; this is best done by listing the treatments used and their outcomes, especially with recurrent disease; if appropriate, reinforce patient and family work as advocates • Advance care planning should be started early and revisited along the disease trajectory; documented components may include power of attorney documents, healthcare proxies, living wills or advance directives, and do-not-resuscitate orders • Use of hospice for the best possible care, and arranging a hospice information visit once it is evident the disease is going to take the person's life
Assessment	Formal assessments for: • Symptoms (ESAS, MSAS-C, CAPC rounding tool) • Spirituality (FICA, or "Are you a religious or spiritual person?") • Distress (Distress Thermometer, others) • Psychosocial (PHQ-2) • Caregiver strain It is not sufficient to just ask "How are you?"; patients and families are sometimes reluctant to share their problems for fear that nothing can be done, or that it is not in the clinician's remit, or that the oncologist will stop treating their cancer, or that they will be labeled a complainer.	After these formal symptom assessments, move on to goal setting. Questions may include: • How do you like to get medical information? • What is your understanding of your disease? • What is important to you? • What are you hoping for? • Have you thought about a time when you might become sicker, such that you would need an advance directive or living will? (some motivational interviewing) The authors of the table have incorporated this into a temporary tattoo that gives oncologists a script to start the most difficult discussions (Fig. 9-1). If progressive disease is evident, it is time to revisit goals of care, prognosis understanding, and advance care planning.
Management	By setting protocols and an interdisciplinary team (APNs, social workers, chaplains, doctors)	Interdisciplinary care and referrals were common elements of all studies. Giving people knowledge of their realistic options and a plan of action was shared across all the studies. Establishing ties with social work or chaplaincy is as important as developing ties with surgeons, radiation oncologists, or other medical professionals.

Abbreviations: APN, advance practice nurse; CAPC, Center to Advance Palliative Care; ESAS, Edmonton Symptom Assessment Scale; FICA, Faith and Belief, Importance, Community, Address in Care; MSAS-C, Memorial Symptom Assessment Scale Condensed; PHQ-2, Patient Health Questionnaire-2.

BREAST CANCER 10

Helen K. Chew, MD, and Tiffany A. Traina, MD, FASCO

RECENT UPDATES

- In patients with node-positive, hormone receptor–positive and HER2-negative early-stage breast cancer, the addition of abemaciclib to adjuvant endocrine therapy improved the secondary endpoints of overall survival (OS) and distant relapse-free survival (DRFS) compared to endocrine therapy alone (7-year OS 86.8% vs 85%; 7-year DRFS 80% vs 74.9%).[1-4]

- OS was significantly improved with inavolisib, a PI3K inhibitor, in combination with fulvestrant and palbociclib (median overall survival [mOS] 34 months) versus fulvestrant, palbociclib, and placebo (mOS 27 months) in patients with PIK3CA-mutated, hormone receptor–positive and HER2-negative advanced breast cancer with endocrine-resistant disease that had progressed during or within 12 months of adjuvant endocrine therapy.[5] Imlunestrant, an estrogen receptor 1 (ESR1) antagonist, was FDA approved in individuals with advanced hormone receptor–positive and HER2-negative breast cancer with an ESR1 mutation after receipt of at least one prior line of endocrine therapy.

OVERVIEW

In the United States, breast cancer is the most common cancer among women. Since 1990, mortality rates have consistently declined, primarily as a result of advances in systemic therapy. For early-stage breast cancer, advances in surgery and radiation oncology have led to the de-escalation of locoregional therapy. Substantial progress has been made toward the approval of new agents for patients who have early-stage and metastatic breast cancers (MBCs). However, more effective therapeutic options are still needed, as are biomarkers, to select patients in whom therapy can be optimized. Advances in supportive care have reduced serious complications of breast cancer treatment and improved both symptom management and quality of life.

EPIDEMIOLOGY

Breast cancer is the most common malignancy among women, with approximately 2.3 million women diagnosed worldwide in 2020, accounting for 11.7% of all new cancer cases.[6] The incidence rates are higher in economically developed regions and lower in economically developing areas, such as sub-Saharan Africa and parts of Asia.

Breast cancer remains the second most common cause of cancer-related death among women (beside lung cancer), with estimated deaths of 42,680 in the United States 2025.[7]

The incidence and mortality rates of breast cancer in the United States differ according to age, race, and ethnicity. The incidence rate of breast cancer has increased by 1% per year since 2012, but this increase is higher in women younger than 50 years (1.4% per year) versus women older than 50 years (0.7% per year). The increased incidence in younger women may be due to decreased number of births, older age at first birth, and increased body weight. The overall incidence of breast cancer is highest among White women and lowest among Asian American/Pacific Islander and Hispanic women, although the annual incidence among these two groups has increased recently.[8]

Although the overall incidence has increased, the overall breast cancer mortality has decreased by 44% in the last three decades. This decline is likely due to earlier detection and improvement in treatments. Although Black women have a 5% lower incidence of breast cancer compared to White women, mortality among Blacks is 38% higher. Multiple factors play a role in this observation. Breast cancer is more likely to develop before the age of 40 years in Black women than in White women; Black women are also more likely to be diagnosed with a more advanced stage of breast cancer and to have high-grade triple-negative tumors. Nonbiologic factors, such as patterns of care and underuse of treatment, likely contribute to the higher mortality rate.[9]

KEY POINTS

- The incidence rate of breast cancer in the United States has been slowly increasing at a rate of 1% annually overall since 2012. By contrast, the mortality rate has consistently declined, primarily as a result of advances in systemic therapy.

- The incidence rate has been steeper among women under 50 years.
- The incidence rate of breast cancer is increasing in nonindustrialized countries, in part due to changing lifestyle patterns (eg, rising rates of obesity and decreased physical activity).
- Compared with non-Hispanic White women in the United States, Black women now have a similar rate of incidence but a higher rate of mortality for breast cancer. The causes behind this significant disparity are not fully understood and are likely multifactorial.

NONMODIFIABLE RISK FACTORS

AGE AND SEX

In the United States, older age and female sex are the most important risk factors for the development of breast cancer (Table 10-1). The lifetime risk of breast cancer among US women is estimated at one in eight (12%), with multiple risk factors identified.[10]

Table 10-1 Established Risk Factors for Breast Cancer: Fixed Factors (Excluding Genetic Mutations)[10]

Factor	Relative Risk
Sex (female vs male)	100
Age (older than 50 vs younger than 50 years)	6.7
Endocrine factors	
Age at first birth (older than 30 years) or nulliparity	1.2-1.7
Age at menarche (younger than 12 years) or age at menopause (older than 55 years)	1.2-1.3
Benign breast disease	
ADH, LCIS	4.0-5.0
Family history (no known mutation)	
One first-degree relative	1.5-2.0
Ashkenazi Jewish ethnicity	1.4
Therapeutic radiation to the chest before age 30 years	7.0-17.0

Abbreviations: ADH, atypical ductal hyperplasia; LCIS, lobular carcinoma in situ.

Breast cancer in men is uncommon, accounting for approximately 1% of all breast cancers.[11] Men are usually diagnosed after the age of 60 years; the specific risk factors for this disease among men include the following:

- Genetic predisposition associated with *BRCA2* or *PALB2* mutations
- Klinefelter syndrome
- Testicular alterations that result in testosterone deficiency (eg, undescended testes and testicular injury)
- Syndromes that increase the estrogen-to-testosterone ratio (eg, obesity and cirrhosis)

FAMILIAL RISK FACTORS

Approximately 5% to 10% of all breast cancers are hereditary and are associated with mutations in highly or moderately penetrant genes. An additional 15% to 20% of women diagnosed with breast cancer have a family history of breast cancer. Having first-degree relatives with breast cancer portends a twofold higher risk of breast cancer.[10] This risk can increase three- to fourfold if a first-degree relative is diagnosed at an age younger than 50 years or when two first-degree relatives are affected.[12,13] Having a history of breast cancer is also associated with a higher risk of developing contralateral breast cancer, which can be compounded if a family history of breast cancer is present.

GENETIC RISK FACTORS

The inherited risk of breast cancer can result from alterations in highly (*BRCA1*, *BRCA2*, *PALB2*, *TP53*, *CDH1*, *STK11*, and *PTEN*) or moderately (*CHEK2*, *ATM*, and *NF1*) penetrant genes (Table 10-2). Pathogenic or likely pathogenic alterations in highly or moderately penetrant genes may be associated with other malignancies.[14-22] High-penetrance alterations (relative risk ≥ 5) are associated with a recognizable autosomal dominant predisposition. Moderate-penetrance alterations (relative risk, 2-5) may be more challenging to identify because of incomplete penetrance. Multigene panel testing is now offered to most patients; however, the panel composition and interpretation vary based on the specific commercial or private test.[23] The challenges of using these panels include uncertainties about the actionability of moderate-penetrance genes and the higher likelihood of detecting variants of uncertain significance.[24,25]

Table 10-2 **Lifetime Cancer Risk for People Who Have High- and Moderate-Penetrance Mutations in Selected Genes**[14-22]

Gene (Associated Disease)	Cumulative Lifetime Risk of Breast Cancer Development (%)	Other Tumors
High penetrance		
BRCA1	55-70	Ovarian cancer
BRCA2	45-70	Prostate cancer Pancreatic cancer Malignant melanoma Gallbladder and bile duct cancer Stomach cancer
TP53 (Li-Fraumeni syndrome)	90	Soft tissue sarcoma and osteosarcoma Brain tumors Leukemia Adrenocortical cancer
PTEN (Cowden syndrome/*PTEN* hamartoma tumor syndrome)	Poorly characterized	Follicular thyroid cancer Endometrial cancer Colon cancer Renal cancer
STK11 (Peutz-Jeghers syndrome)	Poorly characterized	Colon cancer Pancreatic cancer Stomach and small bowel cancer
CDH1 (hereditary diffuse gastric cancer)	50-60 (mainly lobular)	Diffuse gastric cancer
PALB2	40-50	Pancreatic cancer
Moderate penetrance		
ATM	20-30	Pancreatic cancer
BRIP1	Insufficient evidence	Ovarian cancer
BARD1	Insufficient evidence	
CHEK2	20-30	Colorectal cancer
MSH2, MLH1, MSH6, PMS2, EPCAM (Lynch syndrome)	Insufficient evidence	Endometrial cancer, Ovarian cancer
NBN	Insufficient evidence	
NF1	18	
RAD51C	Insufficient evidence	
RAD51D	Insufficient evidence

The most common mutations are localized in the *BRCA1* and *BRCA2* genes. The characteristics of carriers of *BRCA1* and *BRCA2* pathogenic variants (PVs) include the following:

- Among women who have a *BRCA1* PV, the risk of breast cancer up to the age of 70 years ranges from 55% to 70%; it ranges between 45% and 70% in women who have a *BRCA2* PV.[26-29]
- The risk of developing ovarian cancer during a lifetime is higher with a *BRCA1* PV (40%-45%) than with a *BRCA2* PV (15%-20%).[26-29]
- The development of contralateral or second primary breast cancer is increased (*BRCA1* relative risk, 4.5; *BRCA2* relative risk, 3.4). The absolute risk after 10 years is higher for women diagnosed at younger than 30 years (28.2%) than for women older than 50 years (10.8%).[30]
- The risk of breast cancer in men before the age of 80 years is approximately 7% among *BRCA2* PV carriers.[31]

- Approximately 2.5% of people of Ashkenazi Jewish ancestry carry one of three founder variants: 185delAG and 5382insC in *BRCA1* or 6174delT in *BRCA2*. These three mutations account for 12% of breast cancers and 35% of ovarian cancers in this population. An additional 2% to 4% of Ashkenazi Jewish women who have breast cancer have a nonfounder PV, which is similar to the prevalence of alterations in non–Ashkenazi Jewish women.[32]
- *BRCA1* PV carriers are more likely to develop triple-negative breast cancer (TNBC) than *BRCA2* PV carriers or non-*BRCA* PV carriers. Approximately 80% of breast cancers in *BRCA1* carriers are TNBC, whereas the distribution of breast cancer subtypes in *BRCA2* mirrors the general population, being predominantly hormone sensitive. The risk of pancreatic cancer and prostate cancer is higher in *BRCA2* carriers than in *BRCA1*.

The characteristics of other high-penetrance genes include the following:

- Li-Fraumeni syndrome, a rare hereditary cancer predisposition syndrome of multiple cancer types that occur at an early age, is associated with PVs in *TP53*. Carriers have a 90% lifetime risk of developing cancer, with breast cancer being the most common. There is a particular predilection for very–early-onset breast cancer, in addition to other types of malignancies.[14-22] HER2–positive breast cancer is more prevalent in women with a *TP53* germline PV than in women without a *TP53* PV.[33] In addition, patients with Li-Fraumeni syndrome are at an increased risk of secondary malignancies developing in a radiation field.[34] (Note that the HER2 gene is also called the ERBB2 gene.)
- Cowden syndrome is a rare autosomal dominant syndrome; 80% of cases are caused by variants in the *PTEN* tumor suppressor gene (10q23). In this syndrome, breast cancer can occur in conjunction with other cancers, such as thyroid, endometrial, colon, and renal. Specific physical findings among patients with Cowden syndrome include macrocephaly, hamartomas, autism, and trichilemmomas of the face, hands, and feet.[35]
- Germline PVs in *CDH1* are associated with an increased risk of diffuse gastric cancer and invasive lobular carcinoma.
- *PALB2* (partner and localizer of *BRCA2*) has emerged as a relevant gene associated with predisposition to breast cancer. Loss-of-function mutations in *PALB2* are observed in 0.6% to 3.9% of families with a history of breast cancer.[14]
- Germline PVs in *STK11* are associated with Peutz-Jeghers syndrome, a rare syndrome with 55% to 85% lifetime risks of cancer. Individuals with PVs have an increased risk for breast cancer in the range of 32% to 54%.[36]

Multigene panel testing identifies PVs in several moderate-penetrance genes in a significant number of women who have breast cancer. Taken together, PVs in moderately penetrant genes such as *ATM* and *CHEK2* are as common as alterations in *BRCA1* and *BRCA2*.[37] Criteria such as those published by the National Comprehensive Cancer Center Network are less sensitive for the detection of PVs in these genes than they are for high-penetrance variants.[38] Some advocate that multigene panel testing is offered at the time of breast cancer diagnosis to all women and men, regardless of family history.[39] American Society of Clinical Oncology (ASCO), working with the Society of Surgical Oncology, has published guidelines suggesting testing for women diagnosed at age younger than 65 years.[40]

Second cancer risks for women with PVs in *BRCA1* and *BRCA2* are significantly higher than for women with PVs in *PALB2*, *ATM*, and *CHEK2*.[41]

The identification of a PV or likely PV in highly penetrant genes has important therapeutic implications.[41] Women with *BRCA* mutations may choose bilateral mastectomies at the time of a breast cancer diagnosis. In addition, women with *TP53* mutations might be offered mastectomy to avoid radiation therapy (and risk of second cancers). Furthermore, patients with germline *BRCA1* and *BRCA2* PVs or likely PVs and either early-stage or metastatic HER2-negative breast cancer may benefit from PARP inhibitors. Based on therapeutic implications, genetic testing for patients with MBC is recommended.[42]

Guidelines from ASCO and the Society of Surgical Oncology recommend *BRCA1/2* mutation testing to all newly diagnosed patients 65 years or younger and in select patients older than 65 years based on personal and family history, ancestry, or eligibility for PARP inhibitor therapy, as mentioned. Additional gene panel testing should be offered to those who have a supportive family history.[40]

REPRODUCTIVE AND ENDOGENOUS HORMONES

Endogenous and exogenous estrogen plays a well-established role in breast cancer risk and development. Increased levels of premenopausal endogenous hormones are associated with an increased risk of disease among postmenopausal women. Terminal differentiation of breast epithelium occurs after a full-term pregnancy. This histologic change in breast parenchyma seems to be protective and associated with a reduction in breast cancer risk when the first full-term pregnancy occurs at a younger age (less than 30 years). Lactation may also convey protection; however, the duration of lactation required for this benefit is not well defined.

The role of endogenous hormonal risk factors is not the same in all breast cancer subtypes. Early onset of menarche, late age at menopause, and nulliparity, all of which connot extended estrogen exposure, confer an elevated risk of hormone receptor–positive disease.[43] By contrast, TNBC is associated with an increasing number of births and is not associated with nulliparity or age at first full-term delivery.[44]

BENIGN PROLIFERATIVE BREAST DISEASE

Pathologic nonmalignant changes found at biopsy can be associated with an increased risk of breast cancer. Findings such as atypical ductal or lobular hyperplasia or lobular carcinoma in situ convey an increased risk of breast cancer, approximately fourfold for atypical hyperplasia and 10-fold for lobular carcinoma in situ and thus can be termed "high-risk lesions." These lesions are not innately precancerous.[45] Benign proliferative lesions without atypia do not seem to significantly increase breast cancer risk.

Atypical hyperplasia is associated with an approximately 15% to 30% risk of breast cancer developing over 25 years.[46] After a diagnosis of atypical ductal hyperplasia (ADH) using core needle biopsy, it is recommended that most individuals undergo an excisional procedure to exclude the possibility of an associated invasive carcinoma. On the other hand, for atypical lobular hyperplasia (ALH) and lobular carcinoma in situ, given the low reported risk of upgrade to ductal carcinoma in situ (DCIS) or invasive carcinoma, incidental radiologic-pathologic concordant cases diagnosed on core needle biopsy no longer require surgical excision.[47]

MODIFIABLE RISK FACTORS

EXOGENOUS HORMONES

The use of contemporary hormonal contraceptives has been associated with a higher risk of breast cancer compared with never use of hormonal contraceptives; however, the absolute increase in risk is low (Table 10-3).[48]

Table 10-3 Established Risk Factors for Breast Cancer: Modifiable Factors

Factor	Relative Risk
Oral contraceptive pill	0.9-1.0
Estrogen replacement (more than 10 years)	1.1
Estrogen and progesterone	1.4-3.0
Postmenopausal obesity (BMI higher than 30 kg/m^2)	2.5
Alcohol use	1.1-2.2
Diet	1

Abbreviation: BMI, body mass index.

Menopausal hormone therapy in the form of a combination of estrogen and progesterone is associated with an increased risk of invasive breast cancer (hazard ratio [HR], 1.26)[49]; however, the risk returns to normal within 2 years after discontinuation of menopausal hormone therapy.[50] Women who take combined menopausal hormone therapy also have a more advanced stage of breast cancer at the time of diagnosis. The global cessation of combined menopausal hormone therapy in 2002 was associated with an 8.6% reduction in the annual incidence of invasive breast cancer, primarily observed in hormone receptor–positive disease and in women older than 50 years. Interestingly, the use of estrogen alone does not appear to increase the risk of breast cancer,[51] and there are data to support a small (about 20%) reduction in risk.[52]

RADIATION EXPOSURE

Survivors of Hodgkin lymphoma and other malignancies who received therapeutic mediastinal or mantle field radiation have a higher risk of breast cancer development, depending on the dose of radiation and radiation field volume. The risk is greatest when treatment occurs during active proliferation of the breast tissue (ie, between ages 10 and 30 years). The median time for the development of breast cancer after treatment is approximately 18 years; however, increased risk can start as early as 8 years after treatment. Use of lower doses of therapeutic radiation involving smaller volumes has resulted in lower risks of breast cancer.[53-55] For patients who have a history of thoracic radiation received between ages 10 and 30 years, it is recommended that annual screening mammograms and annual breast MRI start at the age of 25 years.[56]

MAMMOGRAPHIC DENSITY

There is a linear trend associated with increasing mammographic density and risk of breast cancer, wherein women with greater than 75% breast density have a four- to six-fold higher risk of disease than those whose breasts are almost entirely fatty.[57] Exogenous hormone use, such as postmenopausal hormone replacement therapy or oral contraceptives, may result in increased mammographic density. Lower mammographic density may be a reflection of involution of the terminal ductal-lobular units, a natural aging process of the breast that is associated with lower breast cancer incidence.[58,59]

Mammographic density is a principal factor in the failure of mammography to detect cancer, which leads to interval cancers (ie, cancers presenting as clinical findings during the interval after a normal mammogram).[60] Digital breast tomosynthesis is

increasingly used as a primary screening examination rather than a supplemental imaging tool and has been shown to detect an additional 1.5 to 2 additional cancers per 1,000 women.[61] Screening breast MRI has been shown in one study to improve cancer detection rates and is recommended by some societies for women with extremely dense breast tissue.[62,63] Contrast-enhanced mammography is also a newer technology with improved sensitivity in women at an increased risk of breast cancer, particularly in women with dense breasts. In a small series, cancer detection rates approached 16 per 1,000, similar although not equivalently sensitive to MRI.[64]

BEHAVIORAL FACTORS

Several modifiable risk factors are associated with an increased risk for breast cancer. Consumption of one alcoholic beverage per day is associated with a 12% increased risk of breast cancer, and a further 10% increase in risk occurs with every additional 10 g per day of alcohol (or 0.75 to one alcoholic beverage per day) consumed. The risk is independent of the type of alcohol consumed and may be related to an increase in serum hormone levels and systemic inflammation.[65-67]

Obesity (body mass index [BMI] more than 30 kg/m^2) increases the risk of breast cancer in postmenopausal women by more than 63% but is inversely correlated with risk in premenopausal women.[68] Larger waist circumference is also associated with a greater incidence of premenopausal estrogen receptor (ER)–negative breast cancer.[69] Waist circumference and BMI are markers of visceral adiposity associated with metabolic syndrome. Several underlying mechanisms contribute to the association of obesity with increased breast cancer risk and mortality, including inflammation, increased bioavailable estrogens, insulin and insulin-like growth factor signaling, and activation of tumor growth factor programs.[70,71]

Smoking tobacco is associated with a moderate increase in breast cancer risk, and there is also evidence for a moderate increase in risk with passive smoking.[72] Physical activity is inversely related to breast cancer risk (see "Lifestyle Modifications" section). Isoflavones (ie, phytoestrogens most often found in soy), dairy products, and high-fat diets have unclear relationships with the incidence of breast cancer, whereas fiber consumption appears to be protective.[73]

RISK DETERMINATION MODELS

Several models are available to predict the risk of breast cancer based on family history and/or the probability of carrying a *BRCA* mutation. The Claus model includes first- and second-degree relatives with breast and/or ovarian cancer and incorporates the age at diagnosis. BRCAPRO, the Tyrer-Cuzick model (also called the International Breast Cancer Intervention Study [IBIS] trial), and the BOADICEA model all calculate risk based on the probability of carrying a genetic mutation.[74-77]

The modified Gail model[78] is the most widely used risk assessment tool; it incorporates nongenetic factors such as the following:

- Current age
- Age at menarche and first full-term pregnancy or nulliparity
- Number of breast biopsies and the presence of atypical hyperplasia
- Number of first-degree relatives with breast cancer
- Race

The original Gail model was modified and validated to incorporate race as a risk factor, specifically assessing breast cancer risk in Black women (the Contraceptive and Reproductive Experience model).[79] The modified Gail model is an excellent tool to determine risk on a population basis; however, the 5-year or lifetime risk of disease calculated for an individual woman is not robust.[80] This model will also underestimate risk if there is a significant genetic predisposition. Prevention strategies are often considered when the modified Gail model calculates a 5-year risk greater than 1.67%; however, this calculation does not take into account factors such as breast density or the presence of lobular carcinoma in situ and may also underestimate the risk associated with atypia.

KEY POINTS

- Menopausal hormone replacement therapy in the form of a combination of estrogen and progesterone (but not estrogen alone) is associated with an elevated risk of invasive breast cancer and correlates with duration of use.
- Patients who received therapeutic mediastinal or mantle field radiation have a higher risk of breast cancer, most pronounced when treatment occurred during active proliferation of breast tissue (ie, between ages 10 and 30 years).
- Atypical ductal or lobular hyperplasia and lobular carcinoma in situ are high-risk, nonmalignant lesions associated with a 30% risk of breast cancer development over 25 years.
- *BRCA1* and *BRCA2* mutations are associated with a 50% to 70% lifetime risk of development of breast cancer.
- Other highly (*PALB2*, *CDH1*, *TP53*, *PTEN*, and *STK11*) and moderately (*ATM*, *CHEK2*, and *NF1*) penetrant genes are associated with a significant risk for breast cancer.

- Postmenopausal obesity and alcohol use are associated with a higher risk of breast cancer.
- Increased breast density is associated with a higher risk of breast cancer.
- Several risk models are available to predict the risk of developing breast cancer on the basis of family history, prior atypia, and other factors.

PREVENTION

The goal of breast cancer prevention is to reduce the risk of the development of the disease with minimal toxicity. Women with a high-penetrance genetic mutation or a strong family history of breast cancer not associated with a pathogenic mutation in a breast cancer susceptibility gene may consider risk-reducing surgery. Lifestyle and medical risk-reducing strategies can be discussed with women with any degree of breast cancer risk.

RISK-REDUCING SURGERY

Prophylactic surgeries for high-risk patients reduce the risk of breast cancer development and include risk-reducing bilateral salpingo-oophorectomy (BSO) and bilateral risk-reducing mastectomy.

Risk-reducing BSO has been associated with the following:

- Decrease in the risk of ovarian cancer (which includes primary peritoneal and fallopian tube cancers) by approximately 85% (HR, 0.14).
- Reduction in the risk of a first diagnosis of breast cancer by 40% and 60% among *BRCA1* and *BRCA2* mutation carriers, respectively (HRs, 0.63 and 0.36, respectively).
- Lower breast cancer–specific mortality (HR, 0.44), lower all-cause mortality (HR, 0.40), and lower ovarian cancer–specific mortality (HR, 0.21) rates.[81]

BSO is recommended for *BRCA1* carriers between the ages of 35 and 40 years when childbearing is complete, and for *BRCA2* carriers between the ages of 40 and 45 years. The concern about the adverse effect of mortality from inducing early menopause may be safely mitigated with short-term menopausal hormone therapy given until age 50 years without an apparent compromise in the overall benefit of risk-reducing BSO on breast cancer risk reduction.[82]

Bilateral risk-reducing mastectomy reduces the risk of breast cancer by more than 90% in women with hereditary breast and ovarian cancer syndromes, with most studies focusing on *BRCA* mutation carriers.[83] Prophylactic risk-reducing mastectomy should be offered to these patients, although the decision should be based on personal preference, given that effective screening is available. Women at a high or moderate risk of breast cancer (ie, known genetic linkage or significant family history without known genetic predisposition) should also have a discussion with their physicians about prevention.

Skin-sparing mastectomy with reconstruction is increasingly being used and seems to be as effective as total mastectomy.[84] Reconstructive surgery after mastectomy does not seem to increase breast cancer risk. Even after prophylactic surgery, residual at-risk breast tissue remains on the chest wall, and new primary breast cancers can arise, although the risk is low.

MEDICAL RISK REDUCTION (CHEMOPREVENTION)

Selective ER Modulators

The observation that adjuvant tamoxifen used to treat invasive breast cancer led to a significant reduction in the development of new primary breast cancers[85] prompted several randomized trials examining the efficacy of selective ER modulators (SERMs) in reducing the risk of breast cancer among high-risk women. The benefit of tamoxifen for chemoprevention has been evaluated in several trials and consistently shows a reduction in the risk of invasive breast cancer between 30% and 50% compared with placebo.[86-89] This reduction is exclusively limited to ER-positive breast cancers. No effect on ER-negative incidence is seen. A meta-analysis of four studies led by the US Preventive Services Task Force[90] concluded that, when compared with placebo, tamoxifen led to the following:

- Reduction in the incidence of invasive breast cancer by 30%
- Significant reduction in the incidence of nonvertebral fractures by 34%
- No effect on breast cancer–specific or all-cause mortality

Tamoxifen and other SERMs have both estrogenic and antiestrogenic activity depending on the tissue, resulting in the following:

- Increased incidence of endometrial cancers (risk ratio, 3.28), which translates to a 1.6% risk with tamoxifen compared with a baseline 0.7% risk over 7 years.[91] Typically presenting with postmenopausal bleeding, adenocarcinomas are commonly

detected at an early stage and affect women older than 50 years. No data support routine screening for endometrial cancer using transvaginal ultrasonography or biopsy unless abnormal vaginal bleeding is present.

- Increased incidence of venous thromboembolic events (deep venous thrombosis: risk ratio, 1.44; pulmonary embolism: risk ratio, 2.15). The risk of stroke was not consistently increased among the tamoxifen studies, and this association is not supported by large population studies. Risks of endometrial cancer and venous thromboembolic events increase with advancing age.
- Increased incidence of cataracts as well as gynecologic (vaginal discharge) and vasomotor symptoms (VMS; hot flashes).
- Bone loss in premenopausal women.[92] However, in the Breast Cancer Prevention Trial P1, a reduction in the incidence of osteoporotic bone fractures (of the hips, spine, or radius) by 29% was seen among women aged 50 years or older.[91]

Tamoxifen at a dose of 5 mg per day for 3 years, compared with placebo (not compared with the standard tamoxifen 20 mg per day for 5 years program), decreased the risk of disease recurrence by half in postmenopausal women with ADH, lobular carcinoma in situ, or DCIS with a favorable toxicity profile.[93,94] The effect in premenopausal women was not significantly improved.[95] Low-dose tamoxifen may be an alternative for women who have intraepithelial neoplasia.

Raloxifene, a second-generation SERM, can also be used for chemoprevention in postmenopausal women. The NSABP P-2 STAR trial compared the efficacy of 5 years of tamoxifen with that of raloxifene.[86] After an extended follow-up of nearly 8 years, raloxifene retained only 76% of the effectiveness of tamoxifen in reducing the risk of invasive cancer.[86] There was no difference in mortality outcome between the two SERMs. Raloxifene use was associated with significantly less toxicity than tamoxifen, specifically, fewer endometrial cancers and thromboembolic events. Raloxifene is approved only for preventing breast cancer and not as a treatment after diagnosis.

A meta-analysis of the individual participant data from all randomized prevention trials involving SERMs (nine trials; 83,399 participants) demonstrated a 10-year cumulative incidence of breast cancer of 4.2% in patients receiving SERMs versus 6.3% in those receiving placebo.[96] The reduction in breast cancer was evident during years 0 to 5 (42%) and during years 5 to 10 (25%). The increased risk of endometrial cancer (HR, 1.64) was confined to years 0 to 5, coinciding with tamoxifen, and was not sustained in years 5 to 10. Although the number of venous thromboembolic events increased overall, there was no effect on the incidence of myocardial infarction, stroke, or transient ischemic attack. SERM use had no effect on the risk of ER–negative breast cancer or on overall mortality.

Aromatase Inhibitors

Similar to tamoxifen, aromatase inhibitor (AI) use in the adjuvant setting was shown to decrease the risk for second primary breast cancers (Fig. 10-1). Subsequently, two large trials have shown the efficacy of AIs in the prevention of invasive breast cancer among postmenopausal women at an elevated risk:

- The NCIC-CTG MAP.3 demonstrated a 65% reduction in the incidence of invasive breast cancer, including a 73% reduction in the incidence of ER–positive invasive breast cancer, among women receiving exemestane for 5 years, compared to placebo.[97]
- In the IBIS-II trial, 5 years of anastrozole reduced the risk of hormone receptor–positive invasive breast cancer and DCIS by more than 50% among postmenopausal women at an elevated risk of developing breast cancer compared with placebo.[98] Anastrozole neither conveyed a risk reduction for ER–negative breast cancer nor improved survival.

Few women with *BRCA* mutations have been specifically evaluated in prevention trials; therefore, the role of primary medical prevention in these women is not well understood. However, data suggest that tamoxifen can reduce the development of contralateral breast cancers in carriers of *BRCA1* (42% risk reduction) or *BRCA2* (52% risk reduction) mutations after the diagnosis of breast cancer.[99] An adjuvant trial of metformin versus placebo failed to demonstrate any beneficial effects in preventing second breast cancers.[100] The use of other medications for breast cancer prevention (eg, aspirin, statins, and vitamin D) remains investigational.

LIFESTYLE MODIFICATIONS

Physical Activity

Prospective cohort studies demonstrated that current total or recreational exercise can reduce the incidence of breast cancer by 20% to 30%, primarily among premenopausal women.[101]

Diet and Weight Change

The correlation among significant alcohol consumption, obesity, and risk of breast cancer is well established.[102] Data are lacking regarding whether moderate alcohol use after a diagnosis of breast cancer influences mortality risk.[103,104] In terms of diet, most studies have not conclusively supported a reduction in risk with increased consumption of fruits and vegetables. Although a study from the Women's Health Initiative suggested a 9% reduction in risk when women consumed a low-fat diet, prospective studies evaluating dietary changes and their effect on breast cancer risk have not been conclusive.[105,106] Vitamin and mineral

supplements, specifically vitamin D and calcium, respectively, have not been shown to date to affect the development of breast cancer, although vitamin D deficiency may correlate with worse survival outcomes after a breast cancer diagnosis.[107,108]

KEY POINTS

- Risk-reducing BSO in *BRCA1* and *BRCA2* carriers is associated with lower breast cancer–specific mortality, lower all-cause mortality, and lower ovarian cancer–specific mortality rates.
- Bilateral risk-reducing mastectomy reduces the risk of breast cancer by more than 90% in *BRCA1* and *BRCA2* carriers.
- Tamoxifen in premenopausal or postmenopausal women and raloxifene, anastrozole, or exemestane in postmenopausal women all reduce the risk of development of ER–positive breast cancer.
- Significant alcohol consumption is associated with an increased risk of breast cancer, and there seems to be a significant dose–response relationship.

SCREENING

AVERAGE RISK

Screening has been shown to have a favorable effect on breast cancer–related mortality given that early-stage disease is associated with a more favorable prognosis. Published randomized trials have been criticized for variable quality of imaging, flawed study design or execution, insufficient duration of follow-up, and problems regarding lead time bias. However, these studies, including a meta-analysis of randomized controlled trials of screening mammography performed predominantly in the 1960s to 1970s, reported a 22% relative reduction in breast cancer mortality; patients in this analysis ranged in age from 39 to 74 years.[109]

The benefit of screening mammography varies with age. The Pan-Canadian Study of Mammography Screening and Mortality demonstrated a 44% reduction in mortality in women aged 40 to 49 years undergoing screening mammography, a 40% reduction in women aged 50 to 59 years, and a 42% reduction in women aged 60 to 69 years. The effect of screening mammography on breast cancer mortality for women aged 70 years or older is less robust.[101]

Harms from screening include anxiety provoked by false-positive findings, unnecessary biopsies, overdiagnosis, and increased detection of DCIS, which may not proceed to invasive cancer.[110]

Frequency of Screening

The optimal frequency for mammographic screening is not known. The advantage of shorter intervals is an increased chance of detecting faster-growing cancers at an earlier stage, but this advantage comes with the disadvantage of a higher false-positive rate. The American Cancer Society updated guidelines from 2015 support annual imaging beginning at the age of 40 years and

strongly recommend annual screening from age 45 to 54 years, followed by biennial or annual screening that continues as long as a woman's overall health is good, and she has a life expectancy of 10 years or more.[111] The National Comprehensive Cancer Center Network, Society of Surgical Oncology, and American College of Radiology recommend annual mammography beginning at the age of 40 years. In 2024, the US Preventive Services Task Force revised their recommendations to initiate biennial screening at the age of 40 years and continue until the age of 74 years on the basis of modeling that estimated benefits, risks, and use of resources and estimated that biennial screening still achieved 81% of the benefit of annual screening with nearly half the number of false-positive results.[112] Although the optimal age to begin screening and optimal interval remain unclear, annual mammography beginning at the age of 40 years prevents the most deaths as a result of breast cancer.

Different Screening Modalities

There has been a gradual and now nearly complete conversion to digital from film screening technology in the United States. Although digital imaging provides only a small increase in sensitivity compared with optimally performed film imaging, the move to digital imaging has greatly improved and standardized image quality across all sites.

Digital breast tomosynthesis mammography enables three-dimensional imaging of the breast, similar to computed tomography (CT).[113] Digital breast tomosynthesis results in slightly greater sensitivity and a significant reduction in recall rates. It is unknown whether digital breast tomosynthesis leads to a reduction in the number of advanced breast cancers because of earlier detection. Interpretation times are longer with digital breast tomosynthesis than with digital imaging, but the amount of radiation exposure is now equivalent to that of standard mammography when a synthesized two-dimensional technology is used.

Breast self-examination has not been found to improve the detection of early-stage breast cancer on a population basis.[114,115] Clinical breast examinations also do not seem to have affected breast cancer detection or mortality rates from a population perspective.[116] However, many groups encourage breast self-examination as a method of increasing breast self-awareness to seek medical attention if abnormalities are detected.[117-119]

Breast MRI screening has been widely studied but remains controversial. It is clearly more sensitive than mammography but results in more subsequent evaluations, including biopsies. It is generally recommended for high-risk women and those with very dense breasts. Among patients with *BRCA* mutations, supplementing mammography with MRI improves the sensitivity to 80% to 100% compared with 25% to 59% with mammography alone; however, the specificity of combined mammography and MRI is lower (73%-93%).[120] Adding annual MRI screening to mammography has been shown to significantly reduce the incidence of larger or lymph node–positive breast cancers and is associated with a survival advantage over mammography alone in individuals with germline *BRCA* mutations.[121]

Annual breast MRI screening as an adjunct to mammography is usually recommended in the following situations:[111,122]

- People with mutations in *BRCA1*, *BRCA2*, *TP53*, *PTEN*, *PALB2*, and *STK11*, and may be considered in individuals with *CDH1*, *CHEK2*, *ATM*, *NF1*, or *BARD1*.
- First-degree relative of a person with mutations *BRCA1*, *BRCA2*, *TP53*, *PALB2*, or *STK11*, who is untested for the presence of a mutation.
- Lifetime risk of 20% or greater as defined by a model that largely depends on family history.
- Radiation to the chest between the ages of 10 and 30 years.

In general, screening for these high-risk individuals begins at the age of 25 years and includes annual breast MRI with biannual clinical breast examinations. Annual mammography should begin at the age of 30 years or be individualized if the earliest onset in the family is in a member younger than 25 years. Women will often have their breast imaging (mammogram and MRI) alternate every 6 months coincidently with their clinical breast examination, although no data support that this screening schedule is superior to that of concurrent breast imaging.[123]

Women who have received chest radiation at an early age are screened with a mammogram and MRI either concurrently or alternating every 6 months, beginning approximately 8 to 10 years after completing radiation therapy.[124] For women at high risk because of familial (nonhereditary) reasons, initiation of screening should begin approximately 10 years earlier than the age of the youngest woman in the family diagnosed with breast cancer but not later than the age of 40 years.

Women with extremely dense breasts may consider breast MRI screening. In the DENSE trial of over 40,000 women aged 50 to 75 years with extremely dense breast tissue and normal screening mammogram, one group was invited to undergo supplemental breast MRI (assigned 1:4 to breast MRI). Fifty-nine percent of those invited for supplemental MRI accepted. The primary outcome of interval cancers in a 2-year period decreased from 5 per 1,000 screenings with a mammogram only to 2.5 per 1,000 screenings with MRI. Importantly, the MRI cancer detection rate was 16.5/1,000 screenings; the positive predictive value was 17.4% for recall for additional testing and 26.3% for biopsy. The false-positive rate was 79.8/1,000 screenings. The optimal screening MRI frequency is not known. To date, not enough evidence supports routine MRI screening for women with scattered fibroglandular density or heterogeneously dense breast or the diagnosis of lobular carcinoma in situ, ADH, or DCIS. In addition, data are insufficient to support routine MRI screening for all women whose only risk factor is a history of invasive cancer.[62]

DIAGNOSIS

Algorithms for imaging evaluation of a palpable breast mass are stratified according to the age of the woman. Ultrasonography is usually the first diagnostic procedure performed to evaluate palpable breast masses in women younger than 30 years, as the incidence of breast cancer is low in this age group.[125] Diagnostic mammography is used for palpable masses in women older than 30 years. Diagnostic mammography differs from screening mammography in that it adds images to the standard two-view imaging used with screening (ie, craniocaudal and mediolateral oblique). If a suspicious finding is seen on a diagnostic mammogram or if the palpable breast mass is mammographically occult, a targeted ultrasonogram is used to obtain specific characteristics that will differentiate a suspicious solid mass from a benign cyst.

In a patient with suspicious imaging findings or a suspicious palpable breast mass after appropriate imaging workup, the next step is biopsy (Fig. 10-2). Although a fine needle aspiration biopsy of a palpable breast mass is less invasive than a core needle biopsy, fine needle aspiration specimens often yield insufficient tissue for analysis and cannot differentiate invasive from noninvasive carcinomas.[126] Fine needle aspiration of suspicious palpable axillary lymph nodes is often acceptable, given the limited variability of tissue present within a lymph node. It is also appropriate to use fine needle aspiration in the evaluation of a simple cyst detected by ultrasound, because drainage of the cystic fluid without re-accumulation can imply a benign etiology and eliminate the need for additional evaluation.

Figure 10-2 Workup of Palpable Breast Mass or Screening Abnormality

Core needle biopsy specimens can be obtained through ultrasound guidance or stereotactically when suspicious calcifications are seen on mammography and do not have an associated density. The amount of tissue obtained by a core needle biopsy is usually sufficient to characterize the lesion and, when cancer is identified, to perform quantitative immunohistochemical analysis of ER, progesterone receptor (PR), and HER2 protein status. These results provide sufficient information about the cancer to allow the initiation of neoadjuvant systemic therapy if needed without compromising future treatment. The need to identify the site of biopsy is crucial, so a radiolucent clip is commonly placed in the lesion as a locator.

MRI can also be used to evaluate the extent of disease within the breast after the detection of invasive breast cancer. A meta-analysis of 19 studies assessing the role of MRI in revealing multifocal or multicentric disease found a 16% incidence of additional disease within the affected breast.[127] This was associated with an 8.1% conversion from breast conservation to mastectomy and an 11.3% need for additional surgery after wide excision. MRI can also be used to detect multicentric DCIS, but it is not accurate in assessing noninvasive tumor size. Caution must be used when assessing the contralateral breast with MRI after the diagnosis of breast cancer, because MRI detects an occult contralateral malignancy in approximately 3% of patients. This results in a high rate of biopsies and contralateral mastectomies despite a lack of evidence that these procedures result in a survival advantage.[128]

KEY POINTS

- Mammographic screening results in a 14% to 32% reduction in breast cancer–related mortality among women aged 50 to 70 years. The effect on mortality for women aged 40 to 49 years or older than 70 years is less robust.
- For women with *BRCA* mutations who have not undergone risk-reducing surgery, annual MRI of the breasts is recommended beginning at the age of 25 years, and annual mammography is recommended beginning at the age of 30 years. For women who have received therapeutic mantle field radiation, beginning 10 years after the completion of radiation

therapy, annual screening mammography (not before the age of 30 years) and annual breast MRI (not before the age of 25 years) are recommended.

- For breast cancer diagnosis, a core needle biopsy of a suspicious breast or lymph node finding is preferable to fine needle aspiration to accurately assess the histology of the tissue and the status of ER, PR, and HER2.

PROGNOSTIC INDICATORS

TNM STAGING

The eighth edition of the American Joint Committee on Cancer (AJCC) staging manual[129] for breast cancer includes biologic features, such as tumor grade, HER2, ER, PR, and genomic assays (when appropriate) as elements required to assign stage in conjunction with the anatomic information provided by the TNM (tumor, node, metastasis) classification. Three stage groups are defined: an anatomic stage solely based on the T, N, and M categories and intended for use when biomarkers are not available; a clinical prognostic stage; and a pathologic prognostic stage. The clinical prognostic stage is used to assign a stage for all patients. It is determined by the clinical T, N, M, and markers, including tumor grade, HER2, ER, and PR status. The pathologic prognostic stage is used to assign a stage for patients who have surgical resection as the initial treatment of their cancer before any systemic or radiation therapy. It is based on the pathologic T, N, M, and biomarker information. Multigene panels are not required for staging but may provide additional prognostic and predictive information. In the eighth edition of the AJCC staging manual, the prognostic stage group is preferred for patient care and should be used for reporting on all patients with breast cancer in the United States.

Additional important updates in the eighth edition of the AJCC staging manual include the removal of lobular carcinoma in situ from TNM staging (lobular carcinoma in situ is now treated as a benign entity) and the determination that the presence of cancer within blood vessels, lymph vessels (lymphovascular invasion), or lymph nodes precludes post-treatment classification as a complete pathologic response.

The prognostic features of breast cancer can be divided into two categories: anatomic and biologic. Recent technologies are leading to an increased understanding of the role of biologic features in determining outcomes, and treatment strategies will continue to evolve as our knowledge increases.

ANATOMIC PROGNOSTIC INDICATORS

Lymph Node Involvement

The most important anatomic prognostic indicator for localized breast cancer is the nodal burden of disease. Ipsilateral axillary lymph nodes are often the first site of invasion. Intramammary lymph nodes are found within the breast parenchyma and are included in the axillary lymph node category when they contain breast cancer metastases. The clinical detection of ipsilateral internal mammary or supraclavicular lymph node involvement is associated with a greater risk of local recurrence and distant metastasis. Regardless of other characteristics of breast cancer, having more axillary lymph nodes involved with the disease is related to increased risk of systemic recurrence and decreased disease-specific survival.

The size of the metastatic component within the axillary lymph node is also important for prognosis. Lymph nodes with macrometastases (more than 2 mm) or micrometastases (more than 0.2 mm or more than 200 cells, but none more than 2 mm) are counted as nodal involvement. There is a greater risk of disease recurrence and death with macrometastases compared with micrometastases.[130] Isolated tumor cell clusters (clusters of cells or single tumor cells less than 0.2 mm or less than 200 cells) found within a sampled axillary lymph node seem to be associated with a prognosis comparable to that of lymph node–negative disease, and the use of immunohistochemistry (IHC) to detect these cells is not recommended.

Lymphovascular Invasion

The presence of tumor emboli within lymphatic or vascular channels is associated with a less favorable prognosis, mainly because of a higher risk of ipsilateral breast recurrence. The presence of lymphovascular invasion does not preclude breast conservation but often factors into determining the need for radiation therapy.

Tumor Size

Tumor size (which refers to the size of the invasive component) is one of the most important prognostic indicators for breast cancer. The size of associated DCIS does not influence the risk of systemic disease but may contribute to the risk of ipsilateral recurrence after breast conservation. A multifocal (ie, two or more foci of disease within one quadrant of the breast) or multicentric (ie, two or more foci of disease in separate quadrants) disease is associated with a higher frequency of positive lymph nodes and risk of ipsilateral breast recurrence after breast conservation therapy. Tumor staging is based on the size of the largest tumor and does not take into account other smaller foci. The sizes of multiple tumors should not be added. The presence of multiple tumors is noted by adding the (m) modifier to the T category.

Histology

A majority of invasive mammary carcinomas (75%) are of no special type, commonly referred to as infiltrating ductal carcinomas. Infiltrating lobular carcinoma is the second most common type of breast cancer (15%). Compared with infiltrating ductal carcinoma, infiltrating lobular carcinoma is characterized by the following:

- More challenging to detect with mammography
- Increased frequency of multifocality and indistinct borders
- Older age at onset
- Larger tumor size
- Lower grade
- Higher incidence of bilateral involvement at the time of diagnosis
- Greater likelihood of late recurrence

Most infiltrating lobular carcinomas are ER-positive and HER2-negative. Infiltrating lobular carcinoma frequently displays mutations in the *CDH1* gene and loss of the adhesion molecule E-cadherin, resulting in a more discohesive and infiltrative growth. Infiltrating lobular carcinomas can have a distinct pattern of metastasis with involvement of serosas, ovaries, meninges, and the gastrointestinal tract.[131]

Rarer subtypes of breast cancer include but are not limited to tubular, mucinous, adenoid cystic, medullary, micropapillary, and metaplastic tumors. The tubular and mucinous subtypes are associated with a favorable prognosis. Although adenoid cystic carcinomas of the breast usually lack hormone receptors and HER2, this rare subtype of TNBC, characterized by alterations in MYB, generally behaves indolently.[132] On the other hand, metaplastic carcinomas, characterized by epithelial and mesenchymal differentiations, have an unfavorable outcome.[133]

BIOLOGIC PROGNOSTIC INDICATORS

Tumor Grade

The histologic grading system for breast cancer is a semiquantitative evaluation of morphologic features consisting of the percentage of tubular formation, degree of nuclear pleomorphism, and mitotic count within a predefined area. On the basis of the scoring of these characteristics, three grades reflect breast cancer differentiation: low (grade 1), intermediate (grade 2), and high (grade 3). The histologic grade is an independent prognostic indicator that has been closely linked to the molecular features of breast cancer.[134]

Hormone Receptors: ER and PR

ER functions as a ligand-dependent transcriptional factor that, when activated by estrogen, regulates gene expression and activates oncogenic pathways.[135] The two isoforms of ER are ER-α and ER-β. The precise role of ER-β is currently unclear, and the term "ER" usually applies to ER-α, a product of the ESR1 gene.[136] IHC measures ER-α levels and is the method currently used to assess ER expression. ER positivity is predictive of response to endocrine therapy. PR is a marker of ER-α signaling. The 2020 ASCO/College of American Pathologists (CAP) guideline defines a tumor as ER or PR positive if 1% or more of the tumor cell nuclei are immunoreactive, but categorizes tumors with ER staining of 1% to 9% as ER low positive, and these tumors may be less sensitive to endocrine therapy.[137] ER-α is expressed in approximately 70% of invasive breast cancers, a majority of which also express PR. Cancers that are ER positive, PR negative also respond to endocrine therapy, but they tend to have a less favorable biology. ER-negative, PR-positive cancers are uncommon, and lack of ER expression can often be attributed to false-negative assay results. Patients with these cancers should still receive endocrine therapy.

Strong hormone receptor expression is frequently associated with older age, lower tumor grade, and negative lymph nodes. ER-positive, PR-positive disease is associated with a modestly superior disease-free interval, local recurrence rate, and overall survival (OS) compared with ER-negative, PR-negative disease, particularly within the first 5 to 10 years after diagnosis. However, in hormone receptor–positive breast cancer, only half of all relapses occur within the first 5 years after diagnosis, and there is a persistent significant risk of late recurrence (up to 20 years after diagnosis), despite therapy.[138,139]

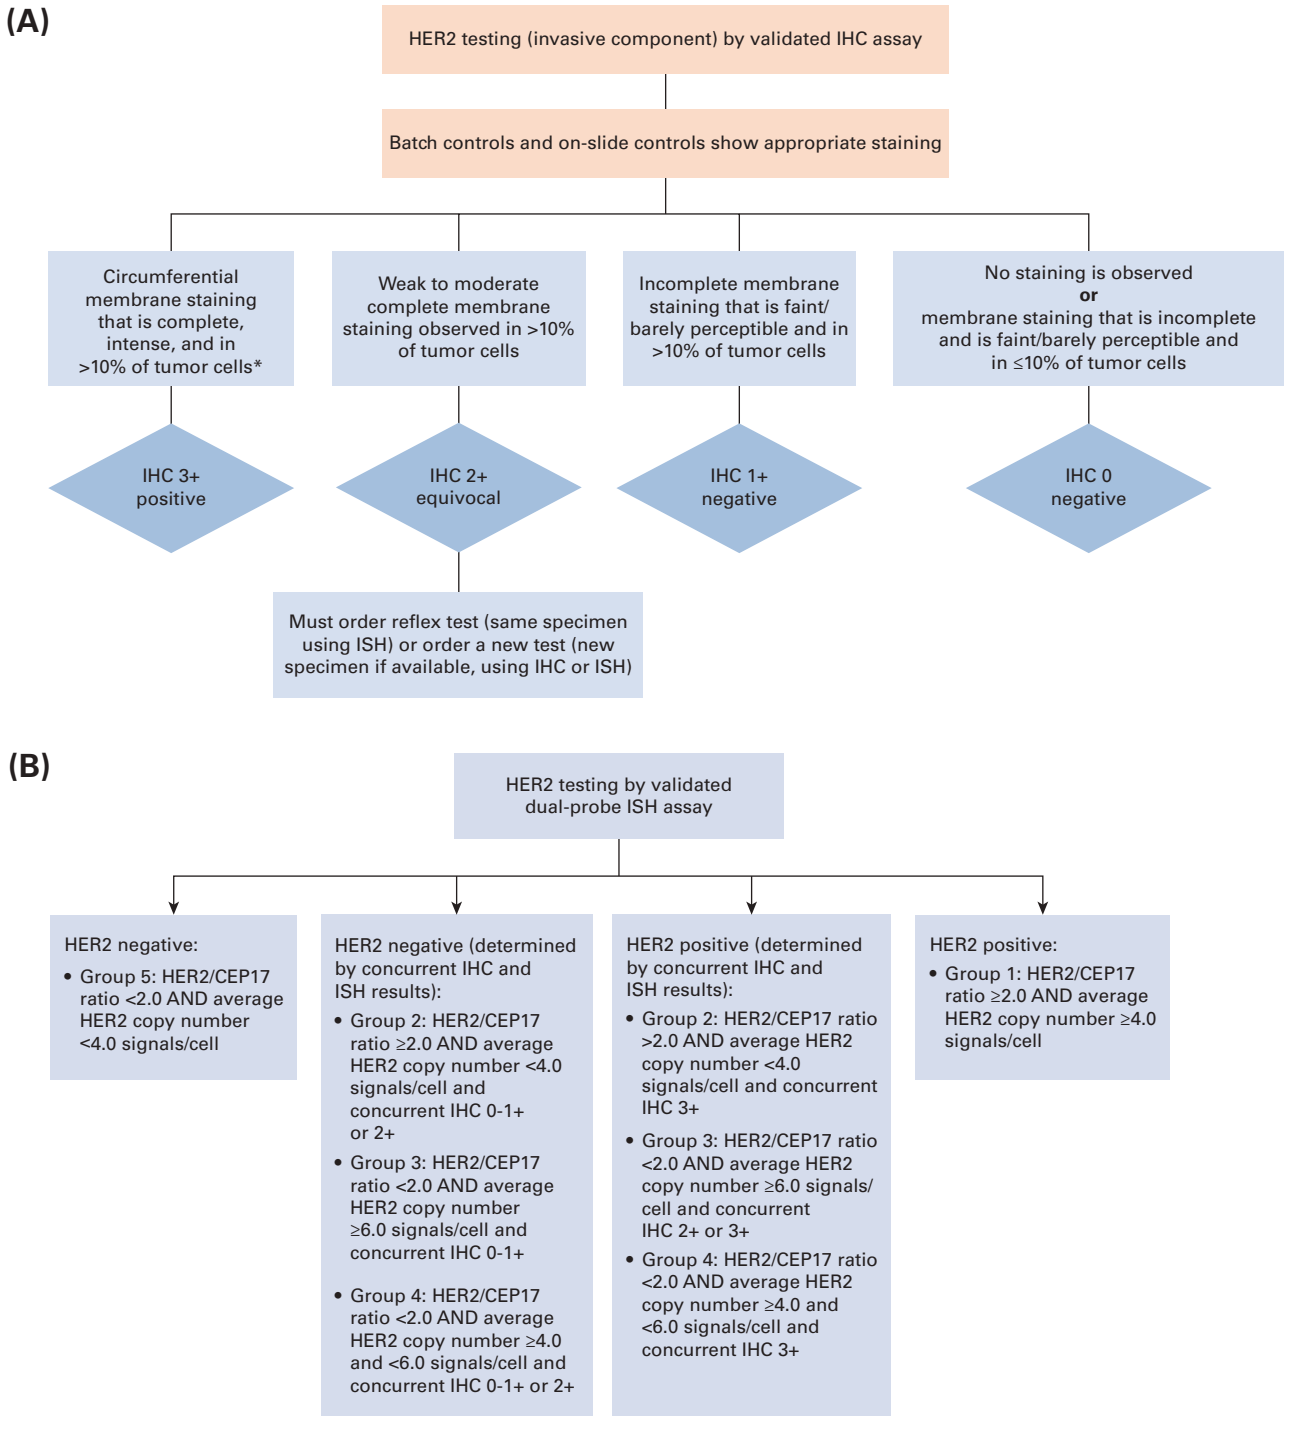
Approximately 25% of breast cancers are hormone receptor–negative, and 15% of breast cancers are triple negative. Risk of TNBC recurrence is greatest within the first 5 years and significantly declines afterward.[140]

HER2 Overexpression

HER2 is a member of the epidermal growth factor receptor (EGFR) tyrosine kinase family, which includes four transmembrane receptor proteins: HER1 (EGFR-1), HER2, HER3, and HER4. Receptor activation, through either ligand binding or ligand-independent effects, results in homodimerization or heterodimerization of the receptor proteins, which stimulate cellular growth, cell survival, migration, and angiogenesis. HER2 is overexpressed or amplified in approximately 20% of all breast cancers. HER2 overexpression is correlated with high proliferation, demonstrated by high-grade histology and a higher incidence of lymph node involvement.[141] In the absence of anti-HER2 therapy, HER2-positive disease is associated with a poor prognosis, independently

of other prognostic indicators, including tumor size, lymph node involvement, and hormone receptor status. HER2 is measured by IHC, often in conjunction with in situ hybridization. HER2 status is defined by the ASCO/CAP guideline,[142] which was updated in 2023 (Fig. 10-3A and B).

Figure 10-3 Summary of the ASCO/College of American Pathologists Guidelines



(A) HER2 testing by validated IHC assay. (B) HER2 testing by validated dual-probe ISH assay.
Abbreviations: IHC, immunohistochemistry; ISH, in situ hybridization.
*Readily appreciated using a low-power objective and observed within a homogeneous and contiguous invasive cell population.
Reproduced from Wolff AC, Hammond MEH, Allison KH, Harvey BE, McShane LM, Dowsett M. HER2 testing in breast cancer: American Society of Clinical Oncology/College of American Pathologists clinical practice guideline focused update summary. *J Oncol Pract.* 2018;14:437-441. doi:10.1200/JOP.18.00206

The updated ASCO/CAP guidelines address metastatic tumors that are not HER2 overexpressed or amplified but may respond to the HER2 antibody-drug conjugate (ADC) trastuzumab deruxtecan (T-DXd). HER2 overexpression or amplification is a strong predictive factor for response to HER2-directed therapy. The degree of HER2 positivity is not directly associated with prognosis, although higher HER2-to-CEP17 ratios may correlate with higher rates of pathologic complete response (pCR) after neoadjuvant chemotherapy and HER2-targeted therapy.[143]

Proliferation Rate: Ki67

The nuclear antigen Ki67 is currently the most used marker of proliferation rate in breast cancer. Increased proliferation correlates with adverse prognostic indicators, such as tumor size, nodal involvement, and histologic grade. Changes in Ki67, particularly after neoadjuvant therapy, have been associated with clinical outcomes and incorporated into multiple research studies. The routine use of Ki67 in clinical management has been limited by the variability of the assay, lack of reproducibility of results among pathologists, and inconsistent value as a predictive marker in clinical trials.[144]

Intrinsic Molecular Subtypes

Gene expression analysis has enabled the classification of breast cancer into distinct groups or intrinsic subtypes,[145] which have specific characteristics and prognoses. Molecular classification according to these intrinsic subtypes is not routinely used for clinical purposes, but the definition of intrinsic subtypes and their applications in research continue to further our understanding of breast cancer biology. Four main breast cancer intrinsic subtypes have been defined: luminal A, luminal B, basal, and HER2-enriched. The general characteristics of these subtypes are summarized in Table 10-4. There is a substantial but not complete overlap between classification according to intrinsic subtypes and routine immunostains for ER, PR, and HER2.

Table 10-4 Molecular Subtypes

Subtype	Characteristic
Luminal A	Favorable prognosis High ER/PR Low proliferation rate Grade 1/2 Lower sensitivity to chemotherapy
Luminal B	Less favorable prognosis Lower ER and PR High proliferation rate Grade 2/3 Higher sensitivity to chemotherapy
HER2 enriched	HER2 positive Hormone receptor positive or negative High proliferation rate Grade 2/3
Basal	ER, PR, and HER2 negative High proliferation rate Grade 3

Abbreviations: ER, estrogen receptor; PR, progesterone receptor.

GENE EXPRESSION SIGNATURES

There are several validated tests to assess the risk of breast cancer recurrence, particularly in early-stage hormone receptor–positive breast cancer.

MammaPrint is a 70-gene signature that classifies tumors as having either a high or low risk of recurrence.[146] MammaPrint was prospectively validated in the MINDACT trial.[147] In this phase 3 study of women with early-stage breast cancer and up to three positive lymph nodes, genomic risk (according to MammaPrint) and clinical risk (according to a modified version of Adjuvant! Online) were determined. Most patients had node-negative and ER–positive tumors.

- Women at low clinical and genomic risk did not receive adjuvant chemotherapy, and those at high clinical and genomic risk received chemotherapy.
- Patients with discordant clinical and genomic risk results were randomly assigned to chemotherapy. Women with high clinical risk but low genomic risk who did not receive chemotherapy had a 5-year survival rate without distant metastases 1.5% lower than those with chemotherapy (this was not a significant difference).
- There was no benefit of chemotherapy in patients with low clinical risk and high genomic risk.
- ASCO guidelines state that the MammaPrint assay may be used to guide decisions on withholding adjuvant systemic chemotherapy in patients with hormone receptor–positive, node-negative breast cancer and in select patients with node-positive breast cancer. MammaPrint should only be used in patients with high clinical risk.[148]

The 21-gene expression assay known as Oncotype DX[149] is the most widely used prognostic and predictive genomic recurrence score test in the United States. The Oncotype recurrence score is reported as a continuous function to assess the risk of systemic recurrence among women with ER-positive breast cancer treated with tamoxifen for 5 years.[150] The risk of recurrence was initially defined as low (recurrence score, less than 18), intermediate (recurrence score, 18-30), and high (recurrence score, greater than or equal to 31) on the basis of prespecified cutoffs. In the initial retrospective validation studies, node-negative tumors with a high recurrence score derived the greatest benefit from chemotherapy.[150] Chemotherapy was not beneficial in women who had a low recurrence score, and its role in women with an intermediate-range recurrence score was unclear. In addition, postmenopausal women who had one to three involved lymph nodes and a recurrence score of less than 18 did not benefit from the addition of chemotherapy to tamoxifen.[151]

The TAILORx trial was a prospective trial to clinically validate the prognostic and predictive value of the 21-gene expression assay in hormone receptor–positive, HER2-negative, and lymph node–negative breast cancer. Patients who had a recurrence score of 0 to 10 received endocrine therapy alone and had a low rate of distant relapse at 5 years.[152] Patients who had a recurrence score of 11 to 25 were randomly assigned to receive either adjuvant chemotherapy and endocrine therapy or endocrine therapy alone, whereas patients who had a recurrence score higher than 25 received chemotherapy in addition to endocrine therapy.

- In general, there was no benefit with the addition of chemotherapy in patients who had a recurrence score of 11 to 25.
- However, the benefit of chemotherapy varied according to age for those with intermediate recurrence scores; women 50 years or younger who received chemotherapy and had a recurrence score of 16 to 20 had a 1.6% lower rate of distant recurrence at 9 years, which increased to 6.5% in women with a recurrence score of 21 to 25. Exploratory analysis has suggested that this benefit may be mediated by the hormonal effect of chemotherapy, inducing menopause in pre/perimenopausal women rather than its direct cytotoxic effects; however, this hypothesis is not yet validated.
- The risk of recurrence and the benefit of chemotherapy were further influenced by tumor size and grade.[153] These factors are integrated into the RSClin score, which estimates recurrence risk with and without chemotherapy, and with tamoxifen versus an AI on the basis of recurrence score, age, tumor grade, and size.[154]

The RxPONDER trial prospectively assessed whether women with low-volume, node-positive breast cancer (one to three nodes) and a recurrence score of 25 or lower could safely avoid chemotherapy.

- This study showed no benefit of chemotherapy in postmenopausal women.[155]
- By contrast, in premenopausal women, the addition of chemotherapy to endocrine therapy was associated with a 5.2% benefit in the invasive disease-free survival (iDFS) rate, regardless of recurrence score.

Although biologically plausible, it is unknown whether chemotherapy-induced amenorrhea played a role in this observation. In the prospective West German Study PlanB trial,[156] women who had fewer than three lymph nodes involved and a recurrence score of 11 or lower had a good outcome with endocrine therapy alone, again supporting the omission of chemotherapy in women who had high clinical risk but favorable biology.

Other signatures, including the PAM50 risk of recurrence (a gene signature derived from the original intrinsic subtype classification), EndoPredict, and the Breast Cancer Index, were retrospectively validated to assess the risk of recurrence, including after 5 years of treatment (late recurrence). Patients with hormone receptor–positive, HER2-negative cancer, and a low Breast Cancer Index score are at lower risk of distant recurrence and derive less benefit from extended endocrine therapy (beyond 5 years). Patients who have a high Breast Cancer Index score have a higher risk of late distant recurrence, and disease-free survival (DFS) seems to improve with extended endocrine therapy.[157,158]

In summary, gene signatures are now commonly used to inform adjuvant chemotherapy in hormone receptor–positive, node-negative and low-volume, node-positive breast cancers, along with other factors. For patients who have node-negative disease, ASCO guidelines recommend the addition of chemotherapy for those who have a recurrence score of 26 or higher, or higher than 16 if younger than 50 years may also be offered chemotherapy.[148,159] For patients who have one to three positive lymph nodes,

chemotherapy should be discussed with premenopausal patients, who derive benefit regardless of recurrence score, and can be omitted in postmenopausal women who have a recurrence score of 25 or lower. Chemotherapy should be discussed with postmenopausal women who have one to three positive lymph nodes and a recurrence score higher than 25, and with any patient who has four or more positive lymph nodes, because there are insufficient data at this time on the role of recurrence score for N2 disease.

KEY POINTS

- Pathologic features associated with a favorable prognosis include small tumor size, negative lymph node status, low tumor grade, absence of lymphovascular invasion, and positive hormone receptor status.
- Quantitative ER expression is predictive of response to endocrine therapy.
- HER2 overexpression/amplification is predictive of benefit from HER2-directed therapy.
- The 21-gene recurrence score and 70-gene signature have been validated prospectively in large trials and may guide the use of adjuvant chemotherapy in addition to endocrine therapy in hormone receptor–positive and HER2-negative breast cancer patients who have either no nodal involvement or one to three lymph nodes involved.

INITIAL EVALUATION

The initial evaluation of patients diagnosed with breast cancer includes a physical examination and breast imaging with diagnostic mammography with or without ultrasonography. Additional diagnostic testing should be individualized, especially the use of breast MRI (see "Diagnosis" section). Baseline laboratory tests, such as a complete blood count and liver function tests, can be obtained for women who will need chemotherapy and/or for those in whom clinical symptoms or signs are suggestive of metastatic disease. In the absence of symptoms, imaging studies to evaluate for metastasis are not routinely recommended for patients who have stage I. It could be considered in patients with stage II to III disease based on clinical concern, particularly those with node-positive disease and high-risk histologies such as HER2-positive or TNBC. Systemic staging consists of either CT imaging of the chest and abdomen (with or without a CT scan of the pelvis) and a bone scan or a fluorodeoxyglucose (FDG) PET scan. PET/CT may reduce the false-positive risk by half compared with CT and bone scan and allow neoadjuvant treatment to start earlier.[160-163] Brain MRIs are not part of routine staging in the absence of symptoms, although a lower threshold should be considered for HER2–positive breast cancer.

Additional considerations for patients who have a new diagnosis of breast cancer include the following:

- Genetic counseling for patients who have a family history positive for cancer or other characteristics that may suggest an inherited predisposition, as outlined in "Risk Factors" section. The American Society of Breast Surgeons and ASCO have recommended that genetic testing be offered to all patients who have a personal history of breast cancer.
- Premenopausal women who use a hormonal method of contraception should be counseled about nonhormonal alternatives. In such cases, referral to a gynecologist or a women's health specialist is indicated.
- All patients of reproductive age should be counseled regarding the risks of infertility (as a result of chemotherapy) and/or delayed childbearing (as a result of adjuvant endocrine therapy). Consultation with a reproductive specialist should occur early for those interested in fertility preservation.[164]

Oocyte, sperm, and embryo cryopreservation are established methods of fertility preservation. Several trials have evaluated suppression of ovarian function with gonadotropin-releasing hormone (GnRH) agonists administered concurrently with chemotherapy as a method of fertility preservation. These trials have yielded conflicting results. However, in the randomized POEMS study, women who had hormone receptor–negative breast cancer who received goserelin starting 1 week before initiation of chemotherapy had a higher likelihood of a successful pregnancy.[165] In a meta-analysis including hormone receptor–positive and hormone receptor–negative breast cancers, the use of GnRH agonists decreased the rate of premature ovarian failure and did not affect breast cancer outcome.[166] The ASCO fertility preservation guideline states that a GnRH agonist may be offered to patients in the hope of reducing the likelihood of chemotherapy-induced ovarian insufficiency. However, GnRH agonists should not be used in place of proven fertility preservation methods.[164]

TREATMENT OF DCIS

DCIS is a neoplastic proliferation of epithelial cells confined to the mammary ductal-lobular system and characterized by subtle to marked cytologic atypia and risk of progression to invasive breast cancer.[167] In TNM staging, DCIS is designated as Tis/stage 0. Although DCIS occasionally may present as a mass or nipple discharge, 80% to 85% of the time, DCIS is detected by a screening mammogram and presents without clinical findings. Calcifications are the most common mammographic presentation of DCIS, and, because of mammographic screening, DCIS accounts for approximately 20% of all breast cancers in the United States.

DCIS is a heterogeneous entity. Pathologic features used to describe DCIS include the following:

- Nuclear grade (low, intermediate, or high)
- Presence of necrosis
- Architectural pattern (comedo, solid, cribriform, micropapillary, or papillary)
- Size or extent of the lesion

DCIS can be associated with a microinvasive tumor (tumor size less than 1 mm), which is staged as T1mi. An estimated 15% to 50% of DCIS tumors will ultimately progress to invasive disease if left intact by either direct transformation or development in parallel from a single progenitor cell.[168] The exact biologic mechanism is not well understood, and we cannot predict which subset of DCIS will progress to invasive breast cancer. ER testing of DCIS is recommended, but there are no current data to support HER2 testing.

Paget's disease of the breast is an unusual form of breast cancer, which begins as adenocarcinoma cells within the epidermis of the nipple-areola complex and extends into the surrounding areola. It frequently presents as eczematous changes of the nipple-areola complex. Surgical treatment usually requires excision of the nipple/areolar complex. Further appropriate local and systemic treatment of Paget's disease depends on the underlying cancer, which may either be completely in situ or may have progressed to invasive disease.

Although surgical excision (lumpectomy or mastectomy) is a current standard of care, surgery leads to potential overtreatment in many cases. Recognizing this risk, studies to compare surgery with active surveillance in cases of low-risk DCIS are ongoing.[169]

The goal of treatment in DCIS is to prevent local recurrence, because approximately half of local recurrences of DCIS are invasive.[170] The risk of local recurrence after a simple mastectomy is 1% to 2%. Based on the data on invasive breast cancer, breast-conserving surgery and radiation therapy (also called breast conservation therapy) were adopted as an appropriate option for treating DCIS. Breast conservation therapy or mastectomy provides equivalent long-term disease-specific survival.[171] The most current guidelines establish 2 mm as the standard for an adequate margin for pure DCIS treated with radiation therapy.[172] If the DCIS is associated with invasive carcinoma, then "no ink on tumor" is considered adequate. Axillary node dissection or sentinel node biopsy is not routinely performed in DCIS. However, sentinel lymph node biopsy (SLNB) should be considered in situations with a higher likelihood of finding invasive cancer in the surgical specimen (large or palpable lesions) or in patients undergoing mastectomy (because SLNB is not feasible after mastectomy if invasive cancer is identified on surgical pathology review).[173]

RADIATION THERAPY

After a margin-negative lumpectomy for DCIS, patients remain at modest risk of local recurrence within the breast. The addition of adjuvant radiation therapy to surgical excision has been evaluated by several randomized trials, revealing that the relative local control benefit of radiation therapy ranges from approximately 30% to 60%, depending on baseline risk.[174,175] Although recent studies have shown low overall recurrence rates (likely because of the concomitant use of endocrine therapy along with improvements in imaging and surgical technique), the relative benefit of radiation therapy persists when studied in a randomized controlled manner. A large body of literature supports both conventional (5-6 weeks) and hypofractionated (3-4 weeks) whole-breast radiation therapy as equivalent options for DCIS.[176,177] Accelerated partial breast irradiation is also a suitable option among appropriately selected patients.[178] Factors associated with increased risk of local recurrence include margins smaller than 2 mm, large tumor size, younger patient age, high nuclear grade, and presence of necrosis, among other histologic features.

Studies have yet to identify a subset of patients who do not benefit from radiation therapy with respect to local control.[177,178] However, although radiation therapy improves local outcomes, no reports to date have demonstrated a survival benefit for adjuvant radiation therapy for DCIS. Given limited absolute rates of recurrence in contemporary practice, some patients may forgo radiation therapy, assuming modest absolute increases in local recurrence risk without impinging on OS outcomes.[179]

ENDOCRINE THERAPY

The long-term outcomes are excellent for noninvasive breast cancer. Therefore, endpoints of adjuvant trials were to lower ipsilateral and contralateral events. In the NSABP B-24 trial, adjuvant tamoxifen at 20 mg for 5 years after breast-conserving surgery and whole-breast irradiation for DCIS resulted in a 32% relative reduction in the risk of local recurrence (from 9% to 6.6%) and a 53% relative reduction in the risk of contralateral disease over 15 years.[170] Premenopausal and postmenopausal women were included. The benefit of tamoxifen was seen only in ER–positive DCIS and was not associated with improved OS.[180] In the NSABP B-35 trial of postmenopausal women who received breast conservation therapy for ER–positive DCIS, adjuvant anastrozole was associated with a small improvement in breast cancer–free interval at 10 years versus tamoxifen (93.5% vs 89.2%), with the benefit mainly limited to women younger than 60 years.[181] Therefore, both adjuvant tamoxifen and anastrozole are appropriate options for postmenopausal women with DCIS, and considerations regarding toxicities should influence treatment choices for individual women. There is no role for endocrine therapy for risk reduction in women who undergo bilateral

mastectomy. Women who have a unilateral mastectomy for ER–positive DCIS may consider endocrine therapy for the prevention of contralateral breast cancer.

The TAM-01 study was a randomized placebo-controlled trial of 500 women who had DCIS, lobular carcinoma in situ, or ADH and evaluated the benefit of tamoxifen 5 mg for 3 years versus placebo. The 10-year follow-up data show a roughly 50% risk reduction in invasive cancer events, similar to the standard tamoxifen 20 mg for 5 years. There was no significant change in menopausal symptoms, such as hot flashes or vaginal dryness, between the two groups. Rates of venous thromboembolic events were the same in the tamoxifen and placebo arms, and one patient receiving tamoxifen developed endometrial cancer (0.4%).[93]

KEY POINTS

- DCIS (stage 0) accounts for approximately 20% of breast cancers in the United States.
- Most cases of DCIS are detected on screening mammograms.
- Whole-breast irradiation decreases the risk of local recurrence after breast-conserving surgery.
- DCIS treated with mastectomy or breast conservation therapy results in equivalent breast cancer–related 5-year survival rates.
- Current guidelines establish 2 mm as an adequate margin of resection in DCIS treated with breast conservation therapy.
- For women with ER–positive DCIS who elect to undergo breast conservation therapy, adjuvant endocrine therapy reduces the risk of ipsilateral and contralateral recurrences with no established survival benefit. For those patients who undergo bilateral mastectomy for DCIS, there is no role for endocrine therapy for prevention.
- Adjuvant tamoxifen (for premenopausal and postmenopausal women) and AIs (for postmenopausal women only) are appropriate options for decreasing subsequent invasive breast cancers in women with ER–positive DCIS treated with breast conservation therapy.

TREATMENT OF NONMETASTATIC OR EARLY-STAGE INVASIVE BREAST CANCER (STAGES I, II, AND III)

Treatment of early-stage invasive breast cancer focuses on reducing the risks of locoregional (breast and regional lymph nodes) and systemic recurrences. The decision to add systemic therapy to the local treatment of breast cancer is based on the risk of development of distant metastasis and the relative and absolute benefit of therapies to reduce that risk. For each patient, a multidisciplinary evaluation should occur at diagnosis to determine the optimal treatment modalities (local and systemic) and their sequencing.

Historically, surgery was typically performed first, followed by chemotherapy (and concurrent anti-HER2 therapy if HER2 positive), and then radiation to the remaining breast or chest wall and endocrine therapy for many subsequent years. The decisions to recommend each (breast preserving therapy vs mastectomy; chemotherapy or not, radiation or not, and targeted nonchemotherapy systemic therapy [endocrine therapy, targeted therapy, and anti-HER2 therapy]) have been based on staging (T, N) and expression of ER and HER2.

Over the last two to three decades, several studies have investigated the benefits of administering systemic therapy before rather than after surgery—termed "neo-adjuvant" therapy. Neo-, compared with classic postsurgical, adjuvant systemic therapy, has several potential advantages:[182,183]

- Possible higher efficacy because of two hypothetical advantages: (1) giving the therapy a few months sooner rather than waiting for surgery and healing, thus minimizing cellular mutation to therapy resistance and (2) giving the therapy before surgery to avoid the growth factor "storm" related to wound healing.
- Downstaging the tumor and permitting more effective surgery or equally effective but less disfiguring surgery.
- Identifying patients for whom the applied systemic therapy is less effective (based on residual disease after the surgery) and who might benefit from additional systemic treatments.
- Investigational studies of the efficacy of novel therapies.

In regard to the first bullet, a meta-analysis showed that preoperative (neoadjuvant) and postoperative (adjuvant) chemotherapies were similarly effective in lowering the risk of distant disease recurrence or breast cancer mortality.[184] Other potential benefits of neoadjuvant chemotherapy are discussed in subsequent sections.

Endocrine therapy and HER2-targeted therapy can safely be administered concurrently with radiation therapy; however, chemotherapy is usually completed before starting radiation therapy. Neoadjuvant endocrine therapy can be used in select patients, although it is uncommon (see "Neoadjuvant Endocrine Therapy" section).

Stage III disease was originally defined as tumors that were either too big (IIIa) or too locally extensive (IIIb) for surgery to be considered effective, and, therefore, these cancers were deemed "inoperable" as defined as follows:

1. IIIa: Patients who have large tumors (T3; 5 cm or larger) or multiple palpable positive lymph nodes, who have disease that can be resected.
2. IIIb: Patients who have inoperable disease (T4) because of skin involvement (nodules or ulcers), disease attachment to the chest wall, inflammatory carcinoma, or extensive nodal involvement that precludes initial surgical resection (eg, matted axillary lymph nodes and supraclavicular lymph node involvement).

Patients who have inoperable disease require neoadjuvant systemic therapy, followed by surgery and radiation therapy.

Locoregional treatment includes decisions regarding breast surgery (breast conservation or mastectomy), surgical management of axillary lymph nodes, and radiation therapy.

BREAST SURGERY

The past decades of research regarding breast and axillary surgery have focused on minimizing interventions to lower morbidity while maintaining equivalence in outcomes.

- The NSABP B-04 study established that there is no difference in OS between a Halsted radical mastectomy (ie, removal of the breast, chest wall muscles, and regional lymph nodes) and total (or simple) mastectomy (ie, removal of the breast).[185]
- The NSABP B-06 trial established that there are no differences in OS between total mastectomy and lumpectomy, either with or without radiation therapy.[185] Patients who received radiation therapy after lumpectomy had fewer local recurrences than those treated with lumpectomy alone, with no difference in local recurrence rates between lumpectomy and radiation therapy compared with mastectomy.

Optimal characteristics for breast conservation therapy include the ability to resect the entire tumor with negative surgical margins and achieve an acceptable cosmetic outcome. If these conditions are not met at diagnosis, neoadjuvant systemic therapy may be favored to downstage the disease in the breast and/or axilla. The current definition of adequate negative surgical margins for invasive breast cancer, according to the Society of Surgical Oncology as well as the St. Gallen International Expert Consensus Conference on the Primary Therapy of Early Breast Cancer, is no tumor present in the inked margin, whereas a margin of 2 mm is considered adequate for DCIS.[186,187] Patients with invasive cancer with DCIS, including those with an extensive intraductal component (defined as DCIS occupying at least 25% of invasive carcinoma or a lesion that is predominantly DCIS with one or more foci of invasive disease), should be treated according to the invasive breast cancer guidelines. Individual judgment, however, is important, particularly in patients thought to be at higher risk of residual disease after breast-conserving surgery.

Patients who are not candidates for breast conservation therapy should undergo a total mastectomy. Relative contraindications to breast conservation therapy for operable disease include the following:

- Multicentric disease (see below)
- Diffuse suspicious calcifications
- Persistently positive margin(s) after re-excision
- Pregnancy in the first or second trimester (women in the second to third trimester might be candidates for breast conservation therapy if radiation therapy is delayed until delivery)
- Prior radiation therapy and autoimmune connective tissue diseases involving the skin are considered relative contraindications.[188] In recent years, breast conservation and reirradiation have gained wider acceptance.[189]

In the case of multicentric disease, treatment can be individualized. The ACOSOG Z11102 trial prospectively evaluated lumpectomies for two to three biopsy-proven foci of ipsilateral N0/1 breast cancer. Patients underwent two to three margin-negative lumpectomies and radiation to each lumpectomy bed. At a median follow-up of 66.4 months, the 5-year local recurrence rate was 3.1%, below the prespecified threshold of 8%. In motivated patients for whom cosmesis would not be significantly compromised, multiple lumpectomies for multicentric tumors are considered a safe approach, provided preoperative MRI does not show evidence of intervening disease between biopsy-proven sites.[190]

SURGICAL MANAGEMENT OF THE AXILLA

Surgical management of the axilla is an integral part of the local treatment of breast cancer. The extent of and even indications for axillary surgery have decreased over time, resulting in less morbidity and similar breast cancer outcomes. The following are some key findings guiding current surgical management of the axilla in patients not receiving neoadjuvant therapy (Fig. 10-4A and B)[191]:

- Women who have a clinically negative axilla are candidates for SLNB at the time of their breast surgery, which results in substantially less morbidity compared with axillary lymph node dissection. Routine immunohistochemical staining

of the sentinel lymph node for cytokeratins is not recommended, and most therapeutic decisions should be based on assessment of tumor presence in the sentinel lymph node as determined by hematoxylin and eosin staining. In women with a negative SLNB specimen, the likelihood of additional nodal involvement is small, and no additional surgery is indicated.[192,193]

- The Society of Surgical Oncology Choosing Wisely Guidelines recommend no axillary surgery in women ≥70 years with early-stage, hormone receptor–positive breast cancer.
- A substantial proportion of women with limited axillary nodal involvement no longer require an axillary lymph node dissection (complete level 1 and level 2 dissection). The ACOSOG Z0011 study showed that, in patients who have clinical T1 or T2 tumors, a clinically negative axilla (N0), and one or two positive sentinel lymph nodes treated with lumpectomy, tangential whole-breast irradiation, and adjuvant therapy, sentinel lymph node dissection was noninferior to axillary lymph node dissection.[194] Axillary lymph node dissection is still usually performed in patients whose tumors do not fit the Z11 criteria (including those undergoing mastectomy), in patients who will not receive radiation therapy, or if the sentinel lymph node is not identified.
- IBCSG 23-01[195,196] showed noninferiority of no axillary dissection compared with axillary dissection in patients with micrometastatic sentinel nodal disease (with most patients in this study treated with lumpectomy and radiation therapy and a minority treated with mastectomy).
- In the AMAROS study, patients who had a T1 to T2 tumor and clinically negative axilla but positive sentinel lymph node were randomly assigned to either axillary surgery or radiation therapy. Most patients had one positive sentinel lymph node. Both patients treated with lumpectomy (82%) and those undergoing mastectomy were enrolled. In this study, local control was excellent in both the radiation therapy and surgical arms, but the rate of lymphedema was lower in the radiation therapy arm. Therefore, omission of axillary lymph node dissection can be considered if radiation to the axilla is planned.[197]
- Data from several randomized trials of SLNB versus observation have identified a group of patients for whom no SLNB is recommended. Postmenopausal women ≥50 to 69 years undergoing breast-conserving surgery for a unifocal grade 1 to 2, hormone receptor–positive and HER2-negative tumor <2 cm and who had a negative axillary ultrasound had excellent iDFS rates and low rates of axillary recurrence without SLNB. Patients received breast radiation.[198,199]

Patients who are candidates for neoadjuvant chemotherapy who present with a clinically negative axilla can undergo sentinel lymph node surgery after completion of neoadjuvant chemotherapy.[200] If the sentinel lymph nodes are negative, no additional axillary surgery is indicated. If any sentinel lymph node is positive, complete axillary lymph node dissection is recommended.[201]

Patients presenting with clinically node-positive disease by physical exam will need axillary lymph node dissection unless they receive neoadjuvant systemic therapy with a favorable response in the lymph node. The likelihood of downstaging the axilla with neoadjuvant chemotherapy is higher in patients presenting with TNBC or HER2-positive breast cancer for whom this approach is particularly favored.[202] Several studies have examined the feasibility of SLNB after neoadjuvant chemotherapy.[203-205] In ACOSOG 1071, the use of dual-tracer mapping and retrieval of at least three sentinel lymph nodes resulted in clinically acceptable false-negative rates of less than 10%, which is similar to the sentinel lymph node false-negative rate in patients who have clinically node-negative disease undergoing up-front SLNB, suggesting that axillary lymph node dissection can be omitted in select cases. Targeted axillary dissection, in which a lymph node is biopsied and clipped before neoadjuvant surgery, is removed in addition to any sentinel lymph nodes, also decreases the false-negative rate, although occasional technical challenges are encountered with this approach.

Ongoing clinical trials are also exploring the optimal locoregional management of the axilla after neoadjuvant chemotherapy. Alliance A011202 randomly assigns patients who have a positive sentinel lymph node after neoadjuvant chemotherapy to axillary dissection or axillary radiation therapy to evaluate which modality provides the best local control and survival. NSABP B-51 examined whether adjuvant nodal radiation therapy is required in patients who convert from biopsy-proven node-positive disease to pathologically node-negative disease after neoadjuvant chemotherapy by randomly assigning them to nodal radiation therapy or no radiation therapy. Evaluable patients (n = 1,556) had similar outcomes whether they received adjuvant regional nodal irradiation or not: 91.8% of patients without radiation and 92.7% of those with radiation were free of invasive breast cancer recurrences 5 years after surgery. Distant recurrence and OS rates were also similar between the arms, with 93.4% of patients in each arm free from distant recurrence 5 years after surgery, and 94% of those without radiation and 93.6% of those with radiation alive after 5 years.[206] Therefore, in cT1-3N1 patients who convert to ypT0-1N0 after neoadjuvant chemotherapy, adjuvant postmastectomy radiation therapy (PMRT)/regional nodal irradiation may be omitted.

ADJUVANT RADIATION THERAPY AFTER BREAST-CONSERVING SURGERY

Radiation to the Breast

Adjuvant breast radiation therapy is recommended for most patients who have invasive breast cancer after breast-conserving surgery. This includes patients treated with neoadjuvant therapy, regardless of clinical or pathologic response. A landmark meta-analysis revealed that radiation therapy after breast-conserving surgery reduced the rate of locoregional recurrences by

approximately half (from 35.0% to 19.3%) and decreased the absolute risk of death as a result of breast cancer by one-sixth (from 25.2% to 21.4%) at 10 and 15 years, respectively.[207] Although the proportional benefit was similar across subgroups, the absolute benefit of radiation therapy differed significantly as a function of patient age, disease stage, tumor grade, ER status, tamoxifen use, and extent of surgery.

Contemporary systemic therapy, along with advances in imaging, surgical, and irradiation techniques, has contributed to improved local control after breast conservation therapy across all tumor types. Recent randomized controlled trials in patients with early-stage breast cancer have reported 10-year local recurrence rates as low as 2% to 7% under favorable circumstances.[208-210]

Hypofractionated whole-breast irradiation, in which the breast receives 40 to 42.5 Gy over 3 weeks (15-16 fractions), is now an established option for most patients undergoing whole-breast treatment. This dosing is based on randomized trials demonstrating equivalent local control and favorable toxicity compared with the more traditional approach of 25 fractions over 5 to 6 weeks.[208-210] A boost to the tumor bed is typically recommended, except in patients at lower risk of recurrence.[211]

In contrast to whole-breast irradiation, accelerated partial breast irradiation targets the region of the tumor bed while sparing more distant breast tissue and is typically administered over 1 to 2 weeks, either once or twice daily. Accelerated partial breast irradiation is an option for appropriately selected patients, and trials over the past decade have increasingly expanded the breadth of suitable indications.[176]

Older patients with favorable tumor characteristics (eg, small, node-negative, ER–positive tumors) who receive endocrine therapy may undergo breast-conserving surgery alone and omit radiation therapy in select circumstances. This approach is based on several studies showing that although radiation therapy decreased the rate of locoregional failure, the absolute risk of locoregional recurrence in the absence of radiation therapy may remain low with no effect on OS, provided endocrine therapy is taken.[209,212] Several studies are ongoing to evaluate whether radiation therapy may be feasibly omitted in younger patients, based on risk stratification using molecular biomarkers.[213]

Regional Nodal Radiation Therapy After Breast Conservation Therapy or Mastectomy

Regional nodal irradiation typically refers to comprehensive targeting of the axilla (levels 1, 2, and 3), supraclavicular fossa, and internal mammary nodal basin (interspaces 1-3), although each case is individualized based on the extent of disease, presenting clinicopathologic features, and type of axillary surgery. Regional nodal irradiation is generally indicated for patients who have three or more involved lymph nodes and may be considered in those who have one to three involved nodes and other risk factors for recurrence. Those without nodal involvement sometimes also qualify for regional nodal irradiation if the risk of recurrence is high based on a constellation of clinicopathologic risk factors. This personalized approach is largely based on the results of two contemporary studies among patients with node-positive or high-risk node-negative breast cancer: NCIC-CTG MA.20[214] and EORTC 22922/10925.[215] These trials evaluated adjuvant radiation to the breast/chest wall versus radiation to the breast/chest wall and regional nodal irradiation. Notably, both studies showed significant improvements in locoregional control, distant metastasis–free survival, and DFS; however, no significant OS benefits were observed.

Landmark surgical studies evaluating the omission of axillary lymph node dissection (in favor of SLNB) have shown excellent outcomes without regional nodal irradiation for select node-positive situations.[194,197] This has led to several randomized trials that allow for differing radiation therapy approaches to be applied in those cases with fewer than three involved nodes. Indeed, axillary nodal management, particularly among patients with a low burden of nodal disease, remains among the most controversial decisions in contemporary locoregional breast treatment.

KEY POINTS

- The goal of systemic therapy in nonmetastatic disease is to reduce the risk of local recurrence and distant metastasis.
- Randomized trials have demonstrated equivalent survival, regardless of whether neoadjuvant or adjuvant chemotherapy is used.
- Patients who present with inoperable disease require neoadjuvant therapy.
- pCR after neoadjuvant systemic therapy is a strong prognostic factor for reduced risk of recurrence, particularly in TNBC and HER2-positive disease.
- The presence of residual disease after neoadjuvant systemic therapy guides adjuvant systemic therapy choices.
- Treatment of operable breast cancer with mastectomy or breast conservation therapy results in equivalent survival in stages I and II breast cancer, with the following exceptions.
- Positive margins. The definition of an adequate margin of resection for invasive breast cancer treated with breast conservation therapy is no tumor present in the inked margin.
- Inability to remove the tumor with adequate margins and a favorable cosmetic outcome.
- Multicentric disease.
- Contraindications to radiation therapy.
- Patients presenting with a clinically negative axilla can undergo SLNB but axillary staging may be omitted in certain populations with low-risk hormone receptor–positive and HER2-negative tumors.

- Patients with clinical T1 to T2 N0 tumors and up to two involved sentinel lymph nodes treated with up-front breast conservation therapy and whole-breast irradiation can avoid axillary lymph node dissection.
- Patients with clinical T1 to T2 N0 tumors with one to two SLN metastases treated with up-front mastectomy may omit axillary lymph node dissection, provided PMRT is indicated based on additional risk factors.
- Patients presenting with clinically positive lymph nodes require axillary lymph node dissection unless neoadjuvant therapy is used, and their approach must be individualized.
- Hypofractionated radiation therapy is now an established option for most patients requiring adjuvant radiation therapy.
- Accelerated partial breast irradiation is a suitable option for appropriately selected patients.
- Adjuvant breast radiation therapy may be omitted in older patients who have favorable tumor characteristics under select conditions.
- Regional nodal irradiation after breast-conserving surgery or mastectomy is typically indicated in patients who have three or more positive lymph nodes and can be considered in patients who have zero to three positive lymph nodes and additional risk factors.

SYSTEMIC THERAPY: GENERAL PRINCIPLES

One of the hallmarks of cancer is genetic instability with increasing clonal evolution, with mutations that confer sensitivity and resistance to systemic therapies. Few, if any, trials have demonstrated long-term OS or cure in patients with established macrometastases. The major objective of adjuvant systemic therapy is to treat micrometastases before they evolve into macrometastases. Multiple clinical trials have demonstrated the benefit of adjuvant systemic therapy in reducing the incidence of distant metastatic disease and mortality.

However, not all patients need or will respond to adjuvant systemic therapy. Stage and biology are used to determine the risk of distant recurrence and guide the choice of adjuvant treatment. Other factors are also considered when making treatment decisions. Age is an independent prognostic feature. Women younger than 35 years have a worse 5-year OS compared with women aged 35 to 69 years (74.7% vs 83.8%-88.3%)[216,217]; therefore, the threshold for offering adjuvant therapy is often reduced in younger women.[218] On the other hand, relatively few clinical trials have included a substantial number of women older than 70 years. Patient preferences, treatment toxicity, and comorbidities are also important treatment considerations (Fig. 10-5).

In general, breast cancers with a tumor size larger than 0.5 cm have a high enough risk of systemic recurrence to warrant consideration of adjuvant treatment. Patients with a tumor size of 0.5 cm or smaller and negative nodes may not gain sufficient benefit from systemic chemotherapy or HER2-directed therapy to justify the expected toxicities. For hormone receptor–positive breast cancers, risk assessment using genomic assays can identify a group of patients who may avoid chemotherapy. Adjuvant endocrine therapy is recommended for hormone receptor–positive breast cancers to reduce the risk of distant and local recurrences and as a secondary prevention, given its favorable safety profile.

The following are general principles regarding adjuvant chemotherapy:

- Full-dose chemotherapy is administered based on height and actual weight. The Hematology/Oncology Pharmacy Association recommends that cytotoxic agents be considered independently for dose rounding within 10% of the prescribed dose.
- Combination chemotherapy is superior to single-agent chemotherapy.
- In general, anthracycline- and taxane-containing regimens are appropriate for higher-risk disease, whereas non–anthracycline-containing regimens can be used for node-negative tumors and select node-positive tumors with more favorable disease biology.
- The absolute benefit of chemotherapy is greater for women with higher-risk disease based on either anatomy (ie, node positive) or biology (ie, high recurrence score or hormone receptor–negative disease).

The choice of regimen depends on the overall risk of disease recurrence and the relative reduction of risk with the administration of chemotherapy, weighed against the toxicity of the regimens, patient comorbidities, and patient preferences.[85,219] Compared with methotrexate-containing regimens, the use of anthracyclines in adjuvant therapy improved the proportional reduction in the risk of breast cancer recurrence by 12% and death by 15%.[85] These data support the use of anthracyclines for adjuvant treatment, with the most used combination being doxorubicin and cyclophosphamide (AC) for four cycles. A meta-analysis of 13 randomized trials involving 22,453 women showed that the addition of taxanes to anthracycline-containing regimens resulted in a 17% reduction in the relative risk of relapse and an 18% reduction in the relative risk of death at 5 years. This translated into a 5% absolute improvement in DFS and a 3% improvement in OS.[220] This benefit was observed regardless of the type of taxane used (paclitaxel or docetaxel) and whether taxanes were used in sequence (ie, doxorubicin/cyclophosphamide, followed by paclitaxel or docetaxel or in combination such as docetaxel/doxorubicin/cyclophosphamide).

Schedule optimization trials next proved that a dose-dense chemotherapy schedule administered every 2 weeks with growth factor support was associated with improved clinical outcomes compared with chemotherapy administration on a conventional

every-3-week schedule. In CALGB 9741, 2,005 women with lymph node–positive disease were randomly assigned to receive similar doses of AC for four cycles, followed by paclitaxel for four cycles, administered on a dose-dense or conventional schedule.[221] The dose-dense regimen resulted in a 26% reduction in the relative risk of recurrence and a 31% reduction in the relative risk of death. A meta-analysis of 26 trials with more than 37,000 women compared dose-dense with standard dosing and confirmed the CALGB 9741 findings of a 14% relative reduction in risk of recurrence and a 13% relative reduction in the risk of death.[222]

The optimal schedule and type of taxane were examined in ECOG 1199, which randomly assigned patients with stage II to III breast cancer to either every-3-week docetaxel or paclitaxel for four cycles or weekly docetaxel or paclitaxel for 12 weeks (after four cycles of AC). At a median follow-up of 12 years, compared with every-3-week paclitaxel, weekly paclitaxel improved DFS with a trend toward improved OS.[223]

Given the potential for long-term cardiotoxicity associated with the use of anthracyclines, identifying who can be safely treated with non–anthracycline-containing regimens is an important question. A randomized trial compared four cycles of AC with four cycles of another two-drug regimen, docetaxel and cyclophosphamide (TC), among women with stage I to III breast cancer.[224] After a 7-year follow-up, there was a 6% improvement in the DFS rate and a 5% improvement in the OS rate with the TC regimen. However, this trial compared TC with non–dose-dense every-3-week AC, shown to be inferior to dose-dense AC (ddAC) in other trials. An analysis of the ABC trials[225] showed that a regimen containing taxanes and anthracyclines, compared with a taxane-only regimen for six cycles, improved iDFS, although the benefit was seen particularly in patients with TNBC and those with hormone receptor–positive breast cancer and a higher number of involved axillary lymph nodes. In the West German Study Group PlanB trial, patients with HER2-negative node-positive or high-risk node-negative breast cancer who received six cycles of TC had noninferior 5-year DFS compared with those who received an anthracycline-containing regimen (four cycles of epirubicin and cyclophosphamide, followed by four cycles of docetaxel). A majority of patients had hormone receptor–positive cancer (TC, 82.2%; epirubicin, cyclophosphamide, and docetaxel, 81.4%) and N0 to N1 disease (TC, 92.6%; epirubicin, cyclophosphamide, and docetaxel, 93.1%).[156]

In summary, the choice of regimen depends on the overall risk of breast cancer recurrence and the relative and absolute reduction of risk with the administration of chemotherapy, all balanced by the toxicity of the regimen, patient comorbidities, performance status, and preferences.

Major considerations associated with the most commonly used adjuvant chemotherapy regimens include the following:

- ddAC followed by paclitaxel
  - AC is considered highly emetogenic.
  - Hematopoietic growth factors are required to maintain dose density.
  - Anthracyclines are associated with cardiac toxicity; doxorubicin-associated cardiac dysfunction is related to cumulative dose. Relatively acute (in the first few years after treatment) congestive heart failure is less than 1% to 2% at cumulative doses of doxorubicin up to approximately 400 mg/m^2 (HD1). Most doxorubicin-containing adjuvant

breast cancer regimens administer less than 300 mg/m^2 total. Risk factors for cardiac toxicity include underlying heart disease, use of anthracyclines concurrently with other cardiotoxic agents or radiation therapy, and previous treatment with mediastinal or chest wall irradiation.[226] A baseline assessment of left ventricular ejection fraction is recommended.
    - Paclitaxel can cause severe hypersensitivity reactions and, therefore, requires premedication with steroids and antihistamines.
    - Alopecia is common with this regimen. Scalp cooling may mitigate some of the risk of alopecia.
    - Sensory peripheral neuropathy is common with paclitaxel and docetaxel. Neuropathy is more likely in patients who are older, have existing neuropathy, or who have previously received taxane chemotherapy.
    - Dose adjustment of doxorubicin or paclitaxel is not required in cases of renal impairment. The need for cyclophosphamide dose reduction in renal insufficiency is controversial.
    - Dose adjustment of doxorubicin, cyclophosphamide, and paclitaxel may be needed in cases of hepatic impairment. It is recommended to administer 50% of the doxorubicin dose if serum bilirubin is 1.2 to 3 mg/dL and 25% if serum bilirubin is 3.1 to 5 mg/dL; doxorubicin is contraindicated if the bilirubin level is higher than 5 mg/dL or in cases of Child-Pugh class C. It is also advised to avoid cyclophosphamide if the serum bilirubin level is higher than 5 mg/dL. Paclitaxel dose should be adjusted on the basis of aminotransferase and bilirubin levels, and paclitaxel should be avoided if aminotransferase levels are 10 times the upper level of normal or higher or if bilirubin level is more than five times the upper level of normal.
- Four cycles of TC
    - Emesis risk is moderate.
    - Steroid treatment before and after docetaxel administration reduces the incidence of docetaxel-induced fluid retention.
    - Alopecia is common with this regimen. Rare cases of permanent alopecia have been reported with docetaxel. Scalp cooling may mitigate some of the risk of alopecia.
    - Sensory peripheral neuropathy is common with paclitaxel and docetaxel. Neuropathy is more likely in patients who are older, have existing neuropathy, or who have previously received taxane chemotherapy.
    - Dose adjustment of docetaxel is not required in cases of renal impairment. The need for cyclophosphamide dose reduction in renal insufficiency is controversial.
    - Regarding hepatic impairment, docetaxel should not be administered when the serum bilirubin level is higher than the upper limit of normal or with aminotransferase elevations more than 1.5 times the upper limit of normal in conjunction with an alkaline phosphatase level more than 2.5 times the upper limit of normal.

PRESENTING CASE STUDY

A 52-year-old woman with mild hypertension presents with persistent lower back pain despite intermittent physical therapy and use of over-the-counter analgesics. Her primary care doctor took plain radiographs of the spine. These revealed questionable lytic lesions in her lumbar spine and the patient was advised to see her oncologist. Her history is notable for a T2N0 estrogen receptor (ER)–positive (90%) and HER2-negative (1+ by immunohistochemistry [IHC]) cancer of the right breast diagnosed 6 years ago. She underwent breast conservation and completed 5 years of adjuvant tamoxifen. She did not receive adjuvant chemotherapy, based on a tumor recurrence score of 12.

As her oncologist, you order a computed tomography (CT) of the chest, abdomen, and pelvis, which is notable for several sclerotic and lytic lesions in the axial skeleton as well as enlarged right hilar, mediastinal, and intra-abdominal lymph nodes. There are two pulmonary nodules in the right lung; the largest measures 1.5 cm. Lymph node biopsy confirms recurrent metastatic breast cancer (MBC).

Which biomarkers do you need to know to develop her treatment plan?

IHC to determine ER, progesterone receptor (PR), and HER2 status is essential to select appropriate first-line therapy for metastatic disease. Discordance in receptor status between the primary tumor and a distant metastatic site can occur in around 15% of cases. Germline genetic testing is important because the presence of a *BRCA1* or *BRCA2* mutation is actionable, with PARP inhibitors such as olaparib and talazoparib showing superiority to cytotoxic chemotherapy. Finally, tissue or circulating tumor DNA (ctDNA) sequencing can identify important alterations in *ESR1*, *PI3K*, *AKT*, or *PTEN*, which can guide use of targeted therapies in combination with endocrine therapy for ER-positive tumors.

Her tumor tests as follows: ER 80%, PR 20%, and HER2 1+ by IHC. Germline genetic testing is negative for pathogenic mutations, and her somatic sequencing lacks *ESR1* and *PI3K* mutations. She is now postmenopausal. Her pain has improved with consistent use of nonsteroidal anti-inflammatory drugs.

What is the preferred approach for first-line treatment of ER-positive HER2-low MBC that is wild type for *ESR1* and *PI3K*?

Endocrine therapy with an aromatase inhibitor (AI) and cyclin-dependent kinase 4/6 (CDK4/6) inhibitor is a preferred first-line therapy option for patients with ER-positive MBC who are not in visceral crisis (see "Hormone Receptor–Positive Disease" section). Ribociclib is the only CDK4/6 inhibitor that has shown a statistically significant overall survival (OS) benefit in the first-line setting. Bisphosphonates and the RANK ligand inhibitor denosumab reduce the incidence of skeletal-related events and the time to occurrence of skeletal-related events in patients with bone metastases.

After 2.5 years on first-line endocrine therapy and a CDK4/6 inhibitor, the patient's disease progresses in her bones and lungs, and new liver lesions appear. Her complete blood count and comprehensive panel are within the reference range. She reports fatigue but is otherwise asymptomatic. You send a ctDNA sample and find that her tumor has an *AKT* mutation.

What therapeutic options are available for patients who progress on a CDK4/6 inhibitor and whose tumors contain an *AKT* mutation?

In November 2023, the FDA approved the AKT inhibitor capivasertib in combination with fulvestrant for patients with ER-positive MBC whose tumors have a *PI3K* mutation, *AKT* mutation, or *PTEN* loss. This is based on the phase 3 CAPitello-291 study, which showed a significant improvement in median progression-free survival (PFS) with the addition of capivasertib to fulvestrant compared with fulvestrant alone (7.3 vs 3.1 months) in those with AKT pathway alterations. If ctDNA sequencing revealed an *ESR1* mutation, the patient would be a candidate for single-agent elacestrant. If her tumor had a *PI3K* mutation, she would be a candidate for either combination therapy with capivasertib or alpelisib, the PI3K inhibitor. Choices based on tolerability and toxicity are reasonable in that setting, as no head-to-head data are available to guide decision-making.

The patient begins fulvestrant and capivasertib. Seven months later, she has additional liver lesions and mild transaminitis. No new mutations have emerged on repeat ctDNA sequencing. She begins first-line chemotherapy with capecitabine. After dose adjustment for hand-foot syndrome, she tolerates treatment well and remains progression-free for about 12 months. However, her most recent CT of the chest, abdomen, and pelvis confirms disease progression with increasing and new bone and liver lesions. Lung nodules are stable, and she has no respiratory symptoms.

Given her disease progression following endocrine therapy and one line of chemotherapy, what would you recommend for the treatment of this patient's HER2-low MBC?

The DESTINY-Breast04 trial randomized patients with HER2-low MBC who had received two or fewer lines of chemotherapy to trastuzumab deruxtecan (T-DXd) or a physician's choice of chemotherapy (capecitabine, eribulin, gemcitabine, paclitaxel, or nab-paclitaxel). Most patients (88.7%) had hormone receptor–positive disease. Among patients who had hormone receptor–positive cancer, median PFS was 10.1 months and median OS was 23.9 months with T-DXd compared with median PFS of 5.4 months and median OS of 17.5 months with chemotherapy (PFS HR, 0.51; $P < .001$; OS HR, 0.64; $P = .003$). Based on these data, the FDA approved fam-T-DXd in 2022 for adult patients with unresectable or metastatic HER2-low breast cancer who received prior chemotherapy in the metastatic setting or developed disease recurrence during or within 6 months of completing adjuvant treatment.

Would your recommendation be any different if she were symptomatic from a large burden of lung metastases with chronic cough and dyspnea on exertion?

In the DESTINY-Breast04 trial, drug-related interstitial lung disease (ILD) occurred in 12.1% of patients, with 0.8% experiencing grade 5 ILD. However, the percentage of patients with a confirmed objective response in the hormone receptor–positive cohort was 52.6% (95% CI, 47.0-58.0) in the T-DXd group and only 16.3% (95% CI, 11.0-22.8) in the physician's choice group. Therefore, the risk–benefit balance favors using T-DXd to most effectively treat the underlying cause of this patient's symptoms, namely, MBC to the lung. There are clear guidelines for the monitoring and managing of T-DXd-related ILD.[227]

SYSTEMIC THERAPY FOR EARLY-STAGE BREAST CANCER

TRIPLE-NEGATIVE BREAST CANCER

Triple-negative breast cancer refers to tumors that test ER 0%, PR 0%, and HER2 0 or low (1+/2+ and fluorescence in situ hybridization [FISH] not amplified). TNBC generally has a higher risk of distant recurrence and a more aggressive phenotype. These tumors do not derive benefit from adjuvant endocrine therapy. In fact, tumors that test ER and PR low (1%-10%) behave biologically more like TNBC than estrogen-dependent cancers and are sometimes included in clinical trials for TNBC. As a result, even small (less than 5 mm) node-negative tumors are considered for adjuvant chemotherapy based on the benefit/risk balance. The introduction of the checkpoint inhibitor pembrolizumab to the neoadjuvant treatment of early-stage TNBC and the effect of adjuvant therapy on those patients who have residual disease following preoperative chemotherapy have driven more of a preoperative systemic therapy approach to the treatment of early-stage TNBC.

Neoadjuvant Chemotherapy

KEYNOTE-522 examined the addition of the checkpoint inhibitor pembrolizumab to anthracycline, taxane, and platinum-based chemotherapy for localized TNBC. Patients who had tumors larger than 2 cm or involved axillary lymph nodes were randomly assigned to neoadjuvant paclitaxel and carboplatin followed by epirubicin or AC, all with pembrolizumab or with a placebo. Pembrolizumab (or placebo) was continued for nine cycles in the adjuvant setting after surgery, regardless of response. The addition of pembrolizumab to chemotherapy demonstrated a statistically and clinically significant improvement in both pCR (64.8% vs 51.2%) and 5-year event-free survival (EFS) rates (81.3% vs 72.3%).[228] The median EFS was not reached in either treatment arm (HR, 0.63; 95% CI, 0.49-0.81). Recently, the final analysis for OS was reported after 75 months median follow-up. The estimated OS at 60 months was 86.6% (95% CI, 84.0-88.8) with pembrolizumab-chemotherapy compared with 81.7% (95% CI, 77.5-85.2) in the placebo-chemotherapy arm ($P = .002$). These data have established the KEYNOTE-522 regimen as standard of care for high-risk, early-stage TNBC.[229]

Monitoring for immune-related adverse events is important, particularly screening for thyroid disease and adrenal insufficiency before surgery (Fig. 10-5).

Neoadjuvant therapy can be considered for T1cN0 TNBC using preferred chemotherapy regimens containing anthracycline, cyclophosphamide, and a taxane to help prognosticate based on residual cancer burden and to escalate therapy in the adjuvant setting for those at greatest risk of recurrence. For patients who have a contraindication to anthracycline, TC-alternate regimens such as taxane and carboplatin may be considered.

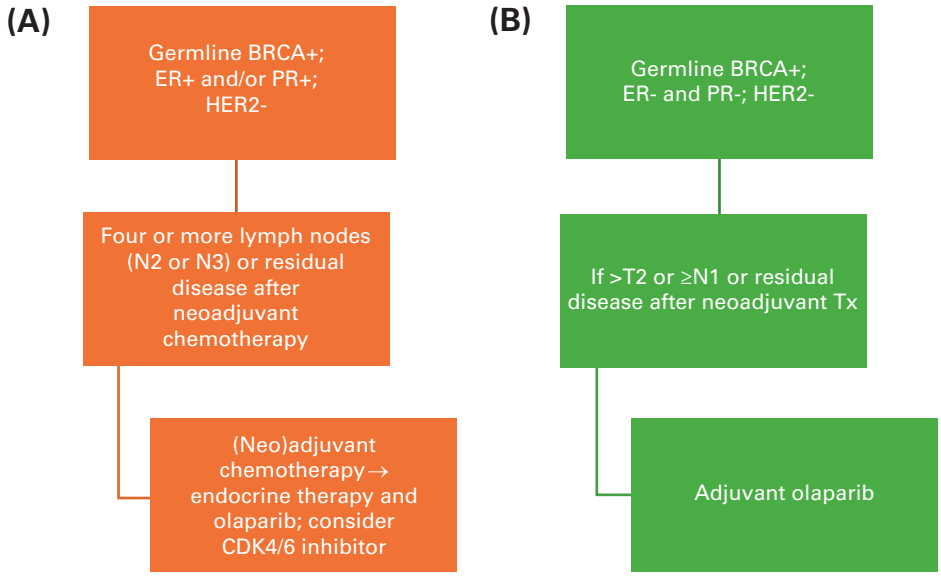
Improved adjuvant treatment options are needed for patients with TNBC who do not achieve pCR with neoadjuvant therapy, as these patients are at high risk of distant recurrence. For example, in KEYNOTE-522, those patients who failed to achieve pCR had a 5-year EFS of 69% and 47% for stage II and III disease, respectively, despite pembrolizumab. The CREATE-X[230] trial randomly assigned 910 patients with HER2-negative breast cancer who received neoadjuvant chemotherapy (containing anthracycline, taxane, or both) and had residual disease at the time of surgery to receive six to eight cycles of capecitabine or placebo. There was an improvement in OS in the capecitabine group compared with placebo (89.2% vs 83.6% at 5 years; HR, 0.59). Patients with TNBC derived the largest benefit, with a DFS rate at 5 years of 69.8% in the capecitabine group versus 56.1% in the control group (HR, 0.58) and an OS rate of 78.8% versus 70.3% (death HR, 0.52; 95% CI, 0.30-0.90). Although KEYNOTE-522 did not allow for adjuvant capecitabine in patients who had residual disease, safety data exist for the combination of capecitabine and pembrolizumab in MBC, and the combination is often used for patients with residual disease. The ASCO guideline update from 2018 recommends that patients with early-stage HER2-negative breast cancer with invasive residual disease at surgery after standard anthracycline- and taxane-based preoperative therapy may be offered up to six to eight cycles of adjuvant capecitabine.[231] The EA1131 trial did not demonstrate noninferiority of adjuvant carboplatin or cisplatin compared with adjuvant capecitabine in patients with stage II to III basal-type TNBC and residual disease of 1 cm or more. Three-year iDFS for patients who received platinum was 42% versus 49% for those who received capecitabine (HR, 1.94; 95% CI, 0.69-5.45).[232]

Adjuvant Chemotherapy

For those patients with TNBC who have up-front surgery, chemotherapy is a consideration for tumors measuring at least 6 mm. Following the principles outlined earlier, an anthracycline- and taxane-based adjuvant regimen is generally preferred for high-risk patients, although non–anthracycline-containing combinations such as TC, taxane/carboplatin, or even cyclophosphamide/methotrexate/fluorouracil may be considered based on personalized risk/benefit assessment.

The OlympiA trial examined the role of PARP inhibitors in patients with germline *BRCA1* and *BRCA2* mutations and high-risk HER2-negative breast cancer. For TNBC, high risk was defined as either residual disease after neoadjuvant therapy or at least T2 or N1 disease in the adjuvant setting. The addition of 1 year of adjuvant olaparib improved iDFS from 77.1% to 85.9% at 3 years (HR, 0.58; 99.5% CI, 0.41-0.82). At the second planned interim analysis with a 3.5-year median follow-up, 3-year OS was 92.0% in the olaparib arm versus 89.1% in the placebo arm (HR, 0.68; 98.5% CI, 0.47-0.97).[233,234] Adjuvant olaparib is recommended for patients with germline *BRCA1* and *BRCA2* mutations and high-risk HER2-negative breast cancer (Fig. 10-6).

Figure 10-6 Suggested Guidelines for (Neo)Adjuvant Systemic Therapy for HER2-Negative Breast Cancer With Germline *BRCA* Mutation



(A) Hormone receptor–positive, HER2-negative disease. (B) Hormone receptor–negative, HER2-negative disease.

HORMONE RECEPTOR–POSITIVE BREAST CANCER

Recommendations for the use of gene expression signatures to guide adjuvant chemotherapy decisions in hormone receptor–positive disease are discussed in "Gene Expression Signatures" section. General principles regarding chemotherapy in early-stage breast cancer were addressed in "Triple-Negative Breast Cancer" section (also see Fig. 10-5). When both chemotherapy and endocrine therapy are recommended, chemotherapy is administered before endocrine therapy.

Endocrine Therapy

The majority of invasive breast cancers are hormone receptor positive. Endocrine therapy reduces the risk of systemic recurrence and death by approximately one-third among women with hormone receptor–positive (ER and/or PR) breast cancer regardless of age, menopausal status, nodal involvement, tumor size, HER2 status, or use of chemotherapy. For this reason, adjuvant endocrine therapy should be recommended for all women who have hormone receptor–positive disease.[235,236]

There are two endocrine therapy options with distinct mechanisms of action and side effects. Tamoxifen is a SERM that binds to the ER but has tissue-specific ER antagonist and agonist properties. ER antagonist side effects include hot flashes and vaginal dryness. However, there is a less than 1% risk of venous thromboembolism and of uterine cancer because of the ER agonist properties in those tissues. In postmenopausal women, tamoxifen is an estrogen agonist regarding bone mineral density (BMD).

AIs block aromatization of androgens into estrogens, which is the primary means of estrogen production in postmenopausal women. As a result, side effects and risks include hot flashes, vaginal dryness, and the potential to decrease BMD, among others. In addition, up to 40% of patients complain of musculoskeletal aches and joint stiffness. Depending on the severity and effect on quality of life, these musculoskeletal symptoms may contribute to noncompliance in 10% to 15% of women. There are three FDA-approved AIs—anastrozole, letrozole (nonsteroidal AIs), and exemestane (steroidal AI)—and they are equivalent in efficacy and side effect profiles.[237,238]

Tamoxifen

Tamoxifen is effective in premenopausal and postmenopausal women. The Early Breast Cancer Trialists' Collaborative Group meta-analysis showed that 5 years of tamoxifen reduced the relative risk of distant recurrence by approximately 41% and the relative risk of death by 34%.[239] Two large studies support extending the duration of tamoxifen treatment to 10 years.[240] In the ATLAS trial, tamoxifen for 10 years compared with 5 years reduced the rate of recurrence by 3.2% and improved the mortality

rate by 2.8%. The difference between the arms of the study did not emerge until year 10, likely because of the carryover protective effect in years 5 to 10 conferred by 5 years of tamoxifen. Prolonged tamoxifen use was associated with an increased incidence of pulmonary embolism and endometrial cancer, with a 3.1% cumulative risk of endometrial cancer after 5 years of tamoxifen therapy, translating into an absolute increase in the endometrial cancer mortality rate of 0.2%. There was no increase in the risk of stroke or cardiovascular events with prolonged treatment. These results were replicated in the aTTom trial, which had a similar design.[241] Although these data support the efficacy of prolonged use of tamoxifen, longer treatment duration must be weighed against potential adverse outcomes on an individual basis, particularly for patients with early-stage disease at low risk of recurrence.

Cytochrome P450 2D6 (CYP2D6) is the primary hepatic enzyme responsible for tamoxifen metabolism to its active metabolite. A CYP2D6 polymorphism can result in a decreased active metabolite, potentially resulting in decreased efficacy. Currently, ASCO guidelines do not recommend the use of testing for CYP2D6 polymorphisms to guide the selection of adjuvant endocrine therapy.[242]

Role of Ovarian Function Suppression

The SOFT and TEXT trials evaluated the role of ovarian function suppression (OFS) as adjuvant therapy for hormone receptor–positive breast cancer.[243] In TEXT, premenopausal women were randomly assigned to receive 5 years of tamoxifen or exemestane with concurrent OFS. In SOFT, women were randomly assigned to receive 5 years of tamoxifen, tamoxifen and OFS, or exemestane and OFS. In both studies, chemotherapy was administered per the physician's choice. The comparisons of exemestane and OFS and tamoxifen and OFS in both trials were analyzed together. At a median follow-up of 13 years, the combination of OFS and exemestane improved 12-year DFS by 21% and distant recurrence-free interval by 17% compared with OFS and tamoxifen.[244] The differences in OS were not statistically significant. For premenopausal women with higher-risk disease, for example, those requiring adjuvant chemotherapy, OFS and AI should be offered.

A consistent finding in these studies was that patients who had low-risk disease did equally well with tamoxifen alone. For these patients, tamoxifen alone remains an appropriate choice, which is particularly important given the added toxicities of OFS and AI therapy, including hot flashes, musculoskeletal symptoms, loss of bone density, and sexual dysfunction.

On the basis of the initial report of the SOFT and TEXT trials, the 2016 ASCO guideline recommends the following:

- For premenopausal women at higher risk of cancer recurrence because of tumor stage (II and III) or biologic features, OFS, in addition to adjuvant endocrine therapy, is recommended, particularly in women younger than 35 years. On the other hand, women who have stage I disease for whom chemotherapy is not deemed necessary should not receive OFS.
- OFS and an AI are favored for patients at higher risk and for younger women.

Aromatase Inhibitors

Although tamoxifen is effective in postmenopausal women, AIs are usually preferred on the basis of data from multiple studies comparing both agents in postmenopausal women. AIs alone are not effective in premenopausal or perimenopausal women and, therefore, should not be used in this group of patients in the absence of concurrent OFS. It is important to remember that chemotherapy-induced amenorrhea can be transient; therefore, the choice of endocrine therapy should be based on menopausal status before treatment, and hormone laboratories should be serially monitored.

Multiple studies have addressed the efficacy of AIs compared with tamoxifen, either evaluating 5 years of tamoxifen versus an AI or switching to an AI after 2 to 3 years of tamoxifen. Data from an Oxford meta-analysis showed that, compared with 5 years of tamoxifen, the use of an AI in postmenopausal women reduced the 10-year risk of recurrence by approximately 30% and the breast cancer mortality rate by approximately 15%.[245]

Although an AI is generally preferred to tamoxifen in postmenopausal women because of efficacy, the absolute difference in risk reduction is small, particularly for early-stage cancers. Therefore, women who are unable to tolerate an AI should be switched to tamoxifen.[246]

AI treatment after 5 years of endocrine therapy was also studied. Switching to an AI after 5 years of treatment with tamoxifen demonstrated an additional reduction in disease recurrence in postmenopausal women.[247] Several other studies have examined the continuation of an AI after 5 years of treatment that included an AI.[248-251] The optimal duration of extended therapy after year 5 was also evaluated.[252,253] These studies are listed in Table 10-5.[254] Taken together, these data show a modest improvement in DFS in patients who continued an AI after an AI treatment, largely driven by prevention of contralateral breast cancer. The Breast Cancer Index (see "Gene Expression Signatures" section) was retrospectively validated to identify patients at higher risk of late distant relapse who may benefit most from extended endocrine therapy. In light of the modest activity of extended AI treatment and added toxicity, patients who have higher-risk disease are the most suitable candidates for extended endocrine therapy.

Table 10-5 **Extended Endocrine Therapy With AI**[255]	
Trial	**Intervention**
Extended adjuvant AI after 5 years of tamoxifen	
MA.17	Letrozole for 5 years or placebo
NSABP B-33	Exemestane for 5 years or placebo
ABCSG 6	Anastrozole for 3 years or placebo
Extended AI after 5 years of therapy that included an AI	
MA.17R	Letrozole or placebo for 5 years after 5 years of letrozole (preceded by 5 years of tamoxifen in most patients)
NSABP B-42	Letrozole or placebo for 5 years after 5 years of endocrine therapy with 5 years of an AI or 3 or fewer years of tamoxifen
DATA	Anastrozole for 6 years, 3 years after 2 to 3 years of tamoxifen
Optimal duration or dosing of AI in years 5-10	
IDEAL	Letrozole for 2.5 vs 5 years after tamoxifen, AI, or both for 5 years
ABCSG-18	Anastrozole for 2 vs 5 years after tamoxifen, AI, or both for 4 to 6 years

Abbreviation: AI, aromatase inhibitor.

ASCO Guidelines recommend that postmenopausal women with node-positive disease be offered extended (10 years) AI therapy.[256] The benefits are likely lower for those with node-negative disease. As the major benefit of extended AI therapy is contralateral breast cancer, and there are risks and side effects with longer therapy, treatment decisions need to be individualized and incorporate patient preferences.

NEOADJUVANT ENDOCRINE THERAPY

Neoadjuvant endocrine therapy is an acceptable treatment for postmenopausal women with hormone receptor–positive disease to either achieve breast conservation or downstage disease that is inoperable at presentation. This approach is particularly valuable in women who have tumors with low chemosensitivity or who are poor candidates for chemotherapy. At least five randomized trials (including patients with stage II disease) have demonstrated superiority with a neoadjuvant AI compared with tamoxifen.[254,255,257] Despite low pCR rates associated with neoadjuvant endocrine therapy, surrogate markers of response can offer prognostic information about long-term clinical outcomes, including the expression of Ki67 in residual tumors (a low value or a decrease compared with baseline is favorable),[258] and prospective validation of these biomarkers is ongoing.

Neoadjuvant endocrine therapy is usually administered for no less than 4 to 6 months to allow maximum response before surgery. Patients who have a clinical response to neoadjuvant endocrine therapy should continue to receive endocrine therapy after surgery. Those who do not have a clinical response should be considered for adjuvant chemotherapy, followed by adjuvant endocrine therapy. Neoadjuvant endocrine therapy in premenopausal women and in men remains investigational.

ADJUVANT CDK4/6 INHIBITORS

Because of their efficacy in the treatment of hormone receptor–positive MBC, the role of cyclin-dependent kinase 4/6 (CDK4/6) inhibitors added to endocrine therapy for localized breast cancer has been the subject of large randomized clinical trials. All three CDK4/6 inhibitors have been studied.

In the monarchE trial, patients who had high-risk node-positive hormone receptor–positive and HER2-negative breast cancer were randomly assigned to standard adjuvant endocrine therapy with or without abemaciclib for 2 years.[259] The addition of abemaciclib resulted in a 3.5% improvement in iDFS at 2 years (92.2% vs 88.7%; HR, 0.75; 95% CI, 0.6-0.93). Based on these data, in 2021, the US FDA approved abemaciclib as adjuvant therapy for patients who have hormone receptor–positive and HER2-negative breast cancer with four or more positive nodes or one to three nodes and a tumor size of 5 cm or larger or a grade 3 tumor. With longer follow-up, the iDFS was maintained, and the 7-year absolute difference was 6.5% (77.4% vs 70.9%; HR, 0.74). In addition, the secondary endpoints to OS and distant relapse-free survival (DRFS) were statistically improved with a median follow-up of 76 months. The 7-year OS was 86.8% with abemacilib and endocrine therapy versus 85% with endocrine therapy alone. The 7-year DRFS was 80% versus 74.9%, respectively.[4]

The NATALEE trial evaluated ribociclib in the adjuvant setting. In addition to node-positive disease, node-negative tumors larger than 2 cm with high-risk features, including grade and high risk based on genomic profiling, were eligible. Ribociclib was dose-reduced and given for 3 years with endocrine therapy. iDFS was improved by 25% with a 3-year iDFS rate of 90.4%

associated with ribociclib and an AI versus 87.1% with an AI alone. Ribociclib was FDA approved in September 2024 for node-positive and high-risk node-negative hormone receptor–positive and HER2-negative breast cancer.

By contrast, the PALLAS trial of adjuvant palbociclib and the PENELOPE-B trial of adjuvant palbociclib after neoadjuvant chemotherapy both failed to meet their primary endpoint of DFS.[260,261]

KEY POINTS

- Adjuvant tamoxifen has efficacy in premenopausal and postmenopausal women.
- OFS improves DFS and freedom from recurrence when combined with 5 years of adjuvant tamoxifen or exemestane in premenopausal women who have high-risk disease.
- Compared with 5 years, 10 years of adjuvant tamoxifen is associated with a small improvement in DFS and breast cancer–specific survival, and extended-duration tamoxifen is an option in premenopausal or postmenopausal patients at high risk.
- AIs are the first-choice adjuvant endocrine treatment in postmenopausal women.
- Administering AIs for 5 years results in similar outcomes as initial tamoxifen for 2 to 3 years, followed by an AI for a total of 5 years.
- An extended duration of AI therapy beyond 5 years should be considered in postmenopausal women who have high-risk disease.
- Neoadjuvant endocrine therapy is an acceptable treatment approach for postmenopausal women who have stage II or III hormone receptor–positive breast cancer, but it infrequently results in pCR.
- Two years of adjuvant abemaciclib in combination with endocrine therapy improves DFS and OS and is an option for patients with node-positive disease. Three years of dose-reduced ribociclib in combination with an AI improves iDFS in patients with high-risk node-negative and node-positive disease.

(NEO)ADJUVANT CHEMOTHERAPY IN HORMONE RECEPTOR–POSITIVE BREAST CANCER

Adjuvant Chemotherapy

A course of adjuvant chemotherapy in addition to endocrine therapy is considered for patients at a higher risk of recurrence, including patients who have four or more positive axillary lymph nodes (N2/N3) or one to three lymph nodes or node-negative disease with a high risk by tumor gene expression assays. See the discussion on adjuvant chemotherapy section in the "Systemic Therapy for Stage IV (Metastatic) Disease."

Neoadjuvant Chemotherapy

For patients receiving preoperative chemotherapy, both KEYNOTE-756 and CheckMate 7 FL revealed improved pCR rates with the addition of pembrolizumab (24.3% vs 15.6%) and nivolumab (24.5% vs 13.8%) to standard neoadjuvant chemotherapy, respectively, versus neoadjuvant chemotherapy alone.[261,262] However, no EFS (the coprimary endpoint in the KEYNOTE trial) has been reported, and neither of these PD-1 inhibitors is FDA approved in early-stage hormone receptor–positive breast cancer.

PARP Inhibitors in Adjuvant Therapy

The OlympiA trial examined the role of PARP inhibitors in patients with germline *BRCA1* and *BRCA2* mutations and high-risk HER2-negative breast cancer. For hormone receptor–positive disease, high risk was defined as four or more positive lymph nodes or non-pCR and clinical pathologic staging-ER grading score of 3 or higher. The addition of 1 year of adjuvant olaparib improved iDFS from 77.1% to 85.9% at 3 years (HR, 0.58; 99.5% CI, 0.41-0.82). At the second planned interim analysis with a 3.5-year median follow-up, 3-year OS was 92.0% in the olaparib arm versus 89.1% in the placebo arm (HR, 0.68; 98.5% CI, 0.47-0.97).[233] Adjuvant olaparib is recommended for patients with germline *BRCA1* and *BRCA2* mutations and high-risk HER2-negative breast cancer (Fig. 10-6).

HER2–POSITIVE BREAST CANCER

Most women diagnosed with early-stage HER2-positive breast cancer receive HER2-targeted therapy and chemotherapy as adjuvant systemic therapy. Exceptions are those with very small tumors (smaller than 0.5 cm; this should not be considered a strict cutoff, and other factors need to be considered) or with significant comorbidities.

Four HER2-targeted therapies are currently used in the adjuvant setting: trastuzumab, pertuzumab, neratinib, and ado-trastuzumab emtansine (T-DM1) (Fig. 10-7).

- Monoclonal antibodies trastuzumab and pertuzumab (HP) both target the extracellular domain of HER2; trastuzumab binds to subdomain IV and disrupts ligand-independent downstream signaling, whereas pertuzumab binds to subdomain II, which blocks dimerization of HER2 and subsequent ligand-dependent signaling.

- Neratinib is an oral irreversible tyrosine kinase inhibitor that blocks signal transduction through the EGFR family, including HER2.
- T-DM1 is an ADC that consists of trastuzumab linked to maytansinoid DM1, a potent microtubule-disrupting agent, joined by a nonreducible stable linker.

Figure 10-7 Targets for HER2-Targeted Therapy

Trastuzumab-Based Adjuvant and Neoadjuvant Therapy Regimens

When added to chemotherapy, trastuzumab substantially improves DFS and OS compared with chemotherapy alone.[263,264] A meta-analysis of five adjuvant therapy studies demonstrated a 38% reduction in the relative risk of recurrence and a 34% reduction in the relative risk of death as a result of any cause.[265] Concurrent administration of chemotherapy and trastuzumab seems to confer greater benefit compared with sequential treatment. This concept was supported by the NCCTG N9831 study, which showed that the concurrent administration of trastuzumab with paclitaxel was associated with a 23% reduction in the risk of an event compared with sequential trastuzumab administration. Concomitant administration of trastuzumab is supported by ASCO clinical practice guidelines. Trastuzumab is continued as a single agent after chemotherapy, commonly administered every 3 weeks and concurrently with endocrine therapy for hormone receptor–positive disease.[266]

The currently accepted duration of adjuvant trastuzumab is 1 year. The HERA trial evaluated combination chemotherapy followed by observation or 1 or 2 years of adjuvant trastuzumab.[267,268] Trial results showed that 1 year of trastuzumab significantly reduced the risk of a DFS event and death compared with observation. Two years of adjuvant trastuzumab did not improve DFS outcomes compared with 1 year of therapy[265,268] and was associated with greater cardiac toxicity.[265,268] Other studies examined the question of the duration of trastuzumab.[269-273] Of these, only the PERSEPHONE trial showed that 6 months of trastuzumab was not inferior to 12-month treatment and was associated with fewer severe adverse events and less cardiac toxicity.[274] Differences in the results of these trials can be explained, at least partially, by the different prespecified statistical analysis plan and patients in each study. At this point, 12 months of adjuvant therapy continues to be the standard for most patients who have HER2-positive disease.

The most used trastuzumab-based regimens in the neoadjuvant or adjuvant setting are the following:

- Combination docetaxel, carboplatin, and trastuzumab with or without pertuzumab
- ddAC followed by paclitaxel and trastuzumab with or without pertuzumab
- Paclitaxel and trastuzumab (in the adjuvant setting only)

The efficacy of the combination of trastuzumab with a non–anthracycline-containing regimen was evaluated in the BCIRG 006 trial. In this study, patients were randomly assigned to a combination of docetaxel, carboplatin, and trastuzumab, administered every 3 weeks for six cycles, or to four cycles of AC every 3 weeks, followed by four cycles of docetaxel with or without trastuzumab. The results of adding trastuzumab to chemotherapy led to improved DFS and OS. There was a non–statistically significant 3% absolute difference in the DFS rate and a 1% difference in the OS rate at 5 years, favoring the arm receiving AC with docetaxel and trastuzumab over the combination of docetaxel, carboplatin, and trastuzumab arm. However, the study was not designed to compare the two trastuzumab-containing arms, and any conclusions about the benefits of one regimen over another should be considered exploratory.[275] The combination of docetaxel, carboplatin, and trastuzumab was associated with less cardiac toxicity and risk of secondary leukemia compared with the AC and docetaxel arms, making it an acceptable treatment alternative.

Additional formulations of trastuzumab are available for patients. Two randomized trials, HannaH and SafeHER, showed comparability between a subcutaneous formulation of trastuzumab and the intravenous version, leading to US FDA approval.[276,277] A subcutaneous formulation of the combination of HP (HP hyaluronidase-oysk) has also received FDA approval. Finally, the FDA has also approved several biosimilar formulations of trastuzumab and noted no difference in safety or efficacy between biosimilars and the original biologic.

HER2-positive breast cancer is associated with a high response rate to neoadjuvant chemotherapy, which is increased substantially with the addition of HER2-directed treatment. Two studies evaluated neoadjuvant trastuzumab-containing regimens in which trastuzumab was administered with an anthracycline.[278,279] Both studies demonstrated that the addition of trastuzumab improved the pCR rate and reduced the risk of recurrence and death. Neoadjuvant HER2-directed therapy is most often used in patients with lymph node–positive disease or tumors larger than 2 cm in combination with pertuzumab (see next section).

Neoadjuvant/Adjuvant Pertuzumab

The NeoSphere trial was an open-label phase 2 study that randomly assigned 417 patients to receive four cycles of docetaxel combined with trastuzumab, pertuzumab, or both agents versus a combination of pertuzumab and trastuzumab without docetaxel (a nonchemotherapy arm).[280] The combination of pertuzumab and trastuzumab with docetaxel achieved the highest pCR rate of 39.3% compared with the other groups. All patients in the NeoSphere trial also received adjuvant treatment with three cycles of combined fluorouracil, epirubicin, and cyclophosphamide chemotherapy administered concomitantly with trastuzumab, followed by completion of 1 year of trastuzumab therapy. The TRYPHAENA trial studied the safety of neoadjuvant pertuzumab in combination with either docetaxel/carboplatin/trastuzumab or fluorouracil, epirubicin, and cyclophosphamide, followed by docetaxel in combination with HP or in sequence. Cardiac safety was acceptable for HP in sequence after anthracycline. pCR rates in breast and nodes were highest for docetaxel/carboplatin/trastuzumab with pertuzumab at 64%.

In the phase 3 APHINITY trial, 4,805 patients with HER2-positive, node-positive breast cancer or high-risk node-negative breast cancer were randomly assigned to adjuvant chemotherapy with trastuzumab and placebo or pertuzumab.[281] With a median follow-up of 74 months, the addition of pertuzumab to chemotherapy and trastuzumab was associated with a modest benefit, resulting in a 6-year iDFS rate of 91% compared with the placebo arm rate of 88% (HR, 0.76; 95% CI, 0.64-0.91). Treatment was effective in all subgroups; however, those who had node-positive and/or hormone receptor–negative disease seemed to derive the most benefit. Diarrhea was increased in the pertuzumab arm, predominantly during chemotherapy and with the combination docetaxel, carboplatin, and trastuzumab regimen. Cardiac toxicity was low and not different between the two arms.

As a result of these data, patients with tumors larger than 2 cm or nodal involvement are recommended to receive a neoadjuvant trastuzumab- and pertuzumab-based chemotherapy regimen, followed by adjuvant HER2-directed therapy; the type of adjuvant HER2 therapy will depend upon the presence of residual disease. The ASCO 2018 clinical practice guidelines state that clinicians may add 1 year of adjuvant pertuzumab to trastuzumab-based combination chemotherapy in patients with high-risk, early-stage, HER2–positive breast cancer for those who did not receive neoadjuvant therapy.[231,282]

Recently, a large neoadjuvant study tested fam-T-DXd, an ADC composed of trastuzumab conjugated to deruxtecan, a derivative of the camptothecin analog exatecan, a DNA topoisomerase 1 inhibitor in early-stage HER2+ breast cancer. In DESTINY-Breast11[264] patients with high-risk early-stage HER2+ breast cancer were randomized to T-DXd ×8 cycles, T-DXd-THP (4 + 4 cycles), or ddAC followed by paclitaxel + trastuzumab + pertuzumab (ddAC-THP; 4 + 4 cycles). The primary endpoint was pCR; pCR rates were 43.0% (T-DXd, *n* = 123), 67.3% (T-DXd-THP, *n* = 216), and 56.3% (ddAC-THP, *n* = 180). EFS data are immature, and the study is not powered for EFS. All-grade drug-related interstitial lung disease (ILD) rates were low and similar across arms (T-DXd-THP, 4.4%). The T-DXd containing arms had lower grade 3 or greater adverse events and fewer serious adverse events as well.

Residual Disease After Completion of Neoadjuvant Therapy

Patients who receive neoadjuvant chemotherapy with HER2 therapy and have residual disease at the time of surgery are at a higher risk of recurrence. In KATHERINE, a study of 1,486 patients who had residual invasive breast cancer after receiving neoadjuvant chemotherapy and HER2 therapy,[283] the use of T-DM1 after surgery was associated with improved DFS and a lower risk of distant recurrence compared with trastuzumab. Updated results after a median of 8.4 years of follow-up revealed a 4.7%

absolute benefit in OS at 7 years with T-DM1.[284] However, there were more serious adverse events with T-DM1 than with trastuzumab (13% vs 8%, respectively). This regimen has been adopted by many as the treatment of choice for patients who have residual disease. If the disease is also hormone receptor positive, adjuvant endocrine therapy is administered concurrently with T-DM1. Radiation may be delivered concurrently with T-DM1.

DESTINY-Breast05[285] reported results for patients who had either inoperable HER2+ breast cancer or residual nodal disease following neoadjuvant therapy. Participants were randomized to receive either T-DXd or T-DM1 for 14 cycles. The primary endpoint, iDFS, significantly favored T-DXd (9% absolute improvement in 3-year iDFS over T-DM1, reflecting a 53% reduction in risk (HR, 0.47; $P < .0001$). Efficacy endpoints, including distant DFS and central nervous system (CNS) recurrence, favored T-DXd. OS is immature, but a favorable trend was seen at this first interim analysis, with rates of 97.4% and 95.7%, respectively (HR, 0.61; 95% CI, 0.43-1.10). Rates of grade 3 or greater treatment-related AEs were comparable between arms; treatment-related ILD occurred in ~9% of patients receiving T-DXd.

Adjuvant Neratinib

In the ExteNET trial, which included 2,840 patients who had early-stage HER2-positive breast cancer who were within 2 years of completing adjuvant trastuzumab therapy, the 2-year iDFS rate was 94.2% among those who received adjuvant neratinib for 1 year compared with a rate of 91.9% in those receiving placebo. The most common adverse events were diarrhea, fatigue, rash, and stomatitis, with 16.8% of patients discontinuing treatment because of diarrhea.[286] These results led to FDA approval of neratinib for the extended adjuvant treatment of patients who have early-stage HER2-positive breast cancer after adjuvant trastuzumab-based therapy. After 8 years of follow-up, the benefit of iDFS was most pronounced in patients with hormone receptor–positive cancers who began neratinib within 1 year of trastuzumab; there is no observed difference in OS.[287] Concurrent administration of antidiarrheal prophylaxis is recommended with initiation of neratinib and is supported by the ASCO 2018 clinical practices guidelines.

Small, Node-Negative Tumors

Retrospective data suggest that small, node-negative, HER2-positive breast cancers have a small but tangible risk of distant recurrence. However, most patients with these cancers were not eligible for enrollment in the pivotal adjuvant trastuzumab clinical trials. The phase 2 APT trial explored the efficacy of a trastuzumab-containing adjuvant therapy regimen with a de-escalation of chemotherapy. The APT trial enrolled 406 patients with node-negative, HER2-positive breast cancer tumor size smaller than 3 cm.[288] In this single-arm study, patients received 12 weeks of paclitaxel (80 mg/m^2) and concurrent trastuzumab, followed by 9 months of single-agent trastuzumab therapy. The 7-year DFS rate was 93.3%, with only four DFS events (1%) being distant metastases. The regimen was well tolerated, with minimal neuropathy and cardiac compromise, and has become a common choice in patients who have node-negative, HER2-positive breast cancers smaller than 2 cm.

Adverse Events With HER2-Directed Therapies

Major toxicities associated with HER2-targeted therapies used in early breast cancer include the following:

- Cardiac toxicity: The addition of trastuzumab in the adjuvant studies resulted in a less than 4% difference in incidence of congestive heart failure or death between the treatment arms. However, up to 18% of patients experienced asymptomatic decreases in ejection fraction that prompted discontinuation of trastuzumab.[289] The risk of cardiac compromise was associated with advanced age, hypertension, preexisting cardiac dysfunction, and high BMI. Cardiac monitoring with echocardiography or multigated acquisition scan is recommended every 3 months during adjuvant trastuzumab treatment. Among patients with asymptomatic low ejection fraction, the decision to use HER2-targeted therapy must be made on an individual basis, assessing the relative risk of cardiac dysfunction from a specific regimen versus disease progression, and in collaboration with a cardiologist.[290] Concurrent administration of anthracyclines with HER2-targeted therapy increases the risk of heart failure and should be avoided.
- Diarrhea: The incidence of all-grade diarrhea across various studies with pertuzumab ranged from 28% to 72%, with grade 3 diarrhea in 0% to 12% of cases.[291] Diarrhea was common, occurred mainly during the first treatment cycle, and was manageable with antidiarrheal medications. Diarrhea is an important adverse effect of neratinib (21% of patients in the TBCRC 022 study had grade 3 diarrhea with low-dose loperamide prophylaxis). Prophylactic antidiarrheal medications should be started concurrently with neratinib.
- Rash: Overall, 22% of patients treated with HER2-targeted therapies,[292] including lapatinib and pertuzumab, experienced rash. Most dermatologic toxicities in patients receiving lapatinib present early and rarely require dose reduction or lead to treatment discontinuation.[293] Rash associated with EGFR inhibitors is typically acneiform, accompanied by pruritus and tenderness in 62% of patients, and can be managed with topical hydrocortisone and oral doxycycline or minocycline in most situations. In a meta-analysis with data from 1,726 patients, pertuzumab increased the risk of rash compared with control (relative risk, 1.53).[294]

KEY POINTS

- The recommended total duration of adjuvant trastuzumab is 12 months.
- The addition of 1 year of adjuvant pertuzumab concurrently with trastuzumab can be considered for high-risk patients because it provides a small absolute improvement in DFS.
- Pertuzumab, when administered concurrently with trastuzumab and taxane-based chemotherapy, is associated with a significantly increased pCR rate.
- In patients with residual disease after neoadjuvant chemotherapy, switching to T-DM1 after surgery is recommended.

INFLAMMATORY BREAST CANCER

Inflammatory breast cancer accounts for up to 2% of all breast cancers in the United States. Inflammatory breast cancer (T4d in TNM staging) is a clinical diagnosis in the setting of documented invasive breast cancer and is characterized by a rapid onset of clinical changes in the breast, including skin erythema, warmth, edema (peau d'orange), breast enlargement, and pain. These clinical criteria differentiate inflammatory breast cancer from a neglected locally advanced breast cancer with secondary inflammatory characteristics, which is associated with a more favorable prognosis.

Pathologically, tumor emboli are seen within dermal lymphatics in 75% of cases.[295] The classic physical findings of the breast are a result of damage to the dermal lymphatics caused by tumor emboli.[296] Breast imaging with mammography usually reveals asymmetrically increased density throughout the affected breast associated with skin thickening and axillary adenopathy. MRI is more sensitive and specific in detecting breast masses and confirming disease response to neoadjuvant chemotherapy compared with mammography.[297] Staging scans to rule out distant metastasis are recommended, given the locally advanced and aggressive behavior of inflammatory breast cancer.

Although all subtypes are seen in inflammatory breast cancer, HER2-positive or triple-negative subtypes are common.

Inflammatory breast cancer is treated with neoadjuvant chemotherapy, followed by mastectomy with axillary lymph node dissection and PMRT with comprehensive regional nodal irradiation.

Standard neoadjuvant chemotherapy, including combination anthracycline and taxane-based regimens, is recommended for inflammatory breast cancer. The combination of chemotherapy and HER2-directed therapy is recommended for HER2-positive inflammatory breast cancer. If the tumor is triple negative, then pembrolizumab and chemotherapy are offered as discussed earlier in this chapter. Adjuvant endocrine therapy and HER2-directed therapy are given as appropriate.

Breast conservation is contraindicated, as is SLNB in inflammatory breast cancer. A total mastectomy with levels 1 and 2 axillary lymph node dissection improves surgical control compared with surgery of lesser extent. Given the elevated risk of local recurrence, reconstruction of the breast is best deferred to avoid delays in the initiation of radiation therapy. Radiation therapy to the chest wall and regional lymph nodes (supraclavicular, infraclavicular, and internal mammary) is included in the treatment field.

If a patient is still not able to undergo surgery after completing an initial course of neoadjuvant chemotherapy, additional treatments should be pursued, including additional chemotherapy using different agents or radiation therapy.[298] For patients who present with metastatic disease or who develop metastatic disease during the initial course of therapy, treatment is similar to that for noninflammatory breast cancer.

KEY POINTS

- Inflammatory breast cancer is treated with neoadjuvant chemotherapy, followed by mastectomy with axillary lymph node dissection, PMRT, and adjuvant endocrine, anti-HER2, immunotherapy, and PARP inhibitor therapy, when indicated.
- Despite optimal multimodality care, DFS is worse in inflammatory breast cancer compared with noninflammatory breast cancer, even for patients who achieve pCR.

TREATMENT OF RECURRENT OR METASTATIC (STAGE IV) DISEASE

LOCOREGIONAL RELAPSE

Locoregional disease relapse can be defined as cancer recurrence in the ipsilateral breast, chest wall, or regional lymph nodes. In breast and even in chest wall, recurrence can be difficult to distinguish from a new primary cancer. Development after 5 years and/or in sites distant from the original site and the presence of in situ cancer, especially in chest wall lesions of normal breast tissue, are all indicators that the lesion may be a new, de novo primary cancer rather than a locoregional recurrence. Nodal recurrence in the contralateral axilla can occur as a result of aberrant drainage patterns, and breast imaging should be performed to exclude a new primary. These should be treated as new primary cancers.

Locoregional recurrences are frequently associated with distant metastases, and, therefore, full-body evaluation for metastases should be performed. If metastases are identified, a patient should be treated as per any patient with metastatic disease.

Although the prognosis for a locoregional recurrence is worse than for a new primary breast cancer, it is superior to that with distant metastases, and isolated locoregional recurrences are treated with curative intent.[299] Ipsilateral breast tumor recurrence

after breast conservation therapy has been associated with a three- to fourfold increase in the risk of developing systemic metastases.[300] Patients who experienced a chest wall recurrence after mastectomy fared worse, with a 6.68-fold greater risk of distant recurrence at 5 years and a 5.85-fold greater risk of death.

The treatment of locoregional recurrences requires a multidisciplinary approach. The standard treatment of ipsilateral in breast tumor recurrences that occur after breast conservation therapy usually occurs in the setting of prior radiation therapy and systemic therapy. Therefore, the standard of care is a total mastectomy, although excision and reirradiation can be considered for select patients.[301] In patients without prior radiation therapy, breast conservation therapy can be considered. If the axilla is clinically negative after assessment by clinical examination and ultrasonography, sentinel lymph node surgery can be attempted; however, it has a lower sentinel lymph node identification rate.[302] Axillary lymph node dissection should be considered in cases in which sentinel lymph nodes are not identified. In cases with clinically positive nodes or positive sentinel lymph nodes, axillary lymph node dissection should be performed.

Chest wall recurrences after mastectomy are more likely to be true recurrences rather than new primary cancer, and they occur most frequently within the first 5 years after treatment and rarely occur after 10 years. A majority of chest wall recurrences develop near the mastectomy incision, whereas fewer recurrences develop in the regional lymph node areas (in order of decreasing frequency: supraclavicular, axillary, and internal mammary). The treatment of an isolated chest wall recurrence requires surgical excision, if feasible, to obtain negative margins. The chest wall and supraclavicular lymph nodes should then receive standard radiation therapy if not administered previously.

Systemic therapy is often administered after completion of local treatment of a locoregional recurrence, although the data supporting its use are limited. The international CALOR (BIG 1-02/IBCSG 27-02/NSABP B-37) trial only enrolled 162 of planned 977 patients with invasive breast cancer in whom an isolated local and/or regional ipsilateral recurrence developed after mastectomy or breast conservation therapy.[303] Patients received radiation therapy and endocrine therapy as appropriate and were randomly assigned to receive chemotherapy of the physicians' choice or not. The 5-year DFS rate was improved with chemotherapy (69%) compared with no chemotherapy (57%). However, the benefits of chemotherapy were limited to ER–negative tumors, a finding confirmed after 9 years of follow-up.[304] Although highly underpowered, this study supports consideration of chemotherapy after local or regional disease recurrence in patients with triple-negative disease.

Patients who have ER–positive breast cancer should receive endocrine therapy. The precise type should be guided by the timing of the recurrence. If the patient was still taking or recurred soon after taking one type, her therapy should be switched to a different type. If the recurrence was many years after stopping prior adjuvant endocrine therapy, physicians can consider restarting that therapy or switching. There are no trial guidelines for this issue. Ongoing trials are addressing the benefits of adding CDK4/6 inhibition to the endocrine therapy after locoregional recurrence and local treatment. There are no trial data assessing the treatment of HER2-positive disease in this setting, but it is reasonable to initiate an effective anti-HER2 treatment.

KEY POINTS

- Locoregional recurrences require a multidisciplinary approach.
- Local recurrence is associated with a high rate of distant metastasis, and systemic imaging is recommended for these patients.
- After breast conservation therapy, the standard treatment of local recurrences involves a total mastectomy.
- The addition of chemotherapy after surgical management of a locoregional recurrence may benefit some patients, primarily those with ER–negative disease.

SYSTEMIC THERAPY FOR STAGE IV (METASTATIC) DISEASE

Treatment options for MBC depend on tumor characteristics, previous treatments, concern for organ failure as a result of metastatic disease (visceral crisis), disease burden, patient performance status, preferences, and comorbidities.[305,306]

The incorporation of new therapies over recent decades has resulted in a gradual improvement in OS rate by 1% to 2% per year.[307] The overall goals of treating MBC are to delay the progression of disease, improve quality of life, and prolong survival while minimizing treatment-associated toxicity. MBC is a chronic disease; sequential therapy is a mainstay of treatment.

Once metastatic disease is diagnosed, its extent should be determined by radiographic imaging. The most common initial sites of metastasis include bone, liver, and lung, which can be imaged by conventional CT and bone scan. FDG PET imaging can complement these studies, especially in the setting of lytic bone metastases, which may be underestimated on bone scan. Fluoroestradiol PET was FDA approved in 2021 for the detection of ER–positive lesions as an adjunct to biopsy in patients with recurrent or MBC. Appropriate use criteria for fluoroestradiol PET have been published.[308] CNS disease is less likely to be present at the initial appearance of metastatic disease, and MRI of the brain is not necessary in the absence of symptoms. Bone metastases are more common in the hormone receptor–positive subtype (68%), whereas TNBC is associated with a high frequency of metastasis to the lungs (40%). HER2-positive disease and TNBC are associated with a higher frequency of brain metastasis compared with the hormone receptor–positive subtype.[309]

Discordance of hormone receptor and HER2 status between the primary tumor and the metastatic disease can occur in 10% to 15% of patients. A biopsy of the metastatic disease at initial presentation is indicated to confirm the presence of MBC rather than another malignancy, either primary or metastatic, and to determine hormone receptor and HER2 status.

Biopsy of a metastatic lesion can also be sent for next-generation sequencing (NGS). NGS of tumors for alterations with a therapeutic target may identify additional therapies or eligibility in a clinical trial. Serum markers, such as cancer antigen 27.29 or 15-3, and carcinoembryonic antigen levels can complement the interpretation of imaging studies in metastatic disease but should not be used alone for monitoring response to treatment.[310] Despite promising data, the use of circulating tumor cells or circulating tumor DNA (ctDNA) in the interpretation of disease response and management remains investigational at this time.

HORMONE RECEPTOR–POSITIVE DISEASE

In hormone receptor–positive and HER2-negative advanced breast cancer, sequential endocrine therapy is preferred over cytotoxic chemotherapy as initial treatment, as endocrine-based therapy can be highly effective and well tolerated. NGS of tumor or of circulating tumor cells can identify tumor alterations for which there are increasing numbers of targeted therapies for patients with hormone receptor–positive and HER2-negative advanced breast cancer who were previously treated with AI therapy with/without CDK4/6 inhibitors for their advanced disease.

First-Line Therapy

CDK4/6 Inhibitors

The addition of CDK4/6 inhibitors to endocrine therapy is a major advance in the treatment of women with metastatic hormone receptor–positive breast cancer.[311] CDK4/6 inhibitors interfere with progression from the G1 to S phase of the cell cycle. When CDK4 and CDK6 are activated by d-type cyclins, they phosphorylate the retinoblastoma-associated protein, releasing its suppression of the E2F transcription factor family. The CDK4/6 inhibitors prevent progression through this checkpoint, leading to cell cycle arrest.[312]

Four prospective trials compared first-line AI therapy to the combination of an AI and a CDK4/6 inhibitor, as summarized in Table 10-6. All four trials revealed a consistent benefit in PFS with the three FDA-approved CDK4/6 inhibitors palboclib, ribociclib, and abemaclicilb. Trials of ribociclib revealed an OS benefit as well. Importantly, the CDK4/6 inhibitors have not been directly compared with one another.[313-324]

Despite extensive research, ER expression remains the only known predictive biomarker of response to CDK4/6 inhibitors. The CDK4/6 inhibitors, as a class, are generally well tolerated. The most common adverse effects of these agents include nausea, diarrhea, fatigue, neutropenia, anemia, and thrombocytopenia. Neutropenia is more common with palbociclib and ribociclib (although febrile neutropenia is rare), whereas diarrhea is the most common adverse effect of abemaciclib. Neutropenia is a common reason for dose reduction. Importantly, dose reduction does not seem to decrease the efficacy of palbociclib.[327] Other potential toxicities, including QT prolongation with ribociclib or elevation of aminotransferase levels, can occur and should be monitored in accordance with the agent chosen.

SONIA was an investigator-initiated trial that questioned the use of first-line CDK4/6 in combination with a nonsteroidal AI.[328] In this phase 3 trial, patients were randomly assigned to the control arm of an AI and a CDK4/6 inhibitor (91% received palbociclib) or an AI alone. Upon disease progression, those who received an AI alone received fulvestrant and the CDK4/6 inhibitor, whereas the control arm received fulvestrant alone. The primary endpoint was PFS after two lines of therapy (PFS2). Although median PFS was improved with up-front combination therapy, consistent with the prior phase 3 studies, there was no difference in median PFS2 at the median follow-up of 37 months. There was no difference in OS. Given the significant and consistent benefit of a first-line AI and a CDK4/6 inhibitor, the combination remains the standard of care as first-line treatment.

The phase 3 INAVO120 study randomized patients with endocrine-resistant hormone receptor–positive and HER2-negative breast cancer to first-line fulvestrant and palbociclib in combination with the PI3K inhibitor inavolisib or placebo. Eligible patients had tumors with a PIK3CA mutation by ctDNA, and patients experienced metastatic recurrence during or within 12 months of completing adjuvant endocrine therapy. The primary endpoint of PFS was improved from 7.3 months with fulvestrant, palbociclib, and placebo to 15 months with the triplet.[329] As will be elaborated further with similar drugs, the inavolisib arm experienced more adverse events of hyperglycemia, diarrhea, stomatitis, and rash. In October 2024, the FDA approved inavolisib in combination with fulvestrant and palbociclib as first-line therapy in patients described above. OS has been reported with a median OS of 34 months with the triplet therapy versus 27 months with fulvestrant and palbociclib.

Although endocrine therapy is recommended as first-line treatment in metastatic hormone receptor+ breast cancer, cytotoxic chemotherapy has been considered for those with visceral metastases. The phase 4 PADMA trial randomized previously untreated patients with hormone receptor+ and HER-negative MBC with an indication for mono-chemotherapy to endocrine therapy and palbociclib or mono-chemotherapy of the physician's choice (paclitaxel, capecitabine, epirubicin, or vinorelbine). The primary endpoint of median time to treatment failure was 17.2 months with endocrine therapy and palbociclib compared to 6.1 months with chemotherapy, and median PFS was 18.7 months versus 7.8 months, respectively. The results of PADMA have not been published, but provide reassuring evidence that first-line endocrine therapy and a CDK4/6 inhibitor remain the standard treatment.[330]

Table 10-6 **Trials With CDK4/6 Inhibitors**

Treatment	Study	Phase	Description	Median PFS, Months (HR, 95% CI)	Median OS, Months (HR, 95% CI)
First line	PALOMA-2	3	Palbociclib/letrozole vs placebo/letrozole	24.8 vs 14.5 (0.58, 0.46-0.72)	53.9 vs 51.2 (0.96, 0.777-1.177)[313]
	MONALEESA-2	3	Ribociclib/letrozole vs placebo/letrozole	25.3 vs 16.0 (0.56, 0.43-0.72)[314]	63.9 vs 51.4 (0.76, 0.63-0.93)[315]
	MONALEESA-7	3	Ribociclib/OFS/AI or tamoxifen vs placebo/OFS/AI or tamoxifen	23.8 vs 13.0 (0.55, 0.44-0.69)[316]	58.7 vs 40.9 (0.76, 0.61-0.96)[317]
	MONARCH-3	3	Abemaciclib/AI vs placebo/AI	28.2 vs 14.7 (0.54, 0.41-0.72)[325]	66.8 vs 53.7 (0.80, 0.64-1.01)[326]
First or second line	MONALEESA-3	3	Ribociclib/fulvestrant vs placebo/fulvestrant	20.5 vs 12.8 (0.59, 0.48-0.73)[318]	67.6 vs 51.8 (0.67, 0.50-0.90)[319]
Second line	PALOMA-3	3	Palbociclib/fulvestrant vs placebo/fulvestrant	9.5 vs 4.6 (0.46, 0.36-0.59)[320]	34.9 vs 28.0 (0.81, 0.65-0.99)[321]
	MONARCH-2	3	Abemaciclib/fulvestrant vs placebo/fulvestrant	16.4 vs 9.3 (0.55, 0.45-0.66)[322]	46.7 vs 37.3 (0.757, 0.61-0.94)[324]
Later line	MONARCH-1	2	Abemaciclib	6[323]	17.7[323]

Abbreviations: AI, aromatase inhibitor; CDK4/6, cyclin-dependent kinase 4/6; HR, hazard ratio; OFS, ovarian function suppression; OS, overall survival; PFS, progression-free survival.

Second-Line Therapy and Beyond

All three CDK4/6 inhibitors have also been evaluated after disease progression on endocrine therapy, as summarized in Table 10-6. The addition of a CDK4/6 inhibitor to fulvestrant improved PFS and OS compared with fulvestrant alone.

PI3K-AKT-PTEN Signaling Pathway

Overactivation of this signaling pathway through activating mutations in *PIK3CA* or *AKT1* or inactivation of *PTEN* occurs in 40% to 50% of hormone receptor–positive and HER2-negative breast cancers. The phase 3 CAPItello-291 trial randomized patients to capivasertib, the oral AKT inhibitor, and fulvestrant or to placebo and fulvestrant.[6] Forty percent of patients had a tumor AKT pathway alteration. Median PFS was significantly improved in the capivasertib versus placebo arms in the overall population (7.2 vs 3.6 months) and in the group with AKT pathway alterations (7.3 vs 3.1 months). The most common adverse event in the capivasertib arm was diarrhea in 72%, with 9.3% grade 3 and no grade 4 diarrhea. Rash was seen in 38%, including 12% with grade 3, followed by grades 1 and 2 nausea in 35%. Hyperglycemia was reported in 16%, with only 2% grade 3. In November 2023, the FDA approved capivasertib for patients with previously treated hormone receptor–positive and HER2-negative advanced breast cancer with alterations in the AKT pathway.

Similarly, the addition of the PIK3CA inhibitor alpelisib to fulvestrant improved median PFS compared with placebo and fulvestrant in the phase 3 SOLAR-1 trial.[331] The incidence of grades 3 and 4 hyperglycemia was 36%; 58% reported diarrhea, 6.7% was grade 3. Alpelisib was FDA approved in 2019 for PIK3CA-mutated hormone receptor–positive and HER2-negative advanced breast cancer. Subjects who had received prior alpelisib were excluded from the CAPItello trial, and the optimal sequencing to target the PI3K-AKT-PTEN pathway is unknown.

Estrogen Receptor 1

Mutations in estrogen receptor 1 (ESR1) result in estrogen-independent ER activation and potential resistance to AIs but not ER inhibitors. Elacestrant is an oral selective estrogen receptor degrader (SERD). In the phase 3 EMERALD trial,[332] patients with previously treated MBC, including a prior CDK4/6 inhibitor, were randomized to endocrine monotherapy or elacestrant. Approximately 48% of the study population had a tumor ESR1 mutation, and PFS was significantly improved in both the overall population and those with tumor ESR1 mutations. The most common adverse event with elacestrant was nausea in 35%, 2.5% with grade 3 or 4. Elacestrant was FDA approved in 2023 for ESR1-mutated hormone receptor–positive and HER2-negative advanced breast cancer. Patients with previously treated MBC, including a prior CDK4/6 inhibitor, were randomized to endocrine monotherapy or elacestrant. Approximately 48% of the study population had a tumor ESR1 mutation, and PFS was significantly improved in both the overall population and those with tumor ESR1 mutations. The most common adverse event with elacestrant was nausea in 35%, 2.5% with grade 3 or 4. Elacestrant was FDA approved in 2023 for ESR1-mutated hormone receptor–positive and HER2-negative advanced breast cancer.

The EMBER 3 trial compared the SERD imlunestrant to standard endocrine monotherapy or to the combination of imlunestrant and abemaciclib after progression on first-line endocrine therapy with/without a CDK4/6 inhibitor. The median PFS was significantly improved with imlunestrant compared with endocrine monotherapy among patients with ESR1 mutations (5.5 vs 3.8 months).[3] The combination of imlunestrant and abemaciclib was associated with improved median PFS compared to imlunestrant alone (9.4 vs 5.5 months). Imlunestrant was FDA-approved in patients with metastatic hormone receptor–positive and HER2-negative breast cancer with an ESR1 mutation after one line of endocrine therapy.

Mammalian Target of Rapamycin Inhibitors

The phosphoinositide-3 kinase–AKT–mammalian target of rapamycin (mTOR) pathway is associated with the development of endocrine resistance.[333] The addition of everolimus, an oral mTOR inhibitor, to endocrine therapy was hypothesized to reverse endocrine resistance. In the phase 3 BOLERO-2 trial, 724 postmenopausal women whose disease progressed or recurred while receiving a nonsteroidal AI were randomly assigned to receive everolimus and exemestane or exemestane alone.[334] The median PFS was improved with combination therapy from 4.1 to 10.6 months. Everolimus is associated with a relatively common risk of stomatitis and a small but potentially serious risk of pneumonitis. Use of a steroidal mouthwash reduces the incidence of stomatitis.[335] A combination of everolimus and exemestane is an option for patients with disease progression after a nonsteroidal AI.

Sequencing of Endocrine Therapy

There is little guidance regarding the optimal sequencing of endocrine therapy in MBC. In patients who do not receive CDK4/6 inhibitors as first-line therapy, the PALOMA-3, MONALEESA-3, and MONARCH 2 trials support the use of these agents in the second line. However, given the efficacy and favorable toxicity profile, almost all patients will receive a CDK4/6 inhibitor for first-line treatment of hormone receptor–positive breast cancer. Select patients may be treated with endocrine therapy alone because of comorbidities and/or indolent low-burden disease (Fig. 10-8).

Patients who experience progression after treatment that includes a CDK4/6 inhibitor can be offered appropriate targeted therapy based on NGS, such as capivasertib, alpelisib, elacestrant, or imlunestrant. There are no data on the optimal sequencing of targeted therapies if a tumor harbors an alteration in both ESR1 and PIK3CA. Likewise, there are no robust data on treatment with another ESR1 antagonist or PID3CA inhibitor after prior treatment.

If no targeted alterations are identified, results of the phase 3 postMONARCH trial suggest changing endocrine therapy and continuing treatment with the CDK4/6 inhibitor abemaciclib.[336] Ninety percent of subjects had received either palbociclib or ribociclib in combination with an AI as first-line therapy for metastatic hormone receptor–positive and HER2-negative breast cancer. Upon progression, patients were randomly assigned to fulvestrant alone or in combination with abemaciclib. Median PFS improved from 5.3 months with fulvestrant to 6 months with fulvestrant and abemaciclib. The FDA has not approved abemaciclib in this setting. Other options include the combination of everolimus and exemestane or tamoxifen.[337] Patients are given sequential endocrine therapy regimens before switching to palliative chemotherapy. Olaparib or talazoparib is an option for patients with germline BRCA mutations (see discussion in "Biomarker-Guided Approach to Metastatic TNBC: Germline BRCA1 and BRCA2 Mutation Carriers" section).

Cytotoxic Chemotherapy

Despite these advances and new agents, patients with hormone receptor–positive breast cancer may either exhaust endocrine therapy options or experience tumor resistance. Cytotoxic chemotherapy and, more recently, ADCs are options. Single-agent therapies are sequenced based on patient preference and side effect profiles. (See discussion in "Triple-Negative Breast Cancer" section.)

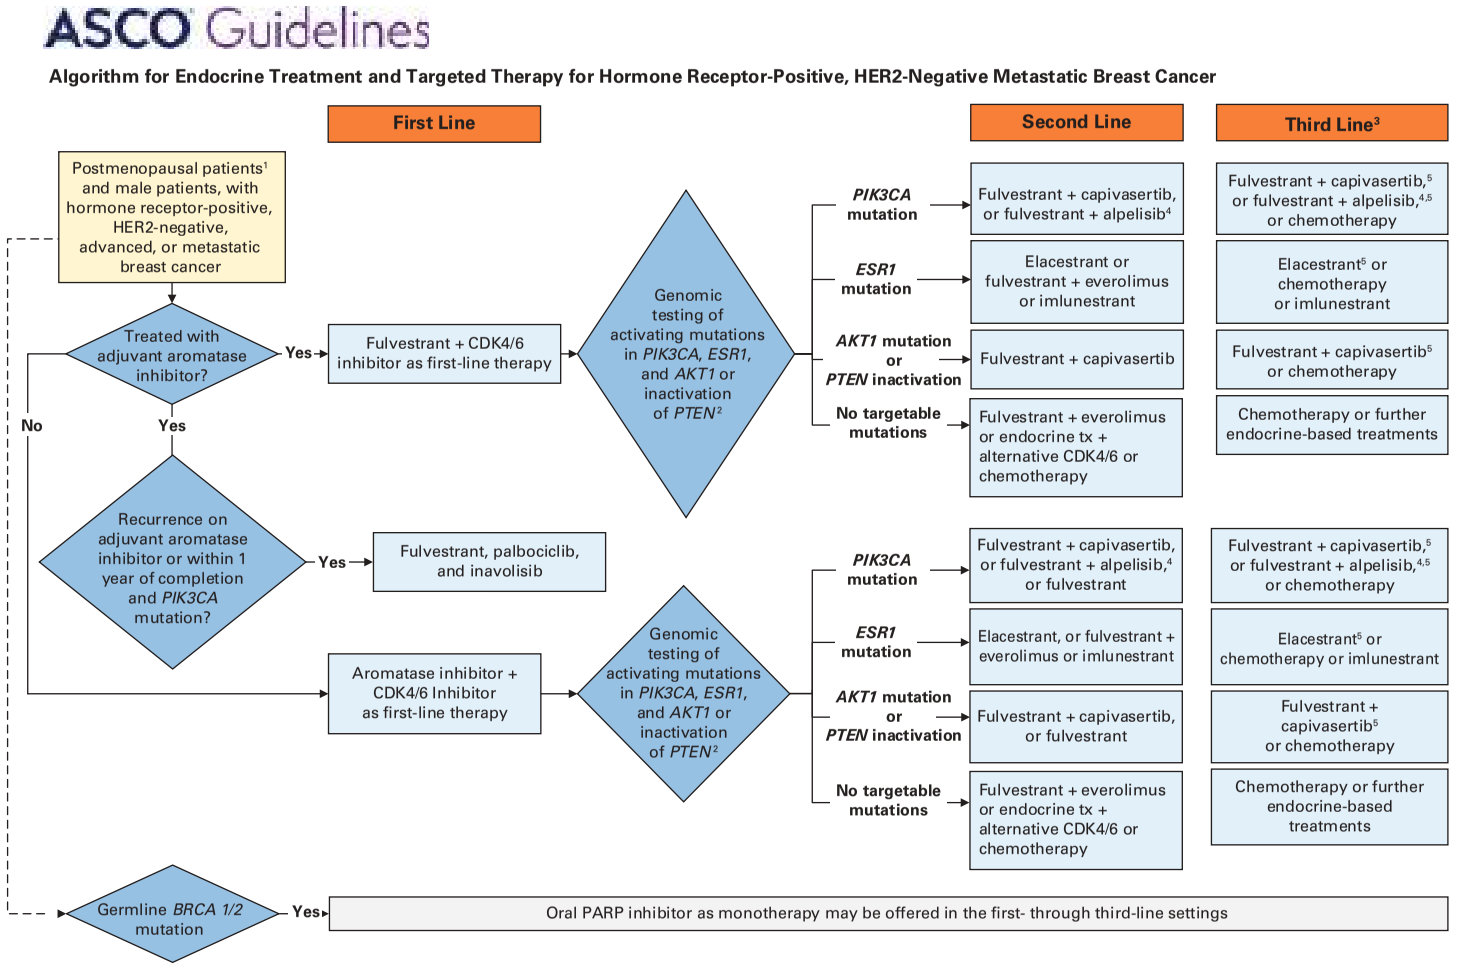
Antibody-Drug Conjugates

T-DXd is a HER2 monoclonal antibody linked to a topoisomerase inhibitor. It is approved in metastatic HER2-positive breast cancer (see discussion in "HER2-Positive Breast Cancer" section). However, T-DXd has demonstrated efficacy in breast cancers with low levels of HER2 (either 1+ staining by IHC or 2+ by IHC and FISH negative). The DESTINY BREAST-04 trial randomized patients with "HER2-low" previously treated advanced breast cancer to T-DXd or the physician's choice of chemotherapy (PCC), which included capecitabine, eribulin, gemcitabine, paclitaxel, or nab-paclitaxel.[338] Notably, 90% of patients had tumors that were hormone receptor positive. Both PFS and OS were significantly improved with T-DXd compared with PCC. T-DXd was FDA approved in 2022 for previously treated "HER2-low" advanced breast cancer.

DESTINY BREAST-06 included patients with hormone receptor–positive and "HER2-low" breast cancer, as defined above, as well as "HER2-ultra low" breast cancer, defined as HER2 0 or 1+ by IHC with some membrane staining. Patients had received more than one line of endocrine therapy but no prior chemotherapy for MBC. They were randomized to T-DXd or PCC, including capecitabine, nab-paclitaxel, or paclitaxel. Median PFS was significantly improved to 13.2 months with T-DXd compared to 8.1 months with PCC. Trastuzumab dertuxtecan was FDA approved in this setting in January 2025.[339]

Sacituzumab govitecan is a Trop-2 monoclonal antibody conjugated to SN-38, the active metabolite of irinotecan. TROPiCS-02 randomized patients with previously treated hormone receptor–positive and HER2-negative advanced breast cancer to sacituzumab govitecan or PCC, which included eribulin, vinorelbine, capecitabine, or gemcitabine.[340] In this phase 3 trial, PFS and,

Figure 10-8 Suggested Treatment Sequencing in Hormone Receptor–Positive and HER2–Negative MBC



Abbreviations: AI, aromatase inhibitor; CDK4/6i, cyclin-dependent kinase 4/6 inhibitor; CLIA, Clinical Laboratory Improvement Amendments; ESR1, estrogen receptor 1; ET, endocrine therapy; HER2, human epidermal growth factor receptor 2; MBC, metastatic breast cancer; OFS, ovarian function suppression; PARPi, poly-ADP-ribose polymerase inhibitor; PTEN, phosphatase and tensin homolog protein.

BRCA mutation options: olaparib or talazoparib.

[1]If patient is premenopausal, initiate ovarian suppression and continue as postmenopausal.

[2]Tumor genomic testing includes sequencing for targetable mutations, accomplished through large panel tumor genomic testing in a CLIA-certified laboratory performed on tissue or plasma obtained either at the time of progression or from archival tissue. In addition to selecting patients whose tumors have increased PIK3CA or AKT1 activity because of the presence of activating mutations, it is also important to identify those whose tumors have inactivation of phosphatase and tensin homolog (PTEN) protein. PTEN inactivation can be identified based on the presence of premature stop codons, frameshift alterations, splice site mutations, PTEN homozygous deletion, PTEN rearrangements that disrupt protein function, or specific missense mutations (*C124R*, *C124S*, *G129E*, *G129V*, *G129R*, *R130Q*, *R130G*, *R130L*, *R130P*, *C136R*, *C136Y*, *S170R*, and *R173C*), on next-generation sequencing.

[3]There are few data on the value of older endocrine treatment options after therapy with modern treatment regimens such as AIs, SERDs, CDK4/6 inhibitors and/or other targeted agents. In select patients—typically those with indolent cancers, limited disease burden or symptoms, and demonstrated clinical benefit from prior endocrine treatments—therapies such as tamoxifen, megestrol acetate, or reintroduction of previously administered treatments may be of clinical value.

[4]Alpelisib is an option for patients with tumors harboring PIK3CA activating mutations but not AKT1 activating mutations or PTEN inactivation.

[5]If not previously given.

subsequently, OS were improved with sacituzumab govitecan compared with PCC (median 5.5 vs 4 months and median 14.4 vs 11.2 months, respectively).[341] Sacituzumab govitecan was FDA approved in 2023 for patients with previously treated hormone receptor–positive and HER2-negative breast cancer.

Datopotamab deruxtecan (Dato-DXd) is a Trop-2 monoclonal antibody conjugated to a topoisomerase inhibitor payload. TROPION-Breast 01 randomized patients with previously treated hormone receptor–positive and HER2-negative advanced breast cancer, who had received up to two lines of chemotherapy in the metastatic setting, to Dato-DXd or to the investigator's choice of chemotherapy (ICC; eribulin, capecitabine, vinorelbine, or gemcitabine). The dual primary endpoints were PFS and OS. PFS was significantly improved on Dato-DXd compared with ICC (median 6.9 vs 4.9 months, respectively). OS data were not mature at this analysis.[342] Dato-DXd was FDA approved in January 2025 for patients previously treated with endocrine therapy or chemotherapy.

TRIPLE-NEGATIVE BREAST CANCER

Patients who have TNBC generally have a worse prognosis than those with either hormone receptor or HER2-positive cancers. Until recently, the only option was standard chemotherapy. However, over the last decade, several new treatments for metastatic TNBC have been introduced, many of them targeted to specific biomarkers present in the cancer.

General Principles of Chemotherapy in MBC

Chemotherapy, in some cases with immunotherapy, has generally been the treatment of choice for metastatic hormone receptor–negative breast cancer. It is also indicated in hormone receptor–positive breast cancer in the setting of rapidly progressing or symptomatic disease, disease associated with visceral crisis, or development of endocrine resistance. Sequential use of single-agent chemotherapy is recommended instead of combination chemotherapy regimens. Although combination chemotherapy is associated with a higher chance of response, it is also associated with more toxicity without a survival benefit. The exception to this rule is the presence of visceral crisis or rapidly progressive disease that would benefit from prompt cytoreduction.

The duration of treatment must be tailored to each patient, considering the toxicity of treatment, control of disease-related symptoms, and patient goals for treatment and quality of life. Patients whose disease is responding well to chemotherapy without significant toxicity may remain on treatment, whereas chemotherapy holidays are appropriate for patients who require time to recover from toxicity and whose disease may be responsive to less toxic targeted therapy.

Biomarker-Guided Approach to Metastatic TNBC: Immunotherapy

The first-line treatment of advanced TNBC is guided by the PD-L1 status of the tumor and influenced by the disease-free interval from any prior adjuvant therapy. Pembrolizumab in combination with chemotherapy has been, until recently, the preferred treatment of patients with previously untreated locally recurrent, unresectable, or metastatic TNBC whose tumors express PD-L1, defined by a combined positive score (CPS) of 10 or higher, based on the results of the KEYNOTE-355 trial.[343] This double-blind phase 3 trial randomly assigned 847 patients to pembrolizumab or placebo in combination with chemotherapy (nab-paclitaxel, paclitaxel, or gemcitabine, and carboplatin). In patients with CPS of 10 or higher, the addition of pembrolizumab to chemotherapy improved PFS from 5.6 to 9.7 months. The median OS was 23.0 months (95% CI, 19.0-26.3) in the pembrolizumab-chemotherapy group and 16.1 months (95% CI, 12.6-18.8) in the placebo-chemotherapy group (HR for death, 0.73; 95% CI, 0.55-0.95; two-sided $P = .0185$). The benefit of checkpoint inhibition with chemotherapy is uncertain upon recurrence after neoadjuvant and adjuvant pembrolizumab (Fig. 10-9).

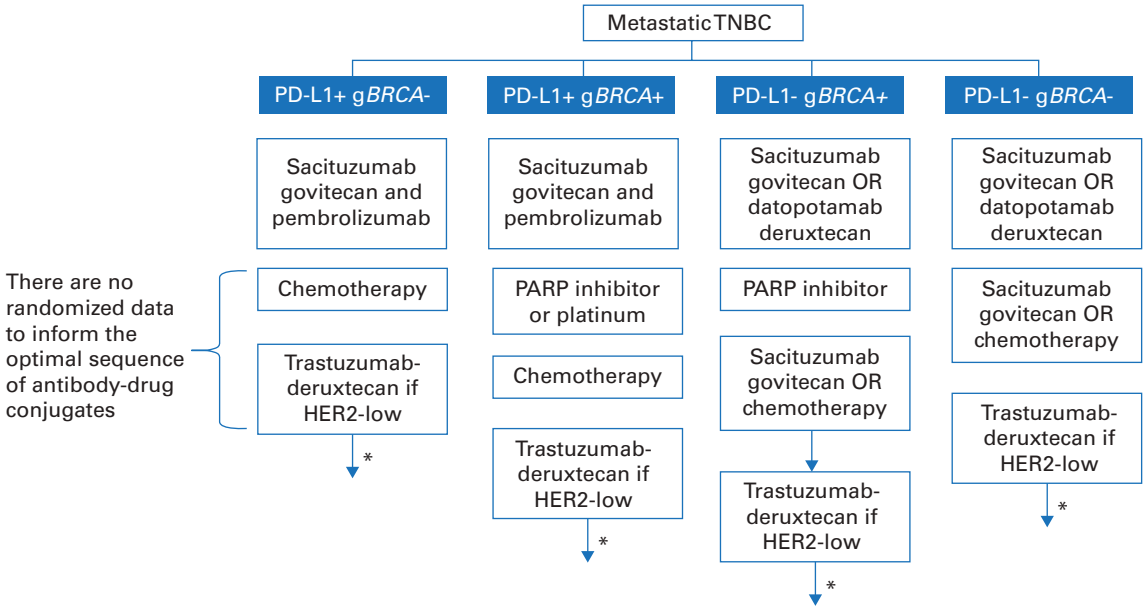
More recently, the phase 3 ASCENT-04 trial evaluated the combination of sacituzumab govitecan plus pembrolizumab versus chemotherapy plus pembrolizumab in the first-line setting. This study demonstrated a clinically meaningful improvement in progression-free survival (median 11.2 vs 7.8 months) and supports the integration of antibody-drug conjugate–based combinations with immunotherapy. As a result, sacituzumab govitecan plus pembrolizumab is emerging as a preferred first-line option for patients with PD-L1-positive metastatic triple negative breast cancer (TNBC).[344]

Single-agent immunotherapy with pembrolizumab may also be appropriate. In the Keynote-119 trial, patients who had MBC and who had received one or more prior chemotherapies were randomly assigned to receive either pembrolizumab (312 [50%]) or chemotherapy of the physician's choice. Median OS was similar in the two groups. Toxicities were as expected in each of the two arms, with one toxicity-related death in the pembrolizumab group and two in the chemotherapy group. Furthermore, pembrolizumab has received an "agnostic" (tumor nonspecific) approval by the FDA for cancers in which the tumor mutational burden is 10 or higher.[345,346]

Biomarker-Guided Approach to Metastatic TNBC: Germline *BRCA1* AND *BRCA2* Mutation Carriers

Patients who have germline *BRCA1* and *BRCA2* mutations seem to derive specific benefit from platinum compared with non-*BRCA1* and non-*BRCA2* mutation carriers. For those patients with germline *BRCA1* and *BRCA2* mutations and a PD-L1–negative tumor, either a platinum or PARP inhibitor is preferred.

Figure 10-9 Approach to Metastatic TNBC



Abbreviation: TNBC, triple negative breast cancer.
*Subsequent lines of therapy should be considered based on performance status and patient goals and values; options include single-agent cytotoxic therapy and select biomarker-driven therapies. Clinical trials may be considered at each decision point.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

In the phase 3 TNT trial,[347] patients who had metastatic TNBC were randomly assigned to carboplatin or docetaxel, and carboplatin was not more active than docetaxel in the unselected population. By contrast, in the group of patients with germline *BRCA1* and *BRCA2* mutations, carboplatin had double the objective response rate of docetaxel (68% vs 33%; $P = .01$).

Two PARP inhibitors, olaparib and talazoparib, are approved for patients who have HER2-negative advanced breast cancer with germline *BRCA1* and *BRCA2* mutations. The phase 3 OlympiAD trial evaluated olaparib as monotherapy compared with chemotherapy (physician choice of capecitabine, eribulin, or vinorelbine) in patients who had germline *BRCA*-mutated HER2-negative advanced breast cancer.[348] Olaparib was associated with an objective response rate of 60% and a superior median PFS of 7.0 months compared with an objective response rate of 29% and a median PFS of 4.2 months for patients receiving chemotherapy (HR, 0.58; $P = .0009$). More low-grade adverse events occurred in those receiving olaparib (primarily nausea and vomiting), whereas there were more high-grade adverse events in those receiving chemotherapy (primarily neutropenia). In the phase 3 EMBRACA trial,[349] 431 patients with advanced breast cancer and a germline *BRCA1* or *BRCA2* mutation were assigned, in a two-to-one ratio, to receive talazoparib (1 mg once daily) or a physician's choice of standard single-agent therapy. The median PFS was significantly longer in the talazoparib group (8.6 vs 5.6 months; HR, 0.54; $P < .001$). Talazoparib caused more grades 3 and 4 anemias than standard chemotherapy (55% vs 38%), although patient-reported outcomes favored talazoparib.

The role of platinum after progression during PARP inhibitor treatment and vice versa is currently unclear, given the concern for similar mechanisms of resistance. The optimal sequencing of therapies for patients with germline *BRCA1* and *BRCA2* mutations and HER2-negative MBC also remains unclear.

Biomarker Negative: BRCA-Wild Type and PD-L1-Negative

For those patients who do not have *BRCA1* or *BRCA2* mutations and a PD-L1–negative tumor, the use of cytotoxic chemotherapy has been the standard of care until recently. Anthracyclines and taxanes are active chemotherapies for MBC. Capecitabine, an antimetabolite, is also commonly used for the treatment of metastatic disease, given that it is an oral drug and has a favorable toxicity profile with little alopecia. However, most patients with TNBC have already received anthracycline, taxane, platinum, and capecitabine in the curative intent setting; when disease recurs, the preferred choice of first-line therapy is an antibody-drug conjugate (ADC). ADCs are a class of therapeutic agents that combine monoclonal antibodies with highly potent anticancer agents through a chemical linker.

Two trials have recently tested the use of anti-TROP2 ADCs in the first-line setting for the treatment of patients with TNBC who are not candidates for immunotherapy. The ASCENT03 trial[350] compared sacituzumab govitecan to investigator choice chemotherapy (taxane or gemcitabine/carboplatin) in patients who had at least a 6-month disease-free interval from adjuvant therapy. The primary endpoint of PFS favored sacituzumab (median PFS 9.7 vs 6.9 months [HR, 0.62, $P < .001$]). The TROPION-Breast 02[351] trial tested Dato-DXd compared to investigator choice chemotherapy (taxane, carboplatin, eribulin, or capecitabine) in patients with advanced TNBC; this study population allowed for rapid progressors with 15% having a disease-free interval

of <6 months. The primary endpoint was powered for both PFS and OS. Dato-DXd was found to have statistically significant superiority of PFS (10.8 months vs 5.6 months, HR, 0.57) and OS (23.7 months vs 18.7 months, HR, 0.79). Although neither study included a significant portion of patients progressing after exposure to checkpoint inhibitors in the (neo)adjuvant setting, they will likely become the new standard of care for first-line metastatic TNBC.

As described, T-DXd was associated with longer PFS and OS in patients who had HER2-low advanced breast cancer in the DestinyBreast-04 trial. This trial was primarily for patients who had hormone receptor–positive breast cancer; however, about 10% of the study included patients with ER/pR–negative HER2-low disease (N = 58). In this hypothesis-generating subset, T-DXd improved median PFS (8.5 vs 2.9 months) and OS (18.2 vs 8.3 months) compared with standard of care chemotherapy. As a result, this ADC is a preferred option for second-line or later treatment of patients with TNBC that is HER2 low.

Tumor sequencing may reveal actionable somatic mutations to allow for third-line and later targeted therapies. For example, a high tumor mutational burden or MSIH is an indication for a single-agent checkpoint inhibitor even if CPS is lower than 1. NTRK fusion allows for larotrectinib or entrectinib therapy, and RET fusion is an indication for selpercatinib. However, these alterations are unfortunately uncommon in breast cancer.

Sacituzumab govitecan-hziy is a monoclonal antibody against Trop-2 conjugated via a cleavable linker to SN-38, the active metabolite of irinotecan. The randomized phase 3 ASCENT trial compared single-agent sacituzumab to treatment of PCC in more than 500 patients with metastatic TNBC who had received at least two previous therapies (inclusive of adjuvant treatment). Sacituzumab demonstrated a median PFS of 5.6 months compared with 1.7 months with chemotherapy (HR, 0.39; 95% CI, 0.31-0.49, $P < .0001$). Median OS was significantly longer with sacituzumab as well (12.1 vs 6.7 months, HR, 0.48; 95% CI, 0.39-0.59, $P < .0001$). The most common adverse reactions (25% or more of patients) associated with sacituzumab govitecan-hziy were nausea, neutropenia, diarrhea, fatigue, anemia, vomiting, alopecia, constipation, rash, decreased appetite, and abdominal pain. There are no prospective randomized data to inform the optimal sequence of ADCs.

HER2+ BREAST CANCER

The introduction of HER2-targeted therapy led to an unprecedented survival gain in metastatic disease compared with the benefit historically reported with chemotherapy alone. The OS of patients who have HER2-positive MBC has increased from 20.3 months reported with chemotherapy alone to 57.1 months seen with the addition of HER2-targeted therapy (trastuzumab, pertuzumab, and docetaxel in the CLEOPATRA trial).[352-355] Given this survival benefit, most patients who have HER2-positive MBC will initiate treatment with chemotherapy in addition to one or more HER2-targeted therapies. The next sections present a summary of the relevant studies in patients who have advanced HER2-positive breast cancer (Fig. 10-10).

The CLEOPATRA trial randomly assigned 808 patients with HER2-positive MBC to receive placebo, trastuzumab, and docetaxel or pertuzumab, trastuzumab, and docetaxel as first-line treatment. The primary endpoint was independently assessed PFS. The addition of pertuzumab led to an improvement of 6.1 months (from 12.4 to 18.5 months) in PFS and 16.3 months (from 40.8 to 57.1 months) in OS. The 8-year landmark OS rates were 37% for the pertuzumab group and 23% for the control group.[352,353] The combination of trastuzumab, pertuzumab, and a taxane is considered optimal first-line therapy per ASCO guidelines.[306,356] The PERUSE trial demonstrated equivalent outcomes, regardless of the specific taxane (docetaxel, paclitaxel, or nab-paclitaxel) combined with HP.[357]

With this regimen, chemotherapy is recommended for at least 4 to 6 months or until maximum response, whereas HER2 therapy is continued until disease progression. For patients who have hormone receptor–positive and HER2-positive disease, endocrine therapy may be added when chemotherapy is discontinued. If a patient completed trastuzumab-based adjuvant treatment in the last 6 months before recurrence (ie, treatment-free interval less than 6 months), second-line therapy should be adopted.

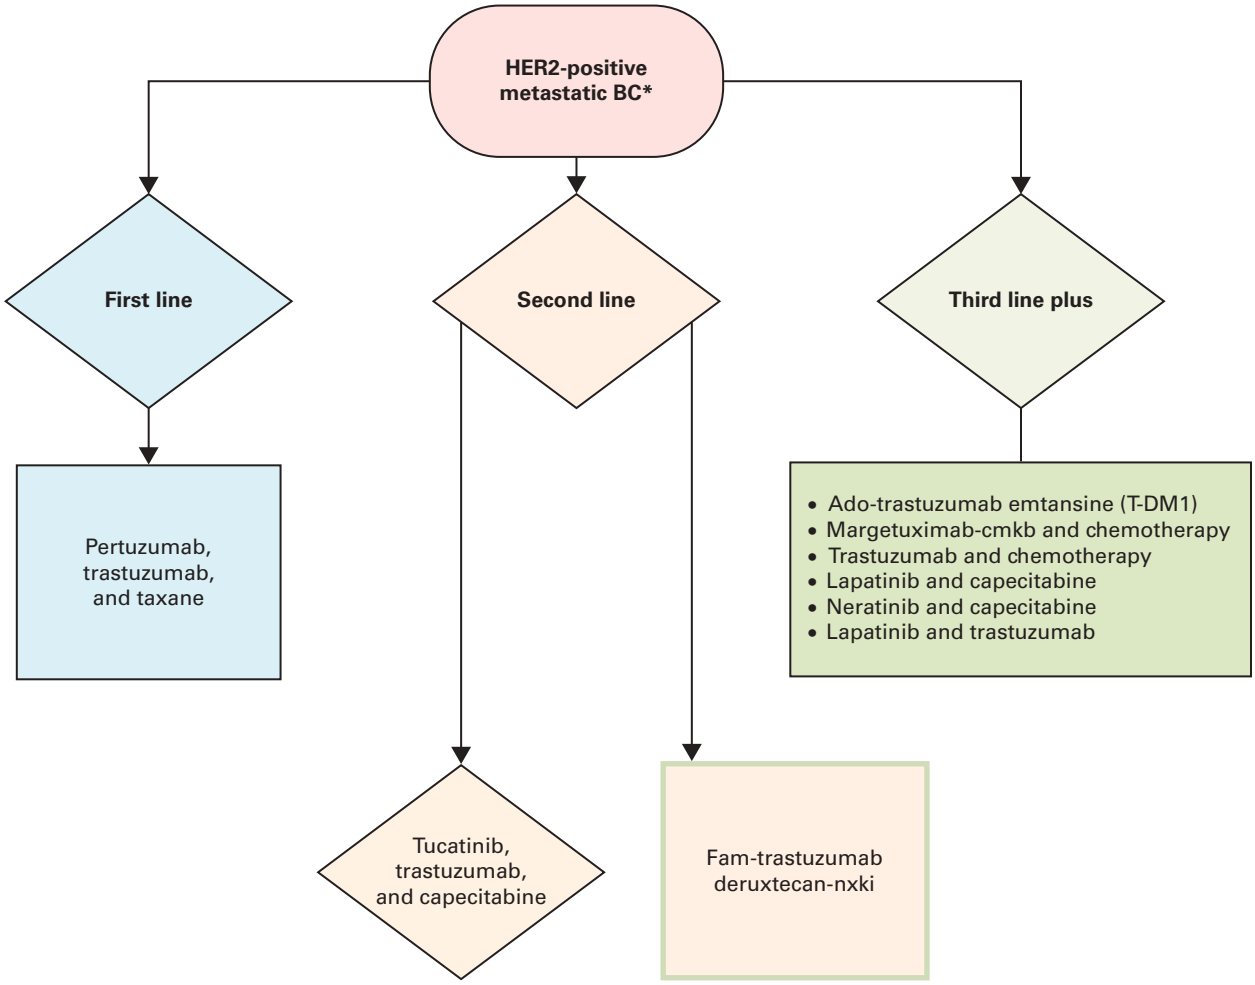
For patients with hormone receptor-positive, HER2-positive breast cancer, the PATINA trial recently demonstrated that adding the CDK4/6 inhibitor palbociclib to standard anti-HER2 and endocrine therapy significantly extended PFS in those who had not progressed following induction chemotherapy with HER2-directed therapy (median PFS 44.3 vs 29.1 months). This may offer a less toxic maintenance approach for certain patients.[358]

Recently, the results of DESTINY-Breast09 were presented at ASCO 2025.[359] This global phase 3 trial randomized patients with HER2+ MBC in the first-line setting to taxane, HP versus Pertuzumab with fam-trastuzumab deruxtecan-nxki, an ADC composed of trastuzumab conjugated to deruxtecan, a derivative of the camptothecin analog exatecan, a DNA topoisomerase 1 inhibitor. The study has met its primary endpoint for PFS with a median PFS of 40.7 months for T-DXd with pertuzumab compared to 26.9 months with THP (HR, 0.56, $P < .00001$). There were no new safety signals. OS data are immature at this time.

Second-Line Therapy: Fam-Trastuzumab Deruxtecan-nxki

In DESTINY-Breast01, a multicenter, open-label, single-arm phase 2 trial, patients with HER2-positive advanced breast cancer previously treated with two or more anti-HER2 therapies were enrolled. The objective response rate was 60.3%, and the median duration of response was 14.8 months. Fatal outcomes because of ILD occurred in 2.2% of patients.[360] The median OS was 24.6 months, and the 18-month OS rate was 74%.[361]

Figure 10-10 Suggested Treatment Sequencing in HER2-Positive Metastatic Breast Cancer



*For select patients with hormone receptor–positive, HER2-positive tumors, endocrine therapy and trastuzumab ± pertuzumab may be considered.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

The DESTINY-Breast03 trial compared T-DXd and T-DM1 in the second-line setting. At the first interim analysis with a median follow-up of 16 months, the median PFS was 6.8 months with T-DM1 and not yet reached with T-DXd (HR, 0.2840; $P = 7.8 \times 10^{-22}$).[362] In the second interim analysis, the median PFS was 28.8 months for T-DXd and 6.8 months for T-DM1 (HR, 0.33; 95% CI, 0.26-0.43; nominal $P < .0001$) with 28.4 and 26.5 months of follow-up, respectively. Two-year OS was 77.4% with T-DXd and 69.9% with T-DM1.[363] Based on these data, T-DXd is recommended as second-line therapy for patients who have experienced progression with trastuzumab and a taxane.

Second-Line Therapy: Tucatinib

Tucatinib is an oral tyrosine kinase inhibitor with selective inhibition of HER2 enzymatic activity and reduced potency against EGFR, which differentiates it from lapatinib and neratinib. The phase 3 HER2CLIMB trial enrolled participants who had HER2-positive MBC previously treated with trastuzumab, pertuzumab, and T-DM1. Patients were randomly assigned to receive tucatinib and trastuzumab and capecitabine or placebo and trastuzumab and capecitabine. The addition of tucatinib led to improvements in PFS (5.6-7.8 months; HR, 0.54) and OS (17.4-21.9 months; HR, 0.66).[364] Overall, 48% of patients had brain metastases at baseline, including patients with untreated brain metastases. In the tucatinib-containing arm, there was a 68% reduction in the risk of CNS PFS and a 42% reduction in the risk of death overall.[365] Tucatinib in combination with capecitabine and trastuzumab is a reasonable second-line treatment option, particularly in patients who have CNS metastases or in patients with contraindication to T-Dxd (such as clinically significant lung disorders).

Third-Line Therapy and Beyond

The EMILIA study compared T-DM1 with lapatinib and capecitabine in patients who had previously received trastuzumab and a taxane. Treatment with T-DM1 resulted in a 3-month improvement in PFS and a 32% reduction in the risk of death compared with lapatinib and capecitabine, with less toxicity. The TH3RESA study demonstrated the superiority of T-DM1 compared with treatment of physician choice, with approximately 30% of the patients enrolled having received more than five prior regimens for recurrent disease.[366]

Lapatinib is an oral dual tyrosine kinase inhibitor selective for the inhibition of EGFR and HER2 and can be administered either in combination with trastuzumab or in combination with capecitabine.[367,368] Neratinib is an irreversible oral pan-HER2 tyrosine kinase inhibitor, whereas lapatinib and tucatinib are both reversible tyrosine kinase inhibitors. The phase 3 NALA trial evaluated the efficacy of neratinib for patients with metastatic HER2–positive breast cancer who received at least two prior anti-HER2–based regimens in the metastatic setting.[369] Patients were randomly assigned to neratinib and capecitabine compared with lapatinib and capecitabine. Neratinib was associated with a statistically significant improvement in PFS (8.8 vs 6.6 months; HR, 0.76; 95% CI, 0.63-0.93) and a non-statistically significant improvement in OS (21 vs 18.7 months; HR, 0.88; 95% CI, 0.72-1.07).

The GBG 26/BIG 3-05 study confirmed the benefit of continuing trastuzumab with alternative chemotherapy after disease progression with combination chemotherapy and trastuzumab. Based on these data, continuing trastuzumab beyond progression is considered standard of care.[370]

Margetuximab is a chimeric Fc-engineered monoclonal antibody that targets HER2. Margetuximab was engineered with an Fc domain to enhance the engagement of the immune system and has HER2 binding and antiproliferative effects similar to trastuzumab. In the SOPHIA study, a phase 3 open-label trial including 536 patients, margetuximab and chemotherapy were associated with an improved median PFS (5.8 vs 4.9 months) and median OS (21.6 vs 19.8 months) compared with trastuzumab with chemotherapy.[371] Exploratory PFS analysis by CD16A genotype suggested that the CD16A-158F allele may predict a benefit of margetuximab over trastuzumab.

Approximately 45% of HER2-positive breast cancers are also hormone receptor positive, and targeted therapy for both receptors is indicated. Cross-talk exists between HER2 and ER, resulting in relative resistance to endocrine therapy alone in HER2-positive disease. In clinical trials, the addition of trastuzumab to anastrozole and lapatinib to letrozole resulted in a significant but modestly improved PFS and clinical benefit compared with endocrine treatment alone in patients with hormone receptor–positive, HER2-positive metastatic disease. However, an OS advantage was not seen, possibly because of the crossover study designs.[372]

BRAIN METASTASES

Brain metastases are diagnosed in approximately 15% of patients with metastatic disease[373] and have become more common with the improvement in systemic therapies. The risk of brain metastases is greater in patients with TNBC and HER2-positive breast cancer. Recommendations regarding presentation, diagnosis, symptomatic control, and supportive care of brain metastases are discussed in Chapter 18: Central Nervous System Tumors.

The approach to brain metastases in breast cancer is determined by tumor subtype, number and size of lesions, the presence or absence of obstruction of cerebrospinal fluid flow, and overall prognosis. Patients with good performance status and controlled systemic disease benefit from aggressive treatment with the goal of optimal local control. Options for local treatment include surgery, stereotactic radiation, and whole-brain radiation therapy, with the following recommendations:

- Surgery should be strongly considered in patients presenting with a single metastasis and stable or absent extracranial disease.[374]
- Surgery has a limited role in patients with more than one brain metastasis, except when a large symptomatic lesion is also present.
- In the presence of multiple lesions, either stereotactic radiosurgery, whole-brain radiation therapy, or the combination is usually preferred.

Whole-brain radiation therapy decreases the risk of intracranial recurrence but does not seem to increase survival, and stereotactic radiosurgery is often preferred to decrease the risk of neurocognitive impairment associated with whole-brain radiation therapy.[375] There are no FDA-approved systemic therapies at this time specifically for the treatment of breast cancer brain metastases.

Brain metastases are common in HER2-positive MBC.[309] They often occur despite optimal systemic control, likely because trastuzumab does not cross an intact blood-brain barrier. Historically, patients with HER2-positive systemic disease not progressing at the time of diagnosis of brain metastases would continue to receive the same systemic therapy.[376] Recent trials suggest that certain HER2-targeted therapies may have more CNS activity, which has led to this paradigm being reexamined.

In the HER2CLIMB trial, patients receiving tucatinib, trastuzumab, and capecitabine had a median CNS PFS of 9.9 months compared with 4.2 months in patients receiving placebo, trastuzumab, and capecitabine (HR, 0.39; 95% CI, 0.27-0.56; $P < .001$).[377]

The use of tucatinib, trastuzumab, and capecitabine was associated with a 68% reduction in the risk of CNS PFS and a 42% reduction in the risk of death overall compared with placebo, trastuzumab, and capecitabine.[365]

In the phase 3 NALA trial, the combination of neratinib and capecitabine resulted in fewer interventions for CNS metastases compared with lapatinib and capecitabine (22.8% vs 29.2%; $P = .043$).[367] The DESTINY-Breast03 trial compared T-DXd and T-DM1 in the second-line setting. In patients who had brain metastases, the median PFS and CNS response were improved for those treated with T-DXd (15 vs 3 months; objective response rate, 67.4% vs 20.5%). The TUXEDO-1 trial[378] found that T-DXd resulted in an intracranial objective response rate (ORR-IC) of 73.3% and a median PFS of 21 months in 15 HER2-positive breast cancer patients with active brain metastases. The DEBBRAH trial demonstrated T-DXd activity in HER2-positive and HER2-low advanced breast cancer with CNS involvement, achieving a 46.2% ORR-IC in patients with active brain metastases and a 13.3-month median OS in a cohort of seven patients with leptomeningeal disease. Given the availability of multiple systemic therapies with effect in the CNS, the development of CNS progression may prompt a change in systemic therapy in HER2-positive MBC.

KEY POINTS

- MBC is incurable; therefore, the goal of treatment is to control disease progression and improve quality of life.
- The choice of systemic therapy is based on hormone receptor and HER2 status as well as on the extent of metastatic disease, the effect of disease on quality of life (eg, symptoms, performance status), and the pace of metastatic disease.
- Germline *BRCA1/2* status, tumor PD-L1 staining, and alterations in tumor PIK3CA and AKT pathways or ESR1 can influence treatment options.
- Endocrine therapy with a CDK4/6 inhibitor is the preferred initial treatment of hormone receptor–positive and HER2-negative metastatic disease unless visceral crisis or extensive visceral involvement is present.
- Sequential single-agent chemotherapy is preferable to combination chemotherapy unless a rapid disease response is required.
- Combined treatment with pertuzumab, trastuzumab, and taxane is the recommended first-line therapy for HER2-positive metastatic disease.
- Pembrolizumab with chemotherapy is approved for use in patients with advanced PD-L1–positive TNBC.
- Patients with brain metastases and good performance status benefit from local control with either surgery, whole-brain radiation therapy, or stereotactic radiosurgery.

BONE-MODIFYING AGENTS

METASTATIC TREATMENT

Approximately 65% to 80% of patients who have MBC will develop bone metastases. Although bone involvement is associated with a more favorable prognosis than visceral metastases, patients are at higher risk of skeletal-related events, including pain, pathologic fracture, hypercalcemia, and spinal cord compression. Breast cancer that metastasizes to bone is treated with appropriate systemic therapy. Palliative radiation to specific disease sites can reduce the morbidity associated with pain and fracture and control disease that may compromise the spinal cord.

Metastases to the bone can produce osteoblastic or osteolytic lesions, both of which are associated with activation of osteoclasts. Breast cancer cells involving the bone can also secrete cytokines that stimulate receptor activator of nuclear factor kB ligand (RANKL) secretion by osteoblasts, which mediates osteoclast maturation and activation. Bisphosphonates are pyrophosphate analogs that are internalized by osteoclasts, which disrupt their function and result in apoptosis. Bisphosphonates (eg, pamidronate and zoledronate) reduce the incidence of skeletal-related events and the time to occurrence of skeletal-related events. Denosumab is a fully human monoclonal antibody that impairs the binding of RANKL to RANK, inhibiting the development and activity of osteoclasts, leading to suppression of bone resorption, and reducing skeletal-related events and time to occurrence of skeletal-related events.[379,380]

Zoledronic acid is associated with renal compromise, whereas hypocalcemia is more common with denosumab. Zoledronic acid is favored over pamidronate because of its ease of infusion. Calcium and vitamin D supplementation should be used for patients receiving all bone-modifying agents, and renal function should be monitored in patients receiving bisphosphonates.

Both bisphosphonates and denosumab are associated with about 2% incidence of osteonecrosis of the jaw; ideally, physicians should avoid administering these agents to patients before or after any invasive dental procedure that involves manipulation of the bone, such as extractions and placement of dental implants.

Dosing interval studies for bone-modifying agents were reported. A randomized trial compared up-front zoledronic acid at monthly versus quarterly intervals for 2 years and demonstrated equivalence.[381] The REaCT trial demonstrated equivalent rates of symptomatic skeletal events for 4- and 12-week dosing schedules of denosumab, zoledronic acid, and pamidronate in 263 patients with metastatic breast cancer or prostate cancer with bone metastases.[382] Final results from the Swiss REDUSE trial, in

which denosumab every 12 weeks was compared with every 4 weeks after an induction phase, which included four doses administered every 4 weeks in patients with metastatic solid tumors, are awaited.[383]

According to ASCO guidelines, bone-modifying agents (eg, bisphosphonates and RANKL inhibitors) are recommended for patients who have evidence of bone destruction. Options include the following[379]:

- Denosumab at 120 mg subcutaneously every 4 weeks
- Pamidronate at 90 mg intravenously every 3 to 4 weeks
- Zoledronic acid at 4 mg intravenously every 12 weeks or every 3 to 4 weeks

The optimal duration of treatment with either a bisphosphonate or denosumab is unknown because the therapeutic intervals in published studies vary from 3 months to indefinitely. The ASCO guideline recommends indefinite use of bone-modifying agents until evidence of a substantial decline in a patient's general performance status.[379]

ADJUVANT TREATMENT

Multiple clinical trials have been conducted to determine the role of bone-modifying agents in the adjuvant setting to decrease the development of metastatic disease. Data are conflicting, as evident in the following:

- The AZURE trial showed no overall effect of zoledronic acid on iDFS among 3,360 patients with stage II or III disease who received chemotherapy. However, zoledronic acid reduced the development of bone metastases and improved iDFS in women who were postmenopausal for at least 5 years before enrollment.[384]
- In the ABCSG-12 trial, use of zoledronic acid was associated with a 36% reduction in risk of disease recurrence among 1,803 premenopausal women who had stage I or II disease who received ovarian suppression and endocrine therapy.[385]
- A meta-analysis of 17 trials with more than 21,000 patients demonstrated a 3.5% absolute reduction in the risk of distant relapse, predominantly bone metastatic relapse, as well as a 2.3% absolute improvement in all-cause mortality (ie, OS), among postmenopausal women who received adjuvant bisphosphonate.[386]
- In the D-CARE phase 3 trial, 4,509 premenopausal and postmenopausal women who had high-risk early breast cancer were randomized to receive denosumab 120 mg subcutaneously every 3 to 4 weeks for 6 months and then every 12 weeks for up to 5 years versus placebo in combination with standard neoadjuvant/adjuvant treatment. No significant difference between bone metastasis–free survival in patients treated with denosumab compared with placebo was reported.[387]
- In the ABCSG-18 trial, postmenopausal women with early-stage hormone receptor–positive breast cancer were randomly assigned to receive subcutaneous denosumab (60 mg) or a matching placebo every 6 months during AI therapy. In the final protocol-defined analysis, there were 309 versus 368 DFS events (HR, 0.83; 95% CI, 0.71-0.97) in the denosumab versus the placebo group, respectively, resulting in an absolute 9-year DFS benefit of 3.5 percentage points (79.4% vs 75.9%).[388]

In 2022, Cancer Care Ontario and ASCO published an updated evidence-based guideline informed by a systematic review of the literature.[389,390] The guideline recommends that bisphosphonates (intravenous zoledronic acid, oral clodronate, or oral ibandronate) be considered for adjuvant therapy for postmenopausal patients (natural or induced menopause) who are deemed candidates for systemic therapy. This panel did not recommend adjuvant denosumab to prevent breast cancer recurrence, because studies did not show a consistent reduction of breast cancer recurrence risk.

KEY POINTS

- Bisphosphonates or denosumab decreases skeletal-related events when bone metastases are present.
- Adjuvant bisphosphonates have been associated with a reduction in risk of recurrence and improvement in OS. Adjuvant denosumab has been associated with improvement in DFS. These agents may be considered for postmenopausal patients who are candidates for adjuvant systemic therapy.
- Renal function should be monitored with bisphosphonate use.
- Calcium and vitamin D supplementation should be strongly encouraged for patients receiving bone-modifying agents.

SURVEILLANCE AND SURVIVORSHIP

There are more than 3.1 million breast cancer survivors in the United States. The primary goal of surveillance after completion of adjuvant therapy is to detect a new and curable cancer at an early stage. ASCO recommendations for surveillance include[391] the following (Table 10-7):

- History and physical examination every 3 to 6 months for the first 3 years and then every 6 to 12 months for the next 2 years.
- For women with remaining breasts, mammography should be performed yearly. Patients should wait 6 to 12 months after the completion of radiation therapy to start annual mammogram surveillance.

Table 10-7 **ASCO Recommendations for Follow-Up Care of Patients Who Have Primary Breast Cancer**[112,392]	
Mode of Surveillance	**Summary of Recommendations**
Breast cancer surveillance: recommended	
History/physical examination	Every 3 to 6 months for the first 3 years after primary therapy, every 6 to 12 months for years 4 and 5, and then annually
Patient education regarding symptoms of recurrence	Physicians should counsel patients about the symptoms of recurrence, including new lumps, bone pain, chest pain, abdominal pain, dyspnea, or persistent headaches; helpful websites for patient education include www.cancer.net and www.cancer.org
Referral for genetic counseling	*BRCA1/2* mutation testing should be offered to all patients diagnosed at the age of 65 years or earlier, or select patients older than 65 years based on personal and family history, ancestry, or eligibility for a PARP inhibitor; further gene panel testing depends on personal and family history
Breast self-examination	All women should be counseled to perform monthly breast self-examination
Mammography	First post-treatment mammogram 1 year after the initial mammogram that leads to diagnosis, but no earlier than 6 months after definitive radiation therapy; subsequent mammograms should be obtained as indicated for surveillance of abnormalities
Coordination of care	Continuity of care is encouraged and should be performed by a physician experienced in surveilling patients with cancer and in breast examination, including the examination of irradiated breasts; if follow-up is transferred to a PCP, the PCP and the patient should be informed of the long-term options regarding adjuvant hormone therapy for the particular patient; this may necessitate referral for oncology assessment at an interval consistent with guidelines for adjuvant hormone therapy
Pelvic examination	Regular gynecologic follow-up is recommended for all women; patients who receive tamoxifen should be advised to report any vaginal bleeding to their care team
Breast cancer surveillance testing: not recommended	
Routine blood tests	CBC and liver function tests are not recommended
Breast MRI	Breast MRI is not recommended for routine breast cancer surveillance; MRI may be considered on an individual basis for high-risk patients
Systemic imaging studies	Chest radiograph, bone scans, liver ultrasonograms, CT scans, and FDG PET scans are not recommended
Tumor markers	CA 15-3, CA 27-29, and carcinoembryonic antigen testing are not recommended

Abbreviations: CA, cancer antigen; CBC, complete blood count; FDG, fluorodeoxyglucose; PCP, primary care provider.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Additional breast imaging is not usually indicated except for women with hereditary breast cancer syndromes and those who had significant medical radiation exposure. The use of other imaging, tumor markers, or laboratory tests among asymptomatic patients has not been found to be beneficial and has been shown to adversely affect quality of life and increase downstream healthcare use.[393] Thus far, the use of ctDNA is not routinely recommended, given the lack of improved clinical outcomes. Surveillance time should also be used to ensure that appropriate referrals for genetic counseling are made. Patients with genetic risks should be screened for second primary cancers as outlined in the "Screening" section.

Most breast cancer recurrences are identified between office visits; therefore, it is crucial to focus on patient education about the signs and symptoms of disease recurrence. Once symptoms occur, appropriate imaging should be performed.

- Clinical outcomes are identical when patients continue their post-treatment surveillance with either their oncologist or primary care provider. However, understanding potential long-term complications of treatment is important.
- Use of AIs can adversely affect bone density, which should be closely monitored. Potential cardiac toxic effects from anthracyclines and trastuzumab may require the involvement of cardiologists.[394]
- Focusing on healthy activities, such as exercise and maintaining a normal BMI, seems to favorably affect the risk of disease recurrence and improve well-being. Moderate exercise (2-3 hours per week) has been associated with reductions in breast cancer recurrence and improved all-cause mortality.[395,396] Ongoing studies are addressing the role of weight loss in breast cancer recurrence. The BWEL study has enrolled approximately 3,200 overweight women with early-stage breast cancer to test whether weight loss decreases the risk of breast cancer recurrence.[397]
- Cognitive dysfunction associated with cancer therapy is a subject of ongoing investigation.[398]
- The psychosocial ramifications of the diagnosis and treatment of breast cancer cannot be minimized and may require ongoing support and therapy.

VASOMOTOR SYMPTOMS

Chemotherapy-induced amenorrhea or ovarian suppression can result in the onset of menopausal symptoms at an earlier-than-expected age.

Hot flashes may be relieved with venlafaxine or gabapentin. Oxybutynin has also been found to be superior to a placebo for the management of hot flashes.[399] In 2025, the OASIS trial randomized patients on adjuvant endocrine therapy and moderate-to-severe VMS to placebo or to elizanetant, a neurokinin (NK)1 and NK3 inhibitor.[400] Both the frequency and severity of VMS significantly decreased on elizanetant; this drug is not yet FDA approved. Fezolinetant, an NK1 inhibitor, was FDA approved in 2023 for postmenopausal women with VMS but was not specifically studied in women with breast cancer. Notably, breast cancer outcomes were not a study outcome in OASIS.

Intravaginal application of estrogens to improve vaginal dryness and sexual dysfunction can be considered but requires a discussion with patients, particularly in patients who have hormone receptor–positive disease because the safety of intravaginal estrogens is not clearly established. Recently, a meta-analysis of eight retrospective observational studies did not demonstrate an increase in breast cancer recurrence.[401] A cancer registry study that used pharmacy records in Scotland and Wales likewise found no increased risk of breast cancer-specific mortality among women with breast cancer who used vaginal estrogens. However, only 5% of the breast cancer patients had a prescription. The details of the cancer and the actual use of the vaginal estrogen are unknown.[402]

AI-ASSOCIATED MUSCULOSKELETAL SYMPTOMS

A common cause for noncompliance with AIs is the musculoskeletal pain associated with their use. A randomized trial of acupuncture versus sham acupuncture in women taking adjuvant AIs demonstrated a significant decrease in pain at 6 weeks with acupuncture.

In 2016, ASCO and the American Cancer Society developed a comprehensive set of recommendations that extend beyond cancer surveillance recommendations to further address symptom management, surveillance, and management of late toxicities of cancer therapy as well as general wellness (eg, weight management, nutrition, and activity).[403]

KEY POINTS

- The primary schedule of disease monitoring after the completion of therapy includes an annual mammogram and a complete history and physical examination every 3 to 6 months for the first 3 years and then every 6 to 12 months for the next 2 years.
- Routine breast imaging is not needed after mastectomy.
- Anthracyclines and trastuzumab are associated with a risk of cardiac toxicity.
- AIs are associated with decreased bone density and musculoskeletal symptoms. Acupuncture may help with the latter.
- Chemotherapy and OFS can result in premature amenorrhea, resulting in menopausal symptoms, such as hot flashes, vaginal dryness, and sexual dysfunction, and affect bone health.

SPECIAL CIRCUMSTANCES

MALE BREAST CANCER

Male breast cancer is rare, accounting for approximately 1% of all breast cancers.[404] Most cases of breast cancer in men are invasive ductal carcinomas, and other histologic subtypes are rare. Presentation as DCIS is also uncommon. Male breast cancer is almost always ER-positive. In a large series study of male breast cancers, only 9% of cancers were HER2-positive.[405] Risk factors for male breast cancer are discussed in the "Risk Factors" section.

Most men with breast cancer present with a retroareolar mass, but nipple changes and axillary adenopathy are also common. Because of the lack of awareness and early detection, men often present with larger tumors and nodal involvement.

The optimal local and systemic treatments of male breast cancer have not been studied in randomized clinical trials. Mastectomy is often performed, as breast cosmesis may not be an issue. However, breast conservation therapy can be offered if standard criteria for breast conservation therapy are met. In general, recommendations for local disease treatment, including adjuvant radiation therapy, should be governed by the same criteria outlined for breast cancer in women.

Adjuvant chemotherapy should also be administered using the same criteria as for women. Tamoxifen is the mainstay of endocrine therapy in hormone receptor–positive male breast cancer. The efficacy of AIs in men is not well established and may be lower than in women, because of incomplete estradiol suppression.[404] In men with contraindications for tamoxifen, AIs should be combined with GnRH analogs to ensure estradiol suppression.[406] There are limited data on the activity of AIs with or without GnRH agonists and fulvestrant in men with hormone receptor–positive MBC. However, guidelines for systemic therapy of advanced disease are the same as for women.

In addition, the 2020 ASCO Guidelines recommend the following[407]:

- Extended adjuvant endocrine therapy (up to 10 years) if the patient has high-risk disease and is tolerating treatment.
- Ipsilateral annual mammogram after breast conservation therapy can be offered, as well as contralateral screening, in men with a history of breast cancer and genetic predisposition. The data on screening in men are limited.
- All men with breast cancer should be offered genetic counseling and testing.

PREGNANCY-ASSOCIATED BREAST CANCER

Cancer during pregnancy is rare, affecting approximately 1 in every 1,000 pregnancies. Breast cancer is responsible for approximately 25% of cases.[408] Two studies that compared women with breast cancer who received chemotherapy during pregnancy with women who were not pregnant at the time of diagnosis found no negative effect on outcome for women diagnosed during pregnancy.[409,410]

In general, the same treatment recommendations apply as for nonpregnant women, with some exceptions to protect the fetus. Perhaps the most important strategies are to minimize exposure to diagnostic and therapeutic radiation and to limit chemotherapy, if indicated, to the second and third trimesters. The selected strategy should also plan for optimal timing and sequencing of local and systemic therapies to avoid delays in treatment and optimize outcomes. The appropriate treatment should be determined with an obstetrician who specializes in high-risk cases.

These recommendations are summarized as follows:

- Breast-conserving surgery or mastectomy is a reasonable option for pregnant women with breast cancer. There is controversy regarding axillary node evaluation, and the use of blue dye is discouraged, making sentinel lymph node surgery difficult.
- If radiation therapy is recommended, it should be administered after delivery.
- Chemotherapy, if indicated, can be safely administered from week 14 and until 3 to 4 weeks before delivery.
- The use of anthracyclines, cyclophosphamide, and taxanes seems feasible and safe during the second and third trimesters of pregnancy with minimal maternal, fetal, or neonatal toxicity.[411,412]
- Trastuzumab is contraindicated during pregnancy (category D), and labeling contains a black box warning about the risk for oligohydramnios and related pulmonary hypoplasia, skeletal abnormalities, and neonatal death. T-DM1 is also contraindicated in pregnancy.
- Pembrolizumab should not be used during pregnancy (category D).
- Administration of granulocyte colony-stimulating factor during pregnancy seems to be safe based on a retrospective review in a limited number of patients.[413]
- Antiemetic and other supportive medicines, including steroids, should be reviewed with the patient's obstetrician.
- Neonatal morbidity seems to be mainly related to prematurity; therefore, if possible, delivery should not be induced before 37 weeks.
- Endocrine therapy should start after delivery.

Interruption of Endocrine Therapy to Become Pregnant

Fertility preservation and future childbearing are important issues facing young women diagnosed with early-stage breast cancer. Pregnancies are challenging given the 5- to 10-year length of endocrine therapy.

The POSITIVE trial prospectively enrolled 516 women with early-stage hormone receptor–positive breast cancer who desired pregnancy.[414] Endocrine therapy was temporarily interrupted for up to 2 years to allow for pregnancy, delivery, and breastfeeding if desired. Eligible patients had been on endocrine therapy for 18 to 30 months before interruption and were strongly encouraged to resume endocrine therapy after interruption to complete 5 to 10 years total. The primary endpoint was the number of breast cancer events deemed acceptable compared with an external cohort of similar patients in the SOFT and TEXT trials (discussed in "Hormone Receptor–Positive Breast Cancer" and "Role of Ovarian Function Suppression" sections).

At a median follow-up of 41 months, the 3-year incidence of breast cancer events was 8.9% (95% CI, 6.3-11.6) in the treatment interruption group compared with 9.2% (95% CI, 7.6-10.8) in the control cohort. This observation did not exceed the safety threshold. Seventy-four percent of participants had at least one pregnancy, and 63.8% had at least one live birth. Although encouraging, the results should be interpreted with caution, given the short follow-up for hormone receptor–positive breast cancer. However, a balanced discussion is recommended to support young women on endocrine therapy who desire pregnancy after breast cancer.

OLDER PATIENTS

Increasing age is a risk factor for breast cancer. Comorbidities are more common in older adults and are independent predictors of worse survival. However, among healthy older women, chemotherapy regimens administered without dose reduction impart the same relative benefit as that in younger women.[415] Older women can be more susceptible to some toxicities associated with chemotherapy, including hematologic and cardiac toxicities.[416]

An adequate interpretation of chemotherapy benefit among high-risk older women is difficult to make, given that women older than 65 years make up only 8% of enrollment in clinical trials. The CALGB 49907 trial randomly assigned 633 women older than 65 years to receive adjuvant therapy with capecitabine or the standard AC or cyclophosphamide, methotrexate, and fluorouracil regimen.[417] Two-thirds of the women were older than 70 years, and 5% were older than 80 years. The standard regimens of AC and cyclophosphamide, methotrexate, and fluorouracil were associated with a 50% lower risk of recurrence or death compared with the less toxic oral capecitabine regimen. These data continue to support the benefit of standard chemotherapy in healthy elderly women who do not have substantial comorbidities.

Similarly, Japanese investigators compared treatment de-escalation in older women with early and advanced HER2-positive breast cancer. In RESPECT, women aged 70 to 80 years were randomized to adjuvant trastuzumab monotherapy or trastuzumab and chemotherapy.[418] Trastuzumab monotherapy failed to meet its noninferiority DFS endpoint, although more toxicities were reported with chemotherapy. The HERB TEA study randomized women over 65 years with advanced, untreated HER2–positive breast cancer to standard docetaxel, trastuzumab, and pertuzumab or the ADC trastuzumab emtansine. The study was terminated early when the interim analysis exceeded the noninferiority margin for the primary endpoint of OS.[419]

To better understand their overall health status, ASCO recommends performing a geriatric assessment in all older patients with cancer.[420] The geriatric assessment is a multidimensional evaluation that can help unravel the functional, nutritional, psychological, cognitive, and social characteristics of older adults and identify deficits undetected by usual oncologic evaluations.[420] This information can help guide treatment by allowing for an estimation of non–cancer-specific life expectancy as well as the risk of chemotherapy toxicity.[421,422] Ongoing efforts to tailor treatment of older women with breast cancer include the design of a breast cancer–specific chemotherapy toxicity calculator, which uses geriatric assessment variables to predict the risk of grade 3 to 4 toxicity.[423]

KEY POINTS

- The treatment of male breast cancer is extrapolated from information about female breast cancer, with tamoxifen as the preferred agent for adjuvant endocrine therapy.
- There are limited data supporting the use of AIs for the treatment of metastatic disease in men.
- Breast cancer during pregnancy should be treated to minimize fetal harm while ensuring the best oncologic outcome.
- Temporary interruption of adjuvant endocrine therapy can be discussed with young women desiring pregnancy, but longer follow-up is needed to assess long-term safety.
- Performance status, comorbidities, and life expectancy, but not age, should be the deciding factors for adjuvant therapy recommendations for breast cancer.
- Additional studies are needed to balance efficacy and toxicities of treatment in the elderly.

HIGH-YIELD TAKEAWAYS

Premalignant Conditions

- High-risk histologies (ALH, ADH)
  - Atypia on breast biopsy confers an increased risk of developing in situ or invasive breast cancer.
  - ADH on biopsy should be followed by excision to exclude in situ or invasive disease.
  - ALH or classic lobular carcinoma in situ can be managed without immediate excision and with continued imaging follow-up. Excision can be performed for high-risk features.
  - In general, re-excision for negative margins is not necessary for atypia.
- Genetic predispositions
  - Consider genetic counseling/testing for all women diagnosed who are 65 years or younger and all men with breast cancer.
  - Consider testing for patients eligible for PARP inhibitors.
- DCIS
  - Local treatment includes lumpectomy followed by radiation or mastectomy.
  - Adjuvant endocrine therapy for ER-positive DCIS after lumpectomy can decrease ipsilateral and contralateral breast events with no established DFS or OS benefits.

- Early Stage
  - All newly diagnosed breast cancer patients should have their hormone receptor and HER2 status determined.
- HER2-positive
  - Neoadjuvant chemotherapy and anti-HER2 monoclonal antibodies (docetaxel, carboplatin, trastuzumab, and pertuzumab [TCHP]) are offered for larger than T2 and/or node-positive disease.
  - For tumors smaller than T2N0, adjuvant weekly paclitaxel and trastuzumab can be offered.
  - The standard duration of anti-HER2 therapy is 1 year.
  - If there is residual disease after neoadjuvant therapy, adjuvant therapy should switch from trastuzumab to trastuzumab emtansine.
  - Adjuvant radiation therapy and endocrine therapy should be offered if appropriate.
- Hormone receptor–positive, HER2-negative
  - Adjuvant endocrine therapy should be offered to hormone receptor–positive breast cancer.
  - Gene tumor expression assays can identify patients with node-negative and low-volume (N1) node-positive disease who do not benefit from adjuvant chemotherapy.
  - Adjuvant abemaciclib or ribociclib can be offered with endocrine therapy for high-risk disease.
  - Adjuvant olaparib can be offered to high-risk patients with germline *BRCA* mutations.
- TNBC
  - Neoadjuvant therapy with AC-taxol/carboplatin and pembrolizumab improves event-free and OS in patients with T2 or larger or node-positive TNBC.
  - Adjuvant olaparib for 1 year following adjuvant chemotherapy improved OS for patients with pathogenic germline *BRCA* mutations.
- Inflammatory
  - Inflammatory breast cancer is a clinical diagnosis characterized by the rapid onset of breast erythema, skin changes, including peau d'orange, edema, and warmth.
  - There is a high incidence of nodal involvement at presentation and worse DFS compared to noninflammatory breast cancer.
  - Neoadjuvant chemotherapy (and, if appropriate, anti-HER2 therapy or pembrolizumab) followed by mastectomy with axillary lymph node dissection and PMRT should be offered.
  - Adjuvant endocrine, anti-HER2, pembrolizumab, and PARP inhibitor should be offered when indicated.

Locally Recurrent

- In-breast recurrence
  - Imaging to rule out distant metastasis is recommended at the time of an in-breast recurrence.
  - If a patient had a prior lumpectomy, radiation, a completion mastectomy is standard, although treatment can be individualized.
  - Tumor hormone receptor and HER2 status should be repeated.
  - Prognosis is worse for locoregional recurrences compared with primary breast cancers, but they should be treated with curative intent.
  - Systemic therapy should be individualized depending on hormone receptor and HER2 status.
- Chest wall recurrence
  - Imaging to rule out distant metastasis is recommended at the time of chest wall recurrence; if no distant metastasis, then excision is recommended.
  - Tumor hormone receptor and HER2 status should be repeated.
  - Radiation should be offered but needs to be individualized based on prior radiation.
  - Systemic therapy should be individualized depending on hormone receptor and HER2 status.
  - Prognosis is worse for locoregional recurrences compared with primary breast cancers, but they should be treated with curative intent.

Metastatic Disease

- HER2-positive
  - First-line treatment of HER2-positive MBC is a taxane with the dual HER2-targeted combination of trastuzumab with pertuzumab.

- T-DXd is a preferred second-line treatment for HER2-positive MBC.
- Tucatinib with capecitabine and trastuzumab is a standard-of-care third-line regimen and may be used in the second-line setting, particularly in patients with CNS metastases.

- Hormone receptor–positive HER2-negative
  - First-line treatment includes endocrine therapy in combination with a CDK4/6 inhibitor.
  - All patients should undergo tumor NGS to identify alterations for which there are subsequent FDA-approved targeted therapies, including ESR1 and PIK3CA.
- TNBC
  - Neoadjuvant therapy with AC-taxol/carboplatin and pembrolizumab improves event-free and OS in patients with T2 or larger or node-positive TNBC.
  - Adjuvant olaparib for 1 year following adjuvant chemotherapy improved OS for patients with pathogenic germline *BRCA* mutations.

Less Common Clinical Scenarios

- Male breast cancer
  - Male breast cancer accounts for about 1% of all breast cancer. Risk factors include germline *BRCA2* or *PALB2* mutations, Klinefelter syndrome, testicular alterations resulting in testosterone deficiency, and conditions that increase the estrogen-to-testosterone ratio (eg, obesity, cirrhosis).
  - Diagnosis, testing, and treatment for men with breast cancer are extrapolated from studies of female breast cancer.
  - Nearly all male breast cancers are ER–positive, and tamoxifen is the mainstay of endocrine therapy. If AIs are used, a GnRH agonist must be used in combination to ensure estradiol suppression.
- Pregnancy-associated breast cancer
  - Workup and treatment for breast cancer during pregnancy follow that for nonpregnant women but should minimize risk to the fetus, especially in the first trimester.
  - Surgery can be offered, but radiation should be given after delivery.
  - If appropriate, neoadjuvant chemotherapy with anthracycline- and/or taxane-based therapies can be safely administered in the second and third trimesters.
  - Trastuzumab and pembrolizumab are contraindicated during pregnancy (category D).
  - Endocrine therapy should start after delivery.

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

BREAST CANCER 10

CHAPTER SUMMARY GUIDE

KEY POINTS

- The incidence rate of breast cancer in the United States has been slowly increasing at a rate of 1% annually overall since 2012. By contrast, the mortality rate has consistently declined, primarily as a result of advances in systemic therapy.
- The incidence rate has been steeper among women under 50 years.
- The incidence rate of breast cancer is increasing in nonindustrialized countries, in part due to changing lifestyle patterns (eg, rising rates of obesity and decreased physical activity).
- Compared with non-Hispanic White women in the United States, Black women now have a similar rate of incidence but a higher rate of mortality for breast cancer. The causes behind this significant disparity are not fully understood and are likely multifactorial.
- Menopausal hormone replacement therapy in the form of a combination of estrogen and progesterone (but not estrogen alone) is associated with an elevated risk of invasive breast cancer and correlates with duration of use.
- Patients who received therapeutic mediastinal or mantle field radiation have a higher risk of breast cancer, most pronounced when treatment occurred during active proliferation of breast tissue (ie, between ages 10 and 30 years).
- Atypical ductal or lobular hyperplasia and lobular carcinoma in situ are high-risk, nonmalignant lesions associated with a 30% risk of breast cancer development over 25 years.
- *BRCA1* and *BRCA2* mutations are associated with a 50% to 70% lifetime risk of development of breast cancer.
- Other highly (*PALB2*, *CDH1*, *TP53*, *PTEN*, and *STK11*) and moderately (*ATM*, *CHEK2*, and *NF1*) penetrant genes are associated with a significant risk for breast cancer.
- Postmenopausal obesity and alcohol use are associated with a higher risk of breast cancer.
- Increased breast density is associated with a higher risk of breast cancer.
- Several risk models are available to predict the risk of developing breast cancer on the basis of family history, prior atypia, and other factors.
- Risk-reducing BSO in *BRCA1* and *BRCA2* carriers is associated with lower breast cancer–specific mortality, lower all-cause mortality, and lower ovarian cancer–specific mortality rates.
- Bilateral risk-reducing mastectomy reduces the risk of breast cancer by more than 90% in *BRCA1* and *BRCA2* carriers.
- Tamoxifen in premenopausal or postmenopausal women and raloxifene, anastrozole, or exemestane in postmenopausal women all reduce the risk of development of ER–positive breast cancer.
- Significant alcohol consumption is associated with an increased risk of breast cancer, and there seems to be a significant dose–response relationship.
- Mammographic screening results in a 14% to 32% reduction in breast cancer–related mortality among women aged 50 to 70 years. The effect on mortality for women aged 40 to 49 years or older than 70 years is less robust.
- For women with *BRCA* mutations who have not undergone risk-reducing surgery, annual MRI of the breasts is recommended beginning at the age of 25 years, and annual mammography is recommended beginning at the age of 30 years. For women who have received therapeutic mantle field radiation, beginning 10 years after the completion of radiation therapy, annual screening mammography (not before the age of 30 years) and annual breast MRI (not before the age of 25 years) are recommended.
- For breast cancer diagnosis, a core needle biopsy of a suspicious breast or lymph node finding is preferable to fine needle aspiration to accurately assess the histology of the tissue and the status of ER, PR, and HER2.
- Pathologic features associated with a favorable prognosis include small tumor size, negative lymph node status, low tumor grade, absence of lymphovascular invasion, and positive hormone receptor status.
- Quantitative ER expression is predictive of response to endocrine therapy.
- HER2 overexpression/amplification is predictive of benefit from HER2-directed therapy.
- The 21-gene recurrence score and 70-gene signature have been validated prospectively in large trials and may guide the use of adjuvant chemotherapy in addition to endocrine therapy in hormone receptor–positive and HER2-negative breast cancer patients who have either no nodal involvement or one to three lymph nodes involved.
- DCIS (stage 0) accounts for approximately 20% of breast cancers in the United States.

- Most cases of DCIS are detected on screening mammograms.
- Whole-breast irradiation decreases the risk of local recurrence after breast-conserving surgery.
- DCIS treated with mastectomy or breast conservation therapy results in equivalent breast cancer–related 5-year survival rates.
- Current guidelines establish 2 mm as an adequate margin of resection in DCIS treated with breast conservation therapy.
- For women with ER–positive DCIS who elect to undergo breast conservation therapy, adjuvant endocrine therapy reduces the risk of ipsilateral and contralateral recurrences with no established survival benefit. For those patients who undergo bilateral mastectomy for DCIS, there is no role for endocrine therapy for prevention.
- Adjuvant tamoxifen (for premenopausal and postmenopausal women) and AIs (for postmenopausal women only) are appropriate options for decreasing subsequent invasive breast cancers in women with ER–positive DCIS treated with breast conservation therapy.
- The goal of systemic therapy in nonmetastatic disease is to reduce the risk of local recurrence and distant metastasis.
- Randomized trials have demonstrated equivalent survival, regardless of whether neoadjuvant or adjuvant chemotherapy is used.
- Patients who present with inoperable disease require neoadjuvant therapy.
- pCR after neoadjuvant systemic therapy is a strong prognostic factor for reduced risk of recurrence, particularly in TNBC and HER2-positive disease.
- The presence of residual disease after neoadjuvant systemic therapy guides adjuvant systemic therapy choices.
- Treatment of operable breast cancer with mastectomy or breast conservation therapy results in equivalent survival in stages I and II breast cancer, with the following exceptions.
- Positive margins. The definition of an adequate margin of resection for invasive breast cancer treated with breast conservation therapy is no tumor present in the inked margin.
- Inability to remove the tumor with adequate margins and a favorable cosmetic outcome.
- Multicentric disease.
- Contraindications to radiation therapy.
- Patients presenting with a clinically negative axilla can undergo SLNB but axillary staging may be omitted in certain populations with low-risk hormone receptor–positive and HER2-negative tumors.
- Patients with clinical T1 to T2 N0 tumors and up to two involved sentinel lymph nodes treated with up-front breast conservation therapy and whole-breast irradiation can avoid axillary lymph node dissection.
- Patients with clinical T1 to T2 N0 tumors with one to two SLN metastases treated with up-front mastectomy may omit axillary lymph node dissection, provided PMRT is indicated based on additional risk factors.
- Patients presenting with clinically positive lymph nodes require axillary lymph node dissection unless neoadjuvant therapy is used, and their approach must be individualized.
- Hypofractionated radiation therapy is now an established option for most patients requiring adjuvant radiation therapy.
- Accelerated partial breast irradiation is a suitable option for appropriately selected patients.
- Adjuvant breast radiation therapy may be omitted in older patients who have favorable tumor characteristics under select conditions.
- Regional nodal irradiation after breast-conserving surgery or mastectomy is typically indicated in patients who have three or more positive lymph nodes and can be considered in patients who have zero to three positive lymph nodes and additional risk factors.
- Adjuvant tamoxifen has efficacy in premenopausal and postmenopausal women.
- OFS improves DFS and freedom from recurrence when combined with 5 years of adjuvant tamoxifen or exemestane in premenopausal women who have high-risk disease.
- Compared with 5 years, 10 years of adjuvant tamoxifen is associated with a small improvement in DFS and breast cancer–specific survival, and extended-duration tamoxifen is an option in premenopausal or postmenopausal patients at high risk.
- AIs are the first-choice adjuvant endocrine treatment in postmenopausal women.
- Administering AIs for 5 years results in similar outcomes as initial tamoxifen for 2 to 3 years, followed by an AI for a total of 5 years.
- An extended duration of AI therapy beyond 5 years should be considered in postmenopausal women who have high-risk disease.
- Neoadjuvant endocrine therapy is an acceptable treatment approach for postmenopausal women who have stage II or III hormone receptor–positive breast cancer, but it infrequently results in pCR.
- Two years of adjuvant abemaciclib in combination with endocrine therapy improves DFS and OS and is an option for patients with node-positive disease. Three years of dose-reduced ribociclib in combination with an AI improves iDFS in patients with high-risk node-negative and node-positive disease.

- The recommended total duration of adjuvant trastuzumab is 12 months.
- The addition of 1 year of adjuvant pertuzumab concurrently with trastuzumab can be considered for high-risk patients because it provides a small absolute improvement in DFS.
- Pertuzumab, when administered concurrently with trastuzumab and taxane-based chemotherapy, is associated with a significantly increased pCR rate.
- In patients with residual disease after neoadjuvant chemotherapy, switching to T-DM1 after surgery is recommended.
- Inflammatory breast cancer is treated with neoadjuvant chemotherapy, followed by mastectomy with axillary lymph node dissection, PMRT, and adjuvant endocrine, anti-HER2, immunotherapy, and PARP inhibitor therapy, when indicated.
- Despite optimal multimodality care, DFS is worse in inflammatory breast cancer compared with noninflammatory breast cancer, even for patients who achieve pCR.
- Locoregional recurrences require a multidisciplinary approach.
- Local recurrence is associated with a high rate of distant metastasis, and systemic imaging is recommended for these patients.
- After breast conservation therapy, the standard treatment of local recurrences involves a total mastectomy.
- The addition of chemotherapy after surgical management of a locoregional recurrence may benefit some patients, primarily those with ER–negative disease.
- MBC is incurable; therefore, the goal of treatment is to control disease progression and improve quality of life.
- The choice of systemic therapy is based on hormone receptor and HER2 status as well as on the extent of metastatic disease, the effect of disease on quality of life (eg, symptoms, performance status), and the pace of metastatic disease.
- Germline *BRCA1/2* status, tumor PD-L1 staining, and alterations in tumor PIK3CA and AKT pathways or ESR1 can influence treatment options.
- Endocrine therapy with a CDK4/6 inhibitor is the preferred initial treatment of hormone receptor–positive and HER2-negative metastatic disease unless visceral crisis or extensive visceral involvement is present.
- Sequential single-agent chemotherapy is preferable to combination chemotherapy unless a rapid disease response is required.
- Combined treatment with pertuzumab, trastuzumab, and taxane is the recommended first-line therapy for HER2-positive metastatic disease.
- Pembrolizumab with chemotherapy is approved for use in patients with advanced PD-L1–positive TNBC.
- Patients with brain metastases and good performance status benefit from local control with either surgery, whole-brain radiation therapy, or stereotactic radiosurgery.
- Bisphosphonates or denosumab decreases skeletal-related events when bone metastases are present.
- Adjuvant bisphosphonates have been associated with a reduction in risk of recurrence and improvement in OS. Adjuvant denosumab has been associated with improvement in DFS. These agents may be considered for postmenopausal patients who are candidates for adjuvant systemic therapy.
- Renal function should be monitored with bisphosphonate use.
- Calcium and vitamin D supplementation should be strongly encouraged for patients receiving bone-modifying agents.
- The primary schedule of disease monitoring after the completion of therapy includes an annual mammogram and a complete history and physical examination every 3 to 6 months for the first 3 years and then every 6 to 12 months for the next 2 years.
- Routine breast imaging is not needed after mastectomy.
- Anthracyclines and trastuzumab are associated with a risk of cardiac toxicity.
- AIs are associated with decreased bone density and musculoskeletal symptoms. Acupuncture may help with the latter.
- Chemotherapy and OFS can result in premature amenorrhea, resulting in menopausal symptoms, such as hot flashes, vaginal dryness, and sexual dysfunction, and affect bone health.
- The treatment of male breast cancer is extrapolated from information about female breast cancer, with tamoxifen as the preferred agent for adjuvant endocrine therapy.
- There are limited data supporting the use of AIs for the treatment of metastatic disease in men.
- Breast cancer during pregnancy should be treated to minimize fetal harm while ensuring the best oncologic outcome.
- Temporary interruption of adjuvant endocrine therapy can be discussed with young women desiring pregnancy, but longer follow-up is needed to assess long-term safety.
- Performance status, comorbidities, and life expectancy, but not age, should be the deciding factors for adjuvant therapy recommendations for breast cancer.
- Additional studies are needed to balance efficacy and toxicities of treatment in the elderly.

CHAPTER TABLES AND IMAGES

Table 10-1 Established Risk Factors for Breast Cancer: Fixed Factors (Excluding Genetic Mutations)[10]

Factor	Relative Risk
Sex (female vs male)	100
Age (older than 50 vs younger than 50 years)	6.7
Endocrine factors	
Age at first birth (older than 30 years) or nulliparity	1.2-1.7
Age at menarche (younger than 12 years) or age at menopause (older than 55 years)	1.2-1.3
Benign breast disease	
ADH, LCIS	4.0-5.0
Family history (no known mutation)	
One first-degree relative	1.5-2.0
Ashkenazi Jewish ethnicity	1.4
Therapeutic radiation to the chest before age 30 years	7.0-17.0

Abbreviations: ADH, atypical ductal hyperplasia; LCIS, lobular carcinoma in situ.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 10-2 **Lifetime Cancer Risk for People Who Have High- and Moderate-Penetrance Mutations in Selected Genes**[14-22]

Gene (Associated Disease)	Cumulative Lifetime Risk of Breast Cancer Development (%)	Other Tumors
High penetrance		
BRCA1	55-70	Ovarian cancer
BRCA2	45-70	Prostate cancer Pancreatic cancer Malignant melanoma Gallbladder and bile duct cancer Stomach cancer
TP53 (Li-Fraumeni syndrome)	90	Soft tissue sarcoma and osteosarcoma Brain tumors Leukemia Adrenocortical cancer
PTEN (Cowden syndrome/*PTEN* hamartoma tumor syndrome)	Poorly characterized	Follicular thyroid cancer Endometrial cancer Colon cancer Renal cancer
STK11 (Peutz-Jeghers syndrome)	Poorly characterized	Colon cancer Pancreatic cancer Stomach and small bowel cancer
CDH1 (hereditary diffuse gastric cancer)	50-60 (mainly lobular)	Diffuse gastric cancer
PALB2	40-50	Pancreatic cancer
Moderate penetrance		
ATM	20-30	Pancreatic cancer
BRIP1	Insufficient evidence	Ovarian cancer
BARD1	Insufficient evidence	
CHEK2	20-30	Colorectal cancer
MSH2, MLH1, MSH6, PMS2, EPCAM (Lynch syndrome)	Insufficient evidence	Endometrial cancer, Ovarian cancer
NBN	Insufficient evidence	
NF1	18	
RAD51C	Insufficient evidence	
RAD51D	Insufficient evidence

Table 10-3 **Established Risk Factors for Breast Cancer: Modifiable Factors**

Factor	Relative Risk
Oral contraceptive pill	0.9-1.0
Estrogen replacement (more than 10 years)	1.1
Estrogen and progesterone	1.4-3.0
Postmenopausal obesity (BMI higher than 30 kg/m^2)	2.5
Alcohol use	1.1-2.2
Diet	1

Abbreviation: BMI, body mass index.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 10-4 **Molecular Subtypes**	
Subtype	**Characteristic**
Luminal A	Favorable prognosis High ER/PR Low proliferation rate Grade 1/2 Lower sensitivity to chemotherapy
Luminal B	Less favorable prognosis Lower ER and PR High proliferation rate Grade 2/3 Higher sensitivity to chemotherapy
HER2 enriched	HER2 positive Hormone receptor positive or negative High proliferation rate Grade 2/3
Basal	ER, P High proliferation rate Grade 3

Abbreviations: ER, estrogen receptor; PR, progesterone receptor.

Table 10-5 **Extended Endocrine Therapy With AI**[255]	
Trial	**Intervention**
Extended adjuvant AI after 5 years of tamoxifen	
MA.17	Letrozole for 5 years or placebo
NSABP B-33	Exemestane for 5 years or placebo
ABCSG 6	Anastrozole for 3 years or placebo
Extended AI after 5 years of therapy that included an AI	
MA.17R	Letrozole or placebo for 5 years after 5 years of letrozole (preceded by 5 years of tamoxifen in most patients)
NSABP B-42	Letrozole or placebo for 5 years after 5 years of endocrine therapy with 5 years of an AI or 3 or fewer years of tamoxifen
DATA	Anastrozole for 6 years, 3 years after 2 to 3 years of tamoxifen
Optimal duration or dosing of AI in years 5-10	
IDEAL	Letrozole for 2.5 vs 5 years after tamoxifen, AI, or both for 5 years
ABCSG-18	Anastrozole for 2 vs 5 years after tamoxifen, AI, or both for 4 to 6 years

Abbreviation: AI, aromatase inhibitor.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 10-6 **Trials With CDK4/6 Inhibitors**

Treatment	Study	Phase	Description	Median PFS, Months (HR, 95% CI)	Median OS, Months (HR, 95% CI)
First line	PALOMA-2	3	Palbociclib/letrozole vs placebo/letrozole	24.8 vs 14.5 (0.58, 0.46-0.72)	53.9 vs 51.2 (0.96, 0.777-1.177)[313]
	MONALEESA-2	3	Ribociclib/letrozole vs placebo/letrozole	25.3 vs 16.0 (0.56, 0.43-0.72)[314]	63.9 vs 51.4 (0.76, 0.63-0.93)[315]
	MONALEESA-7	3	Ribociclib/OFS/AI or tamoxifen vs placebo/OFS/AI or tamoxifen	23.8 vs 13.0 (0.55, 0.44-0.69)[316]	58.7 vs 40.9 (0.76, 0.61-0.96)[317]
	MONARCH-3	3	Abemaciclib/AI vs placebo/AI	28.2 vs 14.7 (0.54, 0.41-0.72)[325]	66.8 vs 53.7 (0.80, 0.64-1.01)[326]
First or second line	MONALEESA-3	3	Ribociclib/fulvestrant vs placebo/fulvestrant	20.5 vs 12.8 (0.59, 0.48-0.73)[318]	67.6 vs 51.8 (0.67, 0.50-0.90)[319]
Second line	PALOMA-3	3	Palbociclib/fulvestrant vs placebo/fulvestrant	9.5 vs 4.6 (0.46, 0.36-0.59)[320]	34.9 vs 28.0 (0.81, 0.65-0.99)[321]
	MONARCH-2	3	Abemaciclib/fulvestrant vs placebo/fulvestrant	16.4 vs 9.3 (0.55, 0.45-0.66)[322]	46.7 vs 37.3 (0.757, 0.61-0.94)[324]
Later line	MONARCH-1	2	Abemaciclib	6[323]	17.7[323]

Abbreviations: AI, aromatase inhibitor; CDK4/6, cyclin-dependent kinase 4/6; HR, hazard ratio; OFS, ovarian function suppression; OS, overall survival; PFS, progression-free survival.

Table 10-7 **ASCO Recommendations for Follow-Up Care of Patients Who Have Primary Breast Cancer**[112,392]

Mode of Surveillance	Summary of Recommendations
Breast cancer surveillance: recommended	
History/physical examination	Every 3 to 6 months for the first 3 years after primary therapy, every 6 to 12 months for years 4 and 5, and then annually
Patient education regarding symptoms of recurrence	Physicians should counsel patients about the symptoms of recurrence, including new lumps, bone pain, chest pain, abdominal pain, dyspnea, or persistent headaches; helpful websites for patient education include www.cancer.net and www.cancer.org
Referral for genetic counseling	*BRCA1/2* mutation testing should be offered to all patients diagnosed at the age of 65 years or earlier, or select patients older than 65 years based on personal and family history, ancestry, or eligibility for a PARP inhibitor; further gene panel testing depends on personal and family history
Breast self-examination	All women should be counseled to perform monthly breast self-examination
Mammography	First post-treatment mammogram 1 year after the initial mammogram that leads to diagnosis, but no earlier than 6 months after definitive radiation therapy; subsequent mammograms should be obtained as indicated for surveillance of abnormalities
Coordination of care	Continuity of care is encouraged and should be performed by a physician experienced in surveilling patients with cancer and in breast examination, including the examination of irradiated breasts; if follow-up is transferred to a PCP, the PCP and the patient should be informed of the long-term options regarding adjuvant hormone therapy for the particular patient; this may necessitate referral for oncology assessment at an interval consistent with guidelines for adjuvant hormone therapy
Pelvic examination	Regular gynecologic follow-up is recommended for all women; patients who receive tamoxifen should be advised to report any vaginal bleeding to their care team
Breast cancer surveillance testing: not recommended	
Routine blood tests	CBC and liver function tests are not recommended
Breast MRI	Breast MRI is not recommended for routine breast cancer surveillance; MRI may be considered on an individual basis for high-risk patients
Systemic imaging studies	Chest radiograph, bone scans, liver ultrasonograms, CT scans, and FDG PET scans are not recommended
Tumor markers	CA 15-3, CA 27-29, and carcinoembryonic antigen testing are not recommended

Abbreviations: CA, cancer antigen; CBC, complete blood count; FDG, fluorodeoxyglucose; PCP, primary care provider.

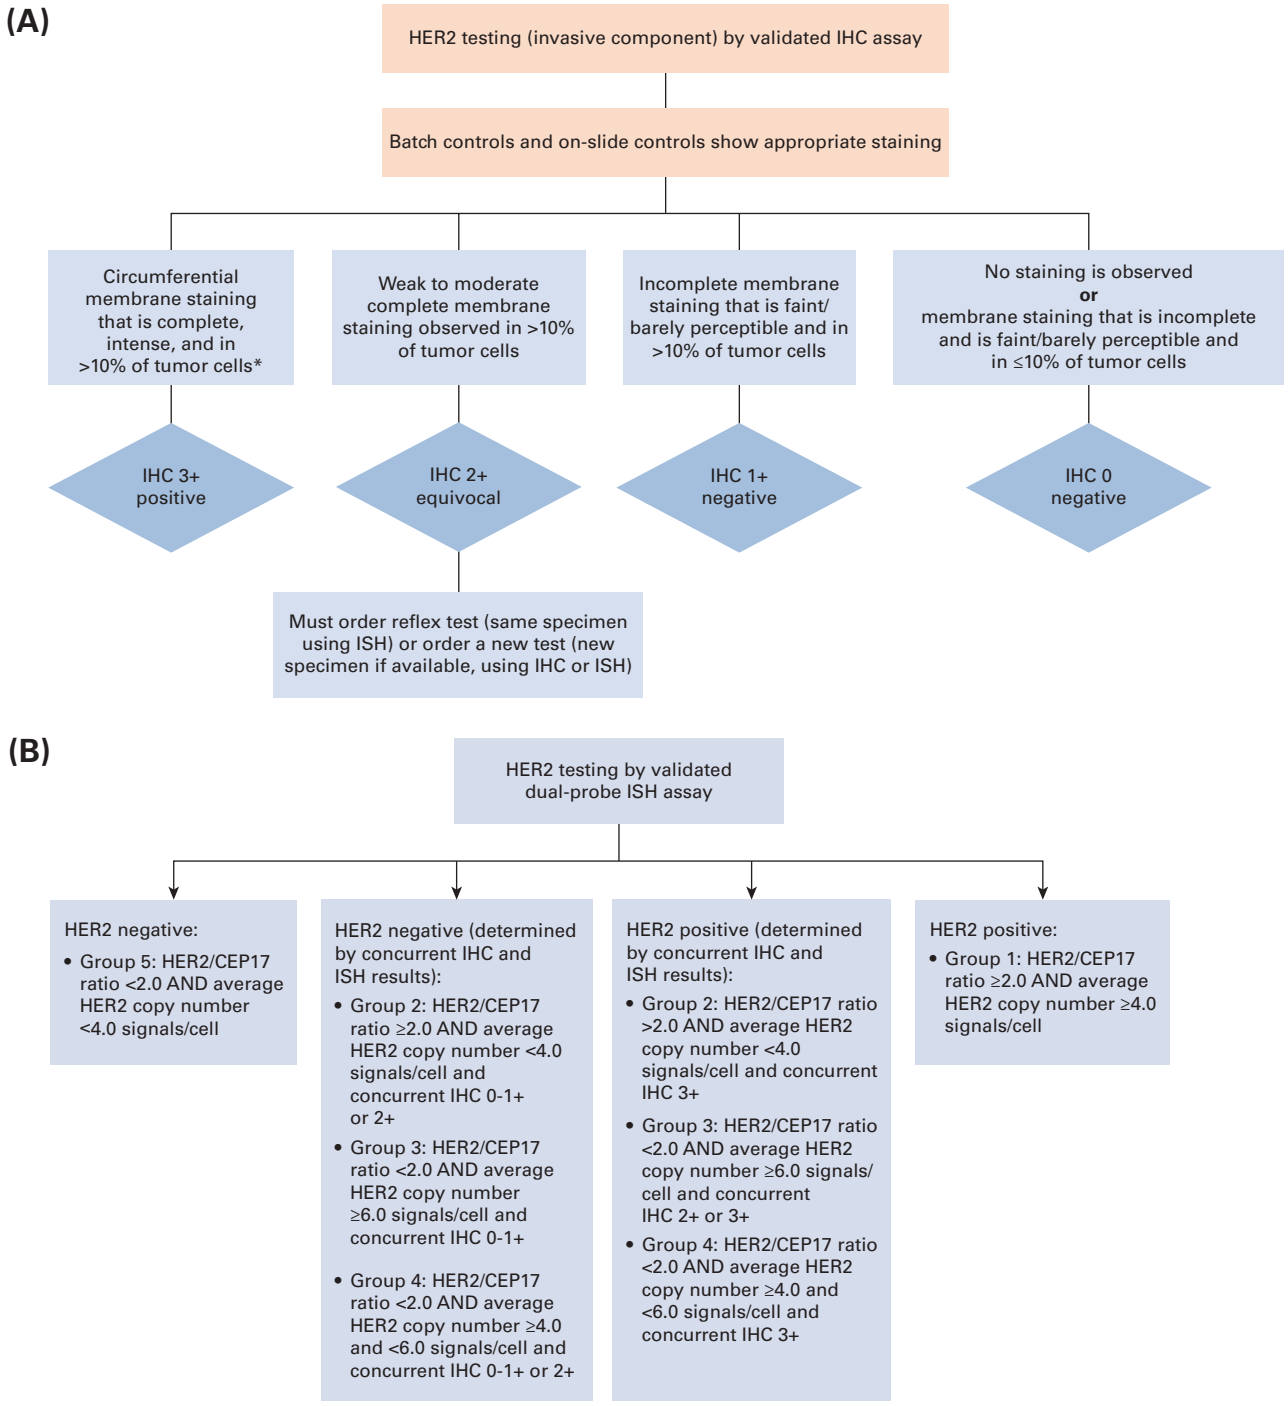
Figure 10-3 Summary of the ASCO/College of American Pathologists Guidelines



(A) HER2 testing by validated IHC assay. (B) HER2 testing by validated dual-probe ISH assay.
Abbreviations: IHC, immunohistochemistry; ISH, in situ hybridization.
*Readily appreciated using a low-power objective and observed within a homogeneous and contiguous invasive cell population.
Reproduced from Wolff AC, Hammond MEH, Allison KH, Harvey BE, McShane LM, Dowsett M. HER2 testing in breast cancer: American Society of Clinical Oncology/College of American Pathologists clinical practice guideline focused update summary. *J Oncol Pract.* 2018;14:437-441. doi:10.1200/JOP.18.00206

Figure 10-4 Suggested Axillary Management for Clinically Node-Negative Axilla

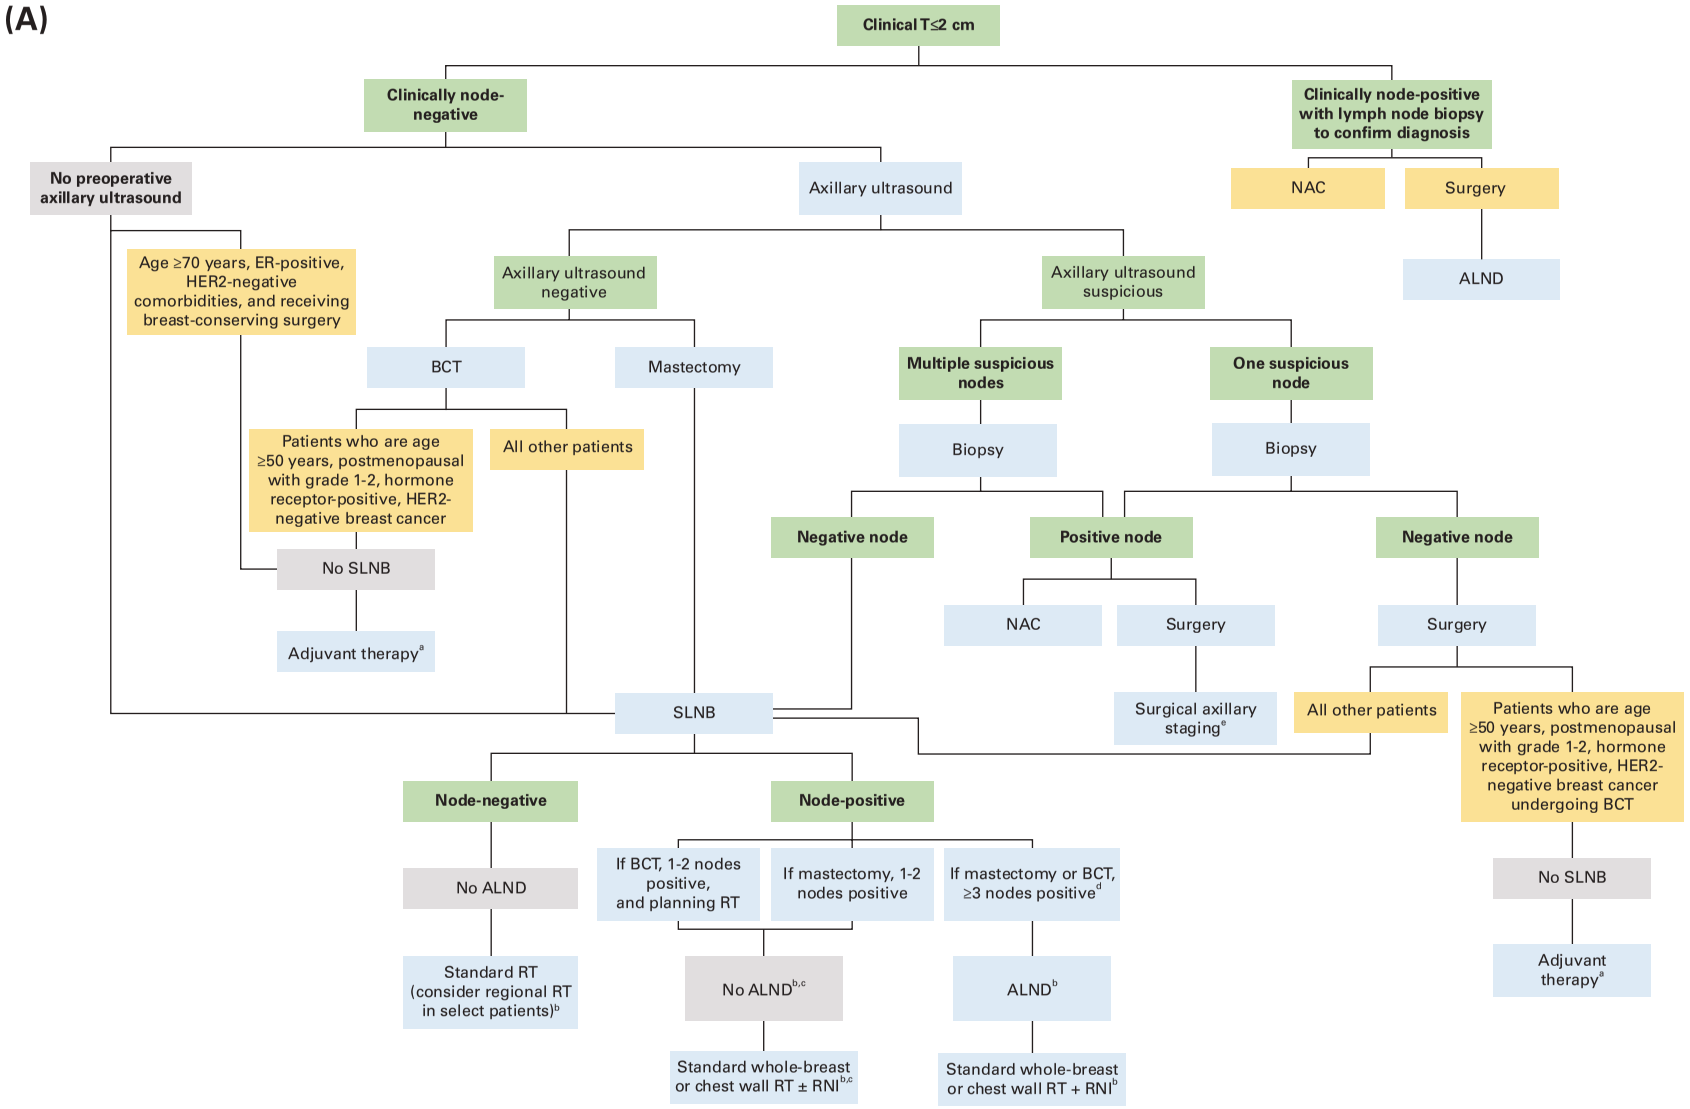


Figure 10-4 Continued

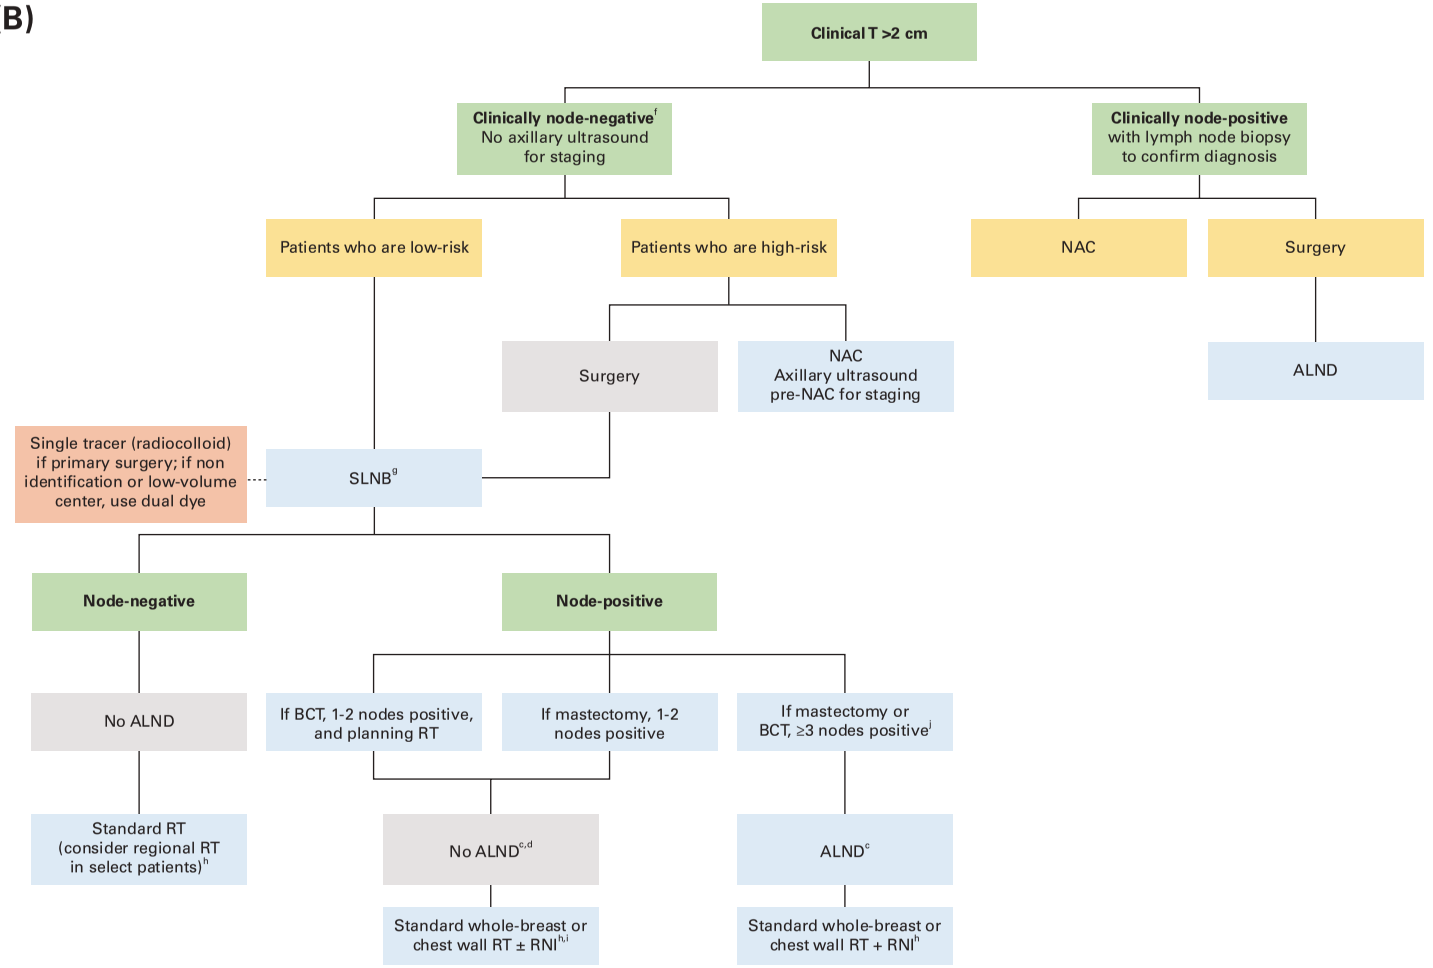
(B)



(A) Management of the axilla for patients with clinical T ≤2 cm breast cancer. (B) Management of the axilla for patients with clinical T >2 cm breast cancer.
Abbreviations: ALND, axillary lymph node dissection; BCT, breast-conserving therapy; ER, estrogen receptor; HER2, human epidermal growth factor receptor 2; NAC, neoadjuvant chemotherapy; PMRT, postmastectomy radiation therapy; RNI, regional nodal irradiation; RT, radiation therapy; SLNB, sentinel lymph node biopsy; T, tumor.
[a]Refers to all patients with no palpable axillary nodes on physical examination, including those who may have had an ultrasound that was equivocal, abnormal, or even biopsy-proven positive.
[b]Do not recommend SLNB before chemotherapy except in special circumstances after multidisciplinary discussion.
[c]Decision making should be made on a case-by-case basis, and include a patient-centered approach; that is, consider and discuss pros and cons of various options in light of patient's specific circumstances, values, and preferences.
[d]Full lymph node dissection may mitigate the need for RT in select patients.
[e]Patients with three positive nodes were underrepresented in trials evaluating the omission of completion ALND.
[f]Refers to all patients with no palpable axillary nodes on physical examination, including those who may have had an ultrasound that was equivocal, abnormal, or even biopsy-proven positive.
[g]Do not recommend SLNB before chemotherapy except in special circumstances after multidisciplinary discussion.
[h]Decision making should be made on a case-by-case basis, and include a patient-centered approach; that is, consider and discuss pros and cons of various options in light of patient's specific circumstances, values, and preferences.
[i]Full lymph node dissection may mitigate the need for RT in select patients.
[j]Patients with three positive nodes were underrepresented in trials evaluating the omission of completion ALND.
Adapted from Park KU, Somerfield MR, Anne N, et al. Sentinel lymph node biopsy in early-stage breast cancer: ASCO guideline update. *J Clin Oncol*. 2025;43(14):1720-1741. doi:10.1200/jco-25-00099

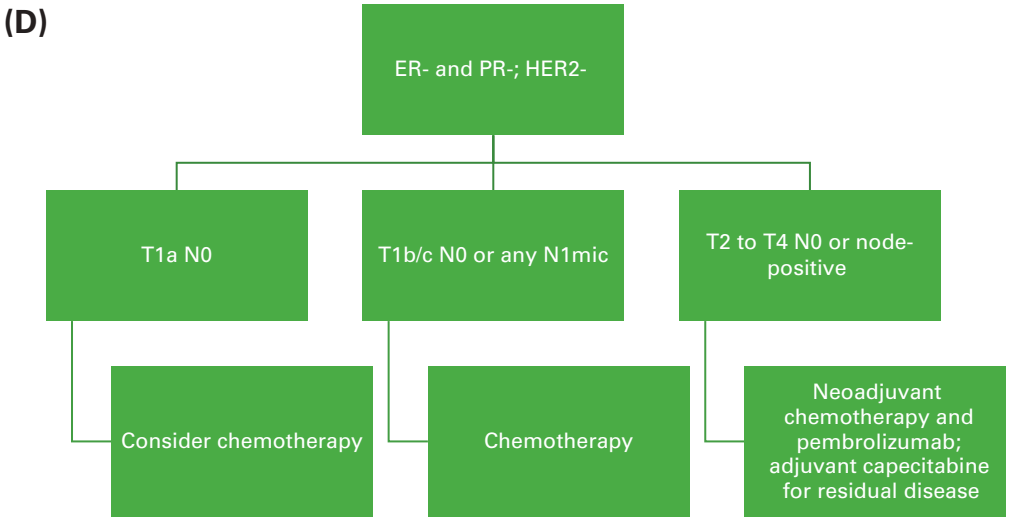
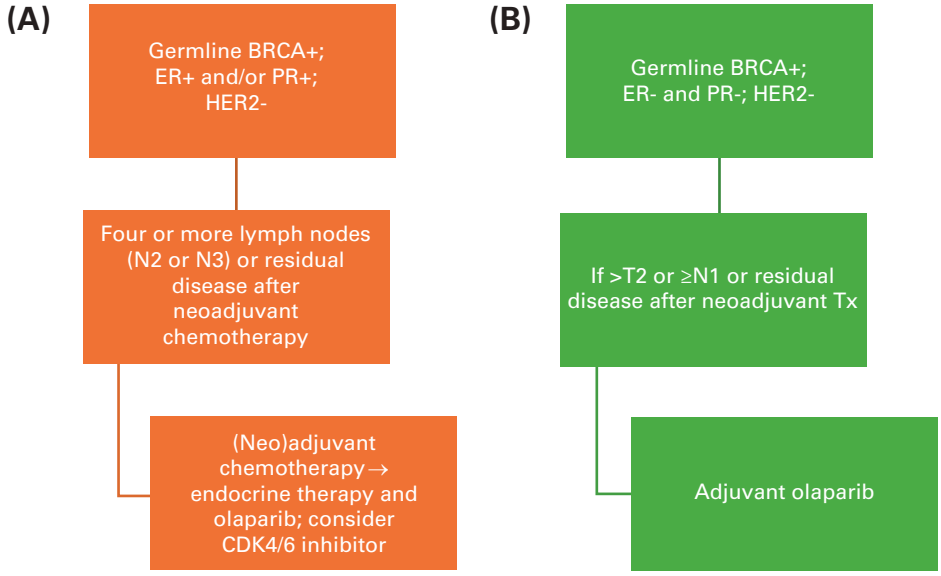
Figure 10-5 Suggested Guidelines for (Neo)Adjuvant Systemic Therapy for Four Main Breast Cancer Subtypes if No Germline *BRCA* Mutation

Figure 10-5 Continued



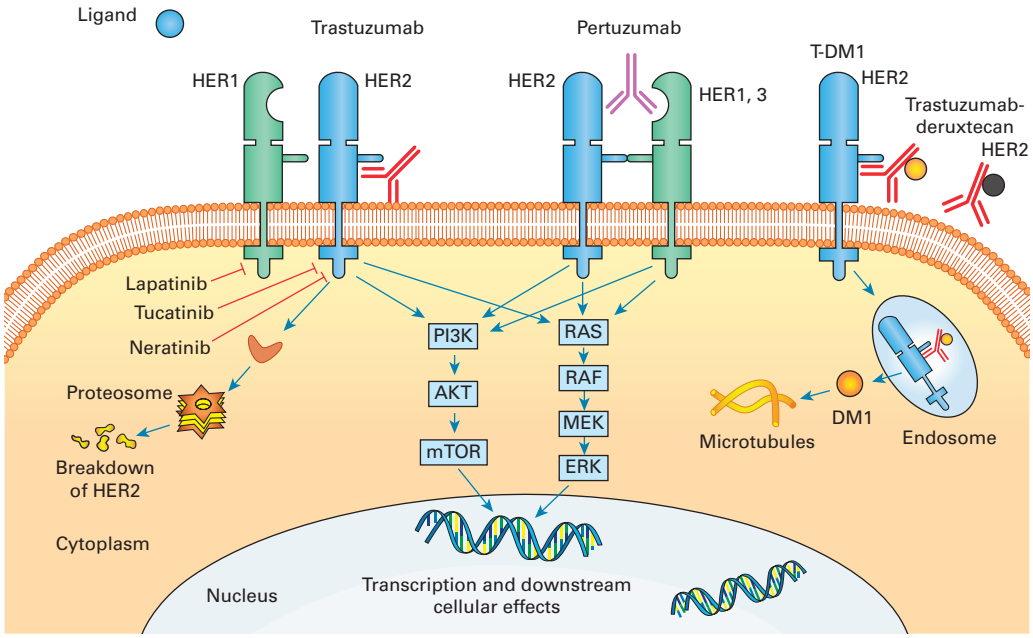
(A) Hormone receptor–positive, HER2-negative disease. (B) Hormone receptor–positive, HER2–positive disease. (C) Hormone receptor–negative, HER2–positive disease. (D) Hormone receptor–negative, HER2–negative disease.
Abbreviations: ER, estrogen receptor; PR, progesterone receptor; Tx, therapy.
*Gene signatures may help with decision-making in appropriate patients. Clinical trials did not include T1c, N0.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 10-6 Suggested Guidelines for (Neo)Adjuvant Systemic Therapy for HER2-Negative Breast Cancer With Germline *BRCA* Mutation



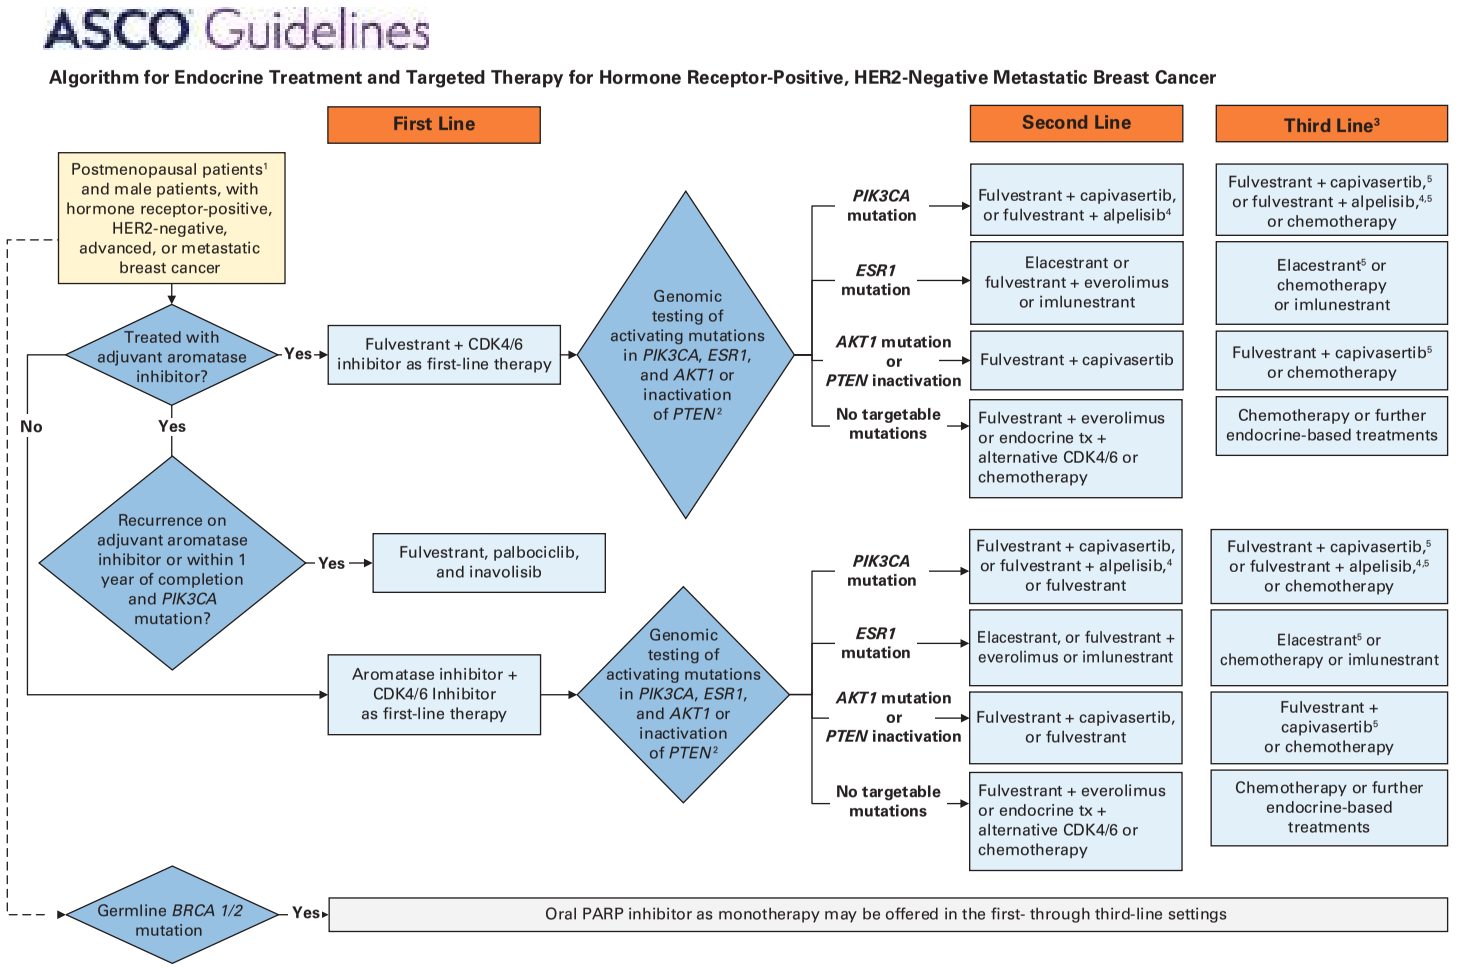
(A) Hormone receptor–positive, HER2-negative disease. (B) Hormone receptor–negative, HER2-negative disease.
Abbreviation: Tx, therapy.
Gene signatures may help with decision-making in appropriate patients. Clinical trials did not include T1c, N0.Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 10-7 Targets for HER2-Targeted Therapy



Abbreviation: T-DM1, ado-trastuzumab emtansine.
Adapted under Creative Commons license CC BY-NC-SA 3.0. Source: Singh JC, Jhaveri K, Esteva FJ. HER2-positive advanced breast cancer: optimizing patient outcomes and opportunities for drug development. *Br J Cancer*. 2014;111:1888-1898. doi:10.1038/bjc.2014.388

Figure 10-8 Suggested Treatment Sequencing in Hormone Receptor–Positive and HER2–Negative MBC



Abbreviations: AI, aromatase inhibitor; CDK4/6i, cyclin-dependent kinase 4/6 inhibitor; CLIA, Clinical Laboratory Improvement Amendments; ESR1, estrogen receptor 1; ET, endocrine therapy; HER2, human epidermal growth factor receptor 2; MBC, metastatic breast cancer; OFS, ovarian function suppression; PARPi, poly-ADP-ribose polymerase inhibitor; PTEN, phosphatase and tensin homolog protein.
BRCA mutation options: olaparib or talazoparib.
[1]If patient is premenopausal, initiate ovarian suppression and continue as postmenopausal.
[2]Tumor genomic testing includes sequencing for targetable mutations, accomplished through large panel tumor genomic testing in a CLIA-certified laboratory performed on tissue or plasma obtained either at the time of progression or from archival tissue. In addition to selecting patients whose tumors have increased PIK3CA or AKT1 activity because of the presence of activating mutations, it is also important to identify those whose tumors have inactivation of phosphatase and tensin homolog (PTEN) protein. PTEN inactivation can be identified based on the presence of premature stop codons, frameshift alterations, splice site mutations, PTEN homozygous deletion, PTEN rearrangements that disrupt protein function, or specific missense mutations (*C124R*, *C124S*, *G129E*, *G129V*, *G129R*, *R130Q*, *R130G*, *R130L*, *R130P*, *C136R*, *C136Y*, *S170R*, and *R173C*), on next-generation sequencing.
[3]There are few data on the value of older endocrine treatment options after therapy with modern treatment regimens such as AIs, SERDs, CDK4/6 inhibitors and/or other targeted agents. In select patients—typically those with indolent cancers, limited disease burden or symptoms, and demonstrated clinical benefit from prior endocrine
treatments—therapies such as tamoxifen, megestrol acetate, or reintroduction of previously administered treatments may be of clinical value.
[4]Alpelisib is an option for patients with tumors harboring PIK3CA activating mutations but not AKT1 activating mutations or PTEN inactivation.
[5]If not previously given.
