LUNG CANCER 11

Jonathan E. Dowell, MD, and Sawsan Rashdan, MD

RECENT UPDATES

- Tarlatamab improves overall survival when compared with standard second-line chemotherapy in patients with extensive-stage small cell lung cancer whose cancer has progressed after initial chemotherapy and immunotherapy.[1]
- Datopotamab deruxtecan is approved for patients with locally advanced or metastatic epidermal growth factor receptor (EGFR)-mutated non–small cell lung cancer (NSCLC) who have received prior EGFR-directed therapy and platinum-based chemotherapy.[2]
- Zongertinib is approved for patients with unresectable or metastatic non–squamous NSCLC whose tumors have HER2 (*ERBB2*) tyrosine kinase domain (TKD) activating mutations.[3]
- Sunvozertinib is approved for patients with locally advanced or metastatic NSCLC with EGFR exon 20 insertion mutations whose disease has progressed on or after platinum-based chemotherapy.[4]
- Telisotuzumab vedotin-tllv is approved for patients with locally advanced or metastatic, non–squamous NSCLC with high c-Met protein overexpression (immunohistochemistry [IHC] 3+ > 50%) who have received a prior systemic therapy.[5]
- Taletrectinib is approved for patients with locally advanced or metastatic *ROS-1* fusion–positive NSCLC.[6]

OVERVIEW

An estimated 226,650 new cases of lung cancer were diagnosed in the United States in 2024, making it the second most common cancer in men (following prostate cancer) and women (following breast cancer).[7] It is also the most lethal cancer in the United States, with approximately 124,730 deaths annually or approximately 20% of all US deaths resulting from cancer. Since 2006, the incidence of lung cancer has decreased by 2.6% annually in men and 1.1% annually in women. This reduction is attributed almost entirely to a reduction in smoking rates. The 3-year relative survival rate for lung cancer has also improved, from 22% in patients diagnosed from 2004 to 2006 to 33% in those diagnosed from 2016 to 2018. Possible reasons for this improvement include improved surgical and medical therapies (eg, targeted therapies and immunotherapies) and earlier detection because of lung cancer screening.[8] There is real hope that these trends will continue with additional improvements in therapy as well as the stage migration that results from the increased use of low-dose chest computed tomography (CT) for lung cancer screening.

KEY POINT

- Lung cancer is the most common cause of cancer-related death in the United States in both men and women.

RISK FACTORS

Although the biology of lung cancer is complex, the link between lung cancer and tobacco use is clear. Numerous epidemiologic and laboratory studies, as well as in vitro data, have tied lung cancer to the carcinogenic effects of tobacco smoke. It is important to recognize, however, that each year in the United States, there are 17,000 to 26,000 deaths resulting from lung cancer in individuals with limited/no tobacco use history, with an even higher proportion in some geographic areas.[9] Other environmental and occupational exposures have also been linked to the development of lung cancer, with varying levels of evidence.

The main risk factors for lung cancer are the following:

- Tobacco smoke[10]
- Environmental exposures (radon, asbestos, arsenic, chromium, and nickel)[11]

- Radiation[12]
- Family history[11,3,14]

TOBACCO

Cigarette smoking is the most common cause of lung cancer and is associated with approximately 85% of all cases. The risk of lung cancer in those who use cigarette tobacco increases with the number of cigarettes smoked and the duration of smoking history; the latter is a stronger risk factor than the former. Tripling of the number of cigarettes smoked per day is estimated to triple the risk of lung cancer, whereas tripling of the duration of smoking is estimated to increase the risk by 100-fold.[15] The risk of lung cancer decreases with smoking cessation and approaches that of the non–smoking population after 10 to 15 years of abstinence. However, one study among women reported that even after 30 years, the risk was not as low as that for the population who had never smoked.[10]

Cigarette smoke contains thousands of constituents, many of which are carcinogenic. Two of the major classes of nicotine-related inhaled carcinogens include polycyclic aromatic hydrocarbons and *N*-nitrosamines, which are metabolized to nitrosamine ketone and N^0-nitrosonornicotine. Both compounds are activated by the cytochrome P450 enzyme system and exert carcinogenic effects through the formation of DNA adducts.

ENVIRONMENTAL EXPOSURES

Radon is a naturally occurring chemically inert gas that is a decay product of uranium. The relative risk of lung cancer is increased for underground miners who are exposed to high levels of radon. For underground miners who smoke, the risk may exceed 10 times the risk for a non–smoking miner. The relationship between indoor residential radon exposure and lung cancer risk is less well defined, although it is estimated that 2% to 10% of lung cancers may be caused by exposure to residential radon.[11] Exposure to asbestos combined with smoking increases the risk of lung cancer. Other occupational or environmental exposures associated with a risk of lung include air pollution and environmental (ie, secondhand) tobacco smoke.[15]

RADIOTHERAPY

High doses of radiation have also been associated with an increased risk of lung cancer. For example, an increased risk has been observed in patients with breast cancer, as well as in long-term survivors of Hodgkin and non–Hodgkin lymphomas, particularly if patients continue to smoke after completing radiation therapy.[15]

FAMILY HISTORY AND GENETIC PREDISPOSITION

Epidemiologic studies have shown that a family history of lung cancer is a predictor of increased risk. Familial aggregation of lung cancer has led to the hypothesis of a genetic susceptibility to lung cancer.[13] This may be related to inherited differences in carcinogen metabolism and DNA repair capacity. Germline polymorphisms in genes with products that activate (eg, cytochrome P450 1A1 [*CYP1A1*]) or detoxify (eg, glutathione *S*-transferases M1 [*GSTM1*] and T1 [*GSTT1*]) chemical carcinogens found in tobacco smoke have been associated with a risk of lung cancer from environmental tobacco smoke that is substantially greater than the risk for individuals who are heterozygous or homozygous carriers of the wild-type *GSTM1* allele. However, some results from these studies are conflicting, suggesting that particular polymorphisms may predict increased risks in specific ethnic populations, limiting generalizability. The *EGFR* T790M mutation, most frequently associated with resistance to first- or second-generation epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors (TKIs), can also be present as a germline risk allele for lung cancer. The germline inheritance of *EGFR* T790M usually occurs in an autosomal dominant pattern, and the presence of an *EGFR* T790M mutation at diagnosis (before treatment) should trigger consideration for referral for genetic counseling and germline testing and CT-based screening.[16]

KEY POINT

- Most cases of lung cancer (85%) are caused by carcinogens in tobacco smoke.

PATHOLOGY

More than 95% of lung cancers consist of one of the four major histologic types: adenocarcinoma, squamous cell carcinoma, large cell carcinoma (three subtypes of non–small cell lung cancer [NSCLC]), or small cell lung cancer (SCLC; Table 11-1).[8,17] Histologic subtype influences treatment selection based on the differences in chemotherapy sensitivity and safety profiles in squamous versus non–squamous tumors.

Table 11-1 **Characteristics of Major Subtypes of Lung Cancer**			
Histology	**Frequency (%)**	**Immunohistochemistry**	**Clinical Features/Comments**
Non–small cell			
Adenocarcinoma	50	TTF-1, Napsin-A, CK7	Most common histology to have actionable driver mutations
Squamous cell carcinoma	25	P63, p40, CK5/6	Often central tumors; may develop cavitation; more commonly seen in those with heavy smoking history
Large cell carcinoma	5	—	Poorly differentiated tumors that do not meet the criteria for adenocarcinoma or squamous cell carcinoma
Pulmonary neuroendocrine tumors			
Typical carcinoid	1-2	Synaptophysin, chromogranin, INSM-1	<2 mitoses/2 mm^2 (10 HPF); lacking necrosis
Atypical carcinoid	1-2	Synaptophysin, chromogranin, INSM-1	2-10 mitoses/2 mm^2 (10 HPF) or necrosis
Large cell neuroendocrine carcinoma	5	Synaptophysin, chromogranin, INSM-1	High mitotic rate (>10 mitoses/2 mm^2; may show organoid nesting and rosettes
Small cell carcinoma	12-13	Synaptophysin, chromogranin, INSM-1	High mitotic rate (>10 mitoses/2 mm^2); small cells; nuclear molding; often crush artifact noted

Abbreviations: CK, cytokeratin; HPF, high-power fields; INSM-1. insulinoma-associated protein 1.

In the United States, the most common form of lung cancer was squamous cell cancer (SCC) until approximately 1987, when it was supplanted by adenocarcinoma. This is largely thought to be because of the introduction of filtered and low-tar cigarettes. SCLC once accounted for approximately 20% of all lung cancer diagnoses, but because of the changes in smoking rates, its incidence has declined to 14%.[18,19] Additional uncommon neuroendocrine tumors that occur in the lung are carcinoid, atypical carcinoid, and large cell neuroendocrine cancer.[17] Rare primary tumors in the lung include sarcomas, cancers with sarcomatoid or sarcomatous elements (eg, giant cell cancer, carcinosarcoma, and pulmonary blastoma), and cancers of the salivary gland (eg, mucoepidermoid cancer and adenoid cystic cancer).[20]

ATYPICAL ADENOMATOUS HYPERPLASIA

Atypical adenomatous hyperplasia is considered as a precursor to adenocarcinoma and is usually identified incidentally, often at the time of resection. Lesions are typically small (a few millimeters) and consist of discrete but ill-defined bronchoalveolar proliferation in which the alveoli are lined by monotonous slightly atypical cuboidal to low-columnar epithelial cells.

ADENOCARCINOMA IN SITU

Adenocarcinoma in situ, previously referred to as bronchioalveolar carcinoma, is defined as an adenocarcinoma of the lung that grows lepidically, along the alveolar septa.[17] Histologically, pure adenocarcinoma in situ is rare; more common is adenocarcinoma, mixed subtype, with both adenocarcinoma in situ features and invasive components. The natural history of both atypical adenomatous hyperplasia and adenocarcinoma in situ is not well characterized. Radiographically, both atypical adenomatous hyperplasia and adenocarcinoma in situ may be initially detected as ground-glass lesions on cross-sectional chest imaging; an increasingly solid or more solid component to a mixed-density nodule often signals evolution of invasive disease.

ADENOCARCINOMA

Adenocarcinoma accounts for approximately 50% of all new lung cancer cases, has been associated with scarring (fibrosis), and is more likely to be peripherally located than squamous cell lung cancer or SCLC. Lung adenocarcinoma typically stains positive by immunohistochemistry (IHC) for cytokeratin (CK) 7 and negative for CK20. Accepted markers for identification of pulmonary adenocarcinoma are TTF-1 and Napsin-A, both of which have a sensitivity of approximately 80%.[20] Adenocarcinoma is the most common lung cancer histology seen in individuals with limited or no tobacco use history. Similarly, the most currently actionable molecular drivers, discussed later in this chapter, are commonly seen in adenocarcinomas (as opposed to other NSCLC subtypes), and NSCLCs occurring in individuals with limited/no tobacco use history tend to be enriched with cancers harboring these actionable oncogenic driver events.

SQUAMOUS CELL CANCER

SCCs account for approximately 25% of lung cancers and occur almost exclusively in patients with a heavy smoking history. These lesions tend to be located centrally in segmental bronchi, involve lobar and main-stem bronchi by extension, and may cavitate, leading to hemoptysis. Histologic features of SCC include intercellular bridging, squamous pearl formation, and individual cell keratinization. Squamous cell lung cancer often overexpresses the squamous histology marker p63 and its isoform p40, as well as CK5/6, all detectable by IHC. The primary site for squamous cell carcinoma cannot typically be determined pathologically, and therefore, review of the clinical and radiographic features of the tumor is required to determine that it is a primary lung cancer as opposed to a metastatic lesion.

LARGE CELL CANCER

Pure large cell lung cancer accounts for fewer than 5% of new lung cancer cases. This diagnosis is restricted to fully resected tumors where any differentiation morphologically or immunohistochemically to squamous cell carcinoma or adenocarcinoma has been excluded.[21] These tumors are typically poorly differentiated and are composed of large cells with abundant cytoplasm and large nucleoli.

PULMONARY NEUROENDOCRINE TUMORS

Neuroendocrine lung tumors represent a spectrum of pathologic entities, including typical carcinoid, atypical carcinoid, large cell neuroendocrine cancer, and SCLC. SCLC and large cell neuroendocrine cancer are high-grade tumors, whereas typical carcinoid and atypical carcinoid are low- and intermediate-grade cancers, respectively. These tumors demonstrate evidence of neuroendocrine differentiation through IHC expression of at least one of the following: chromogranin, synaptophysin, CD56 (neural cell adhesion molecule), or insulinoma-associated protein 1 (INSM-1). Methods for detecting cell turnover, including mitotic count, ki67, and the presence of necrosis, are used to distinguish between these diagnoses. Approximately 20% to 40% of patients with typical or atypical carcinoid have no history of tobacco use, whereas virtually all patients with SCLC and large cell neuroendocrine cancer have a history of smoking. Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH) is a syndrome often seen in middle-aged women with no history of tobacco use that consists of abnormal proliferations of neuroendocrine cells that are not yet invasive and is considered a precancerous lesion with the risk of progression to carcinoid tumors.[22]

Carcinoid Tumors

Carcinoid tumors are low-grade malignant neoplasms of neuroendocrine cells, which are divided into typical and atypical types. Compared with typical carcinoids, atypical carcinoids tend to be larger, have more mitoses per high-power field, and are associated with necrosis. Patients are also more likely to have nodal or distant metastases at presentation, and survival is reduced.

Large Cell Neuroendocrine Cancer

Large cell neuroendocrine cancer is defined as a tumor with neuroendocrine morphologic characteristics, including organoid nesting, palisading, a trabecular pattern, and rosette-like structures. It is differentiated from SCLC on the basis of histologic characteristics, including larger cell size, more abundant cytoplasm, and less prominent nuclear molding.[23]

SMALL CELL LUNG CANCER

SCLC is characterized by small cells with scant cytoplasm, finely granular nuclear chromatin, and absent or inconspicuous nucleoli. Nuclear molding and smearing of the nuclear chromatin may be present because of crush artifact. Mitotic figures are common, necrosis can be extensive, and ki67 often stains more than 80% of cells.[17,23]

KEY POINT

- The four most common histologic subtypes of lung cancer are adenocarcinoma, squamous cell carcinoma, large cell carcinoma (collectively referred to as NSCLC), and SCLC.

STAGING

Accurate staging of lung cancer is critical for proper clinical management and assessment of prognosis. Staging of lung cancer follows the American Joint Committee on Cancer (AJCC) criteria (version 9),[24] which provide a standard classification with three components: the extent of the primary tumor (T), lymph node involvement (N), and distant metastases (M).

MOLECULAR BIOLOGY

A more sophisticated understanding of the biology of lung cancer has led to further subclassification based on molecular characteristics, most notably in lung adenocarcinoma. The presence of specific oncogenic drivers informs biology and prognosis. Importantly, it also guides systemic therapy. In fact, for patients with advanced non–squamous NSCLC, optimal systemic therapy should not be selected without the results of comprehensive tumor molecular profiling. As a result, it is imperative to assess the molecular profile of NSCLC at diagnosis in all treatment-eligible individuals.

GENOMIC PROFILING

Actionable genomic alterations in NSCLC are more commonly identified in tumors with non–squamous histology in patients with limited or no tobacco use history.[25] These include both mutations (single-nucleotide variants and deletions) as well as translocations and gene fusions; to date, amplification of genetic drivers has not proven predictive for therapeutic selection in NSCLC.[26] The current National Comprehensive Cancer Network (NCCN) guideline recommends testing for mutations in *EGFR, BRAF, HER2, KRAS, NRG1*, and *MET* and for translocations/fusions in *ALK, ROS-1, NTRK*, and *RET* in all advanced non–squamous NSCLCs.[26] For each of these alterations, there are targeted agents approved for therapeutic use (described later in this chapter). Per the NCCN guideline, molecular testing should also be considered in those with advanced squamous cell histology (especially patients with little/no tobacco use history), small biopsy specimens that may preclude comprehensive histologic assessment, or mixed histology tumors. Selected molecular testing for *EGFR* and *ALK* is indicated for patients with stage IB to IIIA non–squamous NSCLC for whom surgery is planned because the presence of those alterations can guide perioperative and adjuvant treatment (as detailed below). In addition, as discussed later in the chapter, testing for *EGFR* and *ALK* is indicated for patients with inoperable stage III non–squamous NSCLC because patients with those molecular aberrations do not benefit from immunotherapy as part of their treatment regimen. In addition, patients with an *EGFR* mutation may be considered for EGFR-targeted therapy after chemotherapy and radiation.

BLOOD-BASED GENOMIC TESTING

Circulating tumor DNA (ctDNA) from peripheral blood can be used for molecular analysis of NSCLC, particularly if the available tissue is sufficient to establish a histopathologic diagnosis of NSCLC but insufficient for molecular testing.[27,28] Molecular testing can be performed on blood using various nucleic acid sequencing methods to examine a panel of genes. Assays that use next-generation sequencing (NGS) of DNA and RNA are preferred when available.

A positive blood test is generally specific for the presence of the molecular aberration; however, a negative test should be interpreted with caution, given the known limits of sensitivity (ie, false-negative result). In addition, currently available blood-based assays are limited by the inability to provide validated results for programmed cell death ligand 1 (PD-L1) expression, which is often used for treatment planning for stage IV NSCLC. The absence of validated results for the latter significantly precludes meaningful use of ctDNA for therapeutic selection of palliative systemic therapy in advanced squamous cancers. When possible, uninformative ctDNA testing should be followed by a tissue biopsy to determine the presence or absence of a genomic aberration more conclusively.

IMMUNOHISTOCHEMICAL TESTING

In NSCLC, the presence of PD-L1 can be detected with immunohistochemical staining and is generally expressed as a percentage of tumor cells (Tumor Proportion Score [TPS]) or as a percentage of tumor cells and hematopoietic cells within the tumor (Combined Proportion Score [CPS]). In general, in NSCLC, a higher amount of staining for PD-L1 predicts a greater likelihood of response to PD-1/PD-L1–directed therapies.[29] The utility of PD-L1 staining will be discussed later in this chapter when discussing specific immunotherapies. With the approval of antibody-drug conjugates targeting HER-2 and c-MET for advanced NSCLC that has progressed on prior lines of therapy (discussed later in the chapter), immunohistochemical testing for these proteins is indicated in this population.

KEY POINTS

- Guidelines recommend testing for *EGFR*, *KRAS*, *HER2*, *BRAF*, and *MET* mutations and *ALK*, *ROS-1*, *NTRK*, *RET*, and *NRG1* translocations/fusions in all treatment-eligible patients with stage IV non–squamous NSCLC, with the consideration of testing in select treatment-eligible individuals with stage IV squamous NSCLC.

- *EGFR* and *ALK* testing is indicated for patients with resectable stage IB to IIIA non–squamous NSCLC and patients with inoperable stage III NSCLC who will receive concurrent chemotherapy and radiation.
- When tissue is not available for genomic testing, a blood-based "liquid biopsy" can be utilized for molecular testing; there are limitations to its sensitivity, and uninformative results may need to be confirmed with tissue-based testing.

CLINICAL PRESENTATION

Most patients with lung cancer present with symptomatic disease. The most common symptoms are anorexia, fatigue, weakness, and cough (Fig. 11-1). Metastatic disease at presentation is common in SCLC (75%) and adenocarcinoma (50%), and many metastatic sites are possible, with the most common being brain, bone, liver, and adrenal gland.[30]

Figure 11-1 Signs and Symptoms Associated With Lung Cancer

Key Symptoms	Other Common Symptoms	Less Frequent, but Important Symptoms	Rare/Severe Symptoms
1. Cough 2. Increased sputum production 3. Shortness of breath	1. Fatigue 2. Weight loss 3. Anorexia 4. Low-grade fever	1. Chest pain 2. Hemoptysis 3. Hoarseness (recurrent laryngeal nerve) 4. Bone pain	1. Superior vena cava obstruction 2. Superior sulcus/Pancoast tumor 3. Pericardial tamponade 4. Paraneoplastic syndromes 5. Brain metastases

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

SUPERIOR VENA CAVA SYNDROME

Superior vena cava (SVC) syndrome occurs when the SVC becomes obstructed by either a tumor, a thrombus, or metastases to regional lymph nodes and is considered an oncologic urgency. SVC syndrome is seen in 10% of SCLC cases and 2% to 4% of NSCLC cases, but given the high prevalence of NSCLC, it accounts for approximately 50% of SVC syndrome cases, with SCLC accounting for 25% to 30%.[31] Hospitalization and urgent biopsy should be considered so that prompt treatment may be initiated. Common symptoms include distension of the collateral veins over the anterior chest wall and neck; swelling and puffiness of the neck, face, throat, eyes, and arms; headache; and cyanosis (known as Pemberton sign).

PARANEOPLASTIC SYNDROMES

Paraneoplastic syndromes (PNS) are caused by humoral factors produced by cancer cells that act at a site distant from the primary site and its metastases or by cross-reactivity between host antitumor antibodies and normal tissues.[32,33] For all PNS, treatment of the underlying cancer is recommended. In addition, syndrome-specific therapies may be used.

Two common PNS in patients with NSCLC are hypercalcemia and hypertrophic pulmonary osteoarthropathy (HPOA). Although hypercalcemia is most often caused by diffuse skeletal metastases, it can be the result of ectopic production of a parathyroid hormone-related peptide or other humoral substances. HPOA is seen more commonly in adenocarcinoma[34] and is characterized by clubbing of the digits and, when severe, painful periostitis of the long bones. HPOA may also occur with other non–malignant pulmonary diseases.

Although neurologic PNS are rare and can occur in various cancer types, they are predominately seen in SCLC. Up to 3% of patients with SCLC develop the most common syndrome, known as Lambert-Eaton myasthenic syndrome (LEMS).[35] This syndrome is especially important to recognize because amifampridine is an approved effective therapy for LEMS. Other observed central nervous system (CNS) paraneoplastic disorders include cerebellar degeneration, dementia, limbic encephalopathy, and visual PNS with optic neuritis and retinopathy. Paraneoplastic sensory neuropathy is often associated with the presence of anti-Hu antibody (also known as type 1 antineuronal nuclear antibodies [ANNA1]) and can lead to subacute distal sensory loss and the absence of deep tendon reflexes with normal muscle strength.

In patients with SCLC, ectopic production of ACTH may result in Cushing syndrome with excess cortisol production, resulting in muscle weakness, weight loss, hypertension, hyperglycemia, and profound hypokalemia. As a result of rapid tumor growth,

the classic physical manifestations of Cushing syndrome are often absent. The syndrome of inappropriate antidiuretic hormone (SIADH) leads to euvolemic hypo-osmolar hyponatremia. Most malignancy-associated SIADH cases are seen in SCLC, and symptoms are related to the degree and speed of development of the hyponatremia.

KEY POINTS

- Common symptoms of lung cancer include local symptoms, such as cough, pain, and shortness of breath, and constitutional symptoms, such as fatigue, weakness, anorexia, and weight loss.
- The most common sites for metastatic disease in lung cancer are the lungs (ipsilateral and contralateral), adrenal glands, liver, bone, and brain.
- PNS are commonly seen in patients with lung cancer, notably, hypercalcemia, SIADH, ectopic ACTH production, and neurologic syndromes.

SCREENING

Most patients with lung cancer present with advanced disease, which is associated with a poor prognosis. This has led to great interest in screening to detect lung cancer at an earlier, and therefore theoretically more curable, stage. Although the role of screening patients at high risk of the development of early-stage disease was debated for many years, screening with low-dose CT (LDCT) scan of the chest results in a clear reduction in lung cancer mortality in the screened population.

In LDCT, only the pulmonary parenchyma is examined, negating the use of intravenous contrast medium. This type of scan can usually be performed quickly (within one breath) and involves low doses of radiation. The National Lung Screening Trial (NLST) was a randomized multicenter study comparing annual LDCT with chest x-ray (CXR) for the screening of current and former heavy smokers for lung cancer. LDCT led to more cancer diagnoses and a 20% relative reduction in lung cancer mortality (P = .004) and a 6% decrease in all-cause mortality.[36] As a result of these data, the US Preventive Services Task Force issued recommendations for annual lung cancer screening with LDCT for adults of age 50 to 80 years who have a 20 pack-year smoking history and currently smoke or have quit within the last 15 years. Similar results were seen in the NELSON trial conducted in Belgium and the Netherlands.[37] With 10 years of follow-up, use of LDCT at baseline and years 1, 2, 4, and 6.5 led to a 24% reduction in lung cancer mortality compared with no screening; the benefit was seen in men and women, and cancers detected by screening were primarily early stage (59% stage I cancers). The American Lung Association's 2024 "State of Lung Cancer Report" noted that in 2022, only 16% of eligible patients in the United States were screened for lung cancer.

KEY POINT

- Screening for lung cancer with annual LDCT of the chest is recommended for patients of age 50 to 80 years who have a smoking history of 20 or more pack-years and who are currently smoking or have quit within the last 15 years.

NSCLC MANAGEMENT

DIAGNOSIS AND STAGING WORKUP

Lung cancer is typically detected on chest imaging, either CXR or chest CT. For those with suspected lung cancer, biopsy for confirmation of the diagnosis is required. Based on the size and location of the suspected cancer, biopsy through one of the following procedures is typically pursued:

- Bronchoscopy with or without endobronchial ultrasound (EBUS)
- CT-guided biopsy by interventional radiology
- Surgical biopsy

Once a diagnosis is confirmed, a positron emission tomography (PET) scan is necessary to evaluate local extent and distant disease to common metastatic sites, such as liver and adrenal glands. Magnetic resonance imaging (MRI) of the brain is recommended for patients with clinical stage II or greater NSCLC. PET scans are more sensitive than CT scans and therefore may detect occult nodal or metastatic (especially skeletal) disease not readily seen on CT. Limitations of PET include cost, availability, inability to detect small lesions (<0.5-1 cm), and lack of specificity, particularly in patients with inflammatory or granulomatous disease and in the assessment of intrathoracic nodal involvement, which may be over- or underestimated by PET. Considering these limitations, PET does not replace invasive mediastinal staging (see below) for patients with potentially resectable lung cancer and is not a substitute for brain MRI.

Invasive Mediastinal Staging

Accurate staging of the mediastinum is critical in patients with radiographic evidence of early-stage or locally advanced NSCLC to assign precise tumor stage, guide optimal therapy selection/sequencing, and identify appropriate candidates for surgical

resection. Therefore, invasive mediastinal staging (either before or at the time of surgery) should be considered in all patients with clinical stage I to III NSCLC. The one possible exception is patients with clinical stage IA NSCLC with peripheral tumors who have no evidence of pathologic mediastinal lymphadenopathy by CT and PET because the combined negative predictive value of CT and PET for mediastinal nodal involvement in that setting is greater than 90%.[38] As discussed below, patients with extensive N2 or N3 nodal disease are often not considered for surgery. Transthoracic, transbronchial, and EBUS–guided needle aspirations or biopsy specimens is a minimally invasive method utilized at high-volume centers. Mediastinoscopy is a more invasive historic standard, which has a higher predicative value.[39]

STAGE I AND II NSCLC

SURGERY

Approximately one-third of all patients with lung cancer present with stage I or II disease. The treatment of choice for fit patients is anatomic surgical resection, which can result in cure for many patients. As discussed below, these patients may also be considered for neoadjuvant or perioperative treatment with chemotherapy and immunotherapy. The preferred surgical procedure is lobectomy, although for patients in whom disease crosses a major fissure or involves the proximal main-stem bronchus, bilobectomy or pneumonectomy may be required. Minimally invasive surgery (including robotic or video-assisted approaches) should be performed when feasible and where expertise in those techniques exist as it has been shown to result in increased functional outcomes, decreased pain, and fewer adverse events without compromising cancer outcomes when compared with traditional open lobectomy.[40]

Historically, lobectomy has been the procedure of choice, even for patients with small peripheral lesions, because prior studies suggested that sublobar resections are associated with increased local recurrence and decreased survival.[41] Lobectomy should include resection of bronchial, hilar, and selected mediastinal nodes, on the basis of published guidelines (at least nodes 4R and 7 for right-sided tumors; at least nodes 5/6 and 7 for left-sided tumors). Patients with peripheral chest-wall invasion (T3) should undergo en bloc resection of the involved ribs and underlying lung.

Importantly, a recent randomized trial of sublobar resection (including wedge resection and segmentectomy) versus lobectomy for patients with T1A (<2 cm) node-negative NSCLC demonstrated that sublobar resection was not inferior to lobectomy with respect to disease-free survival (DFS), and overall survival (OS) was similar between the two arms.[41] As a result, this approach should be considered in patients with tumors 2 cm or smaller that are clinically node negative and appropriate for a sublobar resection.

Preoperative Evaluation

The suitability of a patient for a definitive resection depends on two factors: the stage of the lesion and the ability of the patient to undergo surgery. A detailed discussion of the preoperative evaluation and comorbid conditions is beyond the scope of this chapter; however, assessment of pulmonary reserve is important. It should be emphasized that a certified thoracic surgeon, working as part of a multidisciplinary thoracic oncology team, is best qualified to determine whether a patient is a surgical candidate. The key pulmonary function tests are FEV1 and diffusing capacity. Predicted postoperative FEV1 and diffusing capacity should be calculated (based on the number of pulmonary segments to be resected) and expressed as a percentage of normal. A predicted postoperative FEV1 or diffusing capacity percentage of 30% or lower suggests an increased risk of postoperative morbidity or mortality.[42]

RADIATION THERAPY

Stereotactic ablative radiation therapy (SABR), also known as stereotactic body radiation therapy (SBRT), delivers high-dose radiation in a few fractions to small targets with limited toxicity. For patients with NSCLC who are not candidates for surgery, or who decline surgery, and have tumors smaller than 5 cm and no evidence of regional nodal disease, SABR is the preferred alternative therapy and has good local disease control and better OS than conventional radiation therapy. Numerous prospective series of SABR in medically inoperable patients with T1/T2 N0 NSCLC report local control rates of 86% to 97% at 2 to 5 years, with some noting 5-year survival approaching 40%.[43] Although randomized trials comparing SBRT with surgery in medically operable patients with T1/T2 NSCLC have been attempted, they have been challenging to complete, and therefore, there are insufficient data to recommend SABR for patients who are able to undergo surgery.

Other locally ablative treatments, including radiofrequency ablation and microwave ablation, are used in specific clinical situations and may be considered in medically inoperable patients with appropriately sized tumors at centers with expertise or when SABR is not an option.

PANCOAST TUMORS

Pancoast, or superior sulcus, tumors in the upper lobe adjoining the brachial plexus are frequently associated with Horner syndrome (ptosis, miosis, and anhidrosis) or shoulder and arm pain; the latter is caused by rib destruction, involvement of

the seventh cervical vertebra or T1 nerve roots, or both. The SWOG Intergroup phase 2 trial involving patients with T3-4, N0-1, M0 superior sulcus NSCLC established the current standard of care, which consists of a combination of cisplatin and etoposide and concomitant radiation therapy (45 Gy) followed by surgical resection and then two cycles of consolidation chemotherapy after surgery. The 2-year survival rate was 55% for all eligible patients and 70% for patients who had complete resection.[44] This treatment paradigm was developed well before the use of immunotherapy and molecularly targeted therapy in NSCLC, and, therefore, studies are currently evaluating the incorporation of these therapies into the treatment of superior sulcus tumors. Unresectable Pancoast tumors are generally approached similarly to cases of unresectable stage III NSCLC (as discussed below).

ADJUVANT CHEMOTHERAPY

The rationale for adjuvant chemotherapy for patients with resected early-stage lung cancer is based on the observation that distant metastases are the most common sites of failure after potentially curative surgery. Several randomized trials have evaluated the role of adjuvant chemotherapy after surgical resection of early-stage NSCLC. In a meta-analysis of five of these trials, there was a 5.4% absolute survival benefit at 5 years (hazard ratio [HR], 0.89).[45] Importantly, the benefit of adjuvant chemotherapy varied considerably by disease stage, and staging in these trials was per AJCC staging version 7, not the current version 8. In stage IA NSCLC, adjuvant chemotherapy was associated with a trend toward worse survival (HR for death, 1.40), and a nonsignificant trend toward a survival benefit was observed in stage IB disease (HR for death, 0.93). A substantial survival benefit was seen in stage II and III disease (HR for each, 0.83). In the CALGB 9633 trial, patients with resected stage IB NSCLC were randomly assigned to receive postoperative chemotherapy or undergo standard observation. Although the overall study results were negative, an unplanned retrospective subset analysis of patients with tumors 4 cm or larger demonstrated a substantial survival difference in favor of adjuvant chemotherapy (HR, 0.69).[46] Based on these trials, the role of adjuvant chemotherapy for resected stage IIB and III (using AJCC version 8) NSCLC is well established, and adjuvant chemotherapy is not recommended for patients with stage IA disease. In patients with stage IB/IIA NSCLC, the major US guidelines differ in their recommendations, with ASCO recommending against the routine use of adjuvant chemotherapy and the NCCN giving the option of observation or use of adjuvant chemotherapy.[47] ASCO does include a careful discussion of the risks and benefits of adjuvant chemotherapy with a medical oncologist in its recommendations. Some advocate consideration of adjuvant chemotherapy in this population in patients with other high-risk features, such as tumors 4 cm or larger, high-grade histology, lymphovascular invasion, wedge resection, and pleural invasion, although there are no prospective trials demonstrating a survival benefit with chemotherapy in these groups. Cisplatin was combined with vinca alkaloids or etoposide in the adjuvant trials, but it is common practice to use more modern agents along with cisplatin, such as docetaxel, gemcitabine (in squamous histology), or pemetrexed (in non–squamous histology). Despite the fact that treatment with these agents is included in current guidelines, data demonstrating a survival benefit with them are lacking. Carboplatin is often substituted for cisplatin in patients who are not candidates for cisplatin, but again, there are no trials to support a benefit of carboplatin-based adjuvant chemotherapy in resected NSCLC.

ADJUVANT IMMUNOTHERAPY

The IMpower 010 trial revealed that the addition of 1 year of atezolizumab after adjuvant chemotherapy significantly improved DFS (HR, 0.66) in patients with stage II to IIIA NSCLC expressing PD-L1 on 1% or more of tumor cells, and atezolizumab is a US Food and Drug Administration (FDA)–approved option for this population. OS data with atezolizumab remain immature, but a recent update demonstrated an improvement in OS for patients whose tumors had at least 50% PD-L1 expression (HR, 0.43).[48] KEYNOTE-091 led to the FDA approval of 12 months of pembrolizumab after adjuvant chemotherapy significantly improved DFS for PD-L1–unselected patients with completely resected stage IB (T2a ≥ 4 cm), II, or IIIA NSCLC (median DFS in the pembrolizumab group, 53.6 months vs 42.0 months in the placebo group; HR, 0.76; 95% CI, 0.63-0.91; $P = .0014$).[49] Although there has been a shift toward perioperative therapy (discussed below) for patients with clinical stage II or III disease, adjuvant chemotherapy followed by adjuvant immunotherapy remains an important consideration in patients who have not received preoperative systemic therapy and those upstaged at the time of surgery.

MOLECULARLY TARGETED AGENTS

The phase 3 ADAURA trial randomly assigned patients with completely resected stage IB, II, or IIIA (per AJCC version 7 staging) NSCLC with *EGFR* exon 19 deletions or L858R to 3 years of the third-generation EGFR TKI osimertinib versus placebo. Use of adjuvant chemotherapy was not mandated but was similar between the two arms (~60% of patients in both arms received adjuvant chemotherapy). Osimertinib improved DFS for patients with resected stage IB to IIIA NSCLC, with a 2-year DFS rate of 89% with osimertinib versus 52% with placebo and a DFS HR of 0.20. In patients with stage IB to IIIA disease, the 5-year OS rate was 88% in the osimertinib group and 78% in the placebo group (overall HR for death, 0.49; 95.03% CI, 0.34-0.70; $P < .001$).[50]

One potential criticism of the trial is that only 43% of patients assigned to the placebo arm received osimertinib on recurrence of disease. Osimertinib is currently recommended as adjuvant therapy after chemotherapy for patients with completely resected stage IB to IIIA NSCLC harboring a sensitizing *EGFR* mutation.[51]

The phase 3 ALINA trial randomized patients with completely resected *ALK*-positive NSCLC of stage IB (tumors ≥4 cm), II, or IIIA (per AJCC version 7 staging) to receive alectinib for 2 years or four cycles of platinum-based chemotherapy. Of note, the patients receiving alectinib did not receive adjuvant chemotherapy. The primary endpoint was DFS in the stage II and IIIA population, and this endpoint was met, with 93.8% of patients receiving alectinib and 63% of patients receiving chemotherapy alive and disease free at 2 years (DFS HR, 0.24). Based on these data, alectinib was approved for use in the United States for patients with stage II to IIIA *ALK*-positive NSCLC undergoing complete resection. The current trial does not answer the question of whether these patients should also receive adjuvant chemotherapy before alectinib (Fig. 11-2).[51]

PRESENTING CASE STUDY

A 66-year-old woman was diagnosed with non–small cell lung cancer (NSCLC) after having a low-dose screening computed tomography (CT) of the chest 3 months ago. She now presents to an oncologist 6 weeks after undergoing a minimally invasive right lower lobectomy. Final lobectomy pathology identifies a 2.6-cm adenocarcinoma and no pleural invasion. Surgical margins are negative for tumor. Two of the five sampled 11R lymph nodes contain cancer. Three 4R lymph nodes and a level 7 lymph node are negative for cancer. The programmed cell death ligand 1 (PD-L1) tumor proportion score is 60. *EGFR* and *ALK* analyses show no *EGFR* mutation or *ALK* rearrangement. The patient has recovered from thoracotomy; her incisions are well healed, and her Eastern Cooperative Oncology Group (ECOG) performance status is 1. Her medical history is significant for hypertension and no autoimmune disease. Laboratory studies, including complete blood count and comprehensive metabolic panel, are within reference ranges.

Given this patient's stage, medical history, molecular testing, and performance status, what additional treatment options are most appropriate?

This patient has completely resected stage IIB NSCLC, and her tumor is positive for PD-L1 staining. Her functional status is good, and she has no apparent contraindication to chemotherapy or immunotherapy. There is level I evidence to support four cycles of adjuvant cisplatin-based chemotherapy followed by immunotherapy (atezolizumab or pembrolizumab) for 12 months. Given that molecular testing for *EGFR* and *ALK* was negative, there is no indication for *EGFR*- or *ALK*-targeted therapy. For patients with a positive surgical margin following resection, re-resection or radiation therapy is recommended. With this patient undergoing a complete resection with negative surgical margins, there is no role for additional surgery or radiation therapy.

Following completion of four cycles of cisplatin and pemetrexed and 3 months of immunotherapy, the patient develops right upper quadrant abdominal pain. CT of the abdomen reveals multiple new liver lesions concerning for metastases. FGD/PET (positron emission tomography) confirms the liver lesions to be avid along with two new PET-avid pulmonary nodules in the right lung. Biopsy of a liver lesion confirms recurrent adenocarcinoma, and broad panel molecular testing does not reveal any targetable molecular changes. Other than the pain, which is controlled with occasional analgesics, the patient reports no other symptoms, and her ECOG performance status remains at 1.

What management options are most appropriate in this setting?

The patient now has biopsy-proven stage IV NSCLC. Given that she recently received platinum-based chemotherapy and was on immunotherapy at the time of recurrence, there is likely limited benefit to a re-trial of platinum-based treatment and immunotherapy. Given her lack of significant co-morbidities and preserved functional status, second-line chemotherapy with docetaxel (with or without ramucirumab) can be considered. With the development of stage IV disease, it is also reasonable to perform an MRI of the brain to exclude the presence of metastatic disease. Referral to palliative care for symptom management and to initiate goals of care discussions is also appropriate.

NEOADJUVANT AND PERIOPERATIVE IMMUNOTHERAPY AND CHEMOIMMUNOTHERAPY

In patients with surgically resectable NSCLC, there are now multiple approved approaches for sequencing of chemotherapy and immunotherapy: (1) neoadjuvant therapy alone, (2) perioperative (both neoadjuvant and adjuvant therapy), and (3) adjuvant therapy alone. CheckMate 816 was a randomized phase 3 study of three cycles of neoadjuvant nivolumab and platinum-doublet chemotherapy versus chemotherapy alone in resectable stage IB (with tumors >4 cm) to IIIA NSCLC.[52] The study met its primary endpoint, demonstrating a significantly improved pathologic complete response (pCR) rate of 24% with neoadjuvant nivolumab and chemotherapy, compared with only 2% with chemotherapy alone. Nivolumab and chemotherapy also led to significant improvements in event-free survival (median 31.6 vs 20.8 months; HR, 0.63; $P = .005$) and OS (median not reached vs 73.7 months; HR, 0.72; $P = .048$).[53] In the KEYNOTE-671 trial, 797 patients with resectable stage II to IIIB (N2 nodal stage) NSCLC were randomized to neoadjuvant pembrolizumab or placebo for up to four cycles along with cisplatin-based chemotherapy followed by surgical resection and either adjuvant pembrolizumab or placebo for up to 13 cycles. The primary endpoints were DFS and OS.[54] The DFS rate was significantly improved in the group receiving pembrolizumab (62.4% at 24 months vs 40.6%; HR, 0.58; $P < .001$). OS had not reached maturity at this analysis. The similarly designed AEGEAN trial randomized patients with resectable

stage IIA to IIIB (N2 nodal stage) NSCLC to receive durvalumab or placebo with platinum-based chemotherapy for four cycles followed by surgery and then durvalumab or placebo for up to 12 cycles.[55] The primary endpoints were pCR and DFS. The pCR rate was improved in the group receiving durvalumab (17.2% vs 4.3%; $P < .001$), as was the DFS rate at 12 months (73.4% vs 64.5%; HR, 0.68; $P = .004$). The CheckMate 77T trial evaluated the addition of perioperative nivolumab versus placebo to neoadjuvant platinum-based chemotherapy followed by surgical resection and either adjuvant nivolumab or placebo for up to 12 cycles and demonstrated significant improvements in pCR and event-free survival.[56] Note that for all the studies discussed above, the AJCC version 7 staging system was utilized. As a result of these trials, multiple strategies for neoadjuvant and perioperative systemic therapy are now FDA approved and guideline concordant in patients with surgically resectable stage IB (≥4 cm) to IIIA NSCLC without *EGFR*/*ALK* alterations: (1) neoadjuvant platinum-based chemotherapy with nivolumab or (2) perioperative platinum-based chemotherapy with pembrolizumab, durvalumab, or nivolumab. Many unanswered questions remain, such as what to do with patients with a suboptimal response to neoadjuvant treatment and whether a neoadjuvant, perioperative, or adjuvant approach is the most effective (2). Ongoing trials are attempting to answer some of these questions.

KEY POINTS

- The KEYNOTE-091 trials demonstrated that 12 months of pembrolizumab after adjuvant chemotherapy significantly improves DFS for PD-L1–unselected patients with completely resected stage IB (T2a ≥ 4 cm), II, or IIIA NSCLC.
- The IMpower 010 trial revealed that the addition of 1 year of atezolizumab after adjuvant chemotherapy significantly improves DFS in patients with stage II to IIIA NSCLC expressing PD-L1 on 1% or more of tumor cells.
- Adjuvant osimertinib improves DFS and OS for patients with resected stage IB to IIIA *EGFR*-mutated NSCLC.
- Adjuvant alectinib improves DFS for patients with resected stage II to IIIA *ALK*-rearranged NSCLC.

STAGE III NSCLC

Treatment of stage III NSCLC is one of the most controversial issues in the management of lung cancer. In large part, this is because of the heterogeneity of the disease and the patient population. Treatment of stage III NSCLC should be managed by an experienced multidisciplinary team and could include consultation with thoracic surgery, medical oncology, and radiation oncology, with the consideration of systemic therapies (chemotherapy, immunotherapy, targeted therapy), radiation therapy, and surgery, in various combinations and sequences (Fig. 11-3). Interpretation of the results of clinical trials involving patients with locally advanced disease has been clouded by several issues, including changing diagnostic techniques, different staging systems, and the heterogeneity of stage III lung cancer. For example, a patient with bulky, symptomatic, unresectable NSCLC and a patient with resectable NSCLC and incidental lymph node involvement can have the same TNM stage.

MICROSCOPIC STAGE IIIA NSCLC

Occasionally, despite appropriate preoperative staging, patients thought to have stage I or II disease are found to have N2 nodal involvement at the time of surgery. As outlined in the previous section, there is a survival benefit with adjuvant cisplatin-based chemotherapy and immunotherapy for patients with completely resected stage III NSCLC. Postoperative radiation therapy (PORT) is no longer standard of care. In a meta-analysis, PORT reduced locoregional recurrence but did not prolong survival.[57] The randomized phase 3 Lung-ART trial was the first prospective trial to explore the role of PORT. In this study, 501 patients with completely resected NSCLC with confirmed N2 nodal involvement were randomly assigned to PORT or observation after adjuvant chemotherapy.[58] Use of PORT was not associated with a significant improvement in either PFS or OS, with no difference in the 3-year OS rate (66.5% with PORT vs 68.5% with observation), and therefore, its use has fallen out of standard practice.

RESECTABLE STAGE III NSCLC

The optimal treatment of resectable, non–bulky stage IIIA NSCLC generally consists of systemic treatment (see Adjuvant Treatment and Neoadjuvant and Perioperative Chemotherapy and Immunotherapy sections above) combined with a local approach (radiation therapy and/or surgery).[59] Strategies include surgery followed by adjuvant therapy, neoadjuvant chemoimmunotherapy followed by surgery, perioperative chemoimmunotherapy and surgery, or concurrent or sequential chemotherapy with definitive radiation therapy followed by immunotherapy or targeted therapy (Fig. 11-3). For patients who cannot receive immunotherapy, neoadjuvant chemotherapy or chemotherapy and radiation therapy are sometimes used.

UNRESECTABLE STAGE III NSCLC

The standard treatment of unresectable, locally advanced stage III NSCLC is concurrent chemoradiation therapy. This population often includes patients with bulky stage IIIA or IIIA disease with multistation mediastinal lymph node involvement and those with stage IIIB or IIIC NSCLC, although the definition of unresectable is not universally agreed upon. Randomized studies

Reprinted from Daly ME, Singh N, Ismaila N, et al., Management of stage III non–small cell lung cancer: ASCO guideline rapid recommendation update. *J Clin Oncol*. 2024;42(25):3058-3060. doi:10.1200/JCO-24-01324

have demonstrated an improvement in median and long-term survival with chemotherapy and radiation therapy compared with radiation therapy alone.[60] Delivery of concurrent chemoradiation therapy is associated with a survival benefit over sequential chemotherapy and radiation therapy, although this is also associated with greater toxicity.

In the United States, the two chemotherapy regimens most commonly administered with definitive radiation therapy for NSCLC are a combination of cisplatin and etoposide (at full doses) and a combination of carboplatin and paclitaxel (at low weekly doses). The combination of cisplatin and etoposide was studied in a multicenter phase 2 study of patients with stage IIIB NSCLC. In this study, the 5-year survival rate was 15%, and treatment was notable for myelosuppression and a relatively high rate of radiation esophagitis (grades 3-4, 20%).[61] A randomized phase 3 trial compared cisplatin and etoposide with weekly carboplatin and paclitaxel.[62] In this study, 200 patients with stage III NSCLC received 60 to 66 Gy of thoracic irradiation and were randomly assigned to receive either concurrent full-dose cisplatin and etoposide or weekly carboplatin and paclitaxel. There was no significant difference in the median OS between the two arms. The 3-year survival rate was notably higher with cisplatin and etoposide (41.1% vs 26%), although the toxicity rates were also higher, including the incidence of grade 2 or worse radiation pneumonitis (33.3% vs 18.9%) and grade 3 or worse esophagitis (20% vs 6.3%).

Additional platinum doublets have also been explored. In the phase 3 PROCLAIM trial, 598 patients with stage IIIA to IIIB non–squamous NSCLC were randomly assigned to receive thoracic irradiation (60-66 Gy) with either concurrent cisplatin and etoposide for two cycles followed by two cycles of consolidation platinum-based doublet chemotherapy or concurrent cisplatin and pemetrexed for three cycles followed by four cycles of pemetrexed consolidation. This superiority study did not meet its primary endpoint. The combination of cisplatin and pemetrexed did not improve survival over cisplatin and etoposide (HR, 0.98; median, 26.8 vs 25.0 months), although the cisplatin and pemetrexed arm had a lower incidence of any drug-related grades 3 to 4 adverse events (64.0% vs 76.8%), including neutropenia (24.4% vs 44.5%).[63]

The optimal chemotherapy to deliver with radiation therapy remains unclear. Escalating radiation dose, however, does not improve outcomes. Results of a phase 3 trial showed that standard 60-Gy thoracic irradiation is superior to a 74-Gy radiation dose with chemotherapy in terms of OS and locoregional control for treatment of stage III NSCLC.[64] These results were not explained simply by an increase in toxicity.

IMMUNOTHERAPY IN STAGE III NSCLC

Although definitive chemoradiation is a potentially curative approach, long-term survival is unfortunately only achieved in a minority of patients. Based in part on the preclinical evidence demonstrating a synergy between radiation therapy and the use of checkpoint inhibitors, the randomized phase 3 PACIFIC study explored the role of durvalumab as consolidation therapy after concurrent chemoradiotherapy. In this trial, 713 patients with unresectable stage III NSCLC who had completed definitive thoracic irradiation (54-66 Gy) with at least two cycles of concurrent platinum-based chemotherapy and had not experienced progression were randomly assigned at a 2:1 ratio to receive 10 mg/kg of durvalumab or placebo every 2 weeks for up to 12 months. After a median follow-up of 34.2 months, the use of durvalumab significantly improved PFS from 5.6 to 16.9 months (HR, 0.55) and also led to a significant improvement in OS (HR, 0.72).[65] The incidence of new lesions was lower with durvalumab, including the development of new brain metastases (6.3% with durvalumab vs 11.8% with placebo). The incidence of grade 3 or 4 adverse events was slightly higher with durvalumab (30.5% vs 26.1%), with similar rates of pneumonitis (4.8% vs 2.6%). Given the acceptable tolerability and a clear improvement in survival, incorporation of durvalumab in appropriate patients has emerged as standard of care in this setting.[66]

TARGETED THERAPY IN STAGE III NSCLC

The LAURA trial recently established a role for osimertinib in the treatment of patients with unresectable, *EGFR*-mutated stage III NSCLC receiving concurrent chemotherapy and radiation. After completion of chemotherapy and radiation therapy, patients were randomly assigned to osimertinib or placebo until progression or unacceptable toxicity. Patients in the osimertinib arm had a statistically significant improvement in median PFS (39.1 vs 5.6 months).[66] On the basis of this trial, osimertinib is an FDA- and guideline-approved option for *EGFR*-mutated, unresectable stage III NSCLC after completion of concurrent chemoradiation therapy. Ongoing trials are addressing this approach in patients with less common actionable genetic alterations.

KEY POINTS

- Treatment options for stage III NSCLC are complex and varied and generally include some combination of systemic therapy (chemotherapy, immunotherapy, and targeted therapy), radiation therapy, and surgery; treatment decisions should be made in discussion with a multidisciplinary team.
- If microscopic N2 (or N1) disease is detected at surgery in a patient who did not receive neoadjuvant therapy, adjuvant therapy should be administered.
- For patients with *EGFR*-mutated, unresectable stage III NSCLC, osimertinib is an approved option after completion of concurrent chemoradiation therapy.

STAGE IV NSCLC

Most patients with NSCLC present with stage IV disease; the goal of treatment in such patients is typically palliative. Systemic therapy can prolong survival and improve quality of life. Historically, a similar treatment approach was used for all patients with advanced NSCLC; however, current treatment recommendations are guided by performance status (PS), histology, the presence or absence of actionable oncogenic driver alterations, and tumor PD-L1 status.[26] When present, targeted therapy may be the preferred frontline therapy, although the level of evidence for each specific target will vary. For some targets, such as *EGFR*, *ALK*, *RET*,[67] *MET*, and *ROS-1*, FDA-approved agents offer superior outcomes to chemotherapy and/or immunotherapy. For other targets, the evidence supporting targeted therapy is still evolving, but identification of these alterations may influence later lines of therapy or facilitate involvement in a clinical trial.[68] When no actionable alterations are identified, early incorporation of immunotherapy improves outcomes. For all patients, optimizing palliation and supportive measures remains an important consideration.

OLIGOMETASTATIC NSCLC

Although the presence of distant metastases confirms stage IV lung cancer, the extent of disease may play a role in management. Stage IV lung cancer still represents a spectrum of disease, and some advanced cancers can still have a more indolent course.[69] The current AJCC staging system provides for identification of patients with a single extrathoracic metastasis in a single organ (M1b). For patients with NSCLC who have a limited number of metastases, or oligometastatic NSCLC, the potential benefit with definitive therapy at all sites of disease in addition to metastatic systemic therapy was suggested by small trials in the preimmunotherapy era. In a randomized phase 2 study, 49 patients with oligometastatic NSCLC, defined here as three or fewer sites of metastasis, were randomly assigned to receive definitive local consolidative therapy, either surgery or radiation therapy, to the isolated involved sites after receiving first-line systemic therapy.[70] The median PFS favored the local consolidative arm (14.2 vs 4.4 months), as did the median OS (41.2 vs 17.0 months). NRG LU002 randomly assigned patients to receive maintenance systemic therapy and local consolidative therapy or maintenance systemic therapy alone after completing four cycles of first-line systemic therapy and had at least stable disease for metastatic NSCLC with limited metastatic sites. The addition of local consolidative therapy did not provide additional benefit to maintenance systemic therapy with a PFS HR of 0.93 (95% CI, 0.66-1.31) and an OS HR (95% CI, 0.70-1.56) of 1.05 between both arms.[71] The optimal definition of oligometastatic disease and the importance of specific sites of disease involvement will require additional refinement. Although more studies are required, local consolidation is a consideration for a subset of patients with limited sites of disease and good PS.

TARGETED THERAPY IN NSCLC

EGFR MUTATION–POSITIVE NSCLC

EGFR belongs to the HER/erbB family of growth factor receptors, which includes EGFR (HER1 or erbB1), HER2/neu (erbB2), HER3 (erbB3), and HER4 (erbB4). These cell surface proteins consist of an extracellular ligand-binding domain, a transmembrane structure, and an intracellular tyrosine kinase domain. The binding of ligand to receptor activates receptor dimerization and tyrosine kinase autophosphorylation, initiating a cascade of intracellular events and leading to increased cell proliferation, angiogenesis, and metastasis and decreased apoptosis. Inappropriate pathologic activation of this receptor-signal transduction pathway can be caused by specific *EGFR*-activating mutations.[72,73]

In NSCLC, activating mutations in the *EGFR* tyrosine kinase domain are seen in approximately 10% to 30% of lung adenocarcinomas, depending on the region of the world, and are centered around exons 18 to 21.[74] At diagnosis, these mutations are typically mutually exclusive of other driver alterations and are associated with certain clinicopathologic features (eg, female sex, East Asian race, never or light smoking history, and adenocarcinoma histology), although *EGFR* mutations can regularly be detected in patients without these characteristics. Exon 19 deletions, commonly in-frame deletions of amino acids 746 to 750, and L858R in exon 21 (ie, classic activating *EGFR* mutations) account for approximately 90% of *EGFR* mutations. Other *EGFR* mutations exist as well, although with variable responsiveness to available EGFR TKIs. When a TKI-sensitizing *EGFR* mutation is identified in advanced NSCLC, EGFR-directed TKIs are the preferred initial therapy.

There are currently seven different EGFR TKIs FDA approved for the initial treatment of *EGFR*-mutated NSCLC. In this setting, EGFR TKI therapy has been consistently superior to platinum-doublet chemotherapy, with markedly higher response rates and significantly improved PFS and OS. EGFR TKI therapy can be associated with rash, diarrhea, and paronychia, related to wild-type *EGFR* expression in nontumor tissue such as the gastrointestinal tract and skin, but consistently has lower rates of grade 3 or worse toxicity than chemotherapy.

First-generation EGFR TKIs (erlotinib and gefitinib) have an average 9-month benefit, often limited by the development of the resistance mutation T790M. Second-generation TKIs (eg, afatinib and dacomitinib) have increased toxicity associated with irreversible binding and target wild-type *EGFR, HER2*, and *HER4*. The RELAY trial explored the addition of ramucirumab, a monoclonal antibody targeting vascular endothelial growth factor receptor 2 (VEGFR2), to erlotinib. The combination led to a significant improvement in PFS from 12.4 to 19.4 months (HR, 0.59),[75] leading to its FDA approval. Importantly, this study excluded patients with brain metastases.

The third-generation TKI osimertinib was compared with first-generation TKI therapy in the randomized FLAURA trial.[76] Osimertinib had a superior PFS of 18.9 months compared with 10.2 months in the control arm (HR, 0.46). Duration of response (DoR) was greater with osimertinib (17.2 vs 8.5 months), and the incidence of grade 3 or worse adverse events was lower with osimertinib (34% vs 45%). Osimertinib also has greater activity in the CNS, supported by a decreased incidence of CNS progression with osimertinib (6%) compared with the control arm (15%). With longer follow-up, a survival advantage was seen with osimertinib (HR, 0.80), where the median survival was 38.6 months compared with 31.8 months with erlotinib or gefitinib.[77] Osimertinib is approved as a single-agent initial therapy for *EGFR*-mutated NSCLC.

The phase 3 FLAURA2 study,[73] which explored the addition of platinum and pemetrexed to osimertinib in 557 treatment-naive patients with *EGFR*-positive (exon 19 deletion or L858R mutation) NSCLC, reported a significant improvement in median investigator-assessed PFS (HR, 0.62; 95% CI, 0.49-0.79; $P < .001$), with no new safety concerns, although there was an increased incidence of grade 3 or higher adverse events driven by chemotherapy. The objective response rate (ORR) was 83% in the combination arm compared with 76% in the osimertinib arm, with median DoRs of 24 (95% CI, 20.9-27.8) and 15.3 months (95% CI, 12.7-19.4), respectively. There is a significant OS benefit with the combination: median OS 47.5 versus 37.6 months for osimertinib alone HR for death, 0.77; 95% confidence interval, 0.61 to 0.96; $P = .02$.[78] Patients with brain metastases were included; in fact, the median PFS was longer among patients with untreated asymptomatic CNS metastases (24.9 vs 13.8 months) and those with the L858R mutation (24.7 vs 13.9 months) who received osimertinib and chemotherapy than among those who received osimertinib monotherapy. Dose interruption and discontinuation rates were higher in the combination arm (43% and 11%, respectively) compared with the osimertinib monotherapy arm (19% and 6%, respectively). The safety profile of this combination was consistent with the established profile of each individual drug.

MARIPOSA, a randomized phase 3 study, showed that the combination of amivantamab with lazertinib improved median PFS (23.7 vs 16.6 months; HR, 0.70), the primary endpoint, and response rate (86% vs 85%) in treatment-naive patients with *EGFR*-mutated (exon 19 deletion or L858R) NSCLC compared with osimertinib monotherapy. The regimen also showed a significant OS advantage: median OS was not yet reached (95% CI, 42.9 months-not reported [NR]) with amivantamab + lazertinib versus 36.7 months (95% CI, 33.4-41.0) with osimertinib (HR, 0.75; 95% CI, 0.61-0.92; $P < .005$), with 3.5-year survival rates of ~56% and ~44%, respectively.[79] The median PFS was longer among patients with CNS metastases (27.5 vs 18.4 months). Dose interruption and discontinuation rates were higher in the combination arm (83% and 35%, respectively) compared with the osimertinib monotherapy arm (39% and 14%, respectively). There was an increased risk of venous thromboembolism, so prophylactic anticoagulation is required. Additionally, there are increased adverse effects associated with amivantamab (infusion reactions and skin toxicities), which have limited the use of this regimen in the frontline setting.[80] Taken together, these data support combination therapy in frontline classical *EGFR* mutant NSCLC, with singe-agent osimertinib still reasonable for patients with contraindications or objections to this intensified approach. Despite an initial dramatic response to EGFR inhibitors in patients with *EGFR*-mutated NSCLC, resistance generally develops after a median of 1 to 2 years.[81] After the initial use of first- or second-generation EGFR TKIs, approximately half of cases that develop resistance to these inhibitors are associated with a secondary *EGFR* T790M mutation in exon 20, which results in steric hindrance to EGFR TKI binding and altered ATP handling.[82,83] Acquired resistance to EGFR TKIs may also be driven by histologic transformation to SCLC and may respond to chemotherapy regimens active in that disease.[84] An increased incidence of this is seen in those tumors harboring inactivated *RB1* and *TP53* at initial diagnosis.[85] Additional mechanisms of resistance to third-line EGFR TKIs include *MET* amplification, *HER2* amplification, acquired translocation such as *ALK* or *RET*, and *EGFR* C797S mutation.[86,87] In addition to encouraging patients' participation in clinical trials, re-biopsy and repeat NGS are warranted to detect mechanisms of resistance to osimertinib after progression. For patients with *EGFR*-mutated NSCLC with T790M mutation after progression during prior first- or second-generation EGFR TKI therapy, osimertinib is the standard of care. In the randomized phase 3 trial,[88] Osimertinib was associated with a longer PFS (8.5 vs 4.2 months; HR, 0.42), a higher response rate (71% vs 31%), and fewer grade 3 or higher adverse events (23% vs 47%) than carboplatin-pemetrexed chemotherapy.

Patients now receive osimertinib in the first-line setting, making acquired drug resistance to this third-generation agent an area of active investigation. In the MARIPOSA-2 phase 3 study, 657 patients whose *EGFR*-mutated (exon 19 or exon 21 L858R) NSCLC progressed with osimertinib were randomly assigned at a 2:2:1 ratio to receive amivantamab and lazertinib and chemotherapy, chemotherapy, or amivantamab and chemotherapy. The combination, later approved, of amivantamab and carboplatin pemetrexed significantly improved PFS (6.3 vs 4.2 months; HR, 0.48; $P < .001$), the primary endpoint, ORR (64% vs 36%; $P < .001$), and median intracranial PFS (12.5 vs 8.3 months; HR, 0.55) compared with carboplatin pemetrexed. Dose interruption and discontinuation rates were higher in the combination arm (65% and 18%, respectively) compared with the chemotherapy arm (33% and 4%, respectively). The safety profile in the combination was dominated by hematologic EGFR and MET inhibition–related toxicities. Treatment-related adverse events leading to death were infrequent (2% vs 0.4%, respectively).[89] Updated results from CHRYSALIS-2 showed that amivantamab and lazertinib achieved an ORR of 35% with a median DoR of 8.3 months, a median PFS of 4.5 months, and a median OS of 14.8 months in patients with *EGFR* exon 19 deletion or L858R NSCLC after osimertinib and platinum chemotherapy. Activity was seen across resistance mechanisms and in patients with baseline CNS disease.[90,91]

Datopotamab Deruxtecan (Dato-DXd) received accelerated FDA approval in June 2025 for patient with *EGFR*-mutated NSCLC who have progressed after EGFR-directed therapy and platinum-based chemotherapy. This approval was based on pooled efficacy data from the TROPION-Lung05 (phase 2, single-arm) and TROPION-Lung01 (phase 3, randomized) trials involving 114 patients. Dato-DXd achieved a confirmed overall response rate of ~45% (95% CI, 35-54) and a median DoR of 6.5 months (95% CI, 4.2-8.4). Notable adverse events included interstitial lung disease/pneumonitis, ocular adverse reactions, stomatitis, and embryo-fetal toxicity.[92]

EGFR Exon 20 Insertion–Positive NSCLC

Activating insertions in *EGFR* exon 20 are less common and generally resistant to the currently approved EGFR TKIs for the classic mutations, likely because of the homology between exon 20–mutated *EGFR* and wild-type *EGFR*. Amivantamab is an EGFR-MET–bispecific antibody with immune cell–directing activity, binding to the extracellular domain of each receptor and bypassing resistance at the TKI binding site.[89,93] Amivantamab was initially approved following platinum-doublet chemotherapy based on the phase 1 chrysalis trial, which has been supplanted by frontline combination with carboplatin and pemetrexed.[94]

In the PAPILLON study, 308 patients with *EGFR* exon 20 insertion–positive NSCLC were randomly assigned to first-line treatment with chemotherapy with or without amivantamab. The combination of amivantamab with chemotherapy provided a superior median PFS than chemotherapy (11.4 vs 6.7 months; HR, 0.40). Treatment was discontinued in 7% of patients because of adverse events.

Sunvozertinib received FDA-accelerated approval in July 2025, for adults with locally advanced or metastatic NSCLC harboring *EGFR* exon 20 insertion mutations who have progressed on or after platinum-based chemotherapy. The approval was based on the results from the WU-KONG1B phase 1/2 trial, in which 85 evaluable patients achieved a confirmed overall response rate of approximately 46% and a median DoR of 11.1 months. This marks an important addition to the treatment landscape for patients with *EGFR* exon 20 insertion–positive NSCLC but is not yet commercially available.[95]

Less Common *EGFR* Mutations

Less common *EGFR* mutations were included in three trials of afatinib: LUX-Lung 2, LUX-Lung 3, and LUX-Lung 6.[96] Several rare *EGFR* mutations did confer sensitivity, including S768I, L861Q, and G719X. These uncommon *EGFR* mutations can also be responsive to the third-generation EGFR inhibitor osimertinib.[97] Afatinib is FDA approved for NSCLCs harboring nonresistant *EGFR* mutations, including these less common variants. Recent studies have shown that lazertinib monotherapy in treatment-naive NSCLC patients and amivantamab and lazertinib combination therapy either frontline or in previously treated NSCLC harboring uncommon *EGFR* mutations such as G719X, S768I, and L861Q have encouraging results.[98,99]

ALK REARRANGEMENT–POSITIVE NSCLC

Rearrangements in the *ALK* gene can lead to a fusion oncogene with transforming potential and are detected in approximately 2% to 7% of NSCLCs. Although there are multiple described fusion partners, the most common involves a chromosome 2p inversion that results in fusion of the protein encoded by the *EML4* gene with the intracellular signaling portion of the ALK receptor tyrosine kinase. Analogous to *EGFR* mutations, the *EML4::ALK* fusions result in constitutive tyrosine kinase activity, dependence of the cancer cell on activated downstream mitogenic pathways, and sensitivity to ALK inhibition.[100] *ALK* fusions are more common in patients with adenocarcinoma histology, younger age, and a history of light or never smoking.[101] *ALK*-rearranged NSCLC can be identified using IHC, fluorescence in situ hybridization, or NGS.[102]

The first TKI approved for NSCLCs harboring an *ALK* gene rearrangement was crizotinib, now largely supplanted by next-generation inhibitors with better CNS efficacy. Multiple agents have demonstrated efficacy, including ceritinib, alectinib, lorlatinib,[103,104] brigatinib, and ensartinib in the post–crizotinib and frontline setting.[105-107] In the ALEX trial, 303 *ALK*-positive patients were randomly assigned to first-line alectinib or crizotinib.[108] Investigator-assessed PFS was notably longer with alectinib (HR, 0.43), with a median PFS of 34.8 months compared with 10.9 months with crizotinib therapy.[109] In the ALTA-1L study, 275 *ALK*-positive patients were randomly assigned to treatment with first-line brigatinib or crizotinib.[110] Brigatinib had a superior PFS (HR, 0.49), with a much higher intracranial response rate (78% vs 29%). Because of an increased risk of pneumonitis with brigatinib on loading, during the first week of treatment, patients receive a dose of 90 mg followed by an increase to 180-mg dosing if tolerated. Similarly, ensartinib was compared with crizotinib in the eXALT3 trial, leading to the recent FDA approval of ensartinib in frontline treatment of *ALK*-altered NSCLC. In the CROWN study, 296 *ALK*-positive patients were randomly assigned to treatment with first-line lorlatinib or crizotinib. Lorlatinib had a superior PFS (HR, 0.27), with a much higher intracranial response rate in the lorlatinib arm (82% vs 23%).[104] Lorlatinib was associated with a higher rate of grade 3 or 4 adverse events than crizotinib (76% vs 57%), and dose reductions with lorlatinib were often necessary because of neurocognitive adverse effects. After 5 years of follow-up, the median PFS was not reached (>60 months) with frontline lorlatinib, making this a preferred frontline approach.[111]

Acquired resistance is still a significant clinical challenge with all ALK TKIs, given the heterogeneity of resistance mechanisms to ALK TKIs. Secondary *ALK* resistance mutations are seen in approximately 30% of patients whose tumors develop resistance to crizotinib, with the most common being non–G1202R mutations. Lorlatinib is the only approved drug with activity in this

mutation. Solvent-front point mutations in *ALK* have been described in a subset of cases, although other mechanisms have also been identified.[112] Lorlatinib has in vitro activity against a broad spectrum of *ALK* TKI resistance mutations and is approved for the treatment of *ALK*-rearranged NSCLC in patients whose disease has progressed during treatment with crizotinib and another ALK inhibitor or during treatment with first-line alectinib or ceritinib.[104,113] For patients who had received two or more ALK TKIs, the response rate was 42% (n = 11 of 26 patients).

ROS-1 REARRANGEMENT–POSITIVE NSCLC

ROS-1 gene rearrangements are oncogenic drivers present in approximately 1% of NSCLC tumors.[114] *ROS-1* is an orphan tyrosine kinase of the insulin receptor family located on chromosome 6 and with notable sequence homology to *ALK*. Gene rearrangements of *ROS-1* lead to constitutive activation of this tyrosine kinase. Like many oncogene-addicted lung cancers, *ROS-1*–rearranged tumors commonly arise in younger individuals with limited/no tobacco use history and lung adenocarcinoma histology. Crizotinib, entrectinib, repotrectinib, and taletrectinib are all FDA-approved options for initial therapy. Crizotinib was approved after a single-arm study showed a high response rate (72%), with a median PFS of 19.2 months.[115] Entrectinib was approved based on an analysis of 161 patients across three separate phase 1/2 trials; the overall response rate was 67.1%, with a median PFS of 15.7 months.[116] Repotrectinib was recently FDA approved for the treatment of advanced NSCLC with an *ROS-1* fusion after the lung cohort of a single-arm study, TRIDENT-1, showed a high response rate of 79%, with a median DoR of 34.1 months and a median PFS of 35.7 months in ROS-1 TKI–naive patients (n = 71) and a response rate of 38% with a median DoR of 14.8 months and a median PFS of 9.0 months in chemotherapy-naive patients exposed to a prior ROS-1 TKI (n = 56).[117] Most recently, taletrectinib was FDA approved in June 2025 in locally advanced or metastatic ROS-1-positive NSCLC, including after prior ROS-1 TKI therapy. In the phase 2 TRUST-I/II trials, taletrectinib achieved ORRs of ~85 to 90% in TKI-naive patients and ~50 to 60% in previously treated patients, with durable responses and meaningful intracranial activity, offering another option across lines of therapy.[6]

KRAS MUTATION–POSITIVE NSCLC

Dysregulation of the RAS family of GTPases is responsible for driving nearly 30% of all cancer types. Of the three major RAS family isoforms, mutated *KRAS* comprises 84% of all RAS-driven diseases and propagates many aggressive tumor types, including lung, colorectal, and pancreatic cancers. Discovered nearly four decades ago as the oncogenes *NRAS, KRAS*, and *HRAS*, the RAS family has expanded to include approximately 150 members involved in important cellular processes such as cell division, differentiation, migration, and apoptosis. Although long regarded as undruggable because of the unique structure and surface topology of KRAS, recent advances in medicinal chemistry have identified a binding pocket in the glycine-to-cysteine missense-mutated KRAS protein at amino acid 12 (G12C), which comprises the most common *KRAS* mutation in lung adenocarcinoma. Covalent binders to the mutant cysteine were developed that extend into the binding pocket containing the switch II region, generating a selective response in *KRAS* G12C–mutated tumors. In the CodeBreaK100 phase 2 trial, heavily pretreated patients with *KRAS* G12C–mutated NSCLC were treated with sotorasib and had an ORR of 37% and a median PFS of 6.8 months.[118] Treatment was generally well tolerated, and only 20% of patients experienced grade 3 or worse adverse events. In the phase 2 KRYSTAL-1 registration trial, another KRAS G12C inhibitor, adagrasib, showed a 43% ORR, a median PFS of 6.5 months, and a similar toxicity profile.[119] The rates of discontinuation of sotorasib and adagrasib were 7.1% and 6.9%, respectively. The results of these studies led to the FDA approval of sotorasib and adagrasib for patients with NSCLC with *KRAS* G12C mutations in the second-line setting.[120]

To date, many heterogeneous mechanisms of resistance have already emerged and largely converge on reactivation of the downstream mitogen-activated protein kinase pathway, as well as alterations in the tumor microenvironment.[121,122] In the CodeBreaK200 phase 3 trial, sotorasib showed improvement in PFS (primary endpoint), with no difference in OS (secondary endpoint), compared with docetaxel in patients with *KRAS* G12C metastatic NSCLC who experienced progression with platinum chemotherapy and immunotherapy.[123] Many combination strategies with these inhibitors are being actively investigated in trials.

BRAF MUTATION–POSITIVE NSCLC

BRAF mutations are present in 2% to 4% of lung adenocarcinomas. Unlike *EGFR*-mutated or *ALK*-rearranged disease, *BRAF*-mutated lung adenocarcinoma is frequently seen in patients with a smoking history.[124] Unlike melanoma, in which a majority of *BRAF* mutations are V600E, only approximately half of the *BRAF* mutations in NSCLC are the targetable V600E. In a phase 2 trial of combination dabrafenib and trametinib, in 57 patients with previously treated *BRAF* V600E–positive NSCLC, the response rate was 63.2%, and the median PFS was 9.7 months.[125] In a subsequent cohort of treatment-naive *BRAF* V600E–positive patients, the combination of dabrafenib and trametinib had similar outcomes, with a response rate of 64% (including two patients with a CR) and a PFS of 10.9 months.[126] The combination of encorafenib and binimetinib is also FDA approved for the treatment of advanced NSCLC with *BRAF* V600E mutation based on the single-arm PHAROS study, which showed a high response rate (75%), with a median DoR not reached, in BRAF TKI–naive patients (n = 59) and a response rate of 46%, with a median DoR of 16.7 months, in previously treated patients (n = 39).[127] Less pyrexia was reported with this combination compared with other BRAF/MEK combinations. Of note, *BRAF*-mutated lung cancers are associated with high levels of PD-L1 expression and can have a favorable response to immunotherapy.[128]

OTHER DRIVER ALTERATIONS

NTRK1/2/3 Gene Fusion–Positive NSCLC

NTRK fusions have been described in fewer than 1% of lung cancers, but when present, they predict response to NTRK inhibitors. Larotrectinib is a selective NTRK inhibitor approved in a tumor-agnostic manner for use in advanced cancers harboring an *NTRK* fusion. In a report of 55 patients with *NTRK* fusion–positive cancer (n = 4 with lung cancer), the response rate was 75%, with no drug-related grade 3 or 4 adverse events.[129] Entrectinib is another potent NTRK inhibitor with efficacy across tumor types and approval for a tumor-agnostic indication. In an analysis of 54 *NTRK*-positive patients (n = 10 with NSCLC), the response rate was 57%, with a median PFS of 11 months.[130] Entrectinib is also highly CNS penetrant, with an intracranial response rate of 55%.

RET Rearrangement–Positive NSCLC

RET gene fusions have been identified in 1% to 2% of NSCLCs and are more frequently seen in younger patients with no smoking history.[131] Selpercatinib is a selective RET inhibitor that received FDA-accelerated approval for NSCLCs harboring a *RET* fusion. In the phase 1/2 LIBRETTO trial, after showing response rates of 64% overall and 85% in treatment-naive patients,[132] the median DoR was 17.5 months, and only 2% of patients stopped therapy for drug-related adverse events. A second selective RET inhibitor, pralsetinib, also received accelerated approval after efficacy was observed in the phase 1/2 ARROW trial.[133] In *RET* fusion–positive NSCLC, pralsetinib offered a response rate of 65%; the median DoR was not reached, and only 4% of patients receiving pralsetinib discontinued therapy because of treatment-related adverse events.

MET Exon 14 Skipping Mutation–Positive NSCLC

Capmatinib is a MET kinase inhibitor that has received approval in NSCLC with a *MET* exon 14 skipping mutation based on the activity seen in the GEOMETRY trial. In previously treated patients, capmatinib had a response rate of 41%, with a PFS of 5.4 months.[134] In the first-line setting, outcomes were better, with a response rate of 68% and a median PFS of 9.7 months. Tepotinib was also granted accelerated approval based on the efficacy seen in the VISION trial, which enrolled patients with NSCLC harboring an *MET* exon 14 skipping mutation detected by either liquid or tissue biopsy. The response rate was similar, regardless of the method of detection (48% in the liquid cohort and 50% in the tissue cohort), and the median DoR was 11.1 months.[135]

c-MET Protein High NSCLC

A recent advance in lung cancer therapy is the development of agents targeting tumors with high c-MET protein expression. In May 2025, the US FDA granted accelerated approval to telisotuzumab vedotin in previously treated, non–squamous NSCLC characterized by high MET overexpression, defined as strong (3+) immunohistochemical staining in at least 50% of tumor cells and without *EGFR*-activating mutations. Approval was supported by the phase 2 LUMINOSITY trial, which showed an overall response rate of approximately 35% and a median DoR of 7.2 months in patients with MET IHC-high tumors. The most common adverse effects were peripheral neuropathy, fatigue, decreased appetite, and edema. This agent represents the first FDA-approved therapy directed specifically at MET IHC-high NSCLC, broadening treatment options for patients whose tumors do not harbor *MET* exon 14 skipping alterations but display high protein overexpression.[5]

HER2 Mutation–Positive NSCLC and *HER2*-Positive (IHC3+) NSCLC

HER2 mutations have been described in approximately 1% to 2% of NSCLCs. *HER2* can be amplified in lung cancer, as it is in breast cancer, but the *HER2* mutations found in NSCLC are distinct from *HER2* amplification and most commonly are insertions in exon 20.[136] The antibody-drug conjugate ado-trastuzumab emtansine was initially used off label[137] In the phase 2 DESTINY-Lung01 study, 91 patients with *HER2*-mutated NSCLC who progressed on *chemotherapy* were treated with trastuzumab deruxtecan. Based on a response rate of 55% and a median DoR of 9.3 months, trastuzumab deruxtecan was granted accelerated approval for patients with *HER2*. Noteworthy toxicities of this drug included grade 3 or worse drug-related adverse events in 46% of patients, which included neutropenia (19%) and interstitial lung disease (26%). Trastuzumab deruxtecan also showed a response rate between 26% and 34% in the *HER2*-positive (IHC3+) NSCLC cohorts (n = 90) after progression during prior therapy.[138] This study and others in different solid tumors led the FDA to grant accelerated approval of trastuzumab deruxtecan as a tissue agnostic option for refractory *HER2*-positive (IHC3+) solid tumors.

In the phase 1b Beamion LUNG-1 trial, zongertinib produced robust activity in previously treated HER2-mutant NSCLC leading to accelerated FDA approval in August 2025. Among patients with tyrosine kinase domain mutations, the ORR was 71% with a median DoR of 14.1 months and a median progression-free survival of 12.4 months. Responses were also seen in patients with brain metastases, and activity was retained after prior HER2-directed ADC therapy (ORR 48%). Treatment was generally well tolerated, with grade ≥3 drug-related adverse events in 17%, most commonly elevated liver enzymes, and importantly no drug-related interstitial lung disease was observed.[3]

NRG1 Fusion–Positive NSCLC

NRG1 fusions are rare molecular aberrations described in a variety of tumors, including NSCLC and pancreatic cancer. Their detection is likely to be doubled if both DNA- and RNA-NGS methods are used. In NSCLC, *NRG1* fusions have been identified in

0.2% to 0.3% of cases and specifically in the invasive mucinous lung adenocarcinoma histology subtype. Patients with *NRG1* fusion NSCLC have a poor prognosis when treated with chemotherapy and/or immunotherapy.

Zenocutuzumab is an *HER2* × *HER3* bispecific antibody that was granted accelerated approval in previously treated patients with recurrent or metastatic *NRG1* fusion NSCLC. In the phase 2 eNRGy study, 64 patients with NSCLC achieved an ORR of 33% and a median DoR of 7.4 months. PFS and OS data are not yet known.[139,140]

KEY POINTS

- For *EGFR* exon 19–deleted and *EGFR* L858R–mutated NSCLC, the preferred first-line option is osimertinib with or without chemotherapy or amivantamab with lazertinib.
- Amivantamab with chemotherapy is an option for *EGFR* exon 19–deleted and exon 21 L858R–mutated NSCLC after progression during treatment with osimertinib.
- Acquired resistance to first- and second-generation EGFR TKIs is often mediated by the T790M resistance mutation, and osimertinib is indicated in this setting.
- For *EGFR* exon 20 insertion mutations: Amivantamab and chemotherapy are approved as frontline therapy (PAPILLON). Sunvozertinib received FDA-accelerated approval (July 2025) for patients who progressed on platinum-based chemotherapy.
- For *ALK*-rearranged NSCLC, the preferred first-line options include alectinib, brigatinib, and lorlatinib.
- For ROS-1-rearranged NSCLC, taletrectinib was FDA approved (June 2025) and joins crizotinib, entrectinib, and repotrectinib.
- For *KRAS* G12C–mutated advanced NSCLC, both sotorasib and adagrasib are approved treatments in the second-line setting.
- For advanced NSCLC with *BRAF* V600E mutation, a combination of either dabrafenib and trametinib or encorafenib and binimetinib is approved; the latter has less reported pyrexia.
- For advanced NSCLC with *NTRK* fusion, larotrectinib and entrectinib are approved treatments. For advanced NSCLC with *RET* fusion, selpercatinib and pralsetinib are approved treatments. For advanced NSCLC with *MET* exon 14–skipping mutation, capmatinib and tepotinib are approved treatments.
- For MET IHC–high EGFR–wild-type NSCLC, the antibody-drug conjugate telisotuzumab vedotin-tllv (Emrelis) received accelerated approval.
- For advanced NSCLC with *HER2* mutation, zongertinib and trastuzumab deruxtecan are approved in the second-line setting; trastuzumab deruxtecan may also be used as second-line treatment for *HER2*-positive (IHC3+) advanced NSCLC.
- For advanced NSCLC with *NRG1* fusion, zenocutuzumab is approved as treatment in the second-line setting.

IMMUNOTHERAPY

FIRST-LINE IMMUNOTHERAPY

Anti–PD-(L)1 Monotherapy

The introduction of checkpoint inhibitors, specifically antibodies targeting PD-1 and PD-L1, has dramatically changed the treatment paradigm for NSCLC (Fig. 11-4). Although initial studies were conducted in previously treated patients, immunotherapy has now become part of first-line treatment for NSCLC. There are now several validated strategies that incorporate immunotherapy for NSCLC, but the first was the use of PD-1 inhibitor monotherapy (Table 11-2).

In the KEYNOTE-024 trial, 305 patients with PD-L1 expression of at least 50% of tumor cells (ie, TPS, 50%) and wild-type *EGFR* and *ALK* were randomly assigned to receive either pembrolizumab, a PD-1 inhibitor, or platinum-based chemotherapy.[141] The primary endpoint of PFS was superior in the pembrolizumab arm compared with the chemotherapy arm, with a median PFS of 10.3 versus 6.0 months (HR, 0.50). Even with crossover, survival was significantly improved in the pembrolizumab arm, with a median survival of 26.3 versus 13.4 months (HR, 0.62).[142] The 5-year OS rate was 31.9% with pembrolizumab and 16.3% with chemotherapy. Treatment-related adverse events of any grade were less frequent with pembrolizumab (73.4% vs 90.0% of patients). Pembrolizumab was initially FDA approved as first-line treatment for stage IV NSCLC with a PD-L1 TPS of at least 50%.

KEYNOTE-042 compared first-line pembrolizumab monotherapy with chemotherapy for patients with PD-L1–positive NSCLC using a PD-L1 TPS cutoff of 1%.[143] The study met its primary endpoint of improved OS in the pembrolizumab arm, with a median OS of 16.7 versus 12.1 months (HR, 0.81). The benefit was driven, however, by patients with a PD-L1 TPS of 50% or higher. This study provides rationale for frail patients with a PD-L1 TPS of 1% to 49%, who may not be candidates for chemotherapy combinations.

Other PD-L1 and PD-1 antibodies demonstrated comparable results. In the phase 3 IMpower 110 trial of atezolizumab, 572 patients with advanced NSCLC with at least 1% PD-L1 expression were randomly assigned to atezolizumab or platinum-based chemotherapy.[144] For patients with PD-L1–high NSCLC, survival favored atezolizumab, with a median survival of 20.2 versus 13.1 months with chemotherapy (HR, 0.59). Atezolizumab received FDA approval as initial treatment for disease with PD-L1

Figure 11-4 Treatment Paradigms for Advanced Non–Small Cell Lung Cancer by Cancer Subtype and PD-L1 TPS

expression of 50% or greater. Similarly, cemiplimab was also approved for PD-L1–high NSCLC based on the phase 3 EMPOWER-Lung01 trial. In this study, 710 patients with advanced NSCLC and a smoking history (never smokers were ineligible) were randomly assigned to cemiplimab or platinum-doublet chemotherapy. In the PD-L1–high subset (n = 563), survival favored cemiplimab (HR, 0.57), despite the high crossover rate (74%).[142]

Not all trials of first-line immunotherapy in metastatic NSCLC have had positive results. In the CheckMate 026 trial, 541 patients whose tumors were PD-L1 positive (defined as expression in 1% of cells using the Dako 28-8 PD-L1 IHC clone) were randomly assigned to receive the PD-1 inhibitor nivolumab or platinum-based chemotherapy.[144] The primary endpoint was PFS for patients with a PD-L1 expression of 5% or greater was not reached, and there was no difference in survival (median, 14.4 months for nivolumab vs 13.2 months for chemotherapy; HR, 1.02).

Dual-Checkpoint Blockade

CTLA-4 is another immune checkpoint, the blockade of which has been associated with immune-mediated antitumor responses across multiple cancer types. Combined blockade of PD-1 with nivolumab and CTLA-4 with ipilimumab is another FDA-approved first-line strategy for PD-L1–positive NSCLC. In the CheckMate 227 trial, patients with advanced *EGFR* and *ALK* wild-type NSCLC with at least PD-L1 TPS 1% were randomly assigned at a 1:1:1 ratio to receive nivolumab and ipilimumab, nivolumab monotherapy, or chemotherapy.[145] The primary endpoint of improved survival with nivolumab and ipilimumab compared with chemotherapy was met (17.1 vs 14.9 months; HR, 0.79). The response rate with nivolumab and ipilimumab was 35.9%, with a median DoR of 23.2 months. For patients with PD-L1–negative NSCLC, a benefit was also observed (17.2 vs 12.2 months; HR, 0.62), although this analysis was exploratory.

Chemoimmunotherapy Combinations

Combinations of checkpoint inhibitors with cytotoxic chemotherapy have also shown great promise for patients across the strata of PD-L1 expression. Concurrent administration of chemotherapy and immunotherapy has several potential advantages.[146] Chemotherapy can lead to the depletion of immunosuppressive cells and promote neoantigen presentation to facilitate an immune-mediated antitumor response. Data also show that pemetrexed administration can induce an immune activation gene expression signature.[147] Early trials of combined chemotherapy with PD-L1 inhibitors demonstrated the potential for long-term survival, with no significant increase in the toxicity profile.[148]

The first approved chemoimmunotherapy combination for NSCLC was carboplatin, pemetrexed, and pembrolizumab in non–squamous NSCLC. In the confirmatory phase 3 KEYNOTE-189 study, 616 patients with treatment-naive non–squamous NSCLC were randomly assigned at a 2:1 ratio to platinum (carboplatin or cisplatin), pemetrexed, and pembrolizumab (with pembrolizumab and pemetrexed maintenance) or platinum, pemetrexed, and placebo (with placebo and pemetrexed maintenance).[149] The response rate was higher with pembrolizumab in the overall study population (48% vs 19%) and in all PD-L1 subsets (61% vs 23% with PD-L1 TPS ≥ 50%, 48% vs 21% with PD-L1 TPS 1% to 49%, and 32% vs 14% in PD-L1–negative tumors). Survival also favored chemoimmunotherapy, with an HR of 0.49, also seen across PD-L1 subsets.

A four-drug regimen of carboplatin, paclitaxel, bevacizumab, and atezolizumab was approved based on the IMpower 150 study; this regimen was compared with carboplatin, paclitaxel, and bevacizumab.[150] Unlike KEYNOTE-189, IMpower 150 included some patients with *EGFR* or *ALK* alterations, after progression during the appropriate TKI therapy. The addition of atezolizumab to the backbone of carboplatin, paclitaxel, and bevacizumab led to an improvement in PFS (8.3 vs 6.8 months; HR, 0.62) as well as a significant increase in OS (19.2 vs 14.7 months; HR, 0.78). This combination has also been approved for treatment-naive non–squamous NSCLC, independent of PD-L1 expression. Its FDA approval does not include the exploratory subset of *EGFR*- or *ALK*-positive NSCLC, although some approvals outside of the United States do include this subset.

Atezolizumab also has improved outcomes when added to carboplatin and nab-paclitaxel. In the IMpower 130 trial,[151] 724 patients were randomly assigned to carboplatin, nab-paclitaxel, and atezolizumab or placebo. The addition of atezolizumab improved survival from 13.9 to 18.6 months (HR, 0.79), leading to its FDA approval for patients with advanced non–squamous NSCLC.

Chemoimmunotherapy also has improved outcomes in squamous NSCLC. In KEYNOTE-407, 559 patients with untreated stage IV squamous NSCLC were treated with carboplatin and either paclitaxel or nab-paclitaxel (investigator's choice) and were randomly assigned to receive either pembrolizumab or placebo, with pembrolizumab or placebo maintenance for up to 31 cycles.[152] The response rate was higher with pembrolizumab in the overall study population (58% vs 38%) and in PD-L1–high (60% vs 33%), PD-L1–low (50% vs 41%), and PD-L1–negative (63% vs 40%) subsets. Survival also favored the addition of pembrolizumab (HR, 0.64). This regimen has been approved as initial therapy for squamous NSCLC regardless of PD-L1 expression.

Adding chemotherapy to dual-checkpoint blockade has also improved outcomes. In the CheckMate 9LA trial, 719 patients were randomly assigned to receive a four-drug regimen of nivolumab, ipilimumab, and platinum-doublet chemotherapy or chemotherapy alone.[153] In the chemoimmunotherapy arm, chemotherapy was limited to only two cycles. The investigational arm was superior, with an improvement in median survival (15.6 vs 10.9 months; HR, 0.66) that was observed in both non–squamous (HR, 0.69) and squamous (HR, 0.62) histologic subtypes and across PD-L1 strata, although 19% of patients discontinued part of therapy because of treatment-related adverse events.

Similarly, in the phase 3 POSEIDON study, 1,013 patients were randomly assigned (1:1:1) to receive a platinum-based doublet for four cycles in combination with durvalumab and tremelimumab, just durvalumab, or chemotherapy alone.[154] In the chemoimmunotherapy arms, chemotherapy was limited to four cycles, whereas in the chemotherapy arm, up to six cycles of therapy could be administered. Although the median OS improvement with the addition of durvalumab to chemotherapy was nonsignificant (HR, 0.86), adding tremelimumab and durvalumab to chemotherapy reached statistical significance (14.0 vs 11.7 months; HR, 0.77). Treatment-related adverse events led to discontinued treatment in 15.5% of patients receiving chemotherapy and dual-checkpoint inhibitor blockade, compared with 9.9% receiving chemotherapy alone.

IMMUNOTHERAPY AS SECOND-LINE THERAPY IN PATIENTS WITH ACTIONABLE GENOMIC ALTERATIONS

The role of immunotherapy in patients with certain actionable genomic alterations is associated with inferior efficacy as well as excess toxicity. Immunotherapy should not supplant first-line TKI therapy for several molecularly defined subgroups (ie, EGFR and ALK); this may be particularly true for those molecular aberrations that more commonly occur in individuals with limited/no tobacco use history (Table 11-3).[155] In a retrospective analysis of patients with *EGFR* mutations or *ALK* rearrangements, the response to PD-(L)1 inhibition was reported as only 3.6%, compared with 23.3% in an *EGFR* and *ALK* wild-type population.[156] Patients with *EGFR* and *ALK* alterations were excluded from the first-line randomized trials of pembrolizumab and the combination of pembrolizumab, carboplatin, and pemetrexed.[141,148] In KEYNOTE-789, the addition of pembrolizumab to platinum-pemetrexed in patients with *EGFR*-mutated metastatic non–squamous NSCLC who experienced progression during targeted therapy did not significantly prolong PFS or OS compared with placebo and platinum-pemetrexed.[157] Similarly, in CheckMate 722, the addition of nivolumab to chemotherapy did not improve PFS compared with chemotherapy alone in the same population.[158] A phase 2 study explored the role of first-line pembrolizumab for patients with *EGFR*-mutated PD-L1–positive NSCLC and reported no responses.[159] In addition, the use of TKIs, such as osimertinib, after a PD-1 or PD-L1 inhibitor was associated with a high rate of immune-related adverse events, including some cases of fatal pneumonitis. Immunotherapy after TKI therapy was not associated with this risk.[160] For this reason, all patients with non–squamous NSCLC must have molecular testing results before starting immunotherapy. Chemotherapy may be started if patients need treatment during the waiting period.

Table 11-3 Targeted Therapy for Unresectable or Metastatic NSCLC With Targetable Molecular Aberration

Target	Preferred Targeted Therapy
EGFR exons 19 and 21	Osimertinib, osimertinib and chemotherapy, amivantamab and lazertinib
EGFR exon 20	Amivantamab[a]
ALK fusions	Lorlatinib; alectinib, brigatinib, ensartinib
ROS-1 fusions	Crizotinib, entrectinib, repotrectinib, taletrectinib
KRAS G12C	Sotorasib,[b] adagrasib[b]
BRAF V600E	Dabrafenib + trametinib, encorafenib + binimetinib
RET	Selpercatinib, pralsetinib
MET exon 14 skipping mutation	Capmatinib, tepotinib
MET IHC high (3+)	Telisotuzumab vedotin-tllv
HER2 mutation	Zongertinib, trastuzumab deruxtecan[b]
HER-2 IHC high (3+)	Trastuzumab deruxtecan
NTRK1/2/3 fusions	Larotrectinib, entrectinib
NRG fusions	Zenocutuzumab

Abbreviations: EGFR, epidermal growth factor receptor; NSCLC, non–small cell lung cancer.
[a]Preferred in first line in combination with carboplatin and pemetrexed.
[b]Approved after progression during first-line systemic therapy.

KEY POINTS

- NSCLC without an activating alteration in *EGFR* or *ALK* and with high PD-L1 expression (TPS ≥ 50%) can be treated with pembrolizumab, atezolizumab, or cemiplimab, all of which confer an improvement in survival over platinum-doublet chemotherapy.
- Dual-checkpoint blockade with nivolumab and ipilimumab improved survival compared with chemotherapy in PD-L1–positive (TPS ≥ 1%) NSCLC and is also a first-line treatment option. It may be used in the PD-L1–negative squamous NSCLC population as well.
- The combination of an immune checkpoint inhibitor with platinum-doublet chemotherapy improves PFS and survival in patients with squamous and non–squamous NSCLC (*EGFR* and *ALK* wild type) across all PD-L1 subsets.
- The combination of nivolumab and ipilimumab with two cycles of platinum-doublet chemotherapy, or durvalumab and tremelimumab with four cycles of platinum-doublet chemotherapy, is also approved across histologies and PD-L1 levels.
- Use of immunotherapy is not appropriate for certain molecular subtypes of advanced NSCLC (ie, EGFR/ALK), regardless of tumor PD-L1 expression; use of immune checkpoint inhibitors in these subgroups can be associated with both inferior efficacy and excess toxicity.

FIRST-LINE PLATINUM-DOUBLET CHEMOTHERAPY

Most patients with advanced NSCLC without actionable molecular alterations should receive immunotherapy (alone or with chemotherapy) as their initial therapy. For patients who are not candidates for immunotherapy, platinum-doublet chemotherapy remains a relevant option. The landmark ECOG 1594 study randomly assigned 1,207 patients with treatment-naive NSCLC to cisplatin and paclitaxel, cisplatin and gemcitabine, cisplatin and docetaxel, or carboplatin and paclitaxel.[161] The response rate and survival were similar across all arms. Data now support different treatment approaches for specific histologic subtypes of NSCLC, based on efficacy (pemetrexed and gemcitabine) and safety (bevacizumab). A phase 3 trial of more than 1,700 patients with chemotherapy-naive disease compared combination pemetrexed and cisplatin and combination gemcitabine and cisplatin.[162] Although OS was similar in the two arms, in a prespecified subset analysis, survival was statistically superior for cisplatin and pemetrexed compared with cisplatin and gemcitabine for patients with adenocarcinoma (12.6 vs 10.9 months) and large cell carcinoma histologies (10.4 vs 6.7 months). Conversely, patients with squamous cell histology experienced a significant improvement in survival with cisplatin and gemcitabine compared with cisplatin and pemetrexed (10.8 vs 9.4 months). In a phase 3 trial of 1,052 patients with NSCLC comparing carboplatin combined with either paclitaxel or nab-paclitaxel, patients with squamous histology had a significantly higher response rate with carboplatin and nab-paclitaxel (41% vs 24%; $P < .001$), although the OS in each arm was not different. Taken together, for adenocarcinoma histology, the preferred regimen is platinum with pemetrexed; for squamous histology, the preferred regimen is platinum with either gemcitabine, paclitaxel, or nab-paclitaxel.

In advanced-stage disease treated with palliative intent, carboplatin is an appropriate alternative to cisplatin because of the adverse effects of the latter on quality of life.

The phase 3 clinical trial (PARAMOUNT) explored continuation maintenance pemetrexed. Patients with advanced non–squamous NSCLC were randomly assigned to four cycles of cisplatin and pemetrexed followed by observation compared with continuation maintenance pemetrexed every 3 weeks until progression or intolerable toxicity-related effects occurred.[163] Continuation maintenance with pemetrexed improved PFS and OS, with a median OS of 16.9 months compared with 14 months after induction.

BEVACIZUMAB

Bevacizumab is a monoclonal antibody that targets VEGF and inhibits the process of angiogenesis. Bevacizumab was approved for the management of non–squamous NSCLC based on the ECOG 4599 phase 3 trial of 878 patients randomly assigned to chemotherapy (paclitaxel and carboplatin) or chemotherapy and 15 mg/kg of bevacizumab every 3 weeks.[164] The median survival for patients who received chemotherapy and bevacizumab was 12.3 months compared with 10.3 months for patients who received chemotherapy alone. Bevacizumab also improved both PFS (6.2 vs 4.5 months) and the response rate (35% vs 15%). However, because of grades 3 to 4 bleeding episodes observed in a phase 2 study,[165] use of bevacizumab is restricted to patients with non–squamous histology (because of higher levels of severe hemoptysis observed in squamous NSCLC).

A second randomized study of bevacizumab involving more than 1,000 patients was conducted (the AVAIL trial).[166] Unlike the ECOG 4599 study, this study involved gemcitabine and cisplatin, and patients were randomly assigned to chemotherapy and placebo, chemotherapy with 7.5 mg/kg of bevacizumab every 3 weeks, or chemotherapy with 15 mg/kg of bevacizumab every 3 weeks. The study met its primary endpoint of PFS; however, the absolute benefit was modest (median PFS, 6.7 and 6.5 vs 6.1 months), with no improvement in survival. It is unclear whether the lack of survival benefit was a result of the differences in chemotherapy doublets between the ECOG 4599 study and the AVAIL trial, differences in bevacizumab dose, or differences in study design, of which there were many.

CHEMOTHERAPY IN OLDER PATIENTS

The median age of patients with lung cancer is approximately 70 years, and treatment of patients aged 65 years or older tends to be complicated by comorbid conditions and polypharmacy. However, studies show that fit older patients are likely to benefit as much from chemotherapy as their younger counterparts. Despite an increase in toxicity-related effects, platinum-based doublet chemotherapy yields superior outcomes to single-agent chemotherapy in fit older individuals. In a phase 3 trial, 451 previously untreated patients aged 70 to 89 years (median, 77 years) with Eastern Cooperative Oncology Group (ECOG) PS of 0 to 2 were randomly assigned to carboplatin and paclitaxel or monotherapy with vinorelbine or gemcitabine.[167] In each arm of the study, 27% of patients had an ECOG PS of 2. The median survival was 10.3 months in the carboplatin and paclitaxel arm compared with 6.2 months in the monotherapy arm. Subset analyses of other randomized trials showed the response rate, toxicity, and survival for fit older patients receiving platinum-based treatment for NSCLC seemed to be similar to the same variables for younger patients. For patients aged 70 years or older, however, comorbidity is greater, and the frequencies of leukopenia and neuropsychiatric toxicity are higher. Therefore, advanced age alone should not preclude appropriate treatment, but upfront dose reduction and or granulocyte colony-stimulating factor (GCSF) support may be considered.

SECOND- AND THIRD-LINE THERAPIES

For patients whose disease progresses during platinum-doublet therapy and immunotherapy (administered concurrently or sequentially), docetaxel with or without ramucirumab remains the current standard of care.

In two randomized trials, second-line docetaxel was evaluated for patients who did not respond to first-line platinum-doublet chemotherapy. Docetaxel significantly prolonged survival compared with best supportive care.[168] Moreover, docetaxel also improved quality of life and reduced weight loss and the need for pain medication. Previous exposure to paclitaxel did not affect response to docetaxel, suggesting non–cross-resistance between the two agents.

Ramucirumab is a monoclonal antibody that targets VEGFR2. This antiangiogenesis agent, in combination with docetaxel, has been approved for the treatment of metastatic NSCLC with progression of disease during or after platinum-based treatment. Unlike bevacizumab, which is contraindicated in squamous histology NSCLC, ramucirumab is approved and has shown benefit in both squamous and non–squamous subtypes. Approval was based on the results from the randomized phase 3 REVEL trial, in which 1,253 patients with stage IV NSCLC after progression during platinum-based chemotherapy were randomly assigned to docetaxel therapy with or without ramucirumab.[169] Survival (10.5 vs 9.5 months), PFS (4.5 vs 3.0 months), and response rates (23% vs 14%) were all improved with the addition of ramucirumab.

Ramucirumab with pembrolizumab showed an improvement in OS compared with single-agent chemotherapy (HR, 0.69) after progression with platinum and immunotherapy in the phase 2 trial Lung-Map nonmatch substudy S1800A.[170] However, the confirmatory phase 3 study Pragmatica-Lung was negative.

Tumor treating fields (TTFields) are approved to use in combination with immune checkpoint inhibitors or docetaxel based on the improved outcomes noted in the phase 3 LUNAR trial of patients with metastatic NSCLC after progression during platinum-based chemotherapy.[171] The TTFields were delivered to the thorax at continuous frequencies of 150 kHz for at least 18 hours per day, which in preclinical models enhanced antitumor immune response by disrupting the mitosis and downstream induction of immunogenic cell death. There was a statistically significant improvement in the primary endpoint, median OS, with the addition TTFields therapy to standard systemic therapy (13.2 vs 9.9 months, respectively; $P = .04$). Most treatment-related adverse events were mild. Six patients (4%) experienced grade 3 skin toxicity that required a break from treatment.

The improvement in median OS was statistically significant ($P = .02$) in 70 patients who received TTFields therapy with an immune checkpoint inhibitor (19 months; 95% CI, 10.6-28.2) compared with 71 patients who received an immune checkpoint inhibitor alone (10.8 months; 95% CI, 8.3-17.6). Of note, this trial was performed before the incorporation of immunotherapy into the frontline setting, which limits the interpretation of the potential benefit for this approach in ICI-exposed patient populations.

KEY POINTS

- Pemetrexed is an appropriate platinum partner in non–squamous histology; gemcitabine is appropriate for treatment of tumors with squamous histology. Paclitaxel or nab-paclitaxel is a reasonable choice for either histology.
- Fit older patients tolerate chemotherapy and derive the same survival benefit as their younger counterparts.
- The addition of the VEGFR2 antibody ramucirumab to second-line docetaxel improves survival.
- TTFields in combination with immune checkpoint inhibitors or docetaxel have improved outcomes in NSCLC after progression during platinum-based chemotherapy.

SMALL CELL LUNG CANCER

EPIDEMIOLOGY

SCLC most often occurs in patients with significant tobacco use history and is typically centrally located with bulky lymphadenopathy. SCLC accounts for approximately 13% of new lung cancer diagnoses in the United States. The incidence has decreased over the last few decades, with a peak in the early 1990s, when it represented as many as 25% of lung cancer diagnoses. In the 1970s, only 28% of patients with SCLC were female, whereas in the early 2000s, 50% of patients were female. These changes in incidence and demographics are most likely related to tobacco use, as are geographic variations in the incidence of SCLC, which has a strong dose-response relationship with smoking. As noted earlier in this chapter, SCLC is also characterized by a high incidence of PNS.

ESTABLISHING A DIAGNOSIS

Staging

Staging of SCLC uses the same AJCC TNM staging system used in NSCLC. The staging system has been validated in SCLC and carries prognostic value. However, because of the aggressive nature of this disease and the limited role of surgery, the Veterans Affairs Lung Study Group staging system is often applied in clinical practice. In this staging schema, patients with limited stage SCLC (LS-SCLC) are those with tumor limited to one hemithorax, with regional nodes that can be included in a single tolerable radiation therapy port, and patients with extensive-stage SCLC (ES-SCLC) are those with tumor that does not meet the criteria for LS, including those with distant metastases or malignant pericardial or pleural effusions.

SCLC TREATMENT

SCLC is a chemotherapy- and radiation therapy–sensitive tumor with remarkably high response rates to multiple regimens. Unfortunately, it is characterized by rapid relapse, and after recurrence, it is a much more refractory disease. For those with LS-SCLC, definitive therapy offers a chance for cure in a small subset of patients. For those with ES disease, treatment is largely palliative. For those patients with poor PS, there may still be a palliative role for systemic therapy, given the high response rates with chemotherapy, although it is important to discuss the limitations of therapy with patients.

Treatment of LS-SCLC

There is a limited role for surgical resection in SCLC, which is often disseminated or locally advanced at the time of diagnosis. For stage I to IIA (T1/T2, N0) SCLC, limited retrospective series demonstrate good outcomes with surgical resection. Stage I or IIA (T1/T2, N0) SCLC, however, is exceedingly rare (<5% of patients), and before pursuing surgery, extensive staging, including invasive mediastinal staging, is appropriate. If proper staging workup does confirm stage I or IIA SCLC, surgery may be considered. After surgery, adjuvant chemotherapy is recommended regardless of stage, although not on the basis of high-level evidence. Commonly, despite proper staging, histopathologic analysis of the surgical specimen upstages the disease by identifying involved lymph nodes, in which case chemoradiation therapy (as discussed in the next paragraph) is an appropriate consideration.

For most patients with LS-SCLC, the recommended treatment is definitive concurrent chemoradiation.[172] Chemotherapy administered concurrently with thoracic irradiation is more effective than sequential chemoradiation therapy with a median OS of 27.2 months compared with 19.7 months in the sequential arm (P = .097); however, it was associated with substantially more frequent esophagitis and hematologic toxicity. To decrease the morbidity associated with such treatment, as well as to improve overall outcome, investigative efforts have focused on optimizing radiation fields, fractionation, and schedule. In one randomized study, twice-daily hyperfractionated radiation therapy to 45 Gy was compared with a once-daily schedule to 45 Gy; both were administered concurrently with four cycles of cisplatin and etoposide. Survival was significantly higher with the twice-daily regimen (median survival, 23 vs 19 months; 5-year survival, 26% vs 16%), although at the expense of more frequent grade 3 esophagitis.[173] A shortcoming of this trial is that the radiobiologic dose of 45 Gy twice daily was significantly higher than once daily to 45 Gy. Therefore, it was thought that daily radiation administered to a higher dose may produce comparable results. However, a European randomized phase 3 trial (the CONVERT trial) failed to demonstrate a survival advantage for once-daily radiation to 66 Gy over twice daily to 45 Gy, although numeric outcomes and toxicity between the two arms were similar.[165] Both approaches are currently used in clinical practice. Cisplatin and etoposide for four cycles is the current standard regimen used in combination with radiation therapy for LS-SCLC.

With concurrent chemoradiation therapy, response rates are high; 97% of patients achieve a response, and 40% achieve a CR. Long-term survival, however, is uncommon, and the 5-year survival rate is lower than 25%. This discordance between initial sensitivity and frequent relapse has been the subject of intense research. Despite the high risk of recurrence, prolonged or maintenance therapy has not improved outcomes, and until recently, radiographic observation remained standard of care after definitive chemoradiation therapy.[174] This paradigm changed with the presentation of the ADRIATIC trial. In this trial, patients with LS-SCLC received standard chemoradiation and were then randomized to receive the combination of durvalumab and tremelimumab, durvalumab alone, or placebo for 24 months. At the first interim analysis, patients in the durvalumab alone arm experienced significantly improved OS (median, 55.9 vs 33.4 months) and PFS (median, 16.6 vs 9.2 months). Results in the durvalumab-tremelimumab group remain blinded.[174] This study establishes durvalumab as an effective therapy after chemoradiation for eligible patients.

First-Line Treatment of ES-SCLC

Most patients with SCLC will present with ES disease, and most patients with LS-SCLC will experience disease relapse. For ES-SCLC, the cornerstone of treatment is platinum-based chemotherapy in combination with etoposide. The COCIS meta-analysis of individual patient data compared patients with SCLC who received cisplatin and those who received carboplatin. There was no difference in response rate, PFS, or survival based on the choice of platinum, although the toxicity profiles of these two drugs include important differences.[175] Cisplatin remains the standard of care in LS-SCLC; however, carboplatin and cisplatin are both appropriate options in the treatment of patients with ES-SCLC.

The first study to demonstrate an improvement in OS in the first-line treatment of ES-SCLC in several decades was IMpower 133, a randomized phase 3 trial of carboplatin and etoposide with the PD-L1 inhibitor atezolizumab.[176] In this global study, 403 patients with ES-SCLC received four cycles of carboplatin and etoposide and were randomly assigned at a 1:1 ratio to receive either concurrent atezolizumab or placebo followed by atezolizumab or placebo maintenance. The addition of atezolizumab led to a significant improvement in survival (12.3 vs 10.3 months; HR, 0.70) as well as an improvement in PFS (HR, 0.77). The survival benefit was independent of PD-L1 expression. The CASPIAN trial explored durvalumab with first-line chemotherapy and produced strikingly similar results. In this open-label trial, the addition of durvalumab to platinum and etoposide improved survival from 10.3 to 13.0 months (HR, 0.73).[177] Both atezolizumab and durvalumab are FDA approved with chemotherapy as initial treatment for ES-SCLC. In contrast, a phase 3 trial of first-line pembrolizumab with chemotherapy (KEYNOTE-604) improved PFS but failed to demonstrate a survival benefit.[178]

The addition of chemotherapy with lurbinectedin to maintenance atezolizumab was recently approved based on the phase 3 IMFORTE trial. This study randomized patients with ES-SCLC who responded to initial carboplatin, etoposide, and atezolizumab and had a PS of 0-1 to lurbinectedin and atezolizumab or atezolizumab alone as maintenance. Both PFS (HR, 0.54) and OS (HR, 0.73) improved in the combination arm.

Prophylactic Cranial Irradiation

Brain metastases comprise the first site of relapse for approximately one-third of patients who have relapsing SCLC. Another third of such patients will have both brain and systemic metastases as the first sites of relapse, and the remaining one-third will have systemic-only disease. Because of the morbidity and cognitive decline associated with brain metastases, the role of prophylactic cranial irradiation (PCI) to prevent the development of brain metastases has been studied in numerous randomized trials. A meta-analysis of patients with SCLC in complete remission (primarily those with LS disease) concluded that PCI was associated with a 5.4% increase in survival at 3 years.[179] A typical course of PCI is 25 Gy to the whole brain in 10 fractions.

A study from the European Organisation for Research and Treatment of Cancer also showed a survival benefit for patients with ES disease who had any response to induction chemotherapy.[180] Patients with ES-SCLC who had a response to chemotherapy were randomly assigned to undergo PCI or receive no additional therapy. Irradiation was associated with an increase in median survival from 5.4 to 6.7 months and an improvement in the 1-year survival rate (27.1% vs 13.3%), in addition to a lower risk of brain metastases (risk of metastases at 1 year, 14.6% vs 40.4%). One limitation of the study was the lack of baseline brain imaging and MRI surveillance. A recent trial mirrored this study design but required brain imaging at baseline and during surveillance. In that randomized trial of 224 patients with ES-SCLC, there was no difference in survival between patients who underwent PCI and those who were radiographically observed, with a median survival of 11.6 months with PCI and 13.7 months with observation.[181] With no survival advantage with PCI and a risk of neurocognitive toxicity, PCI in ES-SCLC is not typically recommended if MRI for surveillance of the brain is available.

Consolidative Thoracic Irradiation

SCLC is a radiosensitive tumor, and given the high local recurrence rates after initial chemotherapy for ES-SCLC, the role of thoracic irradiation after chemotherapy has been explored. A randomized clinical trial of 498 patients with ES-SCLC with a response to platinum-based induction chemotherapy showed that thoracic irradiation, when added to PCI, significantly increased the PFS.[182] The primary endpoint of the study was an improvement in survival at 1 year. The study did not meet its primary endpoint; survival at 1 year was not significantly prolonged (33% vs 28%; $P = .066$), and the median survival was the same in both arms (8 months). However, in a secondary analysis, there was a significant improvement in 2-year survival (13% vs 3%; $P = .04$). Some of the features of the overall patient population were atypical for ES-SCLC, such as a 46% rate of isolated intrathoracic progression in the control group. Although these studies predate the use of immunotherapy, consolidative radiation therapy may be considered in ES patients who respond to initial chemotherapy and immunotherapy but have residual thoracic disease and limited extrathoracic disease.

Second-Line Therapy

The response rate to second-line agents correlates with the timing of relapse after induction chemotherapy. Patients who experience relapse more than 3 months after completing first-line chemotherapy are considered to have platinum-sensitive disease and are more likely to have a response. Patients who experience disease progression during or within 3 months after receiving a first-line regimen are considered to have resistant disease.

For those with sensitive disease, revisiting platinum and etoposide is an option, especially if the interval from completion of first-line chemotherapy is at least 6 months. For decades, the only drug approved as second-line therapy for SCLC in the United States was topotecan, which is associated with a response rate of approximately 25% and survival of approximately 6 months.[183]

Lurbinectedin, a marine-derived transcription inhibitor, received accelerated approval by the FDA in this setting based on promising single-agent activity in a single-arm phase 2 study.[184] In 105 patients with relapsed SCLC, lurbinectedin achieved a response rate of 35.2%. For patients with a chemotherapy-free interval of less than 90 days (chemotherapy resistant), the response rate was 22.2%, and in those with an interval of at least 90 days, the response rate was 45.0%.[185]

Tarlatamab, a bispecific T-cell engager (BITE) immunotherapy targeting delta-like ligand 3 and CD3, was studied at two doses (10 and 100 mg) in a phase 2 trial in patients with ES-SCLC who had experienced progression during prior platinum-based chemotherapy. The study reported an ORR of 55% in the 10-mg group and 57% in the 100-mg group and a median PFS of 4.9 months in the 10-mg group and 3.9 months in the 100-mg group. Encouragingly, in patients with an objective response, the DoR was longer than 6 months in 59%.[185] The FDA granted tarlatamab at 10 mg fast-track approval for patients with ES-SCLC who have experienced progression during platinum-based therapy. A randomized phase 3 trial of tarlatamab compared with second-line chemotherapy (topotecan, lurbinectedin, or amrubicin) demonstrated that patients who received tarlatamab had a superior median OS (13.6 vs 8.3 months; HR, 0.60, $P < .001$), confirming[1] tarlatamab as the second-line treatment of choice for ES patients who progress after chemotherapy and immunotherapy. Of note, as a BITE therapy, tarlatamab can have significant toxicity,

including cytokine-release syndrome (CRS) and immune effector cell–associated neurotoxicity syndrome (ICANS), which were seen in 56% and 6% of the 10-mg group, respectively. Therefore, centers using tarlatamab must be prepared for and experienced in the management of these adverse effects, which may limit the availability of this treatment to all patients.

KEY POINTS

- SCLC is characterized by high response rates to systemic therapy and high relapse rates.
- The AJCC TNM staging system is appropriate, but the functional staging system proposed by the Veterans Authority Lung Study Group is often used clinically. LS-SCLC can be encompassed in a tolerable radiation therapy port; ES disease cannot.
- For LS-SCLC, the standard approach is cisplatin and etoposide with definitive radiation therapy followed by consideration of PCI and durvalumab for 24 months.
- For ES-SCLC, the standard approach is platinum with etoposide and either atezolizumab or durvalumab, with immunotherapy continued as maintenance after four cycles of chemoimmunotherapy.
- For relapsed SCLC, tarlatamab is the preferred agent for eligible patients.

PALLIATION FOR PATIENTS WITH LUNG CANCER

For patients with good PS, systemic therapy can play an important palliative role by reducing symptoms and improving quality of life. This is particularly the case in highly responsive tumors, such as previously untreated SCLC or NSCLC with an actionable driver alteration. Other ways to offer palliation for patients with lung cancer merit consideration.

PALLIATIVE CARE

Palliative care specialists can provide valuable insight into and guidance on symptom management and psychosocial support but are often involved late in the disease course. In a landmark trial, 151 patients with newly diagnosed metastatic NSCLC were randomly assigned to early integration with a palliative care team or standard oncologic care alone.[186] Early referral to palliative care led to improvements in quality of life and fewer patients with depressive symptoms. Although there were fewer patients who received aggressive end-of-life care in the palliative care arm (33% vs 54%), survival was longer for patients with an early referral to palliative care (11.6 vs 8.9 months).

BONE-TARGETED AGENTS

Bone metastases are common in NSCLC and SCLC and are an important potential cause of patient morbidity. Supportive medications have been effective at preventing complications associated with bone metastases. Bisphosphonates (eg, zoledronate) have resulted in the reduction of skeletal-related complications, such as pain, hypercalcemia, pathologic fractures, and spinal cord and nerve compression, as well as improvements in the quality of life for patients with metastatic bone disease who are likely to have a prolonged clinical course.[187] However, a small risk of osteonecrosis of the jaw is seen. Denosumab, a monoclonal antibody to the receptor activator of nuclear factor-kappa B ligand, was noninferior to zoledronate in delaying or preventing skeletal-related complications for patients with advanced cancer, including patients with lung cancer, in a randomized double-blind study in the treatment of bone metastases for patients with advanced cancer (excluding breast and prostate cancers) or multiple myeloma.[188] The incidence of osteonecrosis is similar to that with bisphosphonates.

RADIATION THERAPY

Palliative radiation therapy is often helpful for controlling pain related to bone metastases or for improving neurologic function for patients with brain metastases. Irradiation of the thorax may also help control hemoptysis, SVC syndrome, airway obstruction, laryngeal nerve compression, and other local complications. Different modalities of radiation therapy, such as SBRT, may have relative advantages over conventional radiation therapy, but dose and modality will vary by specific clinical situation.

MANAGEMENT OF PLEURAL EFFUSION

Palliative thoracentesis should be performed for patients with symptomatic pleural effusion, and management with intermittent thoracentesis can frequently be effective if the effusion does not reaccumulate quickly. When reaccumulation is rapid, pleurodesis may be considered. The two most common methods of pleurodesis are through a chest tube or via thoracoscopy. Common sclerosing agents include doxycycline, talc, and bleomycin, with talc being the most effective. Unfortunately, the procedure is effective in only approximately 50% of cases and is associated with discomfort and a prolonged hospital stay. For these reasons, long-term drainage through a semipermanent catheter is used more frequently.[189] Effective systemic therapy may also reduce malignant effusions.

KEY POINTS

- Early integration with palliative medicine specialists improves quality of life for patients with metastatic lung cancer and may help extend survival.
- Every attempt should be made to palliate the symptoms of patients with lung cancer. In addition to systemic anticancer therapies, approaches include administering antiresorptive agents for bone metastases, incorporating palliative radiation therapy when appropriate, and addressing dyspnea caused by pleural effusions.

THYMIC MALIGNANCIES

Several different tumors can arise in the anterior mediastinum, including thymomas, Hodgkin and non–Hodgkin lymphomas, carcinoid tumors, and germ cell neoplasms. Thymomas are malignant neoplasms originating within the epithelial cells of the thymus, which often contain admixtures of lymphocytes.[190] Thymic carcinomas also are tumors of the thymic epithelium, but they are associated with a paucity of lymphocytes and are more aggressive and have a worse prognosis. Approximately 400 new cases of thymic malignancies are diagnosed annually in the United States. They affect men and women equally, have no known risk factors, and can be found incidentally on imaging.

Thymomas are the most common (~20%-30%) of all anterior mediastinal tumors in adults. Most thymomas are well encapsulated, but they are considered malignant because of their invasive potential. Cytokeratin is a useful diagnostic marker to distinguish thymomas from nonepithelial cell malignancies. Although they usually present in the fourth and fifth decades of life, cases have been reported from infancy into the ninth decade. At presentation, one-third of patients have local symptoms, such as cough, SVC syndrome, and dysphagia. Distant metastases are uncommon, with the most common metastatic site being the pleura. Definitive diagnosis requires tissue evaluation while avoiding a transpleural approach. Complete resection of thymomas is preferred over biopsy to avoid seeding and upstaging by violating the capsule. In the case of thymic carcinomas, consider open biopsy if core biopsy is not feasible or not diagnostic. Several PNS have been associated with thymoma. Myasthenia gravis, an autoimmune disorder caused by circulating acetylcholine receptor antibodies resulting in acetylcholine receptor deficiency at the motor end plate, occurs in approximately one-third of patients with thymoma, although it is rarely seen with thymic carcinoma. Interestingly, thymomas associated with myasthenia gravis tend to be less aggressive, and histologically, they tend to have a larger ratio of lymphocytes to epithelial cells. Surgical removal of all thymic tissue, not just tumor tissue, usually results in an attenuation of the severity of myasthenia gravis, although not all patients achieve resolution of all symptoms. Patients should have their serum anti–acetylcholine receptor antibody levels measured before surgery to determine whether they have myasthenia gravis, thus allowing proper management and avoiding respiratory failure during surgery.

Other PNS include pure red cell aplasia, vasculitis, hypogammaglobulinemia, and other autoimmune disorders. Thymectomy may result in normalization of the bone marrow for 40% or fewer of patients with pure red cell aplasia, although the procedure rarely results in a return to normal immunoglobulin levels for patients with immunodeficiency. The Masaoka staging for thymoma is based on encapsulation of the tumor and invasion into surrounding organs and distant sites outside the chest (Table 11-4).[191] Although the TNM staging provides more clinically relevant differentiation, it does not provide any therapeutic implication because a majority of studies supporting treatment decisions in thymic malignancies were based on Masaoka staging. Important prognostic factors include WHO histologic grade, complete resection status, and size.[190,192] Negative prognostic factors include tumor size larger than 10 cm, tracheal or vascular compromise, age younger than 30 years, the presence of hematologic PNS, incomplete surgical resection, and thymic carcinoma histology.

Table 11-4 Modified Masaoka Clinical Staging of Thymoma

Masaoka Stage	Diagnostic Criteria
I	Macroscopically and microscopically completely encapsulated
II	(A) Microscopic transcapsular invasion
	(B) Macroscopic invasion into the surrounding fatty tissue or grossly adherent to but not through mediastinal pleura or pericardium
III	Macroscopic invasion into neighboring organs (ie, pericardium, great vessels, and lung)
	(A) Without invasion of great vessels
	(B) With invasion of great vessels
IV	(A) Pleural or pericardial dissemination
	(B) Lymphatic or hematogenous metastasis

Data adapted from Wright CD. Management of thymomas. *Crit Rev Oncol Hematol*. 2008;65:109-120.

All patients with thymic malignancies should be treated by an experienced multidisciplinary team. The treatment of choice for thymoma is surgical resection of the thymus and contiguous and noncontiguous disease (eg, pericardium, pleura, lung, phrenic nerve, and major vessels). Surgical clips should be placed at the site of close margin and residual disease to guide the radiation field if needed. Pleural surface should be examined and metastases removed to aim for a pCR (no active cancer in the resected tumor). Minimally invasive procedures are not routinely recommended because of a lack of long-term data. Long-term survival for patients with encapsulated noninvasive (stage I) tumors is excellent, approaching 90% to 95% at 10 years. The role played by PORT after a complete (R0) resection is controversial, but sometimes, the procedure is used for completely resected stage II to IV thymoma. If R0 is uncertain to be achieved, preoperative chemotherapy should be considered. Adjuvant radiation therapy with or without chemotherapy is often recommended for patients with remaining microscopic (R1) or macroscopic (R2) residual disease.[193]

The optimal management of incompletely resected or unresectable thymic malignancies is controversial. Achieving an R0 resection is an important prognostic indicator. Therefore, debulking with chemotherapy for locally advanced disease to attempt to increase the potential for an R0 resection should be considered. Surveillance for recurrence is performed with CT chest with intravenous contrast every 6 to 12 months for 2 years, then annually for 5 years for thymic carcinoma and 10 years for thymoma.

Given the small number of affected patients, no randomized trials have been performed to identify the best chemotherapy regimen for inoperable or recurrent thymoma. Commonly used regimens in the first-line metastatic or unresectable setting include combined cisplatin, doxorubicin, and cyclophosphamide[193]; combined cisplatin and etoposide; and combined carboplatin and paclitaxel.[194]

Thymic carcinomas are aggressive and characterized by a high degree of histologic anaplasia and architectural atypia. The preferred first-line regimen for unresectable or metastatic disease is carboplatin and paclitaxel for up to six cycles with or without ramucirumab; the latter will be continued until progression of disease or unacceptable toxicity.[195] Rarely, these tumors have activating *c-KIT* mutations and can be responsive to sunitinib after progression during a platinum-based regimen.[196] Several different subtypes have been described, although more than half are undifferentiated. These tumors often metastasize to regional lymph nodes and distant sites; therefore, they have a worse prognosis than thymomas, with 5-year survival rates of 20% to 30%. Phase 2 studies of pembrolizumab have shown promising activity, with response rates greater than 20%, but immune-related toxicity was also noted and at a higher incidence than in some other cancers, such as NSCLC; specifically, severe myocarditis was reported in 5% to 9% of patients with thymic carcinoma who were treated with pembrolizumab. Post–platinum therapy: Lenvatinib shows maturing benefit in the phase 2 REMORA study—updated analyses report a median OS ≈28.3 months, reinforcing lenvatinib as an active option after platinum.[197] In pretreated disease, the phase 2 CAVEATT trial of avelumab + axitinib in heavily pretreated thymic carcinoma/WHO B3 thymoma demonstrated a median OS of 23.4 months, with durable benefit in select subgroups (eg, those without liver metastases).[198]

KEY POINTS

- Thymomas are often encapsulated, well differentiated, and associated with PNS such as myasthenia gravis.
- The optimal treatment of thymoma is thymectomy and complete surgical resection, in which case survival is excellent.
- The most important prognostic factors after resection are Masaoka stage, histology, complete resection status, and size.
- Thymic carcinomas are more aggressive than thymomas.
- Platinum-based chemotherapy remains standard therapy for unresectable or recurrent thymoma or thymic carcinoma.
- Immunotherapy is not indicated in the treatment of thymoma.
- The incidence of immune-related adverse events with immunotherapy is higher with thymic carcinoma than with other cancers.

MESOTHELIOMA

Mesothelioma arises from mesothelial cells, which form the serosal lining of the pleura, pericardium, and peritoneal cavities.[199] Although benign mesotheliomas have been described, most are malignant, have an aggressive clinical course, and are difficult to cure. Malignant mesotheliomas are rare, with approximately 2,500 new cases diagnosed annually in the United States. Although approximately 80% are associated with exposure to asbestos, only approximately 5% of asbestos workers are diagnosed with mesothelioma. In contrast to lung cancer and asbestosis, smoking does not increase the risk of mesothelioma.

Carcinogenic effects of asbestos seem to result from its physical properties rather than from its chemical structure, with long rod-like fibers of narrow diameter being more likely to induce tumors in laboratory animals. Pathology remains the most prognostic factor. Three histologic variants of mesothelioma have been described: (1) epithelial, the most common form, which is chemosensitive and associated with the best prognosis; (2) sarcomatoid, associated with the worst prognosis; and (3) mixed (or biphasic).

To distinguish mesotheliomas from metastatic adenocarcinomas, the periodic acid–Schiff stain is frequently used before and after diastase digestion. Neutral mucopolysaccharides that are strongly positive on periodic acid–Schiff staining are found in

intracellular secretory vacuoles and in intra-acinar vacuoles in most adenocarcinomas but are rarely found in most mesotheliomas. In addition, IHC staining for CD15, Ber-EP-4, TTF1, and carcinoembryonic antigen is usually absent in mesotheliomas but is positive in most adenocarcinomas, whereas mesothelioma is characterized by staining for calretinin, Wilms tumor antigen (WT1), vimentin, CK5/6, mesothelin, or HBME-1 (an anti–mesothelial cell antibody).[200]

Mesothelioma most commonly develops in the fifth to seventh decade and affects men and women at a 5:1 ratio. The onset of disease occurs 20 to 50 years after exposure. Family members are also at higher risk of mesothelioma, presumably because of exposure to asbestos fibers brought home on the clothing and bodies of individuals who work with asbestos. The typical presentation consists of B symptoms and dyspnea secondary to a pleural effusion or chest-wall pain. Most mesotheliomas (60%) occur on the right side, and bilateral involvement of the chest wall is present at the time of diagnosis in fewer than 5% of cases. Cytologic examination of pleural fluid may be negative, necessitating either diagnostic thoracoscopy or pleural biopsy.

Mesothelioma tends to be locally invasive. For approximately 20% of patients, a chest-wall mass develops over biopsy tracts, resulting from thoracentesis, chest tubes, or thoracotomy. Therefore, single-port thoracoscopy on the line of potential incision is recommended to prevent seeding and can be excised during definitive surgery. Direct involvement of the ribs, diaphragm, pericardium, and vertebrae is common. Although various staging classifications have been described, the TNM staging system adopted by the AJCC is most used, and its prognostic value was confirmed by the International Association for the Study of Lung Cancer and the International Mesothelioma Interest Group.[201]

The choice of surgical resection for mesothelioma is controversial and has not been shown conclusively to improve survival. Surgical approaches include extrapleural pneumonectomy (EPP) and pleurectomy with decortication (P/D). EPP includes en bloc resection of the parietal pleura, lung, pericardium, and diaphragm. P/D involves careful resection of only the visceral and parietal pleura.[202] In resectable pleural mesothelioma, adding extended pleurectomy/decortication (EPD) to platinum–pemetrexed did not improve outcomes and was associated with worse OS versus chemotherapy alone (median ~19.3 vs 24.8 months) and worse quality of life; perioperative morbidity contributed, and fewer patients in the surgery arm received postoperative chemotherapy. These results do not support routine EPD outside trials.[203]

The prognosis is poor for patients who have unresectable disease at presentation. A phase 3 study demonstrated a 9.3-month median survival for patients treated with cisplatin alone and 12.1-month survival for patients treated with cisplatin and pemetrexed (HR, 0.77; $P = .02$).[204] The response rate with cisplatin and pemetrexed was 41.3% compared with 16.7% with cisplatin alone. This trial led to the first FDA-approved treatment with cisplatin and pemetrexed for unresectable malignant pleural mesothelioma (MPM) in 2004. A similar time to progression (7 vs 6.9 months) and 1-year OS rate (63.1 vs 64%) were found in chemotherapy-naive patients with MPM who received pemetrexed with cisplatin or carboplatin under an international expanded access program (EAP).[205] Based on these data, carboplatin can be considered an alternative to cisplatin in patients who would not be eligible to receive cisplatin. In a randomized phase 3 trial (MAPS), bevacizumab added to cisplatin and pemetrexed improved survival (18.8 vs 16.1 months).[206] More grade 3 or worse hypertension (23% vs 0%) and thrombotic events (6% vs 1%) were noted with bevacizumab. Cisplatin and pemetrexed with bevacizumab should be considered for patients with unresectable MPM who are bevacizumab eligible, although bevacizumab is not FDA approved in this setting. Pemetrexed rechallenge can be considered in patients with MPM who had a response to pemetrexed-based therapy more than 6 months earlier.

Immunotherapy has emerged as a potential new standard of care for eligible patients with advanced mesothelioma. In the CheckMate 743 trial, 605 patients with unresectable pleural mesothelioma were randomly assigned to the PD-1 inhibitor nivolumab and the CTLA-4 inhibitor ipilimumab or standard platinum and pemetrexed chemotherapy.[207] Survival was greater with nivolumab and ipilimumab than with chemotherapy (median OS, 18.1 vs 14.1 months; HR, 0.74). The benefit was more profound in the nonepithelioid subtype (n = 149; OS HR, 0.46) than in the epithelioid subtype (n = 456; OS HR, 0.86). The combination of nivolumab and ipilimumab was approved as first-line therapy for unresectable MPM. In the previously treated setting, single-agent immunotherapy has also shown activity for patients who did not receive it in the first line. In the CONFIRM trial, a randomized placebo-controlled phase 3 study, nivolumab improved the median survival (10.2 vs 6.9 months; HR, 0.69; $P = .009$), median PFS (3.0 vs 1.8 months; HR, 0.67; $P = .001$), and overall response rate (11% vs 1%; OR 14.0; $P = .0008$).[208]

CCTG IND.227 (or KEYNOTE-483), a randomized phase 3 study, showed that the combination of chemoimmunotherapy with a platinum agent, pemetrexed, and pembrolizumab improved the OS (16.1 vs 17.3 months; HR, 0.79; $P = .03$) and response rate (62% vs 38%; $P < .0001$) in treatment-naive patients with MPM compared with chemotherapy across all subgroups, with no new safety signals.[209,210] This combination was approved as first-line therapy for unresectable MPM in 2024.

KEY POINTS

- Approximately 80% of pleural mesotheliomas are associated with exposure to asbestos, including indirect exposure.
- The epithelial histologic form of mesothelioma is associated with a better prognosis than the sarcomatoid or mixed histology form.
- Surgical options are not curative and include EPP and P/D.

- First-line chemotherapy for patients with unresectable mesothelioma consists of cisplatin and pemetrexed with or without bevacizumab.
- The combination of nivolumab and ipilimumab had a survival advantage over chemotherapy for patients with unresectable pleural mesothelioma, specifically with nonepithelioid histology, and is an approved first-line option.
- Combination chemotherapy and immunotherapy in first-line treatment of MPM is a promising strategy.

HIGH-YIELD TAKEAWAYS

Important Clinical Presentation

- SVC syndrome is an oncologic urgency seen in patients with lung cancer. Because of the compression of the SVC by surrounding tumor, patients present with facial, neck, and upper-extremity swelling. It requires prompt diagnosis and treatment.

Staging of NSCLC

- Staging for patients with NSCLC typically includes CT scan of the chest and abdomen as well as a PET scan.
- MRI of the brain is also recommended for patients with clinical stage II or greater NSCLC.
- Mediastinal staging is recommended for most patients with stage IB to III NSCLC.

Resectable NSCLC

- Treatment for stage I and II NSCLC is surgical resection (if the patient is a candidate) or radiation therapy (preferably stereotactic radiation therapy) if the patient is not a surgical candidate.
- Anatomic resection such as lobectomy is preferred, although recent data indicate that sublobar resection is acceptable for patients with tumors 2 cm or smaller and negative lymph nodes.
- Adjuvant chemotherapy consisting of a cisplatin-based combination is indicated for patients with stage IIB to III disease after surgical resection. Adjuvant chemotherapy can be considered for patients with stage IIA disease or higher.
- Adjuvant atezolizumab improves DFS for resected stage II to IIIA NSCLC with PD-L1 of 1% or greater.
- The KEYNOTE-091 trial demonstrated that 12 months of pembrolizumab after adjuvant chemotherapy significantly improves DFS for PD-L1–unselected patients with completely resected stage IB (T2a $\geq$ 4 cm), II, or IIIA NSCLC.
- Adjuvant osimertinib improves DFS and OS for resected stage IB to IIIA *EGFR*-mutated NSCLC; similarly, adjuvant alectinib improves PFS in *ALK* fusion–positive NSCLC.

Stage III NSCLC

- Treatment options for stage III NSCLC are complex and varied and generally include some combination of chemotherapy, radiation therapy, surgery, and immunotherapy; treatment decisions should be made in discussion with a multidisciplinary team.
- If microscopic N2 (or N1) disease is detected at surgery in a patient who did not receive neoadjuvant therapy, adjuvant therapy should be administered.
- The current standard treatment of unresectable stage III *ALK* and *EGFR*–wild-type NSCLC is concurrent platinum-based chemoradiation therapy followed by immunotherapy with durvalumab.

LUNG CANCER 11

CHAPTER SUMMARY GUIDE

KEY POINTS

- Lung cancer is the most common cause of cancer-related death in the United States in both men and women.
- Most cases of lung cancer (85%) are caused by carcinogens in tobacco smoke.
- The four most common histologic subtypes of lung cancer are adenocarcinoma, squamous cell carcinoma, large cell carcinoma (collectively referred to as NSCLC), and SCLC.
- Guidelines recommend testing for *EGFR, KRAS, HER2, BRAF*, and *MET* mutations and *ALK, ROS-1, NTRK, RET*, and *NRG1* translocations/fusions in all treatment-eligible patients with stage IV non–squamous NSCLC, with the consideration of testing in select treatment-eligible individuals with stage IV squamous NSCLC.
- *EGFR* and *ALK* testing is indicated for patients with resectable stage IB to IIIA non–squamous NSCLC and patients with inoperable stage III NSCLC who will receive concurrent chemotherapy and radiation.
- When tissue is not available for genomic testing, a blood-based "liquid biopsy" can be utilized for molecular testing; there are limitations to its sensitivity, and uninformative results may need to be confirmed with tissue-based testing.
- Common symptoms of lung cancer include local symptoms, such as cough, pain, and shortness of breath, and constitutional symptoms, such as fatigue, weakness, anorexia, and weight loss.
- The most common sites for metastatic disease in lung cancer are the lungs (ipsilateral and contralateral), adrenal glands, liver, bone, and brain.
- PNS are commonly seen in patients with lung cancer, notably, hypercalcemia, SIADH, ectopic ACTH production, and neurologic syndromes.
- Screening for lung cancer with annual LDCT of the chest is recommended for patients of age 50 to 80 years who have a smoking history of 20 or more pack-years and who are currently smoking or have quit within the last 15 years.
- The KEYNOTE-091 trials demonstrated that 12 months of pembrolizumab after adjuvant chemotherapy significantly improves DFS for PD-L1–unselected patients with completely resected stage IB (T2a ≥ 4 cm), II, or IIIA NSCLC.
- The IMpower 010 trial revealed that the addition of 1 year of atezolizumab after adjuvant chemotherapy significantly improves DFS in patients with stage II to IIIA NSCLC expressing PD-L1 on 1% or more of tumor cells.
- Adjuvant osimertinib improves DFS and OS for patients with resected stage IB to IIIA *EGFR*-mutated NSCLC.
- Adjuvant alectinib improves DFS for patients with resected stage II to IIIA *ALK*-rearranged NSCLC.
- Treatment options for stage III NSCLC are complex and varied and generally include some combination of systemic therapy (chemotherapy, immunotherapy, and targeted therapy), radiation therapy, and surgery; treatment decisions should be made in discussion with a multidisciplinary team.
- If microscopic N2 (or N1) disease is detected at surgery in a patient who did not receive neoadjuvant therapy, adjuvant therapy should be administered.
- For patients with *EGFR*-mutated, unresectable stage III NSCLC, osimertinib is an approved option after completion of concurrent chemoradiation therapy.
- For *EGFR* exon 19–deleted and *EGFR* L858R–mutated NSCLC, the preferred first-line option is osimertinib with or without chemotherapy or amivantamab with lazertinib.
- Amivantamab with chemotherapy is an option for *EGFR* exon 19–deleted and exon 21 L858R–mutated NSCLC after progression during treatment with osimertinib.
- Acquired resistance to first- and second-generation EGFR TKIs is often mediated by the T790M resistance mutation, and osimertinib is indicated in this setting.
- For *EGFR* exon 20 insertion mutations: Amivantamab and chemotherapy are approved as frontline therapy (PAPILLON). Sunvozertinib received FDA-accelerated approval (July 2025) for patients who progressed on platinum-based chemotherapy.
- For *ALK*-rearranged NSCLC, the preferred first-line options include alectinib, brigatinib, and lorlatinib.
- For ROS-1-rearranged NSCLC, taletrectinib was FDA approved (June 2025) and joins crizotinib, entrectinib, and repotrectinib.
- For *KRAS* G12C–mutated advanced NSCLC, both sotorasib and adagrasib are approved treatments in the second-line setting.

- For advanced NSCLC with *BRAF* V600E mutation, a combination of either dabrafenib and trametinib or encorafenib and binimetinib is approved; the latter has less reported pyrexia.
- For advanced NSCLC with *NTRK* fusion, larotrectinib and entrectinib are approved treatments. For advanced NSCLC with *RET* fusion, selpercatinib and pralsetinib are approved treatments. For advanced NSCLC with *MET* exon 14–skipping mutation, capmatinib and tepotinib are approved treatments.
- For MET IHC–high EGFR–wild-type NSCLC, the antibody-drug conjugate telisotuzumab vedotin-tllv (Emrelis) received accelerated approval.
- For advanced NSCLC with *HER2* mutation, zongertinib and trastuzumab deruxtecan are approved in the second-line setting; trastuzumab deruxtecan may also be used as second-line treatment for *HER2*-positive (IHC3+) advanced NSCLC.
- For advanced NSCLC with *NRG1* fusion, zenocutuzumab is approved as treatment in the second-line setting.
- NSCLC without an activating alteration in *EGFR* or *ALK* and with high PD-L1 expression (TPS $\geq$ 50%) can be treated with pembrolizumab, atezolizumab, or cemiplimab, all of which confer an improvement in survival over platinum-doublet chemotherapy.
- Dual-checkpoint blockade with nivolumab and ipilimumab improved survival compared with chemotherapy in PD-L1–positive (TPS $\geq$ 1%) NSCLC and is also a first-line treatment option. It may be used in the PD-L1–negative squamous NSCLC population as well.
- The combination of an immune checkpoint inhibitor with platinum-doublet chemotherapy improves PFS and survival in patients with squamous and non–squamous NSCLC (*EGFR* and *ALK* wild type) across all PD-L1 subsets.
- The combination of nivolumab and ipilimumab with two cycles of platinum-doublet chemotherapy, or durvalumab and tremelimumab with four cycles of platinum-doublet chemotherapy, is also approved across histologies and PD-L1 levels.
- Use of immunotherapy is not appropriate for certain molecular subtypes of advanced NSCLC (ie, EGFR/ALK), regardless of tumor PD-L1 expression; use of immune checkpoint inhibitors in these subgroups can be associated with both inferior efficacy and excess toxicity.
- Pemetrexed is an appropriate platinum partner in non–squamous histology; gemcitabine is appropriate for treatment of tumors with squamous histology. Paclitaxel or nab-paclitaxel is a reasonable choice for either histology.
- Fit older patients tolerate chemotherapy and derive the same survival benefit as their younger counterparts.
- The addition of the VEGFR2 antibody ramucirumab to second-line docetaxel improves survival.
- TTFields in combination with immune checkpoint inhibitors or docetaxel have improved outcomes in NSCLC after progression during platinum-based chemotherapy.
- SCLC is characterized by high response rates to systemic therapy and high relapse rates.
- The AJCC TNM staging system is appropriate, but the functional staging system proposed by the Veterans Authority Lung Study Group is often used clinically. LS-SCLC can be encompassed in a tolerable radiation therapy port; ES disease cannot.
- For LS-SCLC, the standard approach is cisplatin and etoposide with definitive radiation therapy followed by consideration of PCI and durvalumab for 24 months.
- For ES-SCLC, the standard approach is platinum with etoposide and either atezolizumab or durvalumab, with immunotherapy continued as maintenance after four cycles of chemoimmunotherapy.
- For relapsed SCLC, tarlatamab is the preferred agent for eligible patients.
- Early integration with palliative medicine specialists improves quality of life for patients with metastatic lung cancer and may help extend survival.
- Every attempt should be made to palliate the symptoms of patients with lung cancer. In addition to systemic anticancer therapies, approaches include administering antiresorptive agents for bone metastases, incorporating palliative radiation therapy when appropriate, and addressing dyspnea caused by pleural effusions.
- Thymomas are often encapsulated, well differentiated, and associated with PNS such as myasthenia gravis.
- The optimal treatment of thymoma is thymectomy and complete surgical resection, in which case survival is excellent.
- The most important prognostic factors after resection are Masaoka stage, histology, complete resection status, and size.
- Thymic carcinomas are more aggressive than thymomas.
- Platinum-based chemotherapy remains standard therapy for unresectable or recurrent thymoma or thymic carcinoma.
- Immunotherapy is not indicated in the treatment of thymoma.
- The incidence of immune-related adverse events with immunotherapy is higher with thymic carcinoma than with other cancers.
- Approximately 80% of pleural mesotheliomas are associated with exposure to asbestos, including indirect exposure.
- The epithelial histologic form of mesothelioma is associated with a better prognosis than the sarcomatoid or mixed histology form.

- Surgical options are not curative and include EPP and P/D.
- First-line chemotherapy for patients with unresectable mesothelioma consists of cisplatin and pemetrexed with or without bevacizumab.
- The combination of nivolumab and ipilimumab had a survival advantage over chemotherapy for patients with unresectable pleural mesothelioma, specifically with nonepithelioid histology, and is an approved first-line option.
- Combination chemotherapy and immunotherapy in first-line treatment of MPM is a promising strategy.

CHAPTER TABLES AND IMAGES

Table 11-1 Characteristics of Major Subtypes of Lung Cancer

Histology	Frequency (%)	Immunohistochemistry	Clinical Features/Comments
Non–small cell			
Adenocarcinoma	50	TTF-1, Napsin-A, CK7	Most common histology to have actionable driver mutations
Squamous cell carcinoma	25	P63, p40, CK5/6	Often central tumors; may develop cavitation; more commonly seen in those with heavy smoking history
Large cell carcinoma	5	—	Poorly differentiated tumors that do not meet the criteria for adenocarcinoma or squamous cell carcinoma
Pulmonary neuroendocrine tumors			
Typical carcinoid	1-2	Synaptophysin, chromogranin, INSM-1	<2 mitoses/2 mm^2 (10 HPF); lacking necrosis
Atypical carcinoid	1-2	Synaptophysin, chromogranin, INSM-1	2-10 mitoses/2 mm^2 (10 HPF) or necrosis
Large cell neuroendocrine carcinoma	5	Synaptophysin, chromogranin, INSM-1	High mitotic rate (>10 mitoses/2 mm^2; may show organoid nesting and rosettes
Small cell carcinoma	12-13	Synaptophysin, chromogranin, INSM-1	High mitotic rate (>10 mitoses/2 mm^2); small cells; nuclear molding; often crush artifact noted

Abbreviations: CK, cytokeratin; HPF, high-power fields; INSM-1. insulinoma-associated protein 1.

Table 11-2 **PD-(L)1 Inhibitor Monotherapy in PD-L1–High NSCLC**

Study	Agent	Median Survival vs Chemotherapy (Months)	Survival HR	Response Rate (%)
KEYNOTE-024	Pembrolizumab	26.3 vs 13.4	0.62	44.8
KEYNOTE-042	Pembrolizumab	20.0 vs 12.2	0.69	39.0
IMpower 110	Atezolizumab	20.2 vs 13.1	0.59	38.3
EMPOWER-Lung01	Cemiplimab	NR vs 14.2	0.57	39.0
CheckMate 026	Nivolumab	15.9 vs 13.9	0.9	34.0

Abbreviations: HR, hazard ratio; NR, not reported; NSCLC, non–small cell lung cancer; PD-L1, programmed cell death ligand 1.

Table 11-3 **Targeted Therapy for Unresectable or Metastatic NSCLC With Targetable Molecular Aberration**	
Target	**Preferred Targeted Therapy**
EGFR exons 19 and 21	Osimertinib, osimertinib and chemotherapy, amivantamab and lazertinib
EGFR exon 20	Amivantamab[a]
ALK fusions	Lorlatinib; alectinib, brigatinib, ensartinib
ROS-1 fusions	Crizotinib, entrectinib, repotrectinib, taletrectinib
KRAS G12C	Sotorasib,[b] adagrasib[b]
BRAF V600E	Dabrafenib + trametinib, encorafenib + binimetinib
RET	Selpercatinib, pralsetinib
MET exon 14 skipping mutation	Capmatinib, tepotinib
MET IHC high (3+)	Telisotuzumab vedotin-tllv
HER2 mutation	Zongertinib, trastuzumab deruxtecan[b]
HER-2 IHC high (3+)	Trastuzumab deruxtecan
NTRK1/2/3 fusions	Larotrectinib, entrectinib
NRG fusions	Zenocutuzumab

Abbreviations: EGFR, epidermal growth factor receptor; NSCLC, non–small cell lung cancer.
[a]Preferred in first line in combination with carboplatin and pemetrexed.
[b]Approved after progression during first-line systemic therapy.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 11-4 **Modified Masaoka Clinical Staging of Thymoma**	
Masaoka Stage	**Diagnostic Criteria**
I	Macroscopically and microscopically completely encapsulated
II	(A) Microscopic transcapsular invasion
	(B) Macroscopic invasion into the surrounding fatty tissue or grossly adherent to but not through mediastinal pleura or pericardium
III	Macroscopic invasion into neighboring organs (ie, pericardium, great vessels, and lung)
	(A) Without invasion of great vessels
	(B) With invasion of great vessels
IV	(A) Pleural or pericardial dissemination
	(B) Lymphatic or hematogenous metastasis

Data adapted from Wright CD. Management of thymomas. *Crit Rev Oncol Hematol*. 2008;65:109-120.

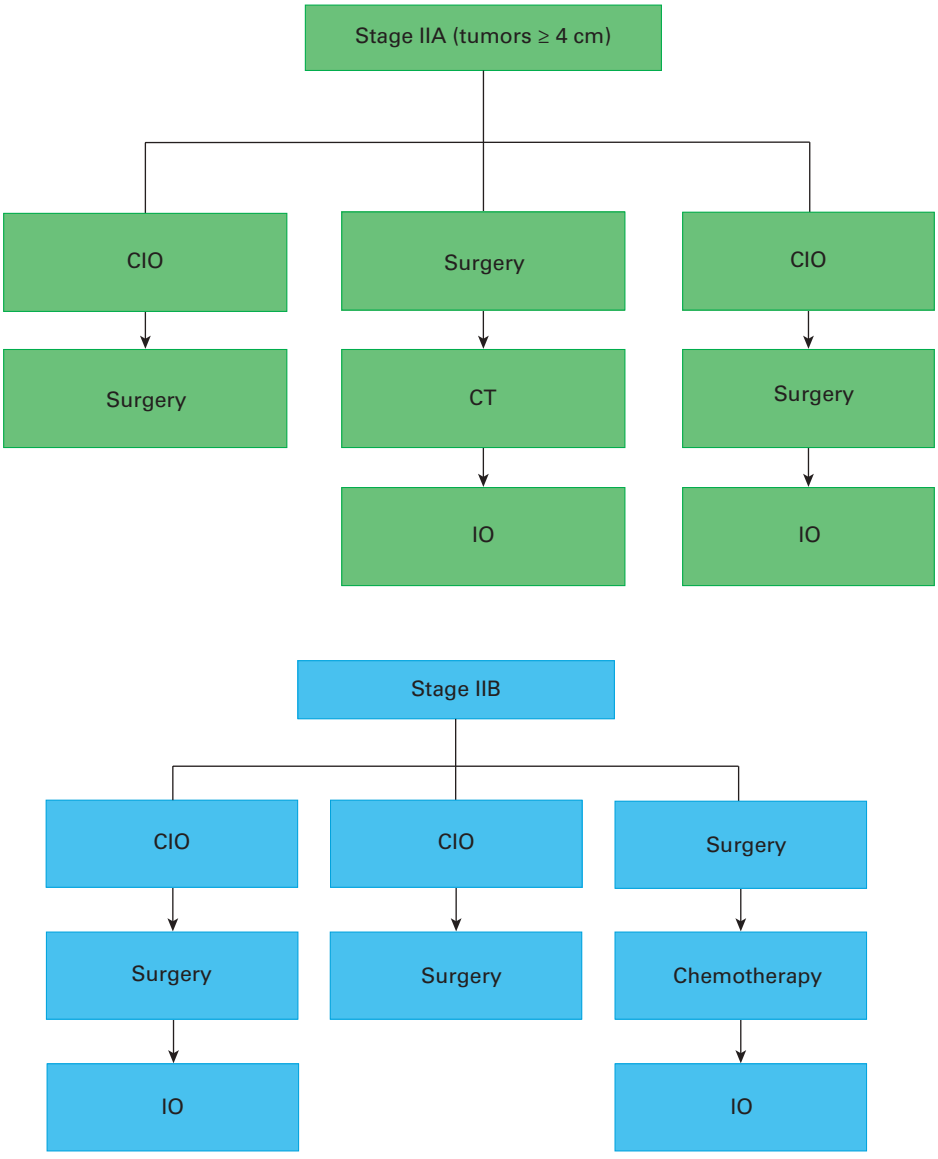
Figure 11-1 Signs and Symptoms Associated With Lung Cancer

Key Symptoms	Other Common Symptoms	Less Frequent, but Important Symptoms	Rare/Severe Symptoms
1. Cough 2. Increased sputum production 3. Shortness of breath	1. Fatigue 2. Weight loss 3. Anorexia 4. Low-grade fever	1. Chest pain 2. Hemoptysis 3. Hoarseness (recurrent laryngeal nerve) 4. Bone pain	1. Superior vena cava obstruction 2. Superior sulcus/Pancoast tumor 3. Pericardial tamponade 4. Paraneoplastic syndromes 5. Brain metastases

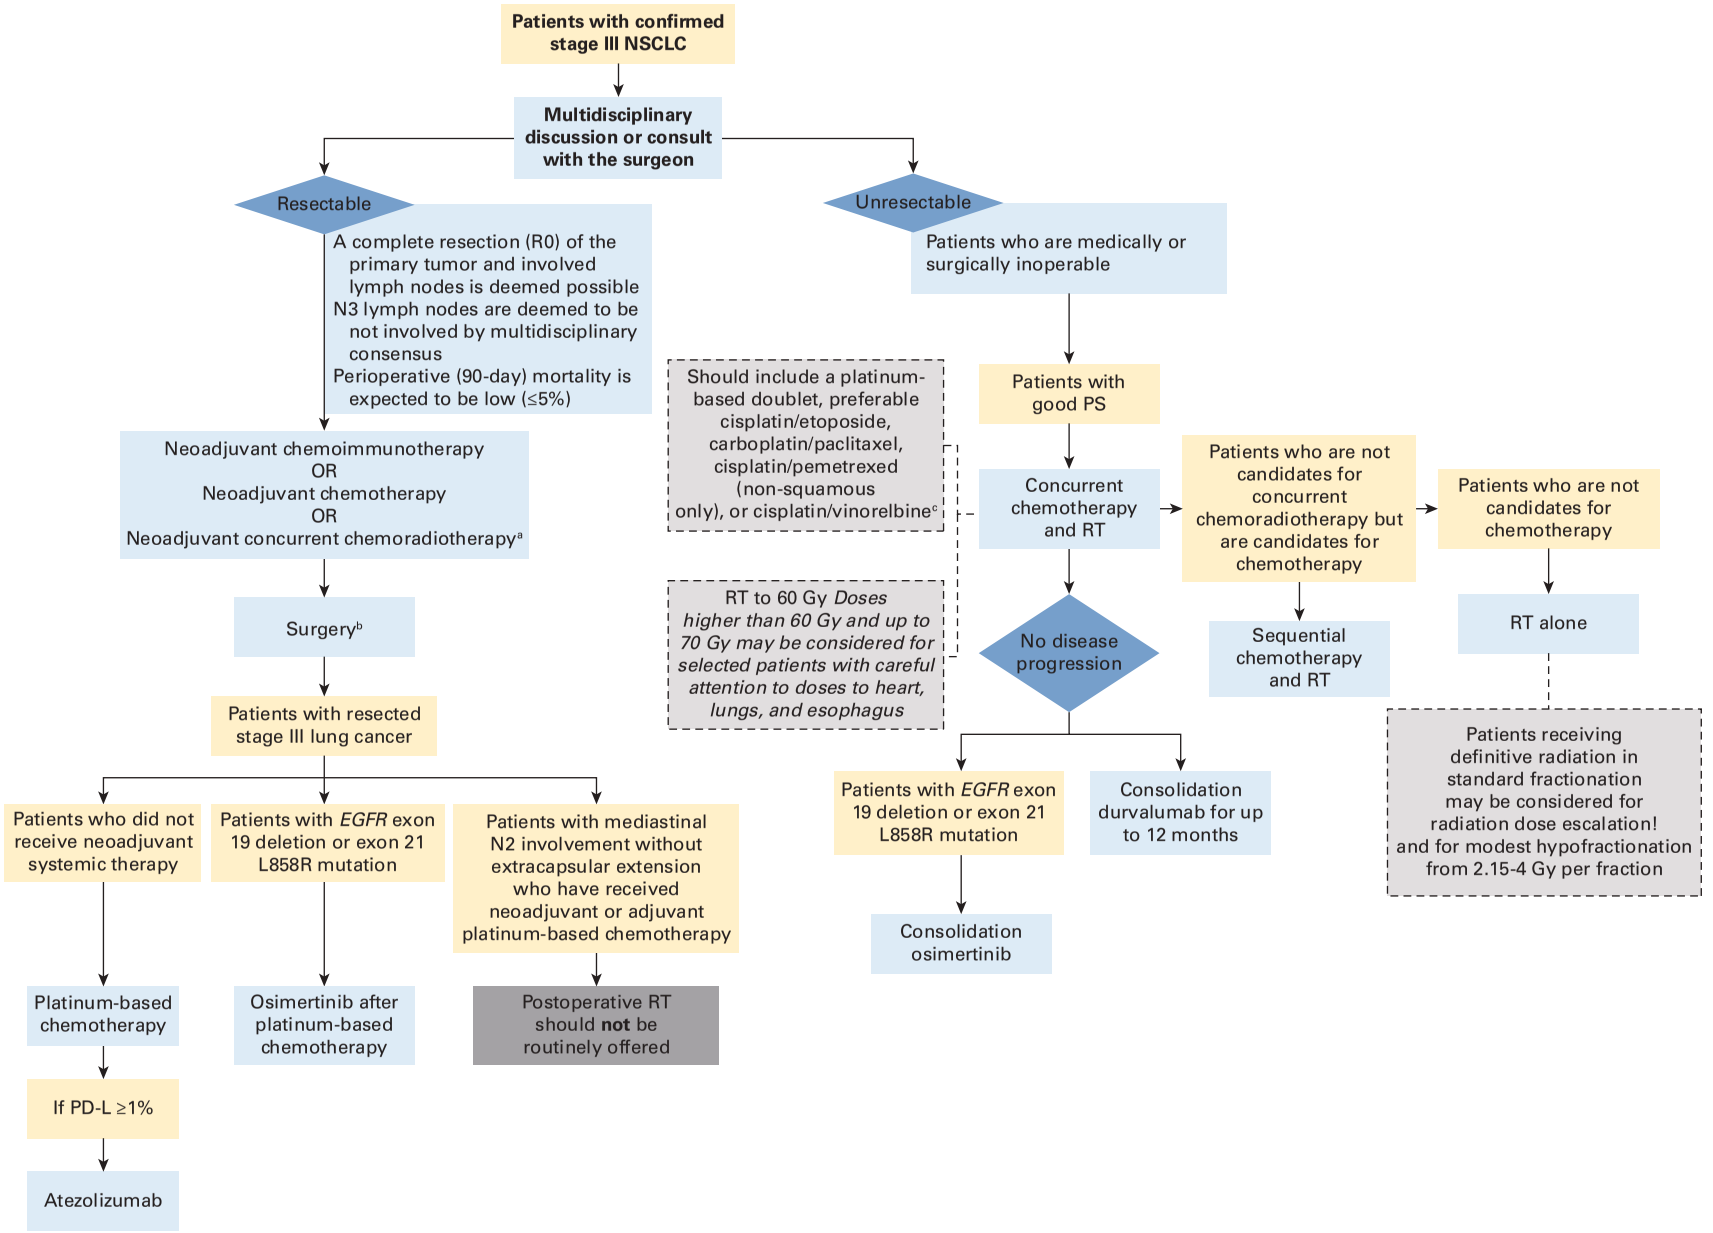
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 11-2 Approved Options for Resectable *ALK* and *EGFR*–Wild-Type Stage IIA and IIB NSCLC



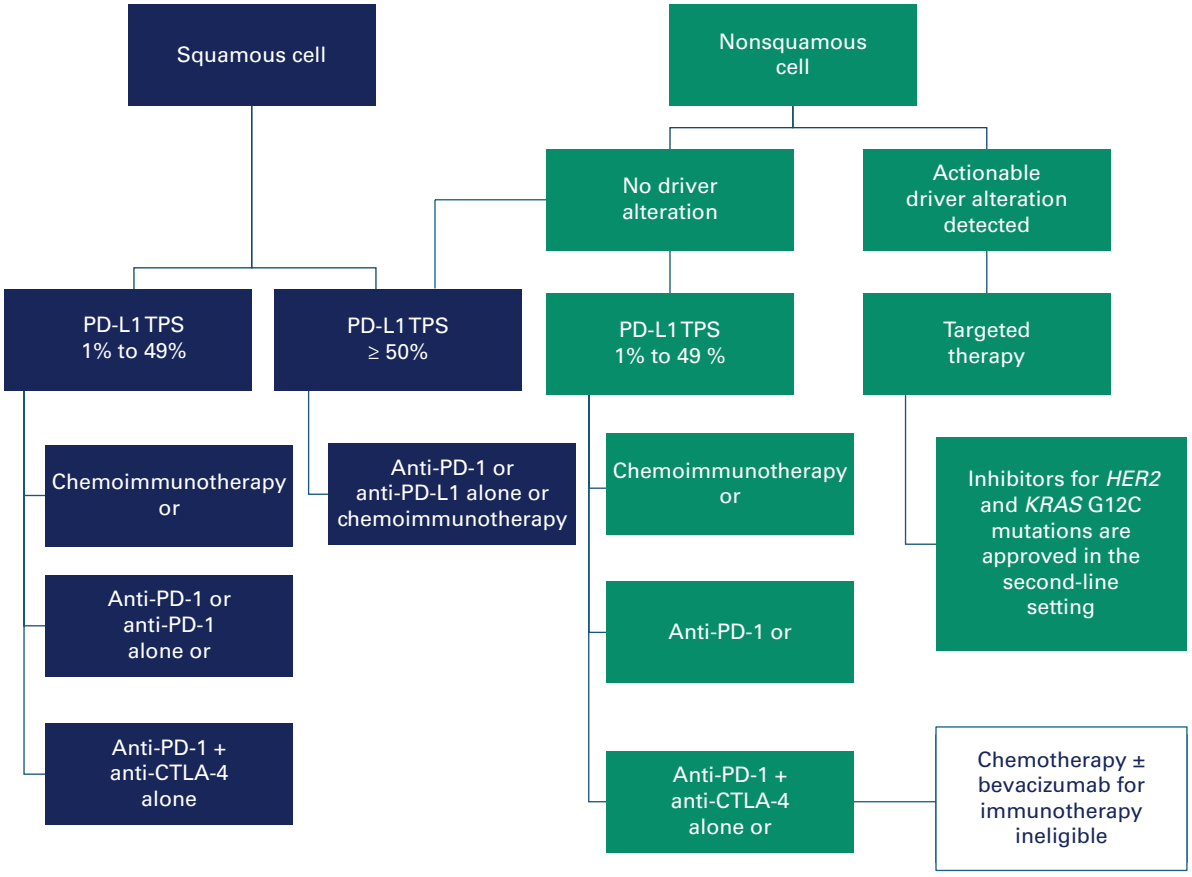
Abbreviations: CIO, chemotherapy with immunotherapy; CRT, chemotherapy and radiation therapy; EGFR, epidermal growth factor receptor; IO, immunotherapy; NSCLC, non–small cell lung cancer.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 11-3 Management of Stage III NSCLC Algorithm



Abbreviations: CT, computed tomography; FDG, fluorodeoxyglucose; MRI, magnetic resonance imaging; NSCLC, non–small cell lung cancer; PET, positron emission tomography; PS, performance status; RT, radiation therapy.
Arrows with dotted lines indicate that the level of obligation is a "may" (moderate) recommendation.
[a]Resectable superior sulcus tumors.
[b]Patients with stage III NSCLC generally should not be excluded from consideration for surgery by nonsurgical physicians.
[c]Carboplatin may be substituted for cisplatin in patients with contraindications to or deemed ineligible for cisplatin.
Reprinted from Daly ME, Singh N, Ismaila N, et al., Management of stage III non–small cell lung cancer: ASCO guideline rapid recommendation update. *J Clin Oncol*. 2024;42(25):3058-3060. doi:10.1200/JCO-24-01324

Figure 11-4 Treatment Paradigms for Advanced Non–Small Cell Lung Cancer by Cancer Subtype and PD-L1 TPS



Abbreviations: PD-L1, programmed cell death ligand 1; TPS, Tumor Proportion Score.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

HEAD AND NECK CANCERS 12

Aarti Bhatia, MD, MPH, and Ari Rosenberg, MD

RECENT UPDATES

- The FDA recently approved penpulimab with cisplatin or carboplatin and gemcitabine for the first-line treatment of adults with recurrent or metastatic nonkeratinizing nasopharyngeal carcinoma (NPC). FDA also approved penpulimab-kcqx as a single agent for adults with metastatic nonkeratinizing NPC with disease progression on or after platinum-based chemotherapy and at least one other prior line of therapy.
- The FDA-approved pembrolizumab for adults with resectable locally advanced head and neck squamous cell carcinoma whose tumors express PD-L1 (combined positive score [CPS] ≥1) as determined by an FDA-approved test, as a single agent as neoadjuvant treatment, continued as adjuvant treatment in combination with radiotherapy with or without cisplatin after surgery, and then as a single agent.

OVERVIEW

Head and neck cancers are a heterogeneous group of malignant tumors arising from the epithelial lining of the upper aerodigestive tract. The specific primary sites are subdivided by anatomic boundaries: lip and oral cavity, pharynx (comprising the nasopharynx, oropharynx, and hypopharynx), larynx, nasal cavity, and paranasal sinuses (Table 12-1). Squamous cell cancer is the most common histologic type, accounting for 85% to 95% of head and neck cancers. Other cancers in the head and neck region are often lumped together under the generic "head and neck cancers" umbrella, and they include neoplasms of the salivary glands and thyroid and tumors of the skull base, such as esthesioneuroblastoma, sinonasal undifferentiated carcinomas, and NUT midline carcinomas. These are biologically distinct and will be covered separately.

Table 12-1 **Head and Neck Cancer: Primary Sites**

Anatomic Area	Primary Cancer Site
Oral cavity and lip	Floor of mouth
	Oral tongue
	Buccal mucosa
	Alveolar ridges
	Hard palate
	Retromolar trigone
Pharynx	Nasopharynx (includes the superior surface of the soft palate)
	Oropharynx (includes the inferior surface of the soft palate, uvula, base of the tongue, tonsil, posterior pharyngeal wall)
	Hypopharynx (pyriform sinus, postcricoid, posterior wall)
Larynx	Supraglottic larynx (false cords, arytenoids, epiglottis)
	Glottic larynx (includes commissures)
	Subglottic larynx
Nasal cavity and paranasal sinuses	Nasal cavity
	Maxillary sinuses
	Ethmoid sinuses
	Frontal sinuses
	Sphenoid sinuses

Etiologic factors include tobacco and alcohol use and viruses such as human papillomavirus (HPV) and Epstein-Barr virus (EBV). Less common risk factors include exposures from betel nut chewing and occupational exposure (eg, formaldehyde, Agent Orange). Head and neck cancers are generally categorized as early-stage disease (localized to the primary site without neck nodal involvement), locoregionally advanced disease (large, bulky tumors [T3 or T4] with or without nodal involvement or smaller primary tumors with nodal involvement), or metastatic disease beyond the neck lymph nodes. Involvement of the neck nodes is prognostically substantial in HPV-negative disease, which reduces the cure rate for patients with a given tumor stage by approximately 50%. Patients with HPV-positive oropharyngeal tumors and multiple ipsilateral neck nodes smaller than 6 cm in size still maintain a favorable prognosis. This is reflected in the American Joint Committee on Cancer (AJCC) *Cancer Staging Manual*, 8th edition, and subsequent versions of the staging system, which have separated staging for p16-positive oropharyngeal squamous cell carcinomas (OPSCCs or oropharyngeal cancers [OPCs]) from p16-negative OPCs. Note that, while p16 immunohistochemistry (IHC) is generally taken as a validated surrogate for HPV-related OPC, this surrogate is not synonymous with HPV-related OPC. Because HPV-specific treatments are emerging, it will be important for clinicians to understand that the gold standard for HPV testing remains either in situ hybridization (ISH) or polymerase chain reaction (PCR) in this situation. Early-stage disease, at times, may be treated with single-modality therapy (ie, surgery, radiation), whereas locally advanced disease is generally treated with multimodality therapy.

Within the aerodigestive tract, second primary malignancies (SPMs) occur most frequently in the lung, followed by the esophagus. SPMs occur as a result of the carcinogenic effect on the upper aerodigestive tract mucosa of chronic exposure to environmental carcinogens (tobacco and alcohol), putting the entire mucosa at risk for forming multiple, independent tumors. The risk and distribution of SPMs vary substantially based on the subsite of the index cancer and are highest for hypopharyngeal cancers. When solitary distant lesions are identified on imaging, patients with early-stage cancers (ie, with no involved neck nodes) are more likely to have an SPM than to have metastases, and treatment should be with curative intent for both the SPM and head and neck cancer. Systemic therapy by itself is palliative and is the mainstay for distant metastatic or recurrent head and neck squamous cell carcinomas (HNSCCs) not amenable to curative approaches.

The other disease sites included in the head and neck region are uncommon base-of-skull and sinonasal tumors and thyroid and salivary gland malignancies. Surgical resection is the standard of care for surgically resectable early-stage or locoregionally advanced salivary gland tumors, followed by radiation when indicated. These diseases are composed of numerous histologies that are associated with differing natural histories. For instance, adrenocortical carcinomas (ACCs) tend to be more indolent, whereas salivary ductal cancers may be more aggressive. For metastatic or recurrent salivary gland cancers, molecular analysis may inform treatment selection in a minority of cases, such as neurotrophic receptor tyrosine kinase (NTRK)-targeting agents for *ETV6::NTRK3* fusion–positive cancers (mammary analog secretory carcinoma [MASC]). In addition, salivary ductal cancers that express either human epidermal growth factor receptor 2 (HER2) or androgen receptor may be treated with HER2-targeting therapies or androgen deprivation therapy (ADT), respectively.

Thyroid cancers include the subtypes of differentiated thyroid cancers (DTCs) such as papillary, follicular, oncocytic, or medullary (MTC), as well as poorly differentiated and anaplastic thyroid carcinomas. Surgical treatment remains the primary modality for patients with DTC who have locoregional disease, and cure rates are very high. Patients with well-differentiated papillary or follicular thyroid cancer typically receive radioactive iodine (RAI) in the postoperative setting for locally advanced disease, and this is the first treatment of choice for metastatic disease if radiolabeled thyroid imaging is positive. Tyrosine kinase inhibitors (TKIs) are approved for the treatment of RAI-refractory disease, regardless of mutation status. Poorly differentiated and anaplastic thyroid cancers (ATCs) often arise from dedifferentiation of DTCs and are associated with a poor prognosis, but data on targeting *BRAF*-mutated ATC with a BRAF and MEK inhibitor combination have been encouraging. MTCs arise from the parafollicular C cells of the thyroid gland and do not respond to RAI. For MTC with known actionable molecular targets such as NTRK and rearrangement during transfection (RET) receptor fusions, targeted agents with remarkably high anticancer activity are FDA-approved agents in the recurrent/metastatic setting. In addition, two multitargeted vascular endothelial growth factor (VEGF)-targeting TKIs are approved for the management of recurrent/metastatic MTC. For both differentiated and medullary thyroid cancers, active surveillance is often appropriate before systemic therapy initiation, even in the metastatic setting, as these cancers can display indolent behavior.

EPIDEMIOLOGY

In 2025, head and neck cancers were expected to account for approximately 4% of all cancers in the United States. It is estimated that 72,700 people will develop carcinomas of the head and neck.[1] The median age at diagnosis is approximately 60 years, and it is also estimated that 16,680 people will die as a result of their disease. Worldwide, head and neck cancer accounts for more than 550,000 cancer cases and 380,000 deaths annually.

Head and neck cancers affect men and women at a ratio of 2.5:1, although the ratio varies according to the primary site (eg, 4:1 for cancer of the oropharynx, 7:1 for cancer of the larynx). OPC incidence has increased substantially since the 1980s, more so in developing countries and often in younger individuals. This increase is related to the rise in HPV-related OPCs, particularly

among men. The prognosis for patients who have HPV-related OPC is much better than for those who have HPV-unrelated OPC. Site-specific cure rates vary, but, in general, environmental carcinogen-induced cancers have a worse prognosis than viral-induced cancers. Overall, the age-adjusted incidence and mortality rates for head and neck cancer are highest among Black men, and the stage-specific survival rates are lowest for this group.

RISK FACTORS

Tobacco and Alcohol

Epidemiologic data document a multiplicative risk relationship between tobacco and alcohol. Those who begin to smoke when they are younger than 18 and who have a cumulative smoking duration of more than 35 pack-years are at the highest risk. In addition, immunosuppression, such as secondary to chronic lymphocytic leukemia, HIV, or immunosuppression after solid organ transplantation, contributes to an increased risk of developing head and neck cancer. Smokeless tobacco and other chewed carcinogens (eg, betel quid, a combination of betel leaf, lime, and areca nut, commonly used in India and parts of Asia) are associated with the development of cancers of the oral cavity. Black air-cured tobacco (used in cigars and pipe tobacco) is more irritating to the respiratory mucosa than blonde or flue-cured tobacco (used in cigarettes) and is associated with a higher risk for head and neck cancer. Preclinical data suggest that, in HPV-related tumors, when tetrahydrocannabinol (THC) is absorbed into the bloodstream, it activates the p38 mitogen-activated protein kinase pathway, which ultimately prevents apoptosis, leading to uncontrolled growth of cancer cells; this is a possible explanation for the epidemiologic observation that the risk of HPV-related OPC is higher in marijuana users.[2,3]

Diet and Genetic Syndromes

Diets low in vitamins A and B and poor oral and dental hygiene are believed to elevate the risk for head and neck cancer. Plummer-Vinson syndrome, which is most commonly seen in postmenopausal women older than 50 years, is associated with iron deficiency anemia, hypopharyngeal webs, dysphagia, and a higher risk for squamous cell carcinomas (SCCs) in the postcricoid region of the hypopharynx, oral cavity, and esophagus. Two inherited syndromes, Fanconi anemia and dyskeratosis congenita, are also linked with the development of head and neck cancers.

Occupational Exposures

Tumors of the sinonasal tract are associated with various occupational toxin exposures (eg, nickel, radium, mustard gas, and chromium, which are byproducts of leather tanning and woodworking).

Viruses

Human Papillomavirus

In the United States between 1984 and 1989, 16% of OPCs were related to HPV; between 2000 and 2019, this increased to 70% of OPCs, predominantly HPV serotypes 16 or 18, revealing a fourfold increase within two decades. This trend was striking, given the decrease in tobacco use in the United States. The incidence of OPCs among men younger than 60 years who have no or minimal use of alcohol or tobacco continues to increase. Although it is clear that HPV can lead to the development of OPCs, the vast majority of humans with evidence of oral HPV exposure do not develop HPV-related OPC, and the latency between HPV exposure and development of HPV-related OPC seems to be in the order of decades. Effective multivalent vaccines against HPV have been developed that provide near-complete immunity against oral and oropharyngeal infection with the highest risk strains of the virus, and they are FDA-approved agents for eligible preteens and young adults up to age 45 years.[4]

The transforming potential of HPV is thought to be from viral proteins E6 and E7, which inactivate the tumor suppressors p53 and pRB and result in loss of cell cycle regulation, cellular proliferation, and chromosome instability.[5]

Expression of p16 is upregulated when HPV E7 oncoprotein degrades the retinoblastoma protein, whereas p16 expression in HPV-negative tumors is silenced by epigenetic promoter methylation or genetic mutation. IHC analysis of tumoral p16 protein expression in OPC serves as a surrogate for determining HPV-related SCC. Thus, the AJCC staging manual, in conjunction with the College of American Pathologists and ASCO guidelines,[6] adopted p16 overexpression by IHC, defined as 70% or higher tumor expression with at least a moderate staining intensity marker, as a surrogate for HPV positivity in OPCs. Because the same survival benefit does not extend to HPV-positive or p16-positive tumors from non-oropharyngeal head and neck sites, p16 IHC staining is not recommended for any other squamous cell head and neck cancers. There is a small risk of discordance between p16 and high-risk HPV testing; 5% of patients with OPC are noted to be HPV DNA–positive but p16-negative.[7] Therefore, confirmatory testing for high-risk HPV should be performed if available. Because more experimental approaches to HPV-related OPC are specific to HPV, and because the prognoses for p16-positive HPV-negative tumors are worse than for HPV-positive OPC, many now consider direct testing for HPV with ISH or PCR to be the gold standard for testing. Patients with HPV-related OPCs have strikingly better survival rates than those with HPV-negative tumors; there is a 3-year progression-free survival (PFS) rate of greater than 90% among low-risk tumors, but, as of 2025, treatment recommendations for the two remain analogous in the curative setting.

Clinical trials attempting to reduce morbidity while preserving cure rates for HPV-associated OPC have, to date, been discordant and not uniformly practice-changing. Therefore, confirmatory testing for high-risk HPV should be performed if available. Because more experimental approaches to HPV-related OPC are specific to HPV, and because the prognoses for p16-positive but HPV-negative tumors are worse than for HPV-positive OPC, many now consider direct testing for HPV with ISH or PCR to be the gold standard for testing. Patients with HPV-related OPCs have strikingly better survival rates than those with HPV-negative tumors; there is a 3-year PFS rate of greater than 90% among low-risk tumors, but, as of 2025, treatment recommendations for the two remain analogous in the curative setting. Clinical trials attempting to reduce morbidity while preserving cure rates for HPV-associated OPC have, to date, been discordant and not uniformly practice-changing.

Detection of circulating tumor HPV DNA (ct HPV DNA) has recently been demonstrated to have a high positive predictive value for relapse after curative treatment of patients with locoregional HPV-associated OPC. The role of this biomarker in the clinical care of these patients remains to be defined because it is not yet known to what extent the use of ct HPV DNA in this or other settings will have an impact on clinically meaningful patient outcomes or decision-making.

Epstein-Barr Virus

Nasopharyngeal carcinoma (NPC) is strongly associated with EBV. However, although the vast majority of humans have serological evidence of EBV exposure as infants or young adults, only a small fraction of those exposed to EBV develop NPC. NPC is common among individuals from endemic areas in southern China and northern Africa, where World Health Organization (WHO) type 2 (nonkeratinizing) and type 3 (undifferentiated carcinoma) NPCs are more common and EBV-driven (Table 12-2). Epstein-Barr-encoding region (EBER) ISH on tumor biopsy is the method of choice for the detection of EBV. WHO type 1 (keratinizing) NPC is more common in Western countries and seems to be more likely related to tobacco exposure or HPV. EBV-associated NPC has a better prognosis than non-EBV-related NPC. A large body of data suggests that, for patients with EBV-related locoregional NPC, baseline ct EBV DNA level is a prognostic biomarker independent of anatomically based AJCC staging parameters. Several studies have also demonstrated that detectable ct EBV DNA after definitive chemoradiation therapy (CRT) for NPC is an independent predictor of poor prognosis. Epidemiologic modeling studies suggest that ct EBV DNA or NPC serological markers might be a cost-effective NPC screening tool in regions of the world with the highest incidence of NPC.[8] Lack of standardization and harmonization of ct EBV DNA assays has substantially restricted the widespread adoption of ct EBV DNA as a tool in the detection and treatment of NPC.[9] Many routinely available assays for EBV DNA in the blood were developed for the study of EBV as an infectious disease or as a marker in EBV-related post-transplantation proliferative disorders. These assays, in general, do not perform at the same levels as those ct EBV DNA assays developed specifically for the study of NPC.

Table 12-2 **WHO Classification Criteria of Nasopharyngeal Carcinoma**

WHO Classification	Former Terminology
Type I: Keratinizing squamous cell carcinoma	Squamous cell carcinoma
Type II: Nonkeratinizing carcinoma Without lymphoid stroma With lymphoid stroma	Transitional cell carcinoma Intermediate cell carcinoma Lymphoepithelial carcinoma (Regaud)
Type III: Undifferentiated carcinoma Without lymphoid stroma With lymphoid stroma	Anaplastic carcinoma Clear-cell carcinoma Lymphoepithelial carcinoma (Schminke)

KEY POINTS

- Tobacco and alcohol use are the major risk factors for non-viral-associated HNSCC, and the use of both results in a multiplicative increase in risk.
- There is a causal association between high-risk oncogenic HPV and cancers of the oropharynx (tonsil, base of the tongue, soft palate) and a causal association between EBV and NPCs, but, in most humans, neither HPV nor EBV exposure results in the development of cancer.
- The prognosis is substantially better for HPV-related OPCs and EBV-related NPCs than for HPV-negative and EBV-negative cancers, respectively, at these sites.
- The incidence of second primary cancers for patients with a history of non-viral-associated HNSCC is 3% to 7% annually; common sites include the head and neck, lung, and esophagus. This high rate of second primaries seems related to a field cancerization effect of tobacco, alcohol, and other toxins.

HEAD AND NECK CARCINOGENESIS

MOLECULAR PROGRESSION MODEL

Among carcinogen-induced cancers, a molecular progression model of multistep carcinogenesis in toxin-related HNSCC has been elucidated for the transformation of normal mucosa to invasive SCC. The earliest genetic alteration noted during transition from normal mucosa to hyperplastic mucosa is the loss of genetic material containing tumor suppressor genes (ie, loss of heterozygosity, allelic imbalance) from chromosome region 9p21 and inactivation (promoter hypermethylation) of the *pl6* tumor suppressor gene.

The next step during the transition from hyperplastic mucosa to dysplasia is the loss of genetic material containing tumor suppressor genes (ie, loss of heterozygosity, allelic imbalance) 3p and 17p, with inactivation (promoter hypermethylation) of the *p53* gene.

Transition from dysplasia to carcinoma in situ is associated with loss of chromosome regions 11q, 13q, and 14q. During the transition to invasive SCC, there is a loss of chromosome regions 6p, 8p, and 4q.

More than half of all patients with tobacco- and alcohol-associated HNSCC have a *TP53* gene mutation and downregulation of p16 protein. By contrast, HPV-associated HNSCC characteristically demonstrates the downregulation of wild-type *TP53* and *RB1* genes and upregulation of p16 protein levels.

ORAL PREMALIGNANCY (INTRAEPITHELIAL) NEOPLASIA

Leukoplakia

Leukoplakia is the most common precancerous lesion in the oral mucosa; the majority (approximately 80%) of leukoplakia lesions are benign.[5] The clinical presentation of these lesions includes white plaques distributed on the patient's lips, buccal mucosa, floor of the mouth, hard palate, tongue, and soft palate.

Erythroplakia

Erythroplakia lesions are associated with a 90% incidence of severe dysplasia, carcinoma in situ, or invasive disease. The clinical presentation of these lesions includes a mucosal red, velvety patch that is separated from the surrounding normal tissue by a distinct interface that occasionally has a pebbled or granular appearance.

KEY POINTS

- The earliest genetic alteration during the transition from normal mucosa to hyperplastic mucosa is the loss of genetic material containing tumor suppressor genes, known as a loss of heterozygosity or allelic imbalance.
- Erythroplakia and leukoplakia lesions are premalignant lesions that can be associated with severe dysplasia, carcinoma in situ, or invasive SCCs.

CLINICAL PRESENTATION, DIAGNOSIS, AND STAGING

In general, cancers of the oral cavity, pharynx, and larynx are characterized by disease confined to the primary site with or without spread to regional lymph nodes at the time of diagnosis, and, for most primary sites, less than 10% of patients have distant disease (beyond regional lymph nodes) at presentation. NPC (see "Nasopharyngeal Cancer" section of this chapter) is an exception. Thus, initial disease staging and management focus on the extent of locoregional involvement and the effect of the choice of treatment on speech and swallowing function, as well as on the risk for recurrence.

PRESENTING SIGNS AND SYMPTOMS

Clinical signs and symptoms vary with the anatomic site affected. The discovery of a painless lump in the neck is a common presenting symptom for a patient with head and neck cancer. The location of cervical adenopathy, denoted by dividing the neck into levels, may direct the physician to the primary site. Higher-level nodes (eg, level 5) may indicate a nasopharyngeal primary, whereas level 2 or 3 nodal involvement more likely dictates a primary from the oral cavity, larynx, or oropharynx. HPV+ OPC may present with occult/small primary with large neck nodes.

DIAGNOSTIC EVALUATION

Because lymph nodes track along the internal jugular vein, examination of the neck for enlarged lymph nodes is facilitated by rotating the head to the side during examination to promote relaxation of the sternocleidomastoid muscle on that side (Fig. 12-1).

ENDOSCOPY

A comprehensive examination of the head and neck with the assistance of mirrors or fiberoptic scopes is central to the evaluation. Examination under anesthesia may be important for patients with tumors of the larynx or pharynx that are not well

Effectiveness of adjuvant radiotherapy in patients with oropharyngeal and floor of mouth squamous cell carcinoma and concomitant histologic verification of singular ipsilateral cervical lymph node metastasis (pN1-state)-a prospective multicenter randomized controlled clinical trial using a comprehensive cohort design. *Trials*. 2009;10:118. doi: 10.1186/1745-6215-10-118

visualized with fiberoptic endoscopic examination. Triple endoscopy (ie, laryngoscopy or pharyngoscopy plus bronchoscopy and esophagoscopy) to rule out synchronous tumors is primarily indicated for patients with evidence of diffuse mucosal abnormalities in the setting of a malignant neck node, especially in levels IV, Vb, and VI without a clear primary site (ie, lower neck nodes), which increases the likelihood of lung or esophageal primary tumors.

IMAGING

High-quality CT scans performed with contrast medium or MRI scans with contrast are the standards for imaging of head and neck cancers. MRI is particularly useful for skull-based tumors and those arising from the sinuses and nasopharynx. CT is thought to be more sensitive for cortical bone erosion evaluation, whereas MRI is the preferred mode to evaluate involvement of extrinsic tongue or pterygoid muscles, nerve involvement, spread to prevertebral fascia, and bone marrow infiltration. In some cases, both CT and MRI are recommended to optimally define the tumor extent, lymph node involvement, and the presence of extracapsular spread.[10]

Thoracic imaging for all but the earliest-stage head and neck cancers is indicated, and for all patients whose tobacco exposure history suggests an increased risk of second primary from field cancerization. Chest radiographs are considered inadequate as screening tests in patients with head and neck cancer. Although both high-resolution thoracic CT with intravenous contrast and PET/CT can be valuable, NCCN guidelines recommend FDG-PET/CT as the preferred modality to evaluate for distant metastatic disease and neck lymph node involvement, even in patients with cN0 disease.[11-13]

Body CT scans and bone scans or FDG-PET/CT imaging scans are also appropriate parts of the workup for patients with NPC, because of the increased incidence of distant metastases for patients with high T and N stages. Bone is the most common site of metastasis in patients with NPC. FDG-PET is also appropriate when the primary site is unknown, to evaluate an equivocal finding on cross-sectional imaging. In approximately 30% of unknown primaries presenting in the neck, the primary site of disease can be located with PET imaging. PET scans should be ordered with cross-sectional imaging of the primary site and neck with contrast, which may be useful for identifying spread to regional nodes in the clinically N0 neck. Identification of the primary site can alter radiation fields or the choice of neck dissection to be performed. FDG-PET is also used to establish a baseline for evaluating response after definitive treatment with CRT (eg, oropharyngeal and nasopharyngeal primaries).

TISSUE DIAGNOSIS

Fine-needle aspiration (FNA) biopsy of a neck lymph node is frequently used to establish tissue diagnosis. Histological examination of needle biopsies with appropriate special stains (eg, p16 IHC or EBER or HPV ISH or PCR) and/or transoral biopsy remains the gold standard for diagnosing head and neck cancer because of their high diagnostic accuracy and ability to be performed in the clinic. In patients with cystic or necrotic lymph nodes whose initial needle biopsy is nondiagnostic, a repeat biopsy under ultrasound or CT guidance, with attention to sampling of the non-necrotic rim of the lymph node, can often establish the diagnosis without a more invasive neck procedure or the need for examination under anesthesia. In patients for whom an alternative definitive pathologic diagnosis, such as lymphoma, is considered, an excisional lymph node biopsy may be preferred. As described above, when SCC of the head and neck is identified in a lymph node, it is important to identify the primary site, but often clinical examination and/or imaging can establish this without the need for a biopsy of a mucosal lesion. A specimen from either the primary site of disease or a clinically involved lymph node is acceptable, depending upon relative feasibility and safety. A biopsy of a primary site is usually preferable to a neck dissection for diagnostic purposes, because open surgical neck procedures for diagnostic purposes can contaminate the field and complicate subsequent treatment plans. It is common for FNAs of cystic lymph nodes to be nondiagnostic because central, necrotic material is obtained. As discussed above, for an initially nondiagnostic needle aspiration of a neck lymph node or transoral biopsy of a suspicious primary site, repeat needle biopsy under ultrasound guidance with attention to sampling of non-necrotic rind material or repeat biopsy of a primary mucosal site is almost always preferable to an open neck procedure performed for diagnostic purposes.

GENERAL RULES FOR CLINICAL STAGING

The stage groupings for all primary sites are based on the TNM classification of the Union for International Cancer Control/AJCC system. The TNM system is based on clinical examination, radiographic information, and pathologic findings. Staging in head and neck cancer is complex and differs according to the primary site of disease as well as p16 or HPV status (in the case of OPC).

For p16-negative tumors, the following is a general summary of the TNM staging guidelines for HNSCC:

- T0 does not apply.
- Oral cavity T stage incorporates primary tumor size and sites of local invasion and depth of invasion (not tumor thickness).
- Primary tumors of the oral cavity and oropharynx that are 4 cm or larger are classified as T3; those with local invasion of adjacent structures are classified as T4.
- Vocal cord paralysis in the setting of a primary tumor of the larynx or hypopharynx indicates a stage of no less than T3.
- Nodal staging system incorporates extranodal extension (ENE) into the N staging (N3b) to reflect the poorer prognosis associated with tumors clinically (skin invasion, dense tethering to adjacent structures, nerve invasion with dysfunction [eg, cranial nerve, brachial plexus]) or pathologically determined to have extension outside the lymph nodes into surrounding connective tissue with or without stromal reaction. Pathologically, it is classified as microscopic (less than 2 mm) or macroscopic (more than 2 mm) and increases the N stage. Radiographic evidence of ENE supports the clinical evidence of ENE but is insufficient alone to upstage N status, according to the AJCC, 8th edition, but this may be incorporated in subsequent AJCC staging manuals.

For p16-positive (HPV-associated) OPC:

- T0 refers to an unidentified primary; other T staging is similar to p16-negative tumors.
- N1 disease refers to any number of involved ipsilateral neck nodes if they are smaller than 6 cm, N2 refers to bilateral or contralateral neck disease, and N3 refers to lymph nodes larger than 6 cm.
- Stage IV is not subdivided into A, B, and C and refers to distant metastatic disease.

For NPCs:

- T2 disease typically involves adjacent muscles, and T4 disease involves prevertebral soft tissue.
- Unilateral or bilateral metastases in cervical lymph nodes larger than 6 cm in greatest dimension are considered N3.
- For all primary sites except the nasopharynx and for p16-positive OPCs, the TNM stage grouping is the same.

Cancers of unknown primary origin for patients who are HPV or EBV positive (ie, p16 positive or EBER positive from cervical nodal biopsy) are regarded as OPCs or NPCs, respectively, and are staged as T0, N-appropriate disease; Tx has been eliminated.

For p16-negative disease, the term early-stage disease refers to stage groups I and II disease and to low-volume stage group III disease (ie, T1 or T2, N0 or N1); the terms locally or locoregionally advanced disease refer to M0 stage groups III and IV disease, specifically a large primary tumor (T3 or T4) or the presence of multiple or bulky neck nodes (N2 or N3).

PRESENTING CASE STUDY 1

A 67-year-old man presents with hoarseness and dysphagia lasting for 2 to 3 weeks. He is a former smoker with a 35 pack-year history of smoking. The patient has a medical history significant for well-controlled hypertension and hypothyroidism. Otolaryngologic evaluation reveals an ulcerative lesion on the right true vocal cord, which is also immobile. He undergoes direct laryngoscopy, and pathology from a biopsy of the lesion shows keratinizing p16-negative SCC. CT of the neck shows two enlarged level 2 lymph nodes on the right side, concerning for metastatic spread. There is no extralaryngeal spread and no thyroid cartilage involvement. PET/CT does not indicate distant spread. The patient completes a medical oncology evaluation; baseline laboratory testing and hearing evaluation findings are unremarkable.

What information would you use in determining the stage of this patient's tumor?

This patient has a glottic larynx tumor. Cord immobility without extralaryngeal spread or thyroid cartilage involvement implies a T3 primary. Multiple involved ipsilateral neck nodes indicate N2b disease, and the absence of distant disease is denoted as M0. This makes the overall stage IVA (cT3N2bM0).

What treatment should you recommend based on the staging?

The three-arm randomized Radiation Therapy Oncology Group (RTOG) 91-11 trial evaluated radiation therapy (RT); induction cisplatin and 5-fluorouracil (5-FU), followed by RT; and concurrent cisplatin and RT. Findings from RTOG 91-11 established the superiority of concurrent chemo RT as a larynx-sparing curative treatment approach. Carboplatin is a less effective radiosensitizer compared with cisplatin, and cetuximab was proven inferior to cisplatin as a radiosensitizer in multiple phase 3 trials in patients with HPV-positive oropharyngeal cancers.[14]

HUMAN PAPILLOMAVIRUS–RELATED OPCS

The AJCC staging system was updated in the eighth edition to account for p16 status, used as a practical but imperfect surrogate for HPV staging of oropharyngeal tumors, given the marked difference in prognosis between patients with p16-positive and p16-negative tumors. The staging system for p16-positive oropharyngeal tumors combines T4a and T4b into a single T4 category. N1 disease indicates one or more ipsilateral lymph nodes with none larger than 6 cm, N2 disease indicates contralateral or bilateral nodal disease, and N3 nodes are those larger than 6 cm.

This p16-positive staging system has three stage groupings for nonmetastatic disease: (1) early stage or stage group I (T0-T2, N0-N1), (2) locally advanced disease or stage group II (T0-T2, N2 or T3, N0-N2), or (3) locoregionally advanced-stage group III (T4 or N3). Stage IV grouping is reserved for M1 disease. Unknown primary cancers that are HPV or EBV positive are treated as OPCs or NPCs with a T0 stage, respectively.

KEY POINTS

- Many presenting signs and symptoms are associated with a particular primary site (eg, hoarseness may refer to the larynx or hypopharynx, and a unilateral otitis media may refer to the nasopharynx).
- The location of pathologic lymph nodes in the neck may suggest the primary site.
- The initial evaluation for head and neck cancer includes a comprehensive examination of the head and neck, including endoscopic examination; imaging of the primary site, neck, and chest; and routine laboratory screenings.
- Early-stage disease is primarily defined as disease limited to a small primary tumor (T1 or T2) with low-risk (N1, one node smaller than 3 cm with no high-risk features) nodal involvement. Locally or locoregionally advanced disease is generally defined as the presence of a large primary tumor (T3 or T4) or the presence of large, multiple, or contralateral regional node involvement (N2 or N3).
- Criteria for unresectable disease include base-of-skull involvement, fixation to the prevertebral fascia, carotid encasement, and involvement of the pterygoid musculature.
- M1 disease is typically not curable and is approached with systemic therapy, although some patients with oligometastatic disease can have long-term remissions using combined modality treatment.

PRINCIPLES OF DISEASE MANAGEMENT

TNM stage groupings help define prognosis and treatment options. Because of their curative potential, surgery and radiation therapy (RT) are the central treatment modalities for head and neck cancers. Chemotherapy may enhance the effects of RT, but, in most cases, by itself, it is not usually considered curative. Although there have been a number of situations in which cures

have been achieved with systemic therapy alone (eg, early-stage larynx cancer),[15] these cure rates are far below what surgery or radiation-based approaches can achieve; therefore, systemic therapy alone is not recommended for HNSCC when a curative option exists.

Management of the primary site and management of the neck are often considered independently, but the overall strategy of minimizing the use of multimodality therapy while maximizing cure potential is used to avoid unnecessary treatment morbidity. Management of head and neck cancer is best served by multidisciplinary treatment planning that involves not only a head and neck surgeon, medical oncologist, and radiation oncologist but also, in certain cases, dentists, prosthodontists, dieticians, pharmacists, audiologists, speech and swallow therapists, physical and occupational therapists, social workers, tobacco cessation support, and psychiatrists.

UNRESECTABLE T4 LESIONS

Primary criteria for unresectability include base-of-skull involvement, fixation to the prevertebral fascia, carotid encasement, and involvement of the pterygoid musculature. Additional criteria include an inability to perform an adequate reconstruction for a functional result and a low likelihood of achieving negative margins.

For p16-negative disease, assignment to the stage group IVB category has implications for prognosis (ie, less favorable) and treatment (ie, primary surgical management not planned, except for oral cavity cancers in which primary surgical resection is the standard upfront approach for resectable disease). For these primary sites, stage group IVB disease includes patients with T4b, any N category, and no metastasis (M0) or any T category and N3 (any neck node larger than 6 cm in greatest diameter). Stage group IVC includes any T and N category as well as M1 disease.

DECISION-MAKING BASED ON PRIMARY SITE OF DISEASE

The primary site of disease, along with stage, dictates initial management decisions. Oral cavity cancers are often initially resected, sometimes with preceding neoadjuvant immunotherapy, followed by appropriate adjuvant therapy. However, for oral cavity tumors, when surgery is not possible, cure rates with CRT are less favorable. Data from randomized trials support integrated chemotherapy and RT as standard treatment options for patients with locally advanced, resectable cancers of the larynx and hypopharynx (with the intent of avoiding total laryngectomy) and for patients with p16-negative or p16-positive cancers of the oropharynx when a nonsurgical approach is chosen. Principles that guide the treatment of laryngeal cancers focus on the ability to provide nonsurgical organ preservation therapy when appropriate. With the increasing use of TransOral Robotic Surgery (TORS) and neoadjuvant immunotherapy, decision-making for OPCs often takes into account stage, functional outcome, and surgical resectability when choosing between surgery and nonsurgical approaches. Once initial management pathways are determined, the stage guides whether to incorporate single or multiple treatment modalities. General guidelines based on the stage are discussed below.

NEWLY DIAGNOSED HPV-NEGATIVE STAGES I, II, AND LOW-BULK III (P16-NEGATIVE T1 OR T2, N0 OR N1, AND M0) OR HPV-POSITIVE STAGE I (NONBULKY DISEASE)

Single-modality treatment with surgery or radiation is typically used for previously untreated early-stage tumors (Fig. 12-2). For T1-2 N1 single lymph node smaller than 3 cm, single-modality surgery or RT should be considered.

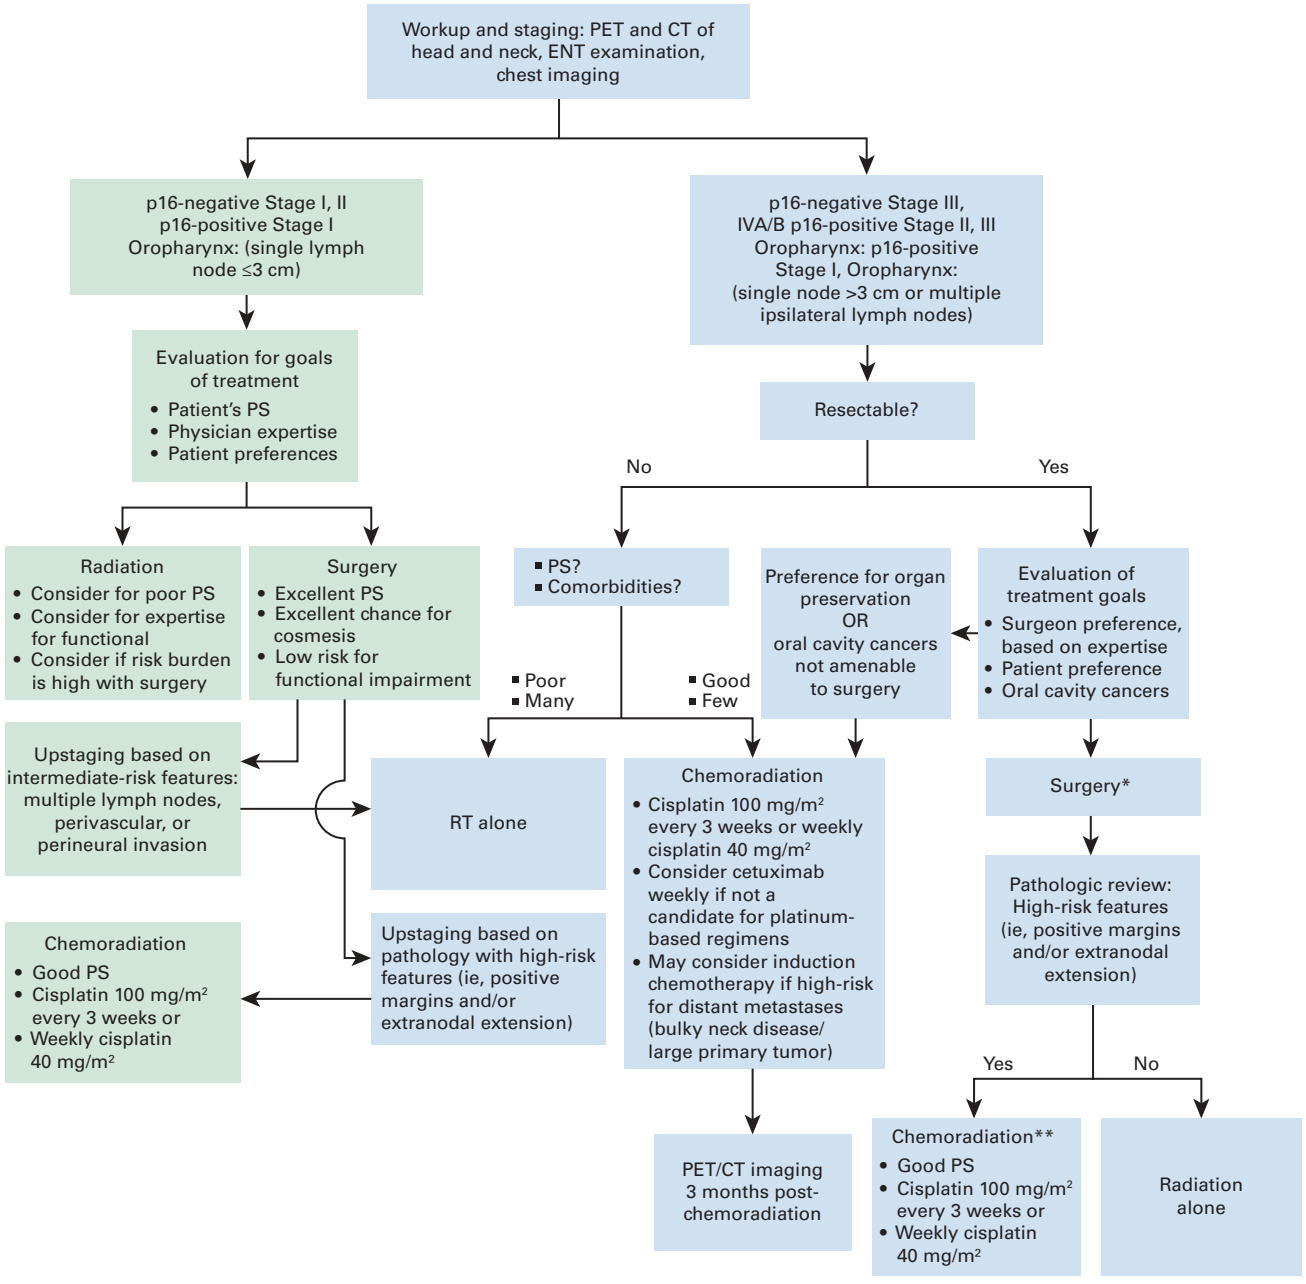
This includes p16-negative stages I, II, or low-bulk (T1-2 N1) III disease (essentially a small primary tumor with or without a single ipsilateral node measuring less than 3 cm in diameter and without clinical or radiographic evidence of ENE) and for p16-positive stage I disease of the oropharynx with a single ipsilateral node measuring less than 3 cm in diameter and without clinical or radiographic evidence of ENE.[16] Based on the Surveillance, Epidemiology and End Results Program (SEER) data, approximately 20% to 30% of head and neck cancers are diagnosed at an early stage. Cure rates for this group range from 52% to 100%, depending on the primary site. Tumors that are upstaged or have positive margins or ENE pathologically typically require additional surgery or adjuvant radiation with or without chemotherapy.

The chosen modality depends on local expertise, anticipated functional outcome, and patient preference. Randomized clinical trials (RCTs) have failed to demonstrate a definite advantage of either an initial surgical or radiation-based approach in terms of survival or quality of life. Because of more favorable survival outcomes and technical concerns of radiation toxicity to the mandible, oral cavity cancers are typically treated surgically. For early-stage larynx cancers, an organ function–sparing strategy is preferred, which may be definitive radiation or organ-sparing laryngeal surgery when feasible.

NEWLY DIAGNOSED, HIGHER-VOLUME HPV-NEGATIVE STAGES III AND IVA/IVB DISEASE OR P16-POSITIVE STAGES I, II, AND III

This group comprises approximately 60% of patients with head and neck cancers at diagnosis, all T3 or greater, all N with more than one lymph node or a lymph node larger than 3 cm. The standard approach is multimodality treatment, often incorporating definitive CRT or surgery followed by radiation or CRT based on pathologic risk factors.

Figure 12-2 Treatment Algorithm for Localized and Locally Advanced HNSCC



Abbreviations: CPS, combined positive score; ENT, ear, nose, and throat; HNSCC, head and neck squamous cell carcinoma; PS, performance status; RT, radiation therapy.
*If PD-L1 CPS ≥1, consider perioperative pembrolizumab.
**If no neoadjuvant immunotherapy, consider adjuvant nivolumab.

When primary CRT is used, surgery is reserved for persistent disease or for recurrence of resectable disease. For locally advanced, resectable cancers of the oral cavity, primary surgical management with appropriate reconstruction and risk-stratified postoperative RT with or without chemotherapy and peri-operative immunotherapy is the mainstay of treatment because anticipated functional and survival outcomes are favorable, even for more advanced tumors, with this treatment approach. KEYNOTE-689 was a phase 3 open-label trial that randomized 714 patients with locally advanced, resectable HNSCC to receive two cycles of neoadjuvant pembrolizumab and 15 cycles of adjuvant pembrolizumab (both at a dose of 200 mg every 3 weeks) in addition to standard care (pembrolizumab group) or standard care alone (control group). Standard care was surgery and adjuvant radiotherapy with or without concomitant cisplatin. The primary endpoint was event-free survival (EFS).[17] EFS at 36 months was 57.6% and 46.4%, respectively (hazard ratio,

0.73; 95% CI, 0.58-0.92; two-sided P = .008), in the total population, almost exclusively HPV negative, and with increasingly diluted benefit with inclusion of lower PD-L1 expressors. Potentially immune-mediated adverse events of grade 3 or higher occurred in 10.0% of the participants in the pembrolizumab group. Based on these results, the FDA-approved pembrolizumab for adults with resectable locally advanced HNSCC whose tumors express PD-L1 (combined positive score [CPS] ≥1) as determined by an FDA-approved test, as neoadjuvant treatment, and continued as adjuvant treatment in combination with RT with or without cisplatin after surgery, and then as a single agent. Thus, neoadjuvant immunotherapy is increasingly used before primary surgical resection for locally advanced HPV-negative and PD-L1-positive HNSCC.

For p16-positive OPC, there is considerable regional variation concerning patterns of treatment and preference for transoral resection and lymph node dissection versus initial CRT. Although two RCTs have been conducted in relatively early-stage p16-positive OPC, neither has been able to definitively answer which approach is superior.[18]

In general, patients who have disease presenting as M1 or recurrent unresectable disease are thought to be incurable, and the standard approach is palliative systemic treatment. An exception to this is patients presenting with low-bulk oligometastatic disease (three or fewer small foci of M1 disease) with a high likelihood of sensitivity to systemic therapy, such as p16-positive OPC and EBV-positive NPC. These patients are often approached with systemic treatment upfront and may be considered for definitive curative therapies in selected cases.[19]

KEY POINTS

- Single-modality treatment with surgery or RT is typically used with curative intent for previously untreated p16-negative stage I, II, or low-bulk III (T1-2, N0, N1: single node smaller than 3 cm) disease or p16-positive stage I (T1-2, N0-1) disease with a single ipsilateral node measuring less than 3 cm in diameter and without clinical or radiographic evidence of ENE.
- Combined modality treatment of surgery and RT or CRT is used with curative intent for previously untreated, higher-volume, p16-negative stage III (T3, N0-1) and stage IVA/B disease or p16-positive stages I (multiple nodes or single node larger than 3 cm), II, and III disease.
- Neoadjuvant and adjuvant pembrolizumab, in addition to risk-stratified standard adjuvant therapy, is associated with improvement in EFS in patients with locally advanced PD-L1-positive (CPS ≥1) HNSCC, where surgery is the initial therapy.
- Metastatic disease below the clavicle and locoregional recurrent disease without a surgical or RT option are generally incurable and are treated with palliative intent. However, there are some patients with oligometastatic disease who are highly sensitive to systemic therapy and for whom curative paradigms of treatment should be considered.

SURGICAL MANAGEMENT OF HEAD AND NECK CANCER

SURGERY OF THE PRIMARY TUMOR

Surgery is used as a definitive modality as well as a salvage option in many types of head and neck cancer. Complete extirpation of the primary tumor with negative margins defines an adequate surgical resection. Nodal surgery (typically a neck dissection) is also required for most head and neck cancers, but it depends on numerous patient factors and tumor characteristics. Recent surgical advances have been made, particularly with TORS. This approach can provide improved visualization and may decrease the morbidity and functional sequelae of surgery. Despite recent advances, surgery in the head and neck anatomic region may lead to significant morbidity and affect a patient's quality of life, particularly when considering operations that necessitate the removal of critical functional structures, like the larynx, tongue, eye, or mandible. The potential adverse effects on cosmesis and function underscore the importance of optimal reconstruction and associated postoperative rehabilitation as part of the treatment strategy. The anticipated adverse effects are also important to consider when discussing surgery with the patient as a possible definitive treatment approach. For example, when considering treatment options for a patient with advanced p16-positive OPC, the decision to choose surgery followed by adjuvant therapy or upfront CRT, for which both options have equivalent survival outcomes, may depend on which modality will lead to better functional outcomes; however, there remain significant regional differences in practice patterns in this area, and there is no consensus on which approach is less morbid.

Improvements in reconstructive techniques have enabled large extirpations with good functional results. A variety of free flaps, frequently composed of skin, muscle, and/or bone (and, occasionally, multiple flaps in the same patient), can successfully address many defects that arise from surgery. In addition, customized obturators and prosthetics can be used alone or in combination with free-flap reconstruction to optimize function.

SURGERY OF THE NECK

Neck dissection plays an integral role in the surgical management of head and neck cancers. The extent of neck dissection depends on a variety of factors, including the location of the primary tumor, extent of clinically positive lymph nodes, and extracapsular extension of nodal disease into surrounding structures (eg, the sternocleidomastoid muscle, internal jugular vein) (Table 12-3).

The use of sentinel lymph node biopsy as part of staging to help guide the need for further treatment has become more common, but has not been widely adopted as a standard of care, replacing lymph node dissection. Neck dissections are typically classified as either radical, modified radical, or selective. A radical or comprehensive neck dissection includes the en bloc removal of all five lymph node levels along with the resection of the sternocleidomastoid muscle, the internal jugular vein, and the spinal accessory nerve. If any or all these structures are preserved, the procedure is considered a modified radical neck dissection. A selective neck dissection removes only specific nodal levels. For example, larynx cancer is typically addressed with a bilateral level 2 to 4 selective neck dissection.

Table 12-3 Lymph Nodal Drainage in Head and Neck Cancers

Primary Cancer	Lymph Nodes
Oral cavity	Submental and submandibular areas (level I), upper and midneck (levels II and III) after level I
Oropharyngeal	Upper and midneck (levels II and III)
Laryngeal (except glottis)	Upper and midneck (levels II and III)
Nasopharyngeal	Upper neck and posterior triangle (levels II and V)
Primary lesion below the clavicle or in the thyroid	Disease confined to the lower part of the neck or supraclavicular area (levels IV and V)
Glottic larynx	Spread to the neck is uncommon
Paranasal sinuses	Spread to the neck is uncommon

Neck dissection is frequently indicated for patients, even those who have no clinically apparent neck disease, given the high risk (20%-35%) of occult nodal metastases, particularly in the oral cavity, and in pharyngeal and supraglottic tumors.[20] In a randomized controlled trial, D'Cruz et al[21] evaluated whether surgeons should treat early-stage oral cavity cancers (cT1-2N0) with elective neck dissection or wait until relapse and then conduct a therapeutic neck dissection at the time of nodal relapse. At 3 years, elective nodal dissection with initial surgery resulted in a better overall survival (OS) rate (80% vs 67.5%) and disease-free survival (DFS) rate (69.5% vs 45.9%). Thus, elective lymph node dissection has been adopted as the standard of care in this scenario.[12]

Sentinel lymph node biopsy could also be used to identify patients with early-stage clinically N0 oral cavity cancer who may benefit from neck dissection, although randomized trials of this approach are ongoing. Reconstruction is frequently required for surgery involving advanced-stage disease.

KEY POINTS

- Function-conserving procedures are applicable for select patients in whom negative margins can be achieved with preservation of structures important for function.
- Debulking surgery is not part of routine clinical practice for head and neck cancer.
- Comprehensive neck dissections involve the removal of all five lymph node levels and are usually performed with therapeutic intent. Selective neck dissections involving the removal of fewer than all five levels are generally done electively to improve staging precision.

PRINCIPLES OF RADIATION THERAPY

The curability of head and neck cancer with RT is inversely related to tumor bulk. HPV- and EBV-positive cancers have higher radiosensitivity compared with HPV- and EBV-negative tumors. The rate of disease control with RT alone decreases with increasing T stage, which explains why RT can be used as a single modality to treat early-stage disease but is generally applied as an adjunct to surgery or combined with chemotherapy for more advanced tumors.

RADIATION DOSE AND FRACTIONATION

Adjuvant Radiation Therapy

Adjuvant RT doses are typically 60 Gy delivered in standard, once-per-day fractionations after surgery and neck dissection and should begin no later than 6 weeks from the postoperative date. Areas of positive margin or nodal extracapsular extension are boosted to 66 Gy, and concurrent radiosensitizing chemotherapy is typically recommended in these high-risk situations.

Uninvolved, nondissected nodal regions considered at risk are typically treated with 50 to 56 Gy. The advantage of locoregional control (LRC) and OS has been demonstrated with adjuvant RT started within 6 weeks of surgery and completed with minimal treatment interruptions. Of note, the ECOG3311 study was a randomized phase 2 trial that tested 60 gray versus 50 gray in the adjuvant setting for intermediate-risk HPV-positive OPC, demonstrating no inferiority, but adoption into clinical practice outside of clinical trials remains controversial.[22]

Technical Aspects of Radiation Therapy

Intensity-modulated radiation therapy (IMRT) is regularly used in the treatment of head and neck cancer and is considered the standard of care. This therapy delivers therapeutic radiation doses specifically to the sites of gross tumor, around the tumor, and the at-risk lymph nodes, with improved conformality defined as the ratio of the dose to the tumor relative to the dose to normal tissues. Advantages of IMRT compared with traditional 2D RT include increased normal tissue-sparing and preservation of anatomic structures (eg, the pharyngeal constrictor muscles necessary for swallowing and the salivary glands). Patients treated with IMRT have a lower incidence of xerostomia than those treated with conventional RT, but they experience higher rates of fatigue during treatment.

Another more recent development is the use of proton beam therapy. In proton beam therapy, the particle delivering the dose of energy is a proton, rather than traditional radiographs or electron therapy. In proton beam therapy, the Bragg peak refers to the physical properties of a proton beam that allow a rapid decrease in RT dose beyond the tumor, leading to lower doses to some normal tissue distal to the radiation source relative to the tumor targeted. Phase 2 data demonstrated efficacy, safety, and favorable toxicity profiles in base-of-skull malignancies, periorbital tumors, NPC, and reirradiation. However, there are no well-controlled data establishing a preferred role for proton beam radiation in most HNSCC situations. Without such data to suggest improved tumor control or decreased toxicity associated with the use of proton beam therapy, its use and cost remain controversial.

Radiation-Related Toxicity

Radiation at the doses previously outlined is associated with predictable acute mucosal and skin toxicities, including mucositis, desquamation, pain, odynophagia, dysgeusia, and thick phlegm or mucus. More aggressive dosing and fractionation schedules, and the addition of concomitant chemotherapy generally increase the severity of these acute toxicities. Rates of any acute and late toxicities higher than grade 3 of 70% to 85% and 40% to 50%, respectively, are associated with a 20% feeding tube dependence at 1 year for patients with HPV-negative disease and 5% for those with HPV-positive disease.[23,24] Feeding tubes will be needed by a subset of patients to get through treatment, especially those who present with swallowing dysfunction and substantial weight loss. Although institutional practices vary, most centers have moved away from prophylactic feeding tubes, given that approximately 50% of patients will never use them.[25] Xerostomia can be a late sequela of RT. Adequate saliva is an important component of oral hygiene; thus, careful dental assessment is recommended before the start of RT, followed by ongoing dental prophylaxis and fluoride treatments. Pain management, nutritional support, swallowing evaluation and therapy, and aggressive oral care are recommended during therapy.

Definitive Radiation

Standard, once-per-day fractionation consists of 2 Gy/d with a total dose of 70 Gy or more to the primary site and gross adenopathy and 50 to 60 Gy to uninvolved nodal stations at risk. Other biologically equivalent fractionation schemes may be used. Altered fractionation schedules consist of more RT doses with a lower dose per fraction, with the goals of improving LRC and widening the therapeutic index. Altered fractionation RT alone is associated with improvements in OS compared with conventional, single-fraction RT alone, but this advantage is not seen when combined with systemic cancer treatment, which is discussed below.

Hyperfractionation refers to twice-per-day treatment, and accelerated fractionation (AF) typically refers to six fractions per week separated by more than 6 hours to allow for normal tissue repair. RTOG 0129 was designed to test the efficacy and toxicity of cisplatin plus AF with a concomitant boost versus standard fractionation (SF). Patients with locally advanced HNSCC were randomly assigned to 70 Gy in 35 fractions over 7 weeks (SF) or 72 Gy in 42 fractions over 6 weeks (AF). Cisplatin doses were 100 mg/m^2 once every 3 weeks for two (AF) or three (SF) cycles. The clinical trial established no benefit from combined concurrent CRT with SF or AF in OS rate (hazard ratio [HR], 0.96; $P = .37$; 5-year rate: 57% vs 60%; 8-year estimated rate: 48% vs 48%), PFS rate (HR, 1.02; $P = .52$; 5-year rate: 49% vs 50%; 8-year estimated rate: 42% vs 41%), or locoregional failure rate (HR, 1.08; $P = .78$; 5-year rate: 31% vs 34%; 8-year estimated rate: 37% vs 39%).[26]

KEY POINTS

- Head and neck RT commonly causes acute toxicities, including mucositis, edema, dermatitis, dysgeusia, and xerostomia. Other potential toxicities include osteoradionecrosis of the mandible.
- IMRT delivers radiation around the tumor and high-risk lymph nodes conformally. It is associated with less dry mouth after treatment than that seen with conventionally planned RT.

PRINCIPLES OF CHEMOTHERAPY

Cisplatin is the most widely used cytotoxic drug in the curative treatment of HNSCC. Other drugs with activity include carboplatin, fluorouracil and related oral analogs, taxanes (ie, paclitaxel, docetaxel, nab paclitaxel), methotrexate, and cetuximab. The reported response proportions with chemotherapy vary with the setting (untreated or pretreated) and with the drugs used (single agent or combination).

Platinum-based regimens are most commonly used as first-line therapy with CRT, with induction regimens, and with disease that is metastatic or incurable. The anticipated major response rate for patients with previously untreated disease is 60% to 90%, with clinical complete responses in 20% to 50% of patients. By contrast, the activity of platinum-based drug combination therapy for patients with recurrent disease is 30% to 40%, and complete responses are rare. Rates of complete and partial responses from single-agent therapy are approximately half the rate of those observed with combination chemotherapy.

When the goal for therapy is to control or cure locoregional disease, the chemotherapy literature can be divided into the following four groups:

- Induction or neoadjuvant chemotherapy administered before definitive local therapy (surgery, RT, or CRT)
- Concurrent CRT in the setting of locally advanced disease
- Adjuvant CRT after definitive surgery
- Adjuvant chemotherapy after definitive CRT or sequential CRT

INDUCTION CHEMOTHERAPY

Historically, induction chemotherapy has not provided improvements in LRC or survival compared with standard concurrent CRT treatments for HNSCC; currently, it is often reserved for patients who are not ideal candidates for upfront concurrent treatment (Table 12-4). However, cisplatin and 5-FU (PF) in one subset analysis demonstrated potential survival benefit. Subsequent induction studies compared the addition of taxanes to cisplatin and 5-FU (docetaxel, cisplatin, 5-FU [TPF]) versus PF followed by definitive RT or CRT. Results from three phase 3 RTCs compared three or four cycles of induction TPF with standard PF.[24] These three trials, along with a meta-analysis of five randomized trials of 1,772 patients comparing PF induction therapy with the TPF regimen, established TPF as the standard of care for HNSCC when induction chemotherapy followed by definitive RT or CRT is elected following a multidisciplinary discussion; however, there is no consensus concerning which patients should be offered induction.[27]

Table 12-4 Induction Chemotherapy Clinical Trials Followed by Definitive Radiation for Patients With HNSCC

Study	No. of Patients	Population	Study Arm	Primary Outcome	Secondary Outcome
GORTEC9 2000-01	213	Larynx and hypopharynx (requiring laryngectomy) for organ preservation	IC with TPF vs IC with PF followed by definitive radiation	3-year laryngeal preservation: 70.3% vs 57.5% (P = .03)	Overall response rate: 80% vs 59.2% (P = .002)
TAX 32310	358	Unresectable oropharynx, hypopharynx, oral cavity, and larynx	IC with TPF vs IC with PF, both followed by definitive radiation	Median PFS, 11 months vs 8.2 months; median OS, 18.8 months	CRR: 33% vs 19.9% (P = .004)
TAX 32411	501	Oropharynx, larynx, hypopharynx, and oral cavity for organ preservation (T3-T4, N2-N3 disease only)	IC with TPF vs IC with PF, both followed by weekly carboplatin (AUC 1.5) with radiation	5-year OS: 52% vs 42% (P = .014)	Median PFS: 38.1 months vs 13.2 months (HR, 0.75; 95% CI, 0.60-0.94)

Abbreviations: AUC, area under the curve; CRR, complete response rate; HNSCC, head and neck squamous cell carcinoma; HR, hazard ratio; IC, induction chemotherapy; OS, overall survival; PF, cisplatin, fluorouracil; PFS, progression-free survival; TPF, docetaxel, cisplatin, fluorouracil.

SEQUENTIAL THERAPY

To test whether induction chemotherapy followed by CRT improved survival compared with CRT alone, three phase 3 randomized trials comparing TPF followed by CRT versus initial CRT alone were conducted; they demonstrated no survival benefit.[28-30] With the exception of treatment of nasopharyngeal and laryngeal primary tumors, induction chemotherapy is considered a category 3 recommendation guideline per the NCCN.[31] Outside of NPC, no sequential CRT or induction CRT regimen has demonstrated an improvement in OS in patients with HNSCC (Table 12-5). However, studies have established that TPF induction carries an OS

benefit relative to PF induction as discussed above. Therefore, if there is a clinical situation in which induction chemotherapy followed by sequential CRT is indicated, TPF should be used if feasible. There is no expert consensus concerning when to use induction instead of starting concurrent CRT initially. The most common scenario for induction chemotherapy outside of NPC is when a change in tumor bulk would have a significant impact on subsequent radiation planning and toxicity from large radiation fields. A specific exception is in patients with NPC. Induction chemotherapy followed by sequential CRT is the standard of care for patients with locoregionally advanced NPC based on RCTs that demonstrate improved OS[32-34] and is discussed in more detail below.

Table 12-5 Sequential Therapy Clinical Trials for Patients With HNSCC

Study	No. of Patients	Population	Study Arm	Primary Outcome	Secondary Outcome	Grades 3 to 4 Toxicity (%)
PARADIGM[28]	145 (study terminated early owing to poor accrual)	Unresectable or T3-T4 or N2-N3 (except for T1, N2), or candidates for organ preservation	IC with TPF for three cycles: response evaluation; NR: weekly docetaxel with RT; PR: weekly carboplatin with RT vs high-dose cisplatin every 3 weeks with RT	3-year OS: 73% vs 78% (HR, 1.09; *P* = .77)	Febrile neutropenia in the IC followed by chemoradiation (16 patients) compared with the chemoradiation arm	Mucositis IC: 47 CRT: 16
						Febrile neutropenia IC: 23 CRT: 1
						PEG tube placement IC: 79 CRT: 85
DeCIDE[33]	280 (planned: 400)	N2-N3 disease	Docetaxel/FU/hydroxyurea and radiation vs TPF three cycles followed by docetaxel/FU/hydroxyurea and radiation	3-year OS 75% vs 73% (*P* = NS)	3-year distant failure: 10% vs 19% (*P* = .025)	Mucositis IC: 9 CRT: 47
						Neutropenia IC: 11 CRT: 2
						PEG tube placement IC: 79
Hitt et al[30]	439	Unresectable; primary sites: oropharynx, oral cavity, larynx, hypopharynx; greater than measurable lesion	IC with TPF or PF three cycles followed by high-dose cisplatin every 3 weeks with radiation vs high-dose cisplatin every 3 weeks with radiation	Median PFS: 14.6 months/14.4 months vs 13.8 months (*P* = .56) TTF 7.9 months/7.9 months vs 8.2 months (*P* = .90)	No statistically significant differences for OS	Stomatitis IC: 44 CRT: 37
						Febrile neutropenia IC: 10 CRT: 1

Abbreviations: CR, complete response; CRR, complete response rate; CRT, concomitant chemoradiation; FU, fluorouracil; HNSCC, head and neck squamous cell carcinoma; HR, hazard ratio; IC, induction chemotherapy; NR, nonresponse; NS, not significant; OS, overall survival; PEG, percutaneous endoscopic gastrostomy; PF, cisplatin, fluorouracil; PFS, progression-free survival; PR, partial response; RT, radiation therapy; TPF, docetaxel, cisplatin, fluorouracil; TTF, time to treatment failure.

CONCOMITANT SYSTEMIC THERAPY AND RADIATION THERAPY

Chemotherapy

A major role of chemotherapy in patients with nonmetastatic disease is a radiation sensitizer. Therefore, priority has focused on agents that show activity against the disease and radiation enhancement properties (eg, cisplatin, carboplatin, cetuximab, taxanes, and 5-FU). Combined modality therapy with chemotherapy and RT is considered standard treatment for patients who have locally advanced, unresectable HNSCC who can tolerate the anticipated added treatment-related toxicity; in some cases, it may preserve organ function.

CRT, typically with concurrent cisplatin, is considered standard of care in organ preservation of locoregionally advanced larynx and hypopharynx cancers and OPCs and NPCs.[35] Toxicities, including hearing loss, protracted nausea and vomiting, renal

dysfunction, and peripheral neuropathy, may preclude patients from receiving all planned cisplatin doses. Based on retrospective data, a cumulative minimum cisplatin dose of 200 mg/m^2 appears optimal. Schedules of 40 mg/m^2 once per week or 100 mg/m^2 once every 21 days are most commonly used. Data from an ongoing prospective RCT comparing cisplatin every 21 days to cisplatin once per week are not yet available, and either administration schedule is considered an acceptable standard of care. It is noteworthy that most phase 3 trials comparing definitive CRT versus RT for locoregionally advanced HNSCC have used 100 mg/m^2 once-every-21-days dosing.

An option for patients who are not eligible for cisplatin is carboplatin and 5-FU, based on improvement in OS and DFS seen in a phase 3 trial when administered in combination with RT versus RT alone (3-year OS: 51% vs 31%, respectively; P = .02; 3-year DFS: 42% vs 20%; P = .04).[36] Another option is docetaxel once per week, based on phase 2/3 data from a trial that randomly assigned patients to docetaxel-RT versus RT alone. Toxicities in the concurrent arm included mucositis, dysphagia, and odynophagia. Compared with RT alone, the addition of docetaxel resulted in an improvement in DFS (30.3% vs 42%) and median OS (15.3 months vs 25.5 months).[37] Weekly carboplatin and paclitaxel remains a commonly utilized concurrent regimen in the cisplatin-ineligible population based on single-arm studies. As discussed below, cetuximab combined with RT is superior to RT alone in HNSCC, but cetuximab is also known to be inferior to cisplatin combined with RT in patients with p16-positive OPC.

When possible, with the exception of advanced laryngeal cancers, which were excluded from landmark organ preservation studies, large, bulky (T4 or N3) tumors should be treated with combined cisplatin and RT.[37,38] A published meta-analysis demonstrated that CRT regimens are associated with an 8% absolute survival benefit at 5 years compared with RT alone (HR, 0.81; 95% CI, 0.76-0.88; P < .0001).[39] An updated analysis of 87 trials involving more than 16,000 patients showed the same absolute benefit for survival with concomitant treatment (HR, 0.81; P < .0001), and multiagent chemotherapy (eg, cisplatin and 5-FU) does not offer an advantage over single-agent cisplatin when combined with RT.[40]

Cetuximab

Epidermal growth factor receptor (EGFR) is highly expressed in HNSCC, and the expression is inversely associated with prognosis. In a multicenter trial, the EGFR inhibitor cetuximab, when administered once per week with RT, demonstrated improvements in locoregional failure-free survival (FFS) and OS compared with RT alone for patients with advanced head and neck cancers.[36] The updated median OS for patients with disease treated with cetuximab and RT was 49.0 months (95% CI, 32.8-69.5) compared with 29.3 months (95% CI, 20.6-41.4) in the RT-alone group (HR, 0.73; 95% CI, 0.56-0.95; P = .018). The 5-year OS rate was 45.6% in the cetuximab and RT group and 36.4% in the RT-alone group. Survival was improved for patients who experienced at least a grade 2 acneiform rash compared with patients with grade 0 or 1 rash (HR, 0.49; 95% CI, 0.34-0.72; P = .002).[41] Unlike cisplatin, cetuximab, when administered with RT, has no effect on distant metastases. Three different randomized trials—RTOG 1016, De-ESCALaTE, and TROG 12.01—established the superiority of cisplatin over cetuximab for HPV-related OPC.[38,42,43] The only indication for cetuximab with RT instead of platinum-based chemotherapy is in the treatment of patients with good performance status for whom the use of platinum-based chemotherapy is precluded (eg, severe hearing loss, creatinine clearance less than 30 mL/min, severe peripheral neuropathy) or because of patient preference, because of a concern for platinum-related toxicities. It is unknown whether docetaxel, carboplatin/paclitaxel, or cetuximab is preferable in this situation.

The addition of cetuximab to cisplatin and RT is not beneficial. RTOG 0522 directly evaluated the addition of cetuximab to standard treatment with cisplatin and RT and did not find a PFS or OS benefit.[44]

Checkpoint Inhibitors in the Curative Setting

As outlined above, KEYNOTE-689 has established the role of pembrolizumab in the perioperative treatment of resectable locally advanced HNSCC with CPS ≥1 disease, while NIVOPOSTOP has shown benefit for nivolumab in combination with CRT in patients with high-risk HNSCC in the adjuvant setting.

To date, numerous phase 3 trials have not supported the use of immune checkpoint inhibitors (ICIs) when administered concurrently with CRT.[45] Both avelumab and pembrolizumab did not improve PFS and EFS, respectively, when added to standard-of-care cisplatin and RT in patients with locally advanced HNSCC, although pembrolizumab did trend toward positivity with longer follow-up, and atezolizumab did not improve EFS when administered after multimodality definitive treatment. In addition, NRG-HN004 was a randomized phase 2 trial that randomized cisplatin-ineligible patients with stages III to IVB p16-negative HNSCC or unfavorable stages I to III p16-positive OPC or unknown primary carcinoma to cetuximab versus durvalumab in combination with curative-intent RT. The trial was suspended following an interim futility analysis after 190 patients were enrolled. Two-year PFS was 50.6% (95% CI 41.5-59.8) in the durvalumab group versus 63·7% (51.3-76.1) in the cetuximab group (HR 1.33, P = 0.89).[46-49] Therefore, this approach is considered investigational.

Adjuvant Chemoradiation Therapy

Adjuvant CRT applies mainly to patients with advanced, resectable oral cavity or larynx, oropharynx, or hypopharynx cancers for whom organ-sparing CRT as the initial modality of treatment is not appropriate.

Two phase 3 RCTs have clarified the role of CRT in the postoperative adjuvant setting. The RTOG[50] and the European Organization for Research and Treatment of Cancer (EORTC)[51] trials addressed the question of whether the addition of high-dose cisplatin to standard postoperative RT (based on pathologic criteria) would improve the outcome for patients compared with postoperative RT alone. In both studies, toxicity was greater with concomitant CRT.[50,51] Although the treatment was similar in these two studies, the high-risk pathologic features were not uniform, and the study populations differed. The RTOG trial high-risk criteria included more than two positive lymph nodes, extracapsular extension of nodal disease, or positive margins. The EORTC trial high-risk criteria included positive margins, ENE, vascular embolism, or perineural disease; for oral cavity or oropharynx primary sites, high risk was defined as positive nodes at level 4 or 5.

Survival differences were statistically significant in the EORTC trial but not in the RTOG trial, partly because of the differences in entry criteria. A pooled analysis of both studies indicated that the subsets of patients in both trials who experienced a substantial benefit from cisplatin with RT had either microscopically involved margins or extracapsular extension of disease in neck nodes.[52] The presence of either or both of these risk factors is considered an absolute indication for adjuvant CRT. The presence of one or more intermediate pathologic risk factors in the absence of involved margins or extracapsular extension, such as close (less than 5 mm) resection margin(s), pathologic T3 or T4a tumor, pathologic N2 disease, lymphovascular, and/or perineural invasion, adjuvant CRT can be considered.[53]

A reanalysis of the RTOG trial, with a median follow-up of 9.4 years, demonstrated a substantial advantage for CRT with LRC of disease and DFS for patients with either positive margins or extracapsular nodal extension, but with only a trend for OS benefit.[54] Cisplatin (100 mg/m^2) administered on days 1, 22, and 43 during RT is one CRT regimen for adjuvant therapy. The phase 2/3 JCOG 1008 trial randomly assigned patients with high-risk (microscopically positive margin and/or ENE) locally advanced HNSCC to cisplatin once every 3 weeks (100 mg/m^2) or once per week (40 mg/m^2) concurrently with adjuvant RT. A total of 261 patients were enrolled, and, at a median follow-up of 2.2 years, CRT with cisplatin once per week was noninferior to 3-weekly cisplatin in terms of OS, with an HR of 0.69 (99.1% CI, 0.374-1.273 [<1.32]; one-sided *P* for noninferiority = .0027 [<.0043]). The once-per-week cisplatin arm was associated with less frequent infection, neutropenia, hearing loss, and renal impairment.[55] For concerns related to poor compliance because of toxicities related to high dose, the NCCN guidelines for head and neck cancer note that once-per-week cisplatin (40 mg/m^2) with RT may be considered in an adjuvant setting.

The NIVOPOST-OP trial was a phase 3, open-label trial that randomized 666 patients with high-risk pathologic features to adjuvant nivolumab before, during, and after cisplatin-RT versus adjuvant cisplatin-RT alone. The 3-year DFS was 63.1% in the nivolumab and CRT arm versus 52.5% in the CRT-alone arm, with an HR of 0.76, and is a treatment option for high-risk resected patients who did not receive neoadjuvant immunotherapy.[56]

KEY POINTS

- For patients with unresectable HNSCC, CRT with concurrent cisplatin improves survival compared with RT alone and is the standard of care.
- The optimal dosing regimen (40 mg/m^2 once per week or 100 mg/m^2 once every 21 days) for concurrent cisplatin remains to be defined. A cumulative dose of 200 mg/m^2 should be prioritized.
- In locally advanced laryngeal cancer (T2 to low-volume T4), LRC and larynx preservation are substantially improved with concomitant cisplatin and RT compared with induction chemotherapy followed by RT or RT alone.
- Cetuximab added to RT improves survival compared with RT alone in locally advanced head and neck cancer, but it is inferior to cisplatin with RT.
- Docetaxel combined with RT in patients who are not candidates for treatment with cisplatin is superior to RT alone in patients with locoregionally advanced disease.[57]
- CRT with cisplatin is the standard of care for postoperative adjuvant treatment of patients with positive resection margins and/or ENE of disease, with an emerging role for immunotherapy.
- The role of induction chemotherapy before CRT has yet to be defined. Several clinical trials have failed to demonstrate an advantage to induction other than for NPC (discussed below).

COMBINED MODALITY TREATMENT: ORGAN PRESERVATION

For patients with locally advanced SCC of the larynx, hypopharynx, or oropharynx, CRT yields better disease control compared with RT alone, although acute toxicities are greater. Successful applications of chemotherapy and RT strategies (ie, management of mucositis, weight loss, hematologic toxicities, swallowing dysfunction necessitating the need for a feeding tube) for organ preservation often use a team approach that may include the head and neck surgeon, radiation oncologist, and medical oncologist, as well as a dietician, swallowing therapist, oncology nurses, advanced care practitioners, pharmacists, and social workers. Close monitoring with comprehensive head and neck examinations and timely integration of salvage surgery, when necessary, are part of the treatment plan and are necessary to avoid compromising survival.

PET imaging 3 months after treatment is useful in the assessment of patients with node-positive disease who were treated with CRT. Rather than having all patients proceed to neck dissection, given the high negative predictive value of FDG-PET, observation can be considered for patients who achieve a complete metabolic response. Premature FDG-PET/CT imaging is associated with a high rate of false-positive incomplete metabolic response, so FDG-PET imaging should not be obtained within 12 weeks after RT completion. For HPV-positive OPC, cancer-specific ct HPV DNA has a high positive predictive value and negative predictive value for relapse after definitive CRT. However, the exact role of ct HPV DNA for routine posttreatment surveillance has not yet been specifically defined. Evaluation of functional and quality-of-life outcomes[58] is also required to assess the overall benefit of organ preservation therapies.

LARYNX AND HYPOPHARYNX

The US Department of Veterans Affairs Laryngeal Cancer Study Group (VALCSG) RCT demonstrated that organ-sparing CRT could substitute for laryngectomy with no significant difference in survival between CRT and surgery.[59] In this trial, patients with locally advanced, resectable T2-T4 laryngeal cancers were randomly assigned to induction chemotherapy with three cycles of cisplatin and 5-FU (PF) followed by RT for chemotherapy-responsive disease or total laryngectomy followed by RT. Total laryngectomy was avoided for approximately two-thirds of survivors who received CRT. Although OS was suboptimal in both arms, long-term follow-up of more than 10 years continued to demonstrate no significant difference in survival between the groups. On multivariable analysis, T4 and N2 disease were both significant predictors of treatment failure, with 56% of patients who had T4 tumors eventually requiring laryngectomy.

The EORTC performed a similar study involving patients with advanced, resectable (T2-T4) cancer of the hypopharynx.[60] No difference in survival between the two groups was noted, and the 5-year estimated rate of successful larynx functional preservation (ie, local control and no tracheostomy or feeding tube) was 35%.

In follow-up to the VALCSG study, the Intergroup RTOG 91-11 trial addressed two unresolved issues: the optimal sequencing of chemotherapy and RT (induction chemotherapy followed by RT or concomitant chemotherapy and RT) and the precise contribution of chemotherapy added to RT.[14] Patients with locally advanced SCC of the larynx were randomly assigned to one of three treatment arms: RT alone (70 Gy), concomitant cisplatin (100 mg/m^2 once every 21 days × 3 and RT [70 Gy]), or three cycles of induction PF followed by 70 Gy RT. Both chemotherapy regimens significantly improved locoregional FFS compared with RT alone. OS did not differ significantly, although there was a possibility of a worse outcome with concomitant relative to induction chemotherapy.[14] For patients who fit the inclusion criteria for this study, concomitant cisplatin and RT or induction followed by RT remain the standard treatment options for preservation of organ function. It is important to note that this strategy was not used in T4 tumors or tumors that had already significantly compromised laryngeal function.[61]

OROPHARYNX

CRT was standard practice for most resectable, advanced oropharynx cancers before the increasing use of transoral surgical techniques. Randomized data between the two modalities are limited, and patient selection for nonsurgical treatment depends on T/N stage and functional preservation.

A retrospective multivariable analysis of patients who received treatment in the RTOG 0129 trial revealed significantly improved 3-year survival rates among patients who were HPV positive compared with those who were HPV negative (84% vs 57%, respectively).[24] Per the ASCO Radiation Oncology Evidence-Based Clinical Practice Guidelines,[62] intermittent bolus dose of cisplatin (100 mg/m^2) delivered with definitive RT (70 Gy) is considered standard of care for locally advanced OPCs. Although it was the intention to deliver three cycles of cisplatin with RT in the control arm, a retrospective analysis of RTOG 0129 established that at least 200 mg/m^2 cisplatin (total dose) was required to attain maximum survival benefit.[24] Alternatively, concurrent cisplatin 40 mg/m^2 once per week with definitive RT may be delivered, based on preliminary noninferiority data in a mostly non-HPV-associated population.[63]

Three studies have reaffirmed that combined modality therapy with cisplatin and RT is the standard of care for most patients with p16-positive OPCs. The RTOG 1016 trial[38] randomly assigned patients with p16-positive OPCs of all stages to RT with concurrent cetuximab or cisplatin. The study was designed as a noninferiority trial; the hypothesis was that cetuximab would reduce toxicity while maintaining survival rates. The 5-year OS, PFS, and locoregional failure rates all favored patients who were treated in the cisplatin arm, and the rates of overall acute and late-grade 3 to 4 toxicities were similar between the two groups. Similar to RTOG 1016, the De-ESCALaTE HPV trial[43] randomly assigned the same population (but included only those with smoking histories of 10 pack-years or less) to cisplatin and RT versus cetuximab and RT. The 2-year OS rate also favored the cisplatin arm (97.5% vs 89.4%; HR, 5.0; 95% CI, 1.7-14.7; P = .001). Finally, the TROG 12.01 study randomly assigned 189 patients with HPV-positive OPC to once-per-week cisplatin versus cetuximab with RT. The 3-year FFS rate favored cisplatin (93% vs 80%), and the use of cetuximab did not improve the toxicity profile.[64]

Concomitant bolus doses of carboplatin (70 mg/m^2 once per day for 4 days) and 5-FU (600 mg/m^2 as a once-per-day 24-hour infusion for 4 days) on days 1, 22, and 43 with RT (70 Gy; 35 fractions) may be administered as an alternative to cisplatin.[37]

This randomized trial treated only patients with OPCs and compared CRT to RT alone. Carboplatin and 5-FU with RT improved 3-year OS (51% vs 31%). The incidence of severe, late (grade 3-4) toxicities was higher (14%) in the combined arm than in the RT-alone arm (9%), with cervical fibrosis being more severe in those receiving chemotherapy. Cetuximab should be considered only when patients are not eligible to receive either cisplatin or carboplatin-based regimens, and as discussed above, concurrent docetaxel is also an option for this platinum-ineligible population. CRT is considered an evidence-based standard treatment option and is particularly applicable for the management of T3-T4 or N2-N3 disease located at the base of the tongue or tonsils.

Given the low volume and favorable prognosis of early-stage disease, radical surgery (total glossectomy) or CRT should be avoided, in general, for patients with T1-T2, N0-N1 HPV-negative disease or for patients with T1-T2, N0-N1 HPV-positive disease when N1 is a single node smaller than 3 cm. Preservation of speech and swallowing function can be attained with RT or organ-sparing surgery. Per the NCCN guidelines, RT, TORS, or open resection at T1 or T2 oropharyngeal primary sites without neck nodal involvement is appropriate. For N0 disease, strong consideration for neck dissection should be given because oropharyngeal tumors often harbor disease in the neck, with a risk of up to 20% of occult metastases noted in observational studies. For patients with HPV-positive N1 disease limited to a single node smaller than 3 cm or HPV-negative disease, a neck dissection should be performed along with surgery to the primary site. Bilateral neck dissections are required for tumors arising from the midline.

Multiple trials are ongoing to evaluate the role of TORS in OPC,[18,65] but no large phase 3 randomized trial data exist to evaluate surgery compared with definitive CRT. Two small studies comparing transoral resection with an RT-based approach to limited stage HPV-positive OPC did not demonstrate substantial differences in functional or cancer outcomes, but one of the trials was closed prematurely because of unexpected early deaths in the transoral surgical patients.[65]

Given the favorable prognosis of HPV-related OPC, recent efforts have focused on attempts to deintensify the definitive standard modalities of RT and chemotherapy. Studies selecting patients for lower doses of RT with concomitant systemic therapy if they demonstrate complete responses to induction chemotherapy remain promising, yet these data are considered exploratory. At this time, any deintensification approach, although potentially attractive for reducing long-term toxicities, should be considered investigational, because no trials have demonstrated improved quality of life with noninferior cancer control.

ct HPV DNA is a potential biomarker that can be followed posttreatment, with a negative predictive value of 93% to 95% for 2-year locoregional failure and PFS, but there is no consensus on how, when, or in which patients to incorporate blood HPV DNA testing, either at baseline or after treatment. Future prospective studies will need to establish the role of ct HPV DNA in this setting.

KEY POINTS

- No definitive data demonstrate that induction chemotherapy followed by CRT leads to better survival compared with CRT alone.
- Induction chemotherapy with TPF is considered the standard induction regimen when induction is recommended because it has been shown to improve both OS and LRC compared with PF.
- For patients with unresectable locally advanced HNSCC, CRT with cisplatin significantly improves survival compared with RT alone and is the standard of care.
- In locally advanced laryngeal cancer, LRC and larynx preservation are best achieved with concomitant cisplatin and RT, although induction chemotherapy followed by RT is a reasonable alternative because long-term data show no difference in laryngectomy-free survival for either treatment paradigm.
- Cetuximab added to RT improves survival compared with RT alone in locally advanced head and neck cancer, as does docetaxel in platinum-ineligible patients, but neither should replace CRT with cisplatin therapy as the standard of care in patients who are candidates for it.
- CRT with cisplatin is the standard of care for postoperative adjuvant treatment of patients with positive resection margins and/or extracapsular extension of nodal disease.

NASOPHARYNGEAL CANCER

OVERVIEW

WHO type 1 (keratinizing) SCC of the nasopharynx has a locoregional behavior more similar to that of other smoking-related head and neck cancers. WHO type 2 (nonkeratinizing, differentiated) and type 3 (undifferentiated) cancers, both of which can occur with lymphoid stroma (previously called lymphoepithelioma), predominate in endemic areas (eg, southern China, southeast Asia, northern Africa) and have a higher propensity for distant metastases. More than 90% of patients who have WHO type 2 or type 3 disease have a disease associated with EBV. If tumors are EBV positive, the presence of HPV is rarely, if ever, seen. However, many EBV-negative NPCs are often HPV positive. Because the overwhelming majority of all clinical trials for patients with NPC have been conducted where NPC is endemic and therefore EBV related, it is unclear to what extent results from these trials can be applied to patients with EBV-unrelated NPC. There is a lack of expert consensus on whether treatment decisions should be made by extrapolation from EBV-related NPC paradigms or by extrapolation from non-EBV HNSCC at other anatomic sites.

RT is the historic mainstay of treatment of M0 NPC. Active agents include cisplatin, taxanes, 5-FU, capecitabine, gemcitabine, cetuximab, and ICI targeting programmed cell death protein 1 (PD-1) or programmed death-ligand 1 (PD-L1). The clinical behavior of NPC varies somewhat according to its histologic subtype and biomarkers. Patients who have WHO type 2 or type 3 respond more favorably to definitive CRT than those who have WHO type 1.

THERAPY

Chemoradiation Therapy

Numerous randomized studies and multiple meta-analyses have established that cisplatin-based CRT is the cornerstone of therapy for newly diagnosed, advanced, locoregional NPC. Current guideline-based standards of care for curative treatment of NPC include induction therapy before CRT for patients with locoregionally very advanced disease. RCTs have confirmed that induction chemotherapy followed by CRT improves OS relative to concurrent CRT alone with or without adjuvant PF chemotherapy. The two most commonly used regimens are gemcitabine and cisplatin (GC) and dose-attenuated TPF. CRT with concurrent cisplatin remains the standard for patients with intermediate-risk locoregional NPC, but there is no consensus on whether a subgroup of these patients also benefits from adjuvant PF. RT alone is used for patients with highly curable early T- and N-stage tumors.

Sequential Chemotherapy With Induction

Sequential therapy, defined as induction chemotherapy with either GC or dose-attenuated TPF followed by CRT, is now accepted as the standard for treatment of locoregionally advanced NPCs (Table 12-6). The GC induction regimen followed by concurrent CRT is used more frequently, but RCTs also support dose-attenuated docetaxel, cisplatin, and 5-FU (TPF) in this setting.[32] A phase 3 randomized trial reported by Zhang et al[66] found that the addition of induction GC to CRT improved recurrence-free survival (85% vs 77% at 3 years) and OS (95% vs 90% at 3 years) compared with CRT alone. Approximately half the patients enrolled had N2, N3A, or N3B disease, and thus were at risk for developing distant metastases. Data incorporating immunotherapy in curative-intent NPC are evolving, with some studies suggesting a benefit.[67]

There remain challenges concerning the identification of which patients are most appropriate for this very aggressive sequential therapy approach, but, in general, it is reserved for patients who have T3-T4 and N2-N3 tumors. Substantial data suggest that markedly elevated levels of baseline ct EBV DNA are an independent risk factor for poor prognosis in patients with EBV-associated NPC. Lack of harmonization of ct EBV DNA has prevented a uniform definition that could be used to define high-risk patients beyond TNM staging.

Cisplatin, on either a once-per-week or once-per-21-days schedule combined with curative dose radiation, typically 70 Gy to all sites of clinical and radiologic disease with lower doses to at-risk areas of the skull and neck, remains the standard CRT paradigm for locoregional NPC. IMRT is the standard because it is associated with the highest rates of LRC. Although there are advocates for the prioritization of proton-based RT treatments for NPC, evidence supporting this approach remains limited to small case series and anecdotal; therefore, although the scientific rationale for proton beam treatment seems valid, there are insufficient data to support claims of superiority to IMRT in terms of OS, LRC, or adverse effects.

Carboplatin is an acceptable substitute for cisplatin with concurrent RT in NPC for patients who are unfit for cisplatin. One randomized trial of carboplatin versus cisplatin with RT in locoregional NPC failed to demonstrate an OS advantage to cisplatin, a finding unique to NPC in HNSCC. Unlike other HNSCC sites, the role of cetuximab or taxanes concurrently with RT has not been defined.

Adjuvant Chemotherapy

The use of adjuvant chemotherapy after CRT in NPC remains highly debated. A phase 3 trial was reported by Al-Sarraf et al[68] in 1998. The design of that RCT incorporated both concurrent cisplatin and adjuvant PF together in the experimental arm compared with RT alone.[69] This relatively small trial in the United States did not shed light on the contribution of adjuvant PF to OS superiority. Subsequent studies, including a trial by Chen et al,[70] have challenged the routine use of adjuvant chemotherapy after CRT. They compared once-per-week CRT with or without adjuvant chemotherapy in 251 patients with nonmetastatic stage III or IV NPC. The primary endpoint was FFS. After a median follow-up of 37.8 months, the estimated 2-year FFS rate was 86% in the CRT plus adjuvant chemotherapy arm and 84% in the CRT-only arm ($P = .13$). However, critics believe that the study was not designed as a noninferiority study against the standard of care (ie, high-dose cisplatin and RT).

A meta-analysis of 20 trials suggested that there is a benefit of adjuvant chemotherapy after concurrent CRT, which led NRG Oncology to conduct an international study (NRG HN001), which unfortunately closed in 2023 before completing accrual. That trial used post-radiation ct EBV DNA as a randomization factor: patients with undetectable ct EBV DNA were randomly assigned to adjuvant PF or to no adjuvant treatment, whereas patients with detectable ct EBV DNA were randomly assigned to adjuvant PF or gemcitabine plus paclitaxel. Given the premature closure of that study, it is not clear whether the questions that the trial set out to ask will be answered.

Table 12-6 **Summary of Clinical Studies for Patients With Locally Advanced Nasopharyngeal Cancer**

Study (Location)	No. of Patients	AJCC Stage (Year)	Study Arm	Median Follow-Up (Months)	Primary Outcome	Secondary Outcome	Grades 3 to 4 Toxicity (%)
Al-Sarraf et al[68] (United States)	147	III to IV (1992)	Cisplatin (100 mg/m^2) every 3 weeks with radiation and adjuvant chemotherapy, cisplatin (80 mg/m^2) and FU (1,000 mg/m^2) for three cycles vs radiation alone	60	OS: 67% vs 37% (P = .001)	PFS 58% vs 29% (P = .001)	RT alone: Stomatitis: 28 Leukopenia: 1 Nausea/vomiting: 10
							CRT: Stomatitis: 37 Leukopenia: 36 Nausea/vomiting: 31
Chan et al[69] (Hong Kong)	350	Ho's N2-N3 or node larger than 4 cm	Weekly cisplatin (40 mg/m^2) with radiation vs radiation alone (no adjuvant chemotherapy)	66	OS: 90% vs 80% (P = .049)	PFS 60% vs 52% (P = .16)	RT alone: Stomatitis: 36 Leukopenia: 0 Nausea/vomiting: 0
							CRT: Stomatitis: 49 Leukopenia: 13 Nausea/vomiting: 12
Zhang et al[66]	480		Compared gemcitabine and cisplatin as induction chemotherapy and concurrent chemoradiotherapy with concurrent chemoradiotherapy alone	42.7	OS: 94.6% vs 90.3%		RT alone: Stomatitis: 76 Leukopenia: 132 Nausea/vomiting: 66
							CRT: Stomatitis: 69 Leukopenia: 63 Nausea/vomiting: 109

Abbreviations: AJCC, American Joint Committee on Cancer; CRT, concomitant chemoradiation; DFS, disease-free survival; FU, fluorouracil; OS, overall survival; PFS, progression-free survival; RT, radiation therapy.

Recently, two RCTs incorporated adjuvant capecitabine as part of a sequential CRT plan for high-risk locoregionally advanced NPC. One trial used low-dose uninterrupted capecitabine for a year, and the other used a higher-dose intermittent regimen for 6 months. Both studies demonstrated improved recurrence-free survival, and one study demonstrated improved OS; tolerability was acceptable, with most patients completing these adjuvant treatments. In one of these trials, the PFS and OS advantage was also seen in the subgroup of patients treated with either GC or TPF induction.[71,72] Therefore, in patients who have high-risk locoregionally advanced NPC, adjuvant capecitabine is recommended after induction and concurrent CRT.

RECURRENT OR METASTATIC NASOPHARYNGEAL CANCER

First-line treatment of recurrent or metastatic (R/M) NPC uses a platinum-based doublet combined with immunotherapy. GC is the preferred doublet over PF on the basis of one randomized study that demonstrated a PFS of 7 months versus 5.6 months, respectively.[73] One difficulty in interpreting these data is that the use of GC in this trial was in an era when GC was not widely used as induction treatment, and, therefore, the superiority in patients with previous exposure to GC is uncertain.

Monoclonal antibodies that interrupt the PD-1/PD-L1 interaction, when added to GC, have demonstrated a meaningful PFS advantage over GC alone for patients with metastatic NPC. In a phase 3 trial, patients were randomly assigned to GC with or without the addition of toripalimab, a PD-1 inhibitor. The outcomes favored the addition of immunotherapy, with a median PFS of 11.7 months versus 8.0 months (HR, 0.52; 95% CI, 0.36-0.74; two-sided $P = .0003$) and 1-year PFS rates of 49% and 28%, respectively.[74] Toripalimab also improved OS relative to placebo (HR 0.63, two-sided $P = .008$). Median OS was not reached in the toripalimab group, while it was 33.7 months in the placebo group.[74] Similar median PFS improvement (9.7 months vs 6.9 months) was seen with the addition of PD-1 inhibitor camrelizumab to GC, penpulimab to GC, and tislelizumab to GC. It seems that this effect is robust across PD-1 inhibitors, and therefore, the combination of GC and a PD-1-targeted ICI is recommended in this setting. A single-arm phase 2 trial tested toripalimab in 190 chemorefractory patients with metastatic NPC and demonstrated an objective response rate (ORR) of 20.5%. Based on cumulative evidence from these trials, toripalimab was FDA-approved treatment in late 2023 for R/M NPC, both as a single agent and in combination with GC.[75] Subsequently, in April 2025, penpulimab received similar FDA approval in combination with GC in the first-line treatment of adults with recurrent or metastatic nonkeratinizing NPC. FDA also approved penpulimab-kcqx as a single agent for adults with metastatic nonkeratinizing NPC with disease progression on or after platinum-based chemotherapy and at least one other prior line of therapy.

Many chemotherapeutic agents are active against NPC, including cisplatin, carboplatin, nedaplatin, docetaxel, paclitaxel, nab paclitaxel, 5-FU, capecitabine, cetuximab, and methotrexate. Many ICIs targeting the PD-1/PD-L1 interaction have demonstrated anticancer activity, occasionally with durable remissions. Fit patients who have relapsed or progressed after the curative or first-line R/M disease regimens can experience significant prolonged benefit from palliative systemic treatments.

Patients with oligometastatic disease, typically having fewer than three metastatic sites, either at presentation or in relapse, may benefit from a multimodality approach that can include definitive CRT to the head and neck region with subsequent focal RT or surgical resection of oligometastatic sites. A typical approach is to begin with systemic treatment and consolidate with locoregional treatments for metastatic sites for patients with demonstrated responses and lack of progression while receiving systemic therapy.

KEY POINTS

- The standard of care (according to stage) is RT alone for limited stage (typically T1-2 N0M0).
- Concurrent cisplatin-based CRT with or without adjuvant PF for intermediate-risk locoregional disease, and sequential CRT including induction GC or TPF, concurrent CRT, and adjuvant capecitabine for patients with the highest-risk locoregionally advanced disease remain the standards of care.
- NPC is a very chemotherapy-sensitive disease. Patients with metastatic disease often experience prolonged benefit from systemic chemotherapy. GC and ICI are the widely accepted first-line treatments of R/M disease, but other platinum-based chemotherapies combined with immunotherapy are also acceptable systemic treatment options.
- For patients with oligometastatic disease, a potentially curative treatment paradigm that includes systemic chemotherapy and local definitive treatment of the head and neck and oligometastatic sites is associated with some long-term survival.
- All treatment paradigms for NPC are largely based on data from EBV-associated NPC.

CANCER OF UNKNOWN PRIMARY SITE

Although a malignant neck lymph node without a clear primary tumor is a common presentation of HNSCC, for most patients, the primary site is found after comprehensive examination of the head and neck, endoscopy, and diagnostic imaging. The location of the lymph node in the neck directs the examiner toward the likely potential primary sites. FDG-PET imaging should be part of the standard evaluation for SCC of unknown primary site; it can help identify the primary site in approximately 30% of cases.

FNA of the lymph node is the first choice for initial biopsy. If negative, repeating FNA with consideration of a core needle biopsy, if feasible, is appropriate. Often, with cystic lymph nodes, ultrasound can facilitate sampling of the viable rind of the tumor instead of the central necrotic debris. Viral testing of the nodal specimen (HPV and EBV) should be performed. If positive, their tumors should be treated as oropharyngeal or primary nasopharyngeal, respectively. The tumor staging classification becomes T0 if subsequent inquiries fail to identify a primary site. If viral staining is negative, the tumor staging classification becomes Tx. If the histologic diagnosis remains inconclusive, a subsequent excisional biopsy should be performed in such a way that the incision can be incorporated into an appropriate neck dissection. Open biopsy may contaminate the surgical field and lead to seeding of tumor cells, and is usually not necessary, because repeat needle biopsy or directed mucosal biopsies can often identify the cancer.

If pathologic findings from the neck indicate a diagnosis of SCC, and a primary lesion above the clavicle is suggested (in particular, if the lymph node is high in the neck), assuming an in-office endoscopy and imaging have not revealed anything, a comprehensive head and neck examination under anesthesia is the next step. Directed biopsies should be performed for suspicious mucosal areas as well as for locations known to be a source of occult tumors, such as the hypopharynx, base of the tongue, and nasopharynx. In addition, bilateral simple tonsillectomies are recommended based on the increasing incidence of tonsillar cancers associated with HPV. Transoral resection of lingual and pharyngeal wall tissues can often uncover occult primary sites in these cases.

The skin, the upper part of the esophagus, and the lung are other potential sources of SCC spread to the neck. If the findings on biopsy specimen of a cervical lymph node indicate an adenocarcinoma, the thyroid gland, salivary gland, or sites below the clavicle should be considered.

Lymphoma is another important diagnostic possibility and may require a core needle biopsy. Similarly, distinguishing lymphoma from anaplastic and undifferentiated or poorly differentiated cancers can be difficult based on the cytologic analysis alone and may require additional IHC studies or more tissue.

The choice of treatment of patients with SCC in a neck node of unknown primary site is controversial and evolving. Historically, either surgery or RT was used to treat patients with low-bulk disease in a single lymph node, whereas both modalities were necessary for patients with more advanced disease. The extent of RT to the potential primary sites requires clinical judgment with regard to the likely source of the tumor, because a larger portal will increase the morbidity associated with treatment. Findings from clinical series indicate that, with longitudinal follow-up, the primary site ultimately is found for approximately 30% of patients. Long-term survival is better for patients in whom the primary lesion remains occult than for those in whom it does not.

The mainstay of treatment is still neck dissection followed by RT with concomitant cisplatin when extracapsular extension of nodal disease is present. However, the majority of these cases are now p16-positive tumors arising from the oropharynx, and definitive CRT is considered another standard treatment option.

KEY POINTS

- The search for the primary site should include FDG-PET/CT imaging and an examination under anesthesia with directed biopsies of the base of the tongue, nasopharynx, and hypopharynx, and bilateral, simple tonsillectomies.
- After an FNA biopsy of the lymph node, HPV and EBV testing should be performed. If the tumors are positive, they should be treated as oropharyngeal or primary nasopharyngeal, respectively.
- Standard treatment consists of neck dissection followed by RT to include the likely primary sites, and concurrent cisplatin is added if extracapsular extension of nodal disease is present.
- In selected patients, CRT is another primary treatment option.

INCURABLE RECURRENT OR DISTANT METASTATIC DISEASE

SYSTEMIC THERAPY

Recurrent or persistent disease that is not appropriate for additional surgery or RT after definitive therapies have been delivered or disease that involves distant organs is considered incurable. Cisplatin, carboplatin, docetaxel, paclitaxel, 5-FU, methotrexate,

and capecitabine are the most commonly used cytotoxic agents to treat R/M HNSCC in the first- and second-line settings. Cetuximab is an active targeted agent that is also commonly used as a second- or third-line regimen (Fig. 12-3).

Pembrolizumab and nivolumab, monoclonal antibodies directed at the PD-1 protein, were first approved by the FDA for the treatment of platinum-refractory R/M HNSCC based on the results of large clinical trials; pembrolizumab was subsequently approved for first-line R/M HNSCC based on KEYNOTE-048.

Historically, randomized trials comparing combination chemotherapy and single-agent therapy show a near doubling of the response rate with platinum-based combinations, but, unless a clinical complete response is achieved, the duration of response is brief (2-4 months) and does not have a substantial effect on OS. Toxicity is generally greater when combination chemotherapy is used. Combination chemotherapy should be limited to patients with a good performance status (eg, Eastern Cooperative Oncology Group [ECOG] performance status of 0-1), who are better able to tolerate the added toxicity.

FIRST-LINE THERAPY

KEYNOTE-048 was a multicenter, three-arm, randomized trial of 882 patients with newly diagnosed R/M HNSCC. Patients were randomly assigned 1:1:1 to pembrolizumab alone, pembrolizumab with chemotherapy (cisplatin or carboplatin in combination with 5-FU), or cetuximab in combination with chemotherapy (aka, the EXTREME regimen). Each experimental pembrolizumab arm was compared independently with the EXTREME arm. The principal outcomes consisted of noninferiority for OS for pembrolizumab versus EXTREME and superiority for pembrolizumab plus chemotherapy versus EXTREME in the study populations whose tumors had a CPS higher than 20 and a CPS higher than 1. CPS is defined as the number of PD-L1-positive cells among tumors, lymphocytes, or macrophages divided by the total number of tumor cells times 100 in evaluable samples (with a minimum of 100 viable tumor cells) as measured by the PD-L1 IHC 22C3 pharmDx kit.

Pembrolizumab and chemotherapy significantly improved OS versus the EXTREME regimen in the CPS 20 or higher population (HR, 0.60; $P = .004$), the CPS 1 or higher population (HR, 0.65; $P < .0001$), and the overall study population (HR, 0.77; $P = .0086$).[76] Updated 5-year survival data have highlighted that some patients have an extension of survival with immunotherapy; up to 24% of the patients were alive at the 5-year landmark for both immunotherapy arms of the trial.[77]

The decision of whether to treat with pembrolizumab monotherapy versus the combination of chemotherapy and immunotherapy depends on PD-L1 expression, the patient's performance status, overall disease burden, and symptoms.

Among patients who have contraindications to immunotherapy, the EXTREME regimen is still an option in the first-line setting. In the phase 3 EXTREME trial, 440 patients with R/M HNSCC were randomly assigned to either the intervention arm (cisplatin or carboplatin with 5-FU and cetuximab) or the standard arm (cisplatin or carboplatin with 5-FU) as first-line treatment of R/M disease.[78] Cetuximab and the platinum and 5-FU combination significantly prolonged the median OS from 7.4 months to 10.1 months (HR for death, 0.80; 95% CI, 0.64-0.99; $P = .04$), significantly prolonged the median PFS from 3.3 months to 5.6 months (HR for progression, 0.54; $P < .001$), and increased the response rate from 20% to 36% ($P < .001$).

Although 5-FU has been partnered with platinum in these trials, it can be associated with increased toxicity and requires the use of an infusion pump. Therefore, taxane doublets are another option instead of PF therapy. Results from an ECOG study showed that survival with paclitaxel (175 mg/m^2) and cisplatin (75 mg/m^2) treatment did not differ significantly (9 months vs 8 months) from standard cisplatin (100 mg/m^2) and 5-FU (1,000 mg/m^2 by continuous infusion over 4 days); the 1-year survival rate was 30% versus 41%, respectively, although the paclitaxel regimen was generally better tolerated.[79] A phase 2 RCT of four cycles of docetaxel plus cisplatin (TPEx) versus six cycles of PF, both arms with cetuximab, suggests that TPEx is an acceptable alternative to the EXTREME regimen. Many oncologists in the United States[80] use a platinum agent plus taxane plus an ICI for PD-L1-positive patients, extrapolating from the KEYNOTE-B10, KEYNOTE-048, TPEx, and ECOG data discussed above. On the basis of data from these trials, the NCCN guidelines provide the option of platinum doublet therapy with taxanes in the first-line setting with pembrolizumab.[34,81]

PRESENTING CASE STUDY 2

A 63-year-old man presents to your clinic following surveillance chest radiograph findings of new bilateral lung nodules. He has a history of T2N1 HPV-associated right tonsil cancer, treated with definitive cisplatin and radiation therapy 2 years ago. He has never smoked. CT of the chest confirms the new lung nodules, the largest measuring 2.4 cm in the right midlung. Pathology from a CT-guided lung biopsy indicates p16-positive (100%), metastatic SCC. PET imaging shows no other sites of disease. The patient is asymptomatic and in otherwise good health.

What additional biomarker information do you need in this patient with treatment-naive metastatic head and neck SCC to guide systemic therapy selection?

PD-L1 testing would inform first-line systemic therapy in this patient with asymptomatic, metastatic head and neck SCC. Pembrolizumab monotherapy is an FDA-approved agent for patients with a PD-L1 CPS of 1 or higher. Pembrolizumab combined with platinum-based chemotherapy is approved regardless of PD-L1 CPS score.

This patient's PD-L1 CPS is 25. What treatment should you initiate? How would your management differ if the PD-L1 CPS were 0?

Both pembrolizumab and pembrolizumab with platinum-based chemotherapy would be appropriate choices if the PD-L1 CPS were 25; however, for this patient with a high PD-L1 CPS score and asymptomatic, small-volume disease, pembrolizumab monotherapy would be the least toxic treatment.[73]

If the PD-L1 CPS were 0, pembrolizumab alone would be unlikely to have significant clinical activity, and platinum-based chemoimmunotherapy would be a more appropriate choice.

SECOND-LINE THERAPY

Both nivolumab and pembrolizumab were originally studied and approved in the platinum-refractory setting without prior immunotherapy. KEYNOTE-040 and CheckMate 141 enrolled patients primarily with a performance status of 0 to 1 in whom platinum-based therapies failed. Both trials randomly assigned immunotherapy versus single-agent standard-of-care therapy with cetuximab, methotrexate, or cetuximab. The number of grade 3 to 4 adverse effects, however, was much higher with the standard-of-care chemotherapy arms (36% in chemotherapy vs 13% pembrolizumab and 35% in chemotherapy vs 13% nivolumab).[82] In general, factors associated with poor response to systemic therapy include poor performance status, the presence of comorbidities, bulky locoregional disease or high tumor volume, and previous treatment of recurrent disease. PD-1 inhibitors are associated with immune-related toxicities. The most common adverse effects in both studies were fatigue, rash, and skin-related toxicities. In addition, the CheckMate study reported stability in several quality-of-life measures in those receiving nivolumab and declines in measures in those receiving chemotherapy.

What is most remarkable about the use of pembrolizumab, nivolumab, and other ICIs for patients with R/M HNSCC is not response rates, which are typically 15% to 20% in this population.[83] Rather, it is the tail on the survival curve, suggesting that a minority of the patients treated seem to benefit from long-term remission of their cancers, an effect not commonly seen with cytotoxic chemotherapy treatments.

Cetuximab is the only molecularly targeted drug to be approved for use in the United States for platinum-refractory metastatic or recurrent head and neck cancer in combination with chemotherapy or as monotherapy. In a randomized trial in which the combination of cisplatin and placebo was compared with cisplatin and cetuximab in 123 patients, no significant difference was found in median PFS (2.7 months vs 4.2 months; $P = .27$), although the rate of major response (complete plus partial) was significantly higher for patients who received cisplatin and cetuximab (10% vs 26%; $P = .03$).[84]

Cetuximab as a single agent demonstrated a response rate of 11% and a disease control rate of 46% for patients with metastatic or recurrent head and neck cancers who experienced progression while receiving platinum therapy, and 19% in patients who received prior immunotherapy. Grades 1 to 4 acneiform rash and dry skin were the most bothersome adverse effects of this agent, occurring in more than 50% of all of patients. Hypomagnesemia is not uncommon and must be monitored, especially in those with a history of cardiac arrhythmias. Because cetuximab is not a fully humanized antibody, care must be taken to monitor for acute and delayed anaphylactic reactions that could lead to cardiopulmonary arrest.

Overall, treatment options beyond the first- or second-line setting are limited. Patients who progress on platinum doublets and immunotherapy overall have a poor prognosis, and monotherapy with taxanes or cetuximab is usually associated with low response rates. Patients who are taxane naive are often treated with paclitaxel or docetaxel monotherapy before cetuximab or other single agents with lower activity. Palliative and supportive care are key tools for patients with recurrent refractory disease. Ongoing trials are studying new immunotherapy combinations, bispecific antibodies targeting EGFR, and antibody-drug conjugates.

KEY POINTS

- Pembrolizumab (if PD-L1 CPS is 1 or higher and preferably 20 or higher) and pembrolizumab combined with platinum and 5-FU or platinum plus taxane are now considered the first-line standard of care for R/M HNSCC. For patients with PD-L1 CPS lower than 1, PF or TP with either cetuximab or pembrolizumab is used.
- Cetuximab combined with PF or TP (or cetuximab with carboplatin and paclitaxel) should be considered in the R/M setting when patients are not candidates for immunotherapy.

- Nivolumab and pembrolizumab are indicated as the second-line therapy for patients in whom platinum-based chemotherapy failed in the R/M setting.
- Taxanes, capecitabine, cetuximab, and methotrexate may be useful as single agents in patients with R/M HNSCC who have not had previous exposure to these agents, but, in general, response rates are low, and the duration of responses is limited.

SALIVARY GLAND TUMORS

Cancers of the major salivary glands (parotid, submandibular, sublingual) and the minor salivary glands are uncommon, accounting for about 5% of epithelial head and neck tumors. Tobacco and alcohol use are not risk factors for tumors of the salivary

glands, but there may be an association with previous exposure to RT. The WHO classification lists 24 histologic subtypes of malignant epithelial salivary tumors. Their small numbers and their histologic and prognostic heterogeneity make them difficult to study (Figs. 12-4 and 12-5).

Pleomorphic adenomas are the most common salivary gland tumors. They have a variable appearance architecturally. Pleomorphic adenomas are diagnosed by FNA, and surgery is the treatment of choice because these tumors can transform into carcinomas (carcinoma ex pleomorphic adenoma).

The most common types of malignant salivary gland cancers are ACC and adenocarcinoma, which originate from the intercalated ducts, and mucoepidermoid carcinoma, which originates from the secretory ducts. A histologic reading of high-grade mucoepidermoid or adenocarcinoma correlates with aggressive behavior and a greater likelihood of eventual metastasis, whereas low-grade cancers of these histologies are more likely to be cured with initial local therapies. An ongoing cooperative group trial is attempting to answer whether cisplatin added to adjuvant RT in high-risk postsurgical patients is beneficial.

ACC, most commonly found in the minor salivary glands, is prone to neurotropic spread. It has the highest propensity of all histologic subtypes for distant metastases, yet it can grow indolently. Therefore, palliative chemotherapy should be attempted only for a symptomatic patient or when substantial tumor growth can be appreciated on serial imaging. In this setting, combinations of cyclophosphamide, doxorubicin, and cisplatin or those drugs as single agents can be considered. Antiangiogenic agents, such as lenvatinib and axitinib, have also been studied. Although these agents demonstrated low response rates in phase 2 trials, they remain a viable treatment option until agents with more efficacy or a better toxicity profile are studied.[85-87] Some providers advocate metastatectomy for patients who have ACC with oligometastatic pulmonary disease, but the benefit of this approach is neither validated nor widely accepted.

Salivary duct carcinoma is an aggressive subtype of adenocarcinoma with a rapid appearance of metastases. Microscopically, it looks similar to ductal breast cancer and frequently overexpresses HER2 and androgen receptors on IHC analysis. Substantial and durable responses in many patients to antiandrogen blockade or HER2 cytotoxic conjugate therapies have been reported in

small phase 2 clinical trials. However, a recent randomized phase 2 trial compared first-line platinum-based chemotherapy versus androgen blockade therapy in these patients demonstrated a numerically superior ORR and PFS in the chemotherapy group (ORR 35% vs 23% with ADT, median PFS 6.5 months vs 4 months with ADT).[88] Dual checkpoint inhibition with ipilimumab and nivolumab has also been studied in non-ACC salivary gland cancers, and preliminary data indicate activity.[89]

Often mistaken for acinic cell carcinoma, the now-classified secretory carcinoma (previously known as MASC) harbors an ETV6::NTRK3 fusion protein. Larotrectinib and entrectinib, both inhibitors of tropomyosin kinase receptors TrkA, TrkB, and TrkC, were recently approved by the FDA for patients with *NTRK* gene fusions. Results from three multicenter, open-label, single-arm clinical trials with larotrectinib demonstrated an overall response rate of 75%, with a 22% complete response rate, and a longer-than-6-month duration of response rate of 73% for patients with *NTRK* fusions. Entrectinib was studied in 57 patients, all with *NTRK* fusions among 10 different tumor types, and produced an ORR of 57% with a complete response rate of 7%. The median duration of response was 10 months (95% CI, 7.1-not estimable). The most common grade 3 or 4 treatment-related adverse effects were increased weight in 10% and anemia in 12%. The most common serious treatment-related adverse effects were nervous system disorders (4%).[90] All metastatic salivary gland tumors should be considered for testing for *NTRK* fusions, especially if the histology is uncertain.[91]

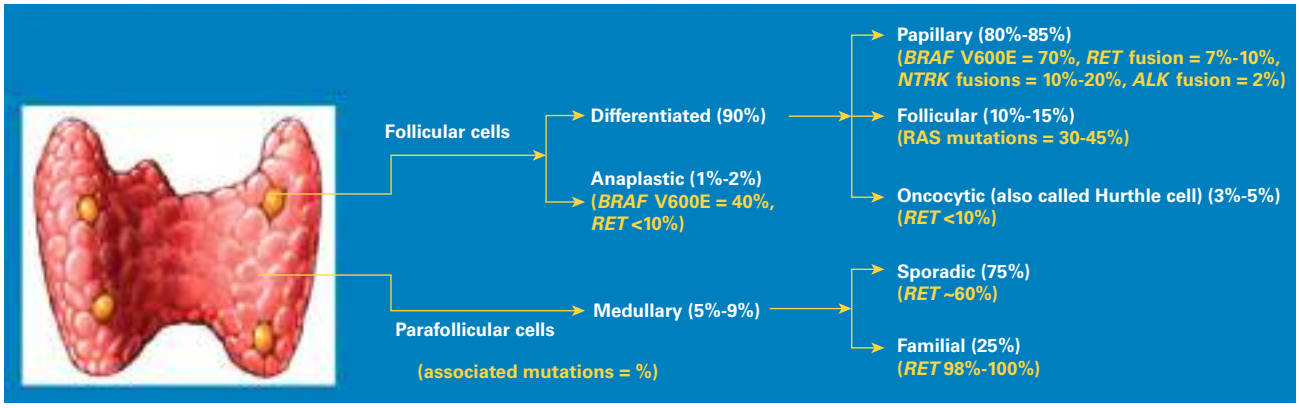
KEY POINTS

- Surgery is the mainstay treatment of salivary gland tumors, followed by RT for those tumors with high-risk features; pleomorphic adenomas should be surgically resected because of their potential for malignant transformation.
- Metastatic ACC and selected other salivary gland cancers are often characterized by an indolent natural history and have no known effective treatments; therefore, they are often followed without systemic treatment.
- For most slow-growing salivary gland cancers, systemic treatment should be delayed until substantial tumor growth can be appreciated on serial imaging studies within 6 months or if the disease is located such that symptom development is imminent (eg, bronchial obstruction). Comprehensive testing, including next-generation sequencing to evaluate for actionable molecular targets and appropriate immunotherapy biomarkers, should be performed for patients with metastatic disease.
- Salivary ductal tumors are histologically similar to breast cancer and can overexpress androgen receptors and HER2. Such tumors are often treated effectively with antiandrogen blockade or HER2-targeted cytotoxic conjugate therapies. Chemotherapy can also be an effective option.
- Secretory carcinomas, formerly known as MASCs, are characterized by the presence of ETV6-NTRK3 fusion proteins; larotrectinib or entrectinib is the treatment of choice for secretory carcinomas that are metastatic or for tumors for which surgery is likely to result in severe morbidity.

THYROID CANCER

Until recently, thyroid cancer was the most rapidly increasing cancer diagnosis among the US population. This increase was believed to be associated with highly sensitive diagnostic tests that could detect very small cancers (Fig. 12-6). The increase has now dropped from 7% annually during the 2000s to 1.5% annually from 2011 to 2015. In 2023, an estimated 43,720 adults (12,540 men and 31,180 women) received a diagnosis of thyroid cancer, with an estimated resultant 2,120 deaths.[92] It is the

Figure 12-6 Classification of Thyroid Cancers



Created for ASCO. Copyright © 2026 by the American Society of Clinical Oncology.

most common cancer in women aged 20 to 34 years. Women are three times more likely to have thyroid cancer than men, but women and men die at similar rates, suggesting that male patients have a worse prognosis than female patients. The 5-year OS rate for thyroid cancer is 98.5%, depending on the type and stage of disease. Thyroid cancers are classified based on the two main parenchymal cells of origin: the follicular cells involved in thyroid hormone production and the parafollicular cells that produce calcitonin.

DIFFERENTIATED THYROID CANCER

Etiology

The only well-documented etiologic factor for DTC is exposure to RT, with an inverse relationship between age at exposure and risk for development of thyroid malignancy. The thyroid glands of children younger than 10 are highly vulnerable to developing thyroid cancer if they are exposed to ionizing radiation. The risk for the development of thyroid cancer is much higher for individuals who have been exposed to RAI isotopes from nuclear reactor accidents and atomic bomb testing, as well as for children and young adults who have received external RT for other cancers (eg, Hodgkin lymphoma, neuroblastoma, Wilms tumor). More than 90% of well-differentiated thyroid cancers, however, are unrelated to radiation exposure. Approximately 5% of DTCs are associated with hereditary syndromes such as Gardner syndrome (familial adenomatous polyposis), Cowden syndrome, Pendred syndrome, Werner syndrome, and Carney complex.

Clinical Presentation and Workup

The sporadic DTCs are usually asymptomatic for a long time and present as a solitary nodule. The familial papillary thyroid cancers (PTCs) seem to be clinically more aggressive than the sporadic ones. The familial DTCs are usually multifocal and bilateral and have a tendency to recur both locoregionally and in distant sites.

PTC and its variants tend to recur locally in the regional lymph nodes, whereas follicular and Hurthle cell cancers tend to recur distantly, especially in bone and lung. Several factors have been widely accepted as being associated with a poor prognosis, including age older than 55 years, male sex, poorly differentiated histology, tumor size larger than 1.5 cm, and extrathyroidal extension at diagnosis. Involvement of the regional lymph nodes is associated with a greater risk for nodal recurrence but does not confer a worse prognosis for survival. The 10-year survival rate for DTC is 90%. The median age at diagnosis is 45 years, and the median age at death is 75 years.

Most thyroid cancers are detected as incidental thyroid nodules found on physical examination or by the patient presenting to the physician with a neck mass. The diagnostic evaluation should include high-resolution ultrasonography to aid in performing an FNA biopsy and to assess the number and characteristics of the nodules, including whether the nodules are solid or cystic. FNA has high sensitivity and specificity and is the test of choice when evaluating solitary thyroid nodules.

Routine thyroid scanning with ^{123}I or technetium-99 is not recommended. These tests provide information on whether a nodule is functional; however, the majority of benign and malignant nodules are "cold" or nonfunctioning, meaning that the test is nonspecific and not cost-effective. However, all patients with a thyroid nodule and suspected familial MTC should have calcitonin level testing.

Treatment

Surgery

The mainstay of treatment for DTC is surgery. The extent of initial surgical therapy is controversial. Some experts recommend removal of the entire thyroid gland, with the caveats that removal of only the affected lobe and the isthmus is necessary for patients with better risk (eg, young patients with small tumors) and that total thyroidectomy is associated with a greater risk for complications, such as recurrent laryngeal nerve injury leading to vocal cord paralysis and hypocalcemia secondary to hypoparathyroidism. After surgery, levothyroxine suppression of thyroid-stimulating hormone (TSH) is the standard of care. Postoperative RAI is used for patients whose disease has high-risk features, which typically include large tumors, those with vascular invasion or extrathyroidal extension, bulky or numerous involved lymph nodes, or postsurgically elevated thyroglobulin. Treatments with external beam RT for localized disease and antiangiogenic agents for widespread, metastatic disease are reserved for the palliative setting.

Radioactive Iodine

A single dose of RAI is usually recommended to ablate any normal thyroid remnant and destroy any microscopic deposits of the remaining thyroid cancer after a total thyroidectomy for patients who are at high risk of recurrence or persistence. In addition to treating residual iodine–avid thyroid cancer, RAI also eliminates residual normal thyroid tissue, which facilitates surveillance by means of thyroglobulin detection. Use of iodinated contrast medium, an iodine-rich diet, and inadequate elevation of the level of TSH (thyrotropin) can all undermine the effectiveness of RAI treatment, and human recombinant thyrotropin has replaced the need for a patient to be put into a hypothyroid state.

Dosing strategies for RAI ablation are determined by the patient's prognostic risk, and they range from 30 to 75 mCi for ablation of remnants after total thyroidectomy for low-risk patients, to 100 to 150 mCi for the treatment of locoregional lymph nodes, to 150 to

250 mCi for the treatment of lung and bone metastases. Ablation of remnants enables improved surveillance because normal thyroid cells are also removed, which could cause false-positive results on whole-body iodine scans or false-positive elevations of serum thyroglobulin. In the absence of all normal thyroid tissue, the serum thyroglobulin is a highly sensitive and specific tumor marker for most patients. After total thyroidectomy and ablation of remnants, the serum TSH level generally should be suppressed to below normal levels with levothyroxine, because TSH is a potential growth factor for microscopic cancer deposits.

Six to 12 months after initial therapy, serum thyroglobulin should be measured while the patient is receiving suppressive doses of levothyroxine. If the serum thyroglobulin is undetectable and the findings of ultrasound imaging of the neck are negative, an annual analysis of thyroglobulin levels and physical examination are sufficient for most low-risk patients. With no detectable level of serum thyroglobulin during treatment with suppressive doses of levothyroxine at 1 year after surgery and ablation, the thyroglobulin level should be determined after two doses of recombinant human TSH. If the level increases to more than 2 ng/mL, a search for remaining disease is warranted. Diagnostic whole-body imaging with iodine scanning should be performed. If this is negative, recombinant human TSH-stimulated FDG-PET helps localize disease in more than 60% of such cases.

If metastases develop, RAI is the treatment of choice. Complete response to treatment has been observed for 45% of patients with distant metastases, although a higher complete response rate has been noted for younger patients and those with small pulmonary metastases. Patients with bulky metastatic disease and FDG-avid disease are less likely to respond to RAI because of dilution of the radiation dose in the former case and lower tumor uptake secondary to sodium/iodine symporter downregulation in the latter case.

Radioactive Iodine–Refractory Differentiated Thyroid Cancer

If DTC no longer takes up iodine on diagnostic scanning, or patients have received a maximum of 600 mCi of RAI, or patients develop recurrent DTC within a year of the last dose of RAI, such tumors are deemed RAI refractory (RAIR). Some thyroid tumors grow slowly, so a period of careful observation is reasonable before committing to treatment. Interest in targeted therapies has been stimulated by the discovery of activating point mutations of the *BRAF* gene that occur early, are associated with more advanced disease at diagnosis, and independently predict recurrence. Point mutations of the *BRAF* gene are found in 45% of PTCs. BRAF serine-threonine kinase can lead to activation of the mitogen-activated protein kinase signaling pathway. Three multitargeted TKIs—lenvatinib, cabozantinib, and sorafenib—have been approved by the FDA for the treatment of RAIR DTC independent of mutational status. It is important to note that the response rate to lenvatinib (approximately 60%) far exceeds that of sorafenib (approximately 10%). Cabozantinib is an FDA-approved agent as a second-line TKI, based on an 18% response rate and 11-month PFS in this setting.[93] Alternative TKIs that have demonstrated robust activity in phase 2 trials include pazopanib and axitinib.

With the advent of newly targeted therapeutic agents for a variety of solid tumors, genetic profiling should be considered for patients with RAIR PTC, poorly differentiated thyroid cancer (PDTC), and ATC. Such patients can harbor *BRAF* mutations (37%-50% of PTCs, 25%-45% of ATCs, and 90%-95% of mixed PTCs and ATCs), RET fusions (10%-20% of PTCs), NTRK fusions (5%-25% of PTCs), and anaplastic lymphoma kinase (ALK) fusions (9% of PDTCs, 4% of ATCs, and 1.6% of PTCs). When treatments with standard multikinase inhibitors are no longer options, patients with *BRAF* mutations may be amenable to treatment with dabrafenib with or without trametinib or vemurafenib. For *BRAF* V600E–mutant DTC, VEGF-targeting TKIs such as lenvatinib remain the first-line choice; although some of these patients respond to BRAF inhibition, the activity of the VEGF TKIs is superior. Larotrectinib and entrectinib are highly effective in tumors with NTRK fusions. Similarly, selpercatinib and pralsetinib have strong affinity for tumors driven by RET fusions. Thyroid cancers with ALK fusions have shown responses to crizotinib, ceritinib, and entrectinib, which are inhibitors of NTRK, reactive oxygen species, and ALK. Finally, cytotoxic chemotherapy has no role in the treatment of this disease.[94]

Lenvatinib

Lenvatinib inhibits VEGFR 1 to 3, fibroblast growth factor receptor 1 to 4, platelet-derived growth factor-A, RET, and KIT. It was approved by the FDA based on the positive results of the phase 3 SELECT trial.[94] In a 2:1 design, 261 patients were randomly assigned to lenvatinib 24 mg once per day, and 131 patients were randomly assigned to placebo. Patients receiving a placebo were allowed to receive lenvatinib upon disease progression. The median PFS was 18.3 months versus 3.6 months, favoring lenvatinib with an HR for progression or death of 0.21 (95% CI, 0.14-0.31; $P < .001$). The response rate to lenvatinib was 64.8%, with four complete responses and 165 partial responses. Treatment-related adverse effects (grade 3 or higher) occurred in 75.9% of patients receiving lenvatinib versus 9.9% receiving a placebo. The most common toxicities included hypertension (68%), diarrhea (59%), fatigue (59%), anorexia (50%), and weight loss (46%). Despite the FDA package insert dose of 24 mg once per day, most patients can tolerate only 20 mg or less per day, and lower doses have demonstrated efficacy.

ANAPLASTIC THYROID CANCER

ATC or giant cell variant thyroid cancer is associated with an extremely poor prognosis; the best available therapy produces a median survival of less than 1 year. Well-differentiated thyroid cancer precedes ATC or coexists with approximately 50% of ATC. Patients with ATC are older (generally in their 60s or 70s), and the distribution between the sexes is balanced. 20% to 50% of ATCs harbor activating *BRAF* V600 mutations.[95]

Distinguishing the tumor from a large-cell lymphoma of the thyroid is of fundamental importance. Clinically, ATC is characterized by a rapidly growing mass in the thyroid that invades the trachea or larynx and causes symptoms of dysphagia, hoarseness, or hemoptysis. Between 20% and 50% of patients have distant metastases at the time of presentation (most often pulmonary), and the remainder usually manifest metastases within 1 or 2 months of diagnosis. Most deaths are a result of aggressive locoregional spread and upper airway respiratory failure.

The treatment of choice is surgical resection if feasible, although these tumors are typically unresectable at presentation, and the patient often requires an urgent tracheostomy. Initial external beam RT, for definitive treatment and as an adjuvant (often with paclitaxel sensitization), is commonly used and considered the standard of care, but a durable response to RT alone is uncommon. Use of radiosensitizing chemotherapy is common, including paclitaxel, paclitaxel plus carboplatin, or doxorubicin. The use of doxorubicin in this setting has fallen out of favor because of severe CRT toxicity. Chemotherapy alone has limited efficacy, and RAI generally plays no role in the treatment of these tumors.

The combination of dabrafenib, a BRAF inhibitor, and trametinib, an MEK inhibitor, has been FDA approved for the treatment of *BRAF* V600E-mutated ATCs. In an open-label, phase 2 study, this combination produced a 69% response rate and estimated 12-month PFS and OS rates of 79% and 80%, respectively.[96] The most significant adverse effects included fatigue (38%), pyrexia (37%), and nausea (35%). A phase 2 trial of neoadjuvant pembrolizumab in combination with dabrafenib and trametinib for BRAF V600E-mutated anaplastic thyroid cancer showed substantial clinical benefit, with improved PFS and OS.[96-98]

MEDULLARY THYROID CANCER

MTC is a neoplasm of the calcitonin-producing cells that reside in the thyroid. It constitutes approximately 5% to 9% of all thyroid cancers and is associated with a mutation in the *RET* proto-oncogene. Both sporadic and familial types occur. The 10-year survival rate for patients with MTC ranges from 75% to 85%. Approximately half of patients with MTC present with disease localized to the thyroid gland, whereby total thyroidectomy often results in a complete cure. The 10-year survival rate for these patients is 95.6%. PET/CT imaging is useful for detecting nodal and distant metastases in this disease, but RAI scans are not useful.

The sporadic form is more common (75% of cases) and tends to occur in an older age group (age 40-45 years). The clinical presentation of the sporadic type of MTC is usually a painless thyroid mass; however, high calcitonin levels may result in a watery, secretory diarrhea as the primary symptom. The diagnosis is made based on a constellation of a thyroid mass, a high calcitonin level, and an FNA specimen that stains positive for calcitonin.

Three distinct familial syndromes account for the remaining 25% of cases. They tend to occur in a younger age group (age 15-25 years). The RET mutation is transmitted in the germline, and familial MTC may be part of multiple endocrine neoplasia type 2A (MTC, pheochromocytoma, and parathyroid hyperplasia) or type 2B (MTC, pheochromocytoma, and intestinal and mucosal ganglioneuromatosis with characteristic marfanoid habitus); it may also be a familial form of MTC not associated with multiple endocrine neoplasia. For the familial syndromes, a dominant inheritance pattern has been recognized, and family members of patients with newly diagnosed cases of the disease should be screened for *RET* mutations, because germline mutations are substantially higher than might be expected based on family history alone. Screening for pheochromocytoma (catecholamine excess) is important for excluding a familial syndrome, and all patients with germline mutations should be referred for a genetic counseling evaluation. Prophylactic total thyroidectomy will prevent MTC in young, at-risk family members (based on *RET* gene testing), even in the absence of clinically detectable thyroid abnormalities.

The treatment of choice for MTC is total thyroidectomy with bilateral central compartment node dissection and unilateral neck dissection (at the least). RT has disappointing efficacy for macroscopic disease, and postoperative RT is not routinely used.

After resection of all disease in the neck, patients should be monitored for two tumor markers: calcitonin and carcinoembryonic antigen levels. Patients whose calcitonin levels double within 6 months have a worse prognosis.

Local recurrences are usually treated surgically. Metastatic disease (commonly to the mediastinum, lung, bone, and liver) often follows an indolent course, and, in this case, observation is reasonable. MRI is required to monitor liver disease, because metastases may be small and not readily visualized with CT scans. Palliative surgery, including tumor debulking, or RT may be used as indicated for symptom control or to manage tumor encroachment on critical structures.

Vandetanib and cabozantinib are FDA-approved agents for the treatment of patients with locally advanced MTC that is not amenable to surgery or for those with metastatic disease. No data exist comparing these agents head-to-head; thus, the choice of which agent to use first may depend on expected adverse effects, and the indications for starting therapy will need to be individualized and balanced with toxicity profiles and quality-of-life outcomes.

Vandetanib is an oral inhibitor that targets VEGFR, RET, and EGFR. Vandetanib was an FDA-approved agent based on the positive results of a phase 3 placebo-controlled trial for patients with symptomatic or progressive unresectable, locally advanced, or metastatic MTC.[99] In the trial, 331 patients with advanced MTC were randomly assigned 1:1 to receive vandetanib 300 mg once per day versus placebo. The primary endpoint was PFS. There was a statistically significant improvement in PFS with vandetanib compared with placebo (HR, 0.46; 95% CI, 0.31-0.69; $P < .001$). The ORR, disease control rate, and biochemical response were also favorable with vandetanib. Common adverse effects of any grade included diarrhea (56%), rash (45%), nausea (33%),

hypertension (32%), and headache (26%). QT prolongation (14%), torsades de pointes, and sudden death are serious adverse effects that have resulted in a black box warning for this drug.

Cabozantinib is an oral TKI that targets MET, VEGFR2, and RET. Cabozantinib was approved for patients with progressive MTC based on the positive results of a phase 3, randomized, double-blind, placebo-controlled trial.[27] In the trial, 330 patients were enrolled and randomly assigned 2:1 to cabozantinib (140 mg/d) or placebo. The primary endpoint was PFS. Response rates were 28% for cabozantinib and 0% for placebo ($P < .001$). Common adverse effects of cabozantinib include diarrhea (63%), palmar-plantar erythrodysesthesia (50%), decreased weight (48%), appetite (46%), nausea (43%), and fatigue (41%), prompting dose reductions in 79% of patients. Patients assigned to cabozantinib therapy achieved a statistically significant improvement in PFS of 11.2 months compared with 4.0 months for the placebo arm ($P < .001$). This drug has black box warnings for serious adverse effects of gastrointestinal perforations (3%) and fistula formation (1%).

For patients who have MTC and whose tumors harbor *RET* mutations known to be sensitive to new, more selective RET inhibitors (selpercatinib, pralsetinib), these agents have displaced vandetanib and cabozantinib as first-line treatments.

Selpercatinib is an FDA-approved selective RET kinase inhibitor for *RET*-altered MTC and *RET* fusion–positive RAIR thyroid cancer in patients who have advanced or metastatic disease. In the LIBRETTO-001 phase 1/2 trial, 143 patients who had MTC (age 12 years or older) and advanced or metastatic disease who also harbored *RET* mutations were treated. Fifty-five of these patients had been previously treated with cabozantinib, vandetanib, or both. The ORR in the previously treated group was 69%, with 76% of these responses lasting for at least 6 months. The median duration of response was not reached. In the treatment-naive MTC group, the ORR was 73%, and 61% of these patients maintained their response for at least 6 months; the median duration of response was 22 months.[100] Common adverse effects with selpercatinib included increased aspartate transaminase (AST) and alanine transaminase (ALT) enzymes in the liver, increased blood sugars, and leukopenia.

Pralsetinib is a selective RET kinase inhibitor for *RET*-altered MTC and *RET* fusion–positive, RAIR thyroid cancer with advanced or metastatic disease. The multicohort, open-label, phase 1/2 ARROW trial included 55 patients with *RET*-mutant MTC previously treated with cabozantinib or vandetanib and had an ORR of 60%.[101] Almost 80% have had responses lasting for at least 6 months. Twenty-nine patients were treatment naive and achieved an ORR of 66%, 84% of whom had responses lasting for at least 6 months. The median duration of response had not yet been reached. Common adverse effects included constipation, hypertension, fatigue, musculoskeletal pain, and diarrhea. Common grades 3 and 4 laboratory abnormalities included lymphopenia, neutropenia, thrombocytopenia, anemia, hypocalcemia, and elevations in liver function tests (ie, AST, ALT, and alkaline phosphatase).

KEY POINTS

- For DTCs, poor prognostic features include age older than 45 years, male sex, poorly differentiated histology, a tumor size larger than 1.5 cm, and extrathyroidal extension at diagnosis. By contrast, involvement of the regional lymph nodes does not confer a worse prognosis for survival. Postoperative suppression of TSH with levothyroxine supplementation is done to decrease recurrence risk.
- RAI is the first-line treatment of metastatic RAI-sensitive disease. RAI generally has no role in the treatment of ATC or MTC.
- Lenvatinib, cabozantinib, and sorafenib are FDA-approved agents for the treatment of locally R/M progressive DTC that no longer responds to RAI treatment.
- All RAIR PTC, PDTC, MTC, and ATC tumors should undergo next-generation sequencing to evaluate for the presence of alterations (*BRAF*, *RET*, *ALK*, *NRTK*) that may be actionable to treatments with targeted therapies.
- Screening for germline *RET* gene mutation in patients who have MTC is recommended because total thyroidectomy, based on the results of genetic testing, often results in complete cures for young, at-risk family members.
- Vandetanib and cabozantinib are FDA-approved agents for the treatment of symptomatic or progressive locally advanced or metastatic MTCs, but, with the emergence of highly active RET inhibitors, use of these agents is now limited to patients without *RET* mutations.
- Selpercatinib is an FDA-approved treatment option for *RET*-altered advanced solid tumors, including MTC.
- The combination of dabrafenib and trametinib is approved for the treatment of *BRAF* V600E-mutated ATCs. Consideration of neoadjuvant TKIs and immunotherapy for patients who have ATC is emerging as a new standard based on multiple case series and a phase 2 trial, and some patients experience long-term survival with multimodality treatment.

MANAGEMENT OF DISEASE IN OLDER PATIENTS

Older patients present with age-specific problems such as multiorgan dysfunction, depression, alteration of mental status, reduced nutritional status, and limited social support, all of which can interfere with the diagnosis and treatment of cancer. A multidisciplinary team with both oncologic and nononcologic providers is needed to optimize a treatment strategy in older patients. Biologic age is more important than chronologic age and takes into account comorbid illnesses and performance status. In a large, single-institution study, 21% of patients with head and neck cancer had moderate to severe comorbidity, and there was a significant relationship between the severity of comorbidity and OS. A comprehensive geriatric assessment can be used to evaluate functional status, mental status,

medications, nutritional status, social support, and comorbid illnesses to provide physicians with a better sense of a patient's life expectancy and tolerance to different treatment modalities when making therapeutic decisions.

Surgery remains an appropriate option for the management of head and neck cancer in older patients, once a full risk assessment is completed and medical optimization is initiated. Postsurgical mortality is associated with older age, severity of comorbid illnesses, and length of the operation.

RT is a potentially curative option for patients diagnosed with early-stage disease or those with nonmetastatic disease who are deemed ineligible for surgical resection. RT can be safely administered in an older population, and most patients can complete their planned treatment. No data demonstrate poorer tolerance or the need to reduce radiation dose because of age.

Based on previous data, patients aged 70 years or older derive little or no incremental survival benefit from adding chemotherapy to RT; however, the use of CRT for patients aged 65 years or older has steadily increased recently. This trend has further increased with the use of cetuximab with RT. However, the OS benefit in an older patient population is not clear.[41] The use of aggressive CRT regimens should still be administered if patients are potential candidates. In some patients, the benefit of CRT may be offset by acute, often severe, treatment-related toxicities. Older patients often have limitations in performance status because they have multiple comorbidities and a lack of physiologic fitness, which makes them more susceptible to the toxic effects of chemotherapy, because of potential delayed clearance from renal or hepatic impairment, decreased bone marrow reserve, malnutrition, and cognitive impairment.

KEY POINTS

- Older patients can safely be treated with RT-based therapy for head and neck cancer, but require additional attention for management of comorbid illnesses.
- Measures of biologic rather than chronologic age are relevant when determining appropriate treatment of patients with locally advanced head and neck cancer.

SURVIVORSHIP

Studies involving survivors of head and neck cancer have mainly focused on social supports, tobacco and alcohol use, the risk for second primary cancers, functional status, and depression, and how these factors influence quality of life. Chronic pain, xerostomia, lymphedema, impairments of speech and swallowing, alterations of taste and smell, and poor cosmesis are some of the long-term sequelae associated with the treatment of head and neck cancer. These variable, long-term toxicities can have a profound psychosocial effect on cancer survivors and their families. Suicide rates for patients with head and neck cancer, including survivors, are three times higher than those of the general population. Advances in reconstructive techniques and organ preservation strategies are having a positive effect on quality of life relative to the functional and cosmetic consequences of the radical local therapies of the past. Nevertheless, quality-of-life and survivorship issues must continue to be a focus of future research.

KEY POINT

- Survivors of head and neck cancer can experience issues with swallowing, breathing, pain, and neck mobility that require ongoing management.

HIGH-YIELD TAKEAWAYS

- Smoking and alcohol exposure remain the commonest etiology for HNSCC, although HPV-related OPCs are on the rise.
- The majority of the patients with HNSCC are diagnosed with locally advanced disease, where multimodality therapy incorporating surgery, radiation, and chemotherapy is the standard of care.
- Definitive chemoradiation is the curative treatment of choice when a critical organ is at risk, for example, the base of the tongue and larynx. Cisplatin is the radiosensitizer of choice for eligible patients and was superior to cetuximab in multiple phase 3 clinical trials.
- Perioperative immunotherapy is an FDA-approved treatment option for resectable head and neck cancer that expresses PD-L1.
- For patients with recurrent or metastatic HNSCC, either pembrolizumab monotherapy or platinum, 5-FU, and pembrolizumab is the first-line treatment of choice.
- For patients with R/M nasopharyngeal cancers, toripalimab, in addition to platinum and gemcitabine, was recently approved by the FDA for first-line treatment based on improvement in PFS and OS.

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

HEAD AND NECK CANCERS 12

CHAPTER SUMMARY GUIDE

KEY POINTS

- Tobacco and alcohol use are the major risk factors for non-viral-associated HNSCC, and the use of both results in a multiplicative increase in risk.
- There is a causal association between high-risk oncogenic HPV and cancers of the oropharynx (tonsil, base of the tongue, soft palate) and a causal association between EBV and NPCs, but, in most humans, neither HPV nor EBV exposure results in the development of cancer.
- The prognosis is substantially better for HPV-related OPCs and EBV-related NPCs than for HPV-negative and EBV-negative cancers, respectively, at these sites.
- The incidence of second primary cancers for patients with a history of non-viral-associated HNSCC is 3% to 7% annually; common sites include the head and neck, lung, and esophagus. This high rate of second primaries seems related to a field cancerization effect of tobacco, alcohol, and other toxins.
- The earliest genetic alteration during the transition from normal mucosa to hyperplastic mucosa is the loss of genetic material containing tumor suppressor genes, known as a loss of heterozygosity or allelic imbalance.
- Erythroplakia and leukoplakia lesions are premalignant lesions that can be associated with severe dysplasia, carcinoma in situ, or invasive SCCs.
- Many presenting signs and symptoms are associated with a particular primary site (eg, hoarseness may refer to the larynx or hypopharynx, and a unilateral otitis media may refer to the nasopharynx).
- The location of pathologic lymph nodes in the neck may suggest the primary site.
- The initial evaluation for head and neck cancer includes a comprehensive examination of the head and neck, including endoscopic examination; imaging of the primary site, neck, and chest; and routine laboratory screenings.
- Early-stage disease is primarily defined as disease limited to a small primary tumor (T1 or T2) with low-risk (N1, one node smaller than 3 cm with no high-risk features) nodal involvement. Locally or locoregionally advanced disease is generally defined as the presence of a large primary tumor (T3 or T4) or the presence of large, multiple, or contralateral regional node involvement (N2 or N3).
- Criteria for unresectable disease include base-of-skull involvement, fixation to the prevertebral fascia, carotid encasement, and involvement of the pterygoid musculature.
- M1 disease is typically not curable and is approached with systemic therapy, although some patients with oligometastatic disease can have long-term remissions using combined modality treatment.
- Single-modality treatment with surgery or RT is typically used with curative intent for previously untreated p16-negative stage I, II, or low-bulk III (T1-2, N0, N1: single node smaller than 3 cm) disease or p16-positive stage I (T1-2, N0-1) disease with a single ipsilateral node measuring less than 3 cm in diameter and without clinical or radiographic evidence of ENE.
- Combined modality treatment of surgery and RT or CRT is used with curative intent for previously untreated, higher-volume, p16-negative stage III (T3, N0-1) and stage IVA/B disease or p16-positive stages I (multiple nodes or single node larger than 3 cm), II, and III disease.
- Neoadjuvant and adjuvant pembrolizumab, in addition to risk-stratified standard adjuvant therapy, is associated with improvement in EFS in patients with locally advanced PD-L1-positive (CPS $\geq$1) HNSCC, where surgery is the initial therapy.
- Metastatic disease below the clavicle and locoregional recurrent disease without a surgical or RT option are generally incurable and are treated with palliative intent. However, there are some patients with oligometastatic disease who are highly sensitive to systemic therapy and for whom curative paradigms of treatment should be considered.
- Function-conserving procedures are applicable for select patients in whom negative margins can be achieved with preservation of structures important for function.
- Debulking surgery is not part of routine clinical practice for head and neck cancer.
- Comprehensive neck dissections involve the removal of all five lymph node levels and are usually performed with therapeutic intent. Selective neck dissections involving the removal of fewer than all five levels are generally done electively to improve staging precision.

- Head and neck RT commonly causes acute toxicities, including mucositis, edema, dermatitis, dysgeusia, and xerostomia. Other potential toxicities include osteoradionecrosis of the mandible.
- IMRT delivers radiation around the tumor and high-risk lymph nodes conformally. It is associated with less dry mouth after treatment than that seen with conventionally planned RT.
- For patients with unresectable HNSCC, CRT with concurrent cisplatin improves survival compared with RT alone and is the standard of care.
- The optimal dosing regimen (40 mg/m^2 once per week or 100 mg/m^2 once every 21 days) for concurrent cisplatin remains to be defined. A cumulative dose of 200 mg/m^2 should be prioritized.
- In locally advanced laryngeal cancer (T2 to low-volume T4), LRC and larynx preservation are substantially improved with concomitant cisplatin and RT compared with induction chemotherapy followed by RT or RT alone.
- Cetuximab added to RT improves survival compared with RT alone in locally advanced head and neck cancer, but it is inferior to cisplatin with RT.
- Docetaxel combined with RT in patients who are not candidates for treatment with cisplatin is superior to RT alone in patients with locoregionally advanced disease.[57]
- CRT with cisplatin is the standard of care for postoperative adjuvant treatment of patients with positive resection margins and/or ENE of disease, with an emerging role for immunotherapy.
- The role of induction chemotherapy before CRT has yet to be defined. Several clinical trials have failed to demonstrate an advantage to induction other than for NPC (discussed below).
- No definitive data demonstrate that induction chemotherapy followed by CRT leads to better survival compared with CRT alone.
- Induction chemotherapy with TPF is considered the standard induction regimen when induction is recommended because it has been shown to improve both OS and LRC compared with PF.
- For patients with unresectable locally advanced HNSCC, CRT with cisplatin significantly improves survival compared with RT alone and is the standard of care.
- In locally advanced laryngeal cancer, LRC and larynx preservation are best achieved with concomitant cisplatin and RT, although induction chemotherapy followed by RT is a reasonable alternative because long-term data show no difference in laryngectomy-free survival for either treatment paradigm.
- Cetuximab added to RT improves survival compared with RT alone in locally advanced head and neck cancer, as does docetaxel in platinum-ineligible patients, but neither should replace CRT with cisplatin therapy as the standard of care in patients who are candidates for it.
- CRT with cisplatin is the standard of care for postoperative adjuvant treatment of patients with positive resection margins and/or extracapsular extension of nodal disease.
- The standard of care (according to stage) is RT alone for limited stage (typically T1-2 N0M0).
- Concurrent cisplatin-based CRT with or without adjuvant PF for intermediate-risk locoregional disease, and sequential CRT including induction GC or TPF, concurrent CRT, and adjuvant capecitabine for patients with the highest-risk locoregionally advanced disease remain the standards of care.
- NPC is a very chemotherapy-sensitive disease. Patients with metastatic disease often experience prolonged benefit from systemic chemotherapy. GC and ICI are the widely accepted first-line treatments of R/M disease, but other platinum-based chemotherapies combined with immunotherapy are also acceptable systemic treatment options.
- For patients with oligometastatic disease, a potentially curative treatment paradigm that includes systemic chemotherapy and local definitive treatment of the head and neck and oligometastatic sites is associated with some long-term survival.
- All treatment paradigms for NPC are largely based on data from EBV-associated NPC.
- The search for the primary site should include FDG-PET/CT imaging and an examination under anesthesia with directed biopsies of the base of the tongue, nasopharynx, and hypopharynx, and bilateral, simple tonsillectomies.
- After an FNA biopsy of the lymph node, HPV and EBV testing should be performed. If the tumors are positive, they should be treated as oropharyngeal or primary nasopharyngeal, respectively.
- Standard treatment consists of neck dissection followed by RT to include the likely primary sites, and concurrent cisplatin is added if extracapsular extension of nodal disease is present.
- In selected patients, CRT is another primary treatment option.
- Pembrolizumab (if PD-L1 CPS is 1 or higher and preferably 20 or higher) and pembrolizumab combined with platinum and 5-FU or platinum plus taxane are now considered the first-line standard of care for R/M HNSCC. For patients with PD-L1 CPS lower than 1, PF or TP with either cetuximab or pembrolizumab is used.
- Cetuximab combined with PF or TP (or cetuximab with carboplatin and paclitaxel) should be considered in the R/M setting when patients are not candidates for immunotherapy.

- Nivolumab and pembrolizumab are indicated as the second-line therapy for patients in whom platinum-based chemotherapy failed in the R/M setting.
- Taxanes, capecitabine, cetuximab, and methotrexate may be useful as single agents in patients with R/M HNSCC who have not had previous exposure to these agents, but, in general, response rates are low, and the duration of responses is limited.
- Surgery is the mainstay treatment of salivary gland tumors, followed by RT for those tumors with high-risk features; pleomorphic adenomas should be surgically resected because of their potential for malignant transformation.
- Metastatic ACC and selected other salivary gland cancers are often characterized by an indolent natural history and have no known effective treatments; therefore, they are often followed without systemic treatment.
- For most slow-growing salivary gland cancers, systemic treatment should be delayed until substantial tumor growth can be appreciated on serial imaging studies within 6 months or if the disease is located such that symptom development is imminent (eg, bronchial obstruction). Comprehensive testing, including next-generation sequencing to evaluate for actionable molecular targets and appropriate immunotherapy biomarkers, should be performed for patients with metastatic disease.
- Salivary ductal tumors are histologically similar to breast cancer and can overexpress androgen receptors and HER2. Such tumors are often treated effectively with antiandrogen blockade or HER2-targeted cytotoxic conjugate therapies. Chemotherapy can also be an effective option.
- Secretory carcinomas, formerly known as MASCs, are characterized by the presence of ETV6-NTRK3 fusion proteins; larotrectinib or entrectinib is the treatment of choice for secretory carcinomas that are metastatic or for tumors for which surgery is likely to result in severe morbidity.
- For DTCs, poor prognostic features include age older than 45 years, male sex, poorly differentiated histology, a tumor size larger than 1.5 cm, and extrathyroidal extension at diagnosis. By contrast, involvement of the regional lymph nodes does not confer a worse prognosis for survival. Postoperative suppression of TSH with levothyroxine supplementation is done to decrease recurrence risk.
- RAI is the first-line treatment of metastatic RAI-sensitive disease. RAI generally has no role in the treatment of ATC or MTC.
- Lenvatinib, cabozantinib, and sorafenib are FDA-approved agents for the treatment of locally R/M progressive DTC that no longer responds to RAI treatment.
- All RAIR PTC, PDTC, MTC, and ATC tumors should undergo next-generation sequencing to evaluate for the presence of alterations (*BRAF*, *RET*, *ALK*, *NRTK*) that may be actionable to treatments with targeted therapies.
- Screening for germline *RET* gene mutation in patients who have MTC is recommended because total thyroidectomy, based on the results of genetic testing, often results in complete cures for young, at-risk family members.
- Vandetanib and cabozantinib are FDA-approved agents for the treatment of symptomatic or progressive locally advanced or metastatic MTCs, but, with the emergence of highly active RET inhibitors, use of these agents is now limited to patients without *RET* mutations.
- Selpercatinib is an FDA-approved treatment option for *RET*-altered advanced solid tumors, including MTC.
- The combination of dabrafenib and trametinib is approved for the treatment of *BRAF* V600E-mutated ATCs. Consideration of neoadjuvant TKIs and immunotherapy for patients who have ATC is emerging as a new standard based on multiple case series and a phase 2 trial, and some patients experience long-term survival with multimodality treatment.
- Older patients can safely be treated with RT-based therapy for head and neck cancer, but require additional attention for management of comorbid illnesses.
- Measures of biologic rather than chronologic age are relevant when determining appropriate treatment of patients with locally advanced head and neck cancer.
- Survivors of head and neck cancer can experience issues with swallowing, breathing, pain, and neck mobility that require ongoing management.

CHAPTER TABLES AND IMAGES

Table 12-1 **Head and Neck Cancer: Primary Sites**	
Anatomic Area	**Primary Cancer Site**
Oral cavity and lip	Floor of mouth
	Oral tongue
	Buccal mucosa
	Alveolar ridges
	Hard palate
	Retromolar trigone
Pharynx	Nasopharynx (includes the superior surface of the soft palate)
	Oropharynx (includes the inferior surface of the soft palate, uvula, base of the tongue, tonsil, posterior pharyngeal wall)
	Hypopharynx (pyriform sinus, postcricoid, posterior wall)
Larynx	Supraglottic larynx (false cords, arytenoids, epiglottis)
	Glottic larynx (includes commissures)
	Subglottic larynx
Nasal cavity and paranasal sinuses	Nasal cavity
	Maxillary sinuses
	Ethmoid sinuses
	Frontal sinuses
	Sphenoid sinuses

UPPER GASTROINTESTINAL CANCERS 13.1

Daneng Li, MD, and Wen Wee Ma, MBBS

RECENT UPDATES

Esophageal Squamous Cell Carcinoma

- RATIONALE 306[1] was a global trial randomizing unresectable, locally advanced, recurrent or metastatic esophageal squamous cell carcinoma (ESCC) regardless of PD-L1 expression to receive tislelizumab or placebo in combination with a chemotherapy doublet of investigator's choice in the first-line setting. In patients with PD-L1 expression of 1 or higher, the median overall survival (OS) in the tislelizumab arm was 16.8 versus 9.6 months in the chemotherapy alone arm (hazard ratio [HR], 0.66, 95% CI 0.53-0.82). The US FDA-approved tislelizumab plus platinum-containing chemotherapy for the frontline treatment of adult patients with unresectable or metastatic ESCC with a tumor PD-L1 expression of 1 or higher on March 4, 2025.
- RATIONALE 302 was a global phase 3 study that compared tislelizumab with investigator's choice of chemotherapy as second-line treatment of patients with unresectable, locally advanced, or metastatic ESCC. The primary endpoint of OS was significantly improved in the tislelizumab arm; OS was 8.6 months (95% CI, 7.5-10.4) versus 6.3 months (95% CI, 5.3-7.0) in the chemotherapy arm (HR, 0.70; 95% CI, 0.57-0.85; $P = .0001$). However, given that current standard treatments include immune anti-PD1/anti-CTLA-4 agents in the first-line setting, the FDA approval of this agent for immunotherapy-naive ESCC (granted on March 14, 2024) will likely have limited impact on clinical practice.[2]

Esophagogastric Adenocarcinoma

- The approaches to treating patients with high-risk resectable esophageal or gastroesophageal junction (GEJ) adenocarcinoma (cT1 cN+, cT2–4a cN+, or cT2–4a cN0 disease) who are candidates for surgery has changed significantly over the last few years which now include neoadjuvant chemoradiation per the CROSS trial versus perioperative systemic treatment (FLOT plus durvalumab). This is supported by positive results from the ESOPEC and MATTERHORN trials.[3]
- Perioperative FLOT is a standard approach for patients with resectable gastric or GEJ adenocarcinomas who are candidates for surgery based on the positive results from the FLOT4-AIO study. The MATTERHORN trial,[4] reported in 2025, extended that approach by defining the role of immune checkpoint inhibitor. This phase 3 multinational trial randomized resectable gastric or GEJ adenocarcinoma to receive perioperative durvalumab plus FLOT followed by durvalumab for additional 10 cycles versus placebo plus FLOT. The 2-year OS was 75.7% in the durvalumab group versus 70.4% in the placebo group (HR, 0.67 for month 12 onwards; $P < .0001$).
- NCCN guidelines on esophageal and esophagogastric junction cancers list durvalumab plus FLOT as category 1 recommendation for the treatment of resectable GEJ and gastric adenocarcinoma. Although not included in the MATTERHORN trial, the NCCN guideline lists durvalumab plus FLOT as category 2A recommendation for resectable esophageal adenocarcinoma with PD-L1 combined positive score (CPS) ≥1 or tumor area positivity (TAP) ≥1.
- In patients with resected esophageal or GEJ adenocarcinoma who received neoadjuvant chemoradiation, 12 months of adjuvant nivolumab are recommended for those who have residual pathologic disease at the time of resection per CheckMate 577.[5] With a median follow-up of 78.3 months,[6] adjuvant nivolumab achieved superior disease-free survival (DFS) versus placebo (HR, 0.76; 95% CI, 0.63-0.91), and median OS was numerically longer with nivolumab versus placebo (51.7 vs 35.3 months). This is an alternative for patients who are not a candidate for perioperative FLOT +/− durvalumab.[6]

- On October 28, 2024, the FDA-approved zolbetuximab, a claudin 18.2 directed antibody, in combination with fluoropyrimidine and platinum-containing chemotherapy for the first-line treatment of advanced gastric and GEJ adenocarcinoma. This approval was based on the results from two phase 3 studies (SPOTLIGHT and GLOW) that demonstrated that the addition of zolbetuximab improves OS in patients whose tumors are positive for claudin 18.2 (as determined by an FDA-approved test) and negative for HER2. The median OS were 18.2 versus 15.5 months (HR, 0.750) in the zolbetuximab plus FOLFOX6 arm compared with the control in the SPOTLIGHT trial; and 14.4 versus12.2 months (HR, 0.771) in the zolbetuximab plus capecitabine and oxaliplatin (CAPOX) compared with the control in the GLOW trial.[7,8]
- On December 27, 2024, the FDA-approved tislelizumab in combination with chemotherapy for first-line treatment of HER2-negative gastric or GEJ adenocarcinoma with PD-L1 1% or greater. This approval was based on the results of the randomized phase 3 RATIONALE-305 trial, which demonstrated significant improvement in OS with tislelizumab's addition. In patients with a PD-L1 TAP score of 1 or greater, tislelizumab improved OS compared with placebo plus chemotherapy with HR of 0.78 (median OS, 15.0 vs 12.8 months).[9]

Hepatocellular Carcinoma

- The phase 3 open-label HIMALAYA study of single-dose tremelimumab and monthly durvalumab versus sorafenib showed improved OS (median OS, 16.43 vs 13.77 months; HR, 0.78; 96.02% CI, 0.65-0.93; $P = .0035$) but not PFS in the first-line treatment of patients with advanced hepatocellular carcinoma (HCC).[10] Tremelimumab and durvalumab received FDA approval on October 21, 2022, for the first-line treatment of unresectable HCC.
- The phase 3 open-label CheckMate-9DW study of combination nivolumab plus ipilimumab versus investigator's choice of sorafenib or lenvatinib showed improved OS (median OS, 23/7 vs 20.6 months; HR, 0.79; 95% CI, 0.65-0.96; $P = .018$) but not PFS in the first-line treatment of patients with advanced HCC.[11] Nivolumab and ipilimumab received FDA approval on April 11, 2025, for the first-line treatment of unresectable HCC.

Biliary Tract Carcinoma

- The phase 2 HERIZON-BTC-01 study assessed the safety and efficacy of zanidatamab, a bispecific HER2-directed antibody, in patients with unresectable or metastatic HER2-amplified biliary tract cancer (BTC), who had previously received gemcitabine-based therapy. The objective response was 41% with a duration of response of 12.9 months. Based on these results, the FDA granted accelerated approval of zanidatamab in previously treated HER2-positive (IHC 3^+) advanced BTC on November 20, 2024.[12]

Pancreatic Adenocarcinoma

- The phase 3 randomized open-label NAPOLI-3[13] study of liposomal irinotecan combined with 5-fluorouracil (5-FU) and oxaliplatin (NALIRIFOX) versus nab-paclitaxel and gemcitabine demonstrated improved OS (median OS, 11.1 vs 9.2 months; HR, 0.83; 95% CI 0.70-0.99; $P = .036$) and PFS (median PFS, 7.4 vs 5.6 months; HR, 0.69; 95% CI 0.58-0.83; $P < .0001$) with NALIRIFOX in the first-line treatment of patients with previously untreated metastatic pancreatic adenocarcinoma, which led to FDA approval of NALIRIFOX on February 13, 2024.[14]
- Zenocutuzumab, a bispecific antibody that targets HER2/HER3 dimerization and NRG1 protein binding, has received accelerated FDA approval for patients with advanced or metastatic pancreatic cancer harboring a *NRG1* gene fusion and disease progression after a prior systemic therapy. In the phase 2 study, objective responses were seen in 44% of pancreatic cancer cases.[15]

OVERVIEW

In 2025,[16] approximately 174,660 new cancers of the upper digestive system (gastroesophageal, hepatobiliary, and pancreatic) were diagnosed in the United States. About 113,500 patients would die annually because of upper gastrointestinal (GI) cancers, including 51,980 patients with pancreatic cancer, 34,490 patients with hepatobiliary cancer, and 27,030 patients with gastroesophageal cancer.

Many upper GI cancers are aggressive,[17-22] with survival measured in months. While some cancers, including gastroesophageal and pancreatic, may have a hereditary component,[23-25] the majority of upper GI cancers are sporadic. Systemic treatments for upper GI cancers include immunotherapy-based regimens, targeted therapies, and chemotherapy. Biomarkers[17-22] to assess disease prognosis and response to treatment are available for many upper GI cancers; however, their validity and reliability are lacking in certain diagnoses, particularly hepatocellular carcinoma (HCC). The majority of upper GI cancers require multidisciplinary

management. To provide patients with the best possible care, medical oncologists may need to collaborate with surgeons, radiation oncologists, interventional radiologists, gastroenterologists, and pathologists. A key role of the medical oncologist is coordinating the various members of a patient's care team to determine which treatment strategies to recommend.

GASTROESOPHAGEAL CANCER

Gastroesophageal cancers (GECs) are a group of heterogeneous diseases that exhibit great variation in histology, geographic distribution, clinical behavior, and molecular classification. The esophageal squamous cell carcinoma (ESCC) molecular profile resembles those of squamous cell carcinoma (SCCs) of other organs. Meanwhile, gastric and gastroesophageal junction (GEJ) adenocarcinomas comprise four molecularly defined subtypes based on gene copy alteration, point mutations, gene expression patterns, and changes in DNA methylation: tumors positive for Epstein–Barr virus, microsatellite instability-high (MSI-H) tumors, genomically stable tumors, and tumors with chromosomal instability (CIN). Esophageal adenocarcinoma resembles the CIN subtype found in the gastric cardia and gastric carcinoma.[26-28]

Despite the noted differences between esophageal, GEJ, and gastric adenocarcinomas, these tumor types are often grouped together as esophagogastric adenocarcinomas (EGAs) especially in metastatic settings when considering therapy. Numerous histological subtypes have been described, particularly pertinent to EGA, including histological differentiation (ie, well, moderate, or poor), Lauren classification (ie, intestinal, diffuse, or mixed type), presence of signet-ring cells, and a host of other subtypes in the WHO criteria.[29] However, tumor classification has now evolved beyond location and histology and relies on molecular biomarkers to guide treatment selection.

KEY POINTS

- Beyond known histopathologic and epidemiological distinctions, molecular features differentiate ESCC from esophageal adenocarcinoma with SCC resembling SCCs of other organs more than it does esophageal adenocarcinoma, whereas esophageal adenocarcinoma predominantly resembles the CIN type found in gastric adenocarcinoma.
- The Cancer Genome Atlas project proposed a molecular classification dividing esophageal and GEJ adenocarcinomas and gastric adenocarcinoma (together, gastroesophageal adenocarcinoma (GEA)) into four subtypes: tumors positive for Epstein–Barr virus, MSI-H unstable tumors, genomically stable tumors, and tumors with CIN.

EPIDEMIOLOGY, ETIOLOGY, AND PREVENTION

ESOPHAGEAL SQUAMOUS CELL CARCINOMA

Worldwide, ESCC is a significant health issue and the most common esophageal malignancy. As the eighth most common cancer globally, ESCC is the sixth most common cancer–related death. In the United States, ESCC is infrequent (~20% of esophageal cancer), constituting approximately 1% of all cancers and approximately 6% of GI malignancies. ESCC is more likely to occur in Black patients.[30] The primary risk factors are cigarette smoking and excessive alcohol consumption, but others include achalasia, caustic injury, tylosis, and Plummer–Vinson syndrome. Infection with human papillomavirus (HPV) has been correlated with an increased incidence of SCC of the upper cervical esophagus.[31] Patients with ESCC are at risk for synchronous or metachronous head and neck or lung SCC, which are molecularly more similar to ESCC than to esophageal and GEJ adenocarcinomas. With increased awareness and decreased exposure to the primary risk factors of smoking and alcohol use, the incidence of ESCC has decreased substantially in recent decades in the United States. However, worldwide, there remains a high incidence, particularly in areas of Iran, Russia, and northern China.

ESOPHAGEAL ADENOCARCINOMA AND GEJ ADENOCARCINOMA

For the last three decades, the incidence of esophageal and GEJ adenocarcinomas has increased significantly in Western countries, including the United States.[32] It is one of the fastest-growing cancers, typically diagnosed after age 60 years and affecting men at least five times more often than women. Esophageal and GEJ adenocarcinomas typically arise in the metaplastic epithelium.[33] Murine carcinogenesis models suggest migration of precursor cells from the gastric cardia proximally into the distal esophagus.[34,35] This premalignant condition is characterized by the replacement of the stratified squamous epithelium by the columnar epithelium, which develops as a consequence of chronic gastroesophageal reflux disease (GERD). The incidence of Barrett esophagus is 10% to 20% among symptomatic patients who undergo endoscopy and 30% to 50% among patients with peptic strictures. Risk factors associated with Barrett esophagus include GERD, White or Hispanic race, male sex, advanced age, smoking, diabetes, Western diet, and obesity.[36,37] However, there is heterogeneity in carcinogenesis, and not all tumors arise within a Barrett esophagus background. Approximately 60% of esophageal and GEJ adenocarcinomas have evidence of the precursor Barrett esophagus.

Detection of low-grade dysplasia on index endoscopy was associated with an adenocarcinoma incidence of 5.1 cases per 1,000 person-years. Risk estimates for patients with high-grade dysplasia (HGD) are slightly higher. In contrast, the incidence among patients without dysplasia was one case per 1,000 person-years.[38]

There is an inverse association between *Helicobacter pylori* infection and esophageal and GEJ adenocarcinomas, potentially as a result of the reduced acidity associated with atrophic gastritis.[39] Whether rigorous medical management of GERD with long-term use of proton-pump inhibitors can affect the natural history of the disease or the development of malignancy has long been debated.

A large randomized preventive study, AspECT, evaluated this question for patients with Barrett esophagus ≤1 cm and no HGD or esophageal adenocarcinoma.[40] A total of 2,563 patients were randomly assigned to high-dose (40 mg twice daily) or low-dose (20 mg once daily) esomeprazole alone or combined with 300 mg of aspirin per day. The primary composite endpoint was time to all-cause mortality, esophageal adenocarcinoma, or HGD. The use of a high-dose proton-pump inhibitor, especially in combination with aspirin, substantially improved outcomes for patients with Barrett esophagus.[40]

Another recent large population-based retrospective analysis in Nordic countries evaluating 942,906 patients with GERD reported that medical and surgical treatments for GERD were associated with a similar reduced esophageal adenocarcinoma risk with the risk decreasing to the same level as that in the background population over time, supporting the hypothesis that effective treatment of GERD might prevent esophageal adenocarcinoma.[41] Other than antiacid medication[40] and antireflux surgery,[41] typical treatment of patients with Barrett esophagus is surveillance using upper endoscopy and biopsy to evaluate for dysplasia.[37] HGD is an indication for more aggressive management, including surgical resection.[42,43]

GASTRIC ADENOCARCINOMA

In the United States, gastric adenocarcinoma is seen twice as often in men as in women and more frequently in Black men than in White men, and its incidence increases with age, starting at 50 years.[44] The incidence of gastric adenocarcinoma has varied considerably during the last century. In the United States, the incidence of gastric adenocarcinoma has decreased by approximately 75% during the last few decades.[36] Although gastric adenocarcinoma rates have declined worldwide, it is still prevalent in regions of the world where the storage of fresh food and the quality of water are poor and in some industrialized nations as well (eg, Japan).[45] Gastric adenocarcinoma is a major health issue in Japan and Korea, and both countries have nationwide screening programs. In Japan and Korea, gastric adenocarcinoma is associated with a better prognosis than in Western cultures. When controlling baseline tumor characteristics, patient demographics, and surgical factors, there is a difference in survival that remains unexplained.[46] Studies of migrant populations support evidence for the effect of environmental influences on the development of gastric adenocarcinoma.[47,48] Factors associated with an increased risk of gastric adenocarcinoma include nutritional factors, such as high salt and nitrate intake, a diet low in vitamins A and C, consumption of large amounts of smoked or cured foods, lack of refrigerated foods, and poor-quality drinking water.[49] Occupational exposure to rubber and coal also increases the risk. Cigarette smoking, *H. pylori* infection,[50,51] Epstein–Barr virus,[52] radiation exposure, and prior gastric surgery for benign ulcer disease are also implicated as risk factors. Together, these data support the belief that gastric adenocarcinoma is strongly influenced by nutritional, socioeconomic, and medical factors rather than dominated by genetic predisposition. Awareness of and decreased exposure to these factors have contributed to a decline in the incidence and mortality rate of gastric adenocarcinoma in the United States.

Genetic risk factors include type A blood, pernicious anemia, family history of gastric adenocarcinoma, Lynch syndrome, Li–Fraumeni syndrome, and hereditary diffuse gastric cancer (HDGC) caused by mutations in the E-cadherin gene, *CDH1*. HDGC is a genetic predisposition syndrome characterized by a family history of gastric adenocarcinoma with poorly cohesive diffuse-type histology, often with early onset of disease (generally age <40 years). The cumulative risk of the development of diffuse gastric adenocarcinoma by age 80 years for *CDH1* mutation carriers is 70% for men and 56% for women. Women who have germline *CDH1* mutations are also at higher risk of developing lobular breast cancer with a cumulative risk of 42% by age 80 years.[53] Individuals with a germline *CDH1* mutation should undergo risk-reducing prophylactic gastrectomy to prevent future development of HDGC.[54] The optimal timing of prophylactic gastrectomy is unknown and is usually highly individualized. The current consensus is that the procedure should be discussed with and offered to carriers of pathogenic germline *CDH1* mutation in early adulthood, generally between ages 20 and 30 years.

Results from several studies demonstrate an increased likelihood of gastric cancer, especially cancer originating in the distal stomach, in association with *H. pylori* infection.[50,51] Although cancer does not develop in most people with *H. pylori* infections, the increased risk in infected patients led to the hypothesis that *H. pylori* treatment might decrease the risk of gastric adenocarcinoma. Indeed, several population studies demonstrate that *H. pylori* eradication in at-risk individuals reduces the incidence of gastric cancer. All patients with evidence of *H. pylori* infection should be treated.[55]

KEY POINTS

- Individuals who carry a germline *CDH1* mutation are at substantial lifetime risk of developing gastric cancer and should undergo risk-reducing prophylactic gastrectomy as early as in their 20s.
- All patients with *H. pylori* infection should undergo treatment.

CLINICAL PRESENTATION, DIAGNOSIS, AND STAGING

The most common clinical presentation of esophageal and GEJ cancers is dysphagia resulting from the obstructive nature of the tumor and subsequent weight loss. Additional presenting symptoms include occult or frank bleeding (usually manifested by melena, iron-deficiency anemia, and fatigue) and treatment-refractory heartburn.[45] Patients with more proximal tumors can have tracheobronchial invasion and may present with laryngeal nerve paralysis, cough, and/or postobstructive pneumonia.[56] In contrast, patients with gastric adenocarcinoma commonly experience anorexia and early satiety leading to weight loss as their presenting symptom in addition to iron-deficiency anemia.

Because of vague symptoms that go unaddressed for some time, it is unfortunately common for patients with upper GI cancers to present with synchronous metastatic disease when symptoms become more severe, persistent, and compounded by metastatic spread. Common sites of disseminated disease are liver, lung, distant lymph nodes (LNs), bone, and peritoneum. Peritoneal carcinomatosis is seen in approximately 30% of patients with gastric adenocarcinoma and 10% to 15% of those with esophageal or GEJ adenocarcinoma (particularly those with diffuse or mixed-type histology or tumors with signet-ring features) and results in the development of ascites and abdominal pain, culminating in severe anorexia, dysfunctional bowel, and in many cases partial or complete bowel obstruction.[45]

An upper endoscopic examination should be performed to obtain a diagnostic biopsy. Diffuse-type gastric adenocarcinoma may be elusive during routine upper endoscopy because there is no obvious mass. Therefore, repeated endoscopy with endoscopic ultrasound (EUS) and other specialized endoscopic techniques may be required to arrive at a confirmed diagnosis if there is still high clinical suspicion of gastric adenocarcinoma. CT imaging of the chest, abdomen, and pelvis should be performed with tomographic slices through the liver to evaluate the extent of disease in the upper abdomen. A thorough clinical examination with careful attention paid to the LNs in the supraclavicular regions is essential.

For patients without obvious metastatic disease by CT scan, additional staging should include EUS, which is a standard component when evaluating patients with GEC eligible for locoregional therapy to determine the depth of invasion of the primary tumor (T stage) and locoregional LN involvement (N stage).[57,58] PET, preferably as a PET-CT scan, is part of the routine pretreatment diagnostic workup for patients with esophageal or GEJ cancer for detecting occult metastatic disease. PET allows for the detection of occult sites of distant metastatic spread; therefore, it may spare a patient the morbidity of aggressive locoregional treatments.[59-61] PET may not be sensitive to diagnose occult peritoneal spread in gastric cancer and staging laparoscopy should also be considered. Given the similar risk factors for lung and ESCCs, consideration of two separate primaries is important for patients with a primary ESCC and a solitary lung lesion at staging. It should be noted that diffuse-type gastric adenocarcinoma tumors can be negative on PET staging scans.[58] Given the similar risk factors for lung and ESCCs, consideration of two separate primaries is important for patients with a primary ESCC and a solitary lung lesion at staging. Staging laparoscopy is essential in the workup of locoregional gastric adenocarcinoma and should be offered to all patients without radiologically evident metastatic disease and who have at least T2 or node-positive disease on EUS. Diagnostic laparoscopy can identify up to 20% to 30% of occult peritoneal metastases in these cases; therefore, this is considered a standard staging procedure for these patients, which should be performed before initiating therapy.[61,62] The biology of Siewert III GEJ cancer is similar to gastric cancer and should be staged similarly to gastric cancer.

Staging has evolved through various editions of the American Joint Committee on Cancer (AJCC) manual, but three distinct staging systems have been maintained for ESCC, esophageal and GEJ adenocarcinomas, and gastric adenocarcinoma, respectively, based on the extent of involvement of the esophagus and stomach. Within esophageal and GEJ adenocarcinomas, subdivision into three Siewert types (type I, esophageal adenocarcinoma; type II, GEJ; and type III, gastric cardia), largely for surgical anatomic planning, was named after the German surgeon who defined these.[63] The Siewert types are now often used as criteria for enrollment in clinical trials. However, practically speaking, these distinctions are difficult to accurately characterize by upper endoscopy because tumors often span these artificial boundaries. The eighth edition of the AJCC staging manual incorporated consideration of clinical staging at diagnosis before any therapy or surgery (c stage), pathologic stage after neoadjuvant therapy (yp stage), and pathologic stage in those not receiving neoadjuvant therapy (p stage) and the prognostic estimates by stage for each scenario.[64-70]

KEY POINTS

- Common presenting symptoms for GEC include dysphagia, anorexia, early satiety, nausea, dyspepsia, pain, bleeding, and hematemesis.
- Cross-sectional imaging including PET, EUS, and laparoscopic staging for patients with gastric and Siewert III GEJ tumors are critical to determine the location and stage of the tumor.

TREATMENT

LOCAL DISEASE

Surgery plays a critical role in managing patients with early-stage esophagogastric tumors except for patients with proximal ESCC that are treated with definitive concurrent chemotherapy plus radiation therapy (chemoRT). Aside from very early-stage disease, multimodality approaches are essential.

Patients who have GEC limited to the mucosa (HGD or tumors invading the lamina propria or muscularis mucosae; T1a) may be managed with endoscopic resection (endoscopic mucosal resection or endoscopic submucosal dissection) because there is a relatively low risk (2%) of occult regional LN metastasis.[71-73] For lesions that have penetrated the submucosa without LN involvement on staging studies (tumor invading the submucosa; T1b), surgical resection with lymphadenectomy is recommended because of the approximately 15% to 40% risk of occult LN involvement.[74]

Unfortunately, most patients are diagnosed with more advanced disease for which surgery alone is insufficient. For any lesions that are at least T3 (tumor invading through the muscularis propria) and/or node-positive disease amenable to surgical resection, multimodal management with chemotherapy or chemotherapy with concurrent radiation therapy before and/or after surgery has become the standard given the high risk of micrometastatic dissemination.[3,21,40] It is controversial whether all patients who have T2N0 GEC (ie, tumor invading the muscularis propria; T2) should receive perioperative or neoadjuvant therapy and surgery versus surgery alone because some studies have included such patients as eligible and other studies have not, and some reports suggest a lack of benefit in the setting of adequate surgery.[75-78] Currently, a discussion of potential risks and benefits of perioperative therapy and surgery versus surgery alone with the patient and family is prudent, and a personalized approach for patients with T2N0 disease is recommended, including enrollment in a clinical trial if available. The NCCN guideline[79] recommends T2N0 GEC with high-risk lesions, defined as presence of lymphovascular invasion, ≥3 cm and/or poorly differentiated histology) to be considered for neo-adjuvant or perioperative therapy then surgery. The identification and treatment of patients who have minimal residual disease postresection are emerging areas of investigation to reduce the risk of recurrence and improve long-term outcomes for high-risk patients.[80]

SURGERY

The optimal curative treatment approach for patients who have locally advanced GEC includes surgical resection with preoperative chemotherapy or concurrent chemoradiation.[81] For distal ESCC and esophageal and GEJ adenocarcinomas, the two most commonly used surgical techniques are transhiatal esophagectomy and a transthoracic approach (eg, an Ivor–Lewis resection). The results associated with the two approaches are similar.[82-84] Reports suggest a higher retrieval rate of LNs with an Ivor–Lewis approach.[85,86] The surgical approach is determined by the experienced surgeon on the basis of the tumor location and patient details, including transthoracic esophagectomy with two-field lymphadenectomy; transhiatal esophagectomy with lower mediastinal and upper abdominal lymphadenectomy; and proximal, subtotal, or total gastrectomy. Minimally invasive approaches via laparoscopy and robotic surgeries are becoming more common in GEC without evidence of detriment in efficacy.[87]

For gastric cancer, the number of LNs removed is important.[88-90] D2 lymphadenectomy is defined as the contiguous resection of the second tier of LNs along the branches of the celiac trunk (eg, common hepatic artery, left gastric artery, and splenic artery). After 15-year follow-up of a randomized Dutch trial that included 1,078 patients with distal gastric adenocarcinoma, D2 lymphadenectomy was associated with lower locoregional recurrence (12% vs 22%) and gastric cancer–related death rates (37% vs 48%) than D1 surgery (fewer LNs removed).[91] Although D2 dissection was associated with higher operative morbidity, these data suggest D2 lymphadenectomy should be considered the surgical standard of care. Larger meta-analyses confirm the benefit of D2 lymphadenectomy, particularly in patients who have undergone D2 resection without resection of the spleen or distal pancreas or nodal stations around these (ie, modified D2) as well as in patients who have higher risk T3 to T4 or node-positive cancer.[92,93] The NCCN guideline recommends that gastric resection should include regional D1 and D2 lymph node dissection with a goal of examining ≥16 LNs. Operative mortality rates for GEC should be <5% when surgery is performed by an experienced surgeon at a high-volume center.[94] Historically, survival has been poor for patients with GEC treated with surgery alone with 5-year survival rates ranging from 5% to 34%,[56] leading to several studies evaluating the benefit of perioperative therapies.

NEOADJUVANT, ADJUVANT, OR PERIOPERATIVE TREATMENT

Various neoadjuvant, adjuvant, or perioperative (a course of both neoadjuvant and adjuvant therapies) combined-modality approaches for the treatment of GEC have been evaluated because of the poor outcomes observed with surgery alone. Combined-modality treatment involves surgery, chemotherapy with or without radiation therapy, or both. The interpretation of the results from these clinical trials is complicated by EGA classification and differential incidence of upper GI cancer subtypes based on geographic distribution, making cross-trial comparisons challenging and potentially misleading. Similarly, the different makeup of ESCC and adenocarcinoma within different esophageal studies makes comparison across studies challenging because these subtypes have a different biology, natural history, and sensitivity to perioperative therapies. This ultimately led to a fragmented treatment approach with each approach deemed to be more effective than surgery alone, and until recently, it remained unclear which, if any, is superior.[3,80,95] The positive results of the phase 3 CROSS trial established neoadjuvant concurrent chemoradiation followed by surgical resection as a standard for localized resectable esophageal cancer. Then recent positive results from two prospective phase 3 studies evaluating perioperative treatments in EGA support perioperative chemotherapy as another standard approach to the management of these patients.[3,95] Neoadjuvant chemoradiation remains the optimal therapeutic approach for patients who have resectable ESCC, followed by adjuvant nivolumab for those who have residual pathologic disease at resection.

ESOPHAGEAL SQUAMOUS CELL CARCINOMA

Local recurrence rates of muscle-invasive or node-positive ESCC are high with surgery alone, similar to other SCC tumor sites.[56,81] Data from the phase 3 CROSS trial, which enrolled patients who had ESCC (25%) and adenocarcinoma (75%), confirmed the superiority of a neoadjuvant CRT approach (with weekly carboplatin and paclitaxel) compared with surgery alone for patients who have localized ESCC.[5] These results confirm CRT as the standard of care option for patients who have locally advanced ESCC.[96]

With 10-year follow-up, the OS survival benefit continued with perioperative treatment per CROSS; however, systemic recurrences were similar between the control (surgery alone) and CRT arms across all enrolled patients,[97] suggesting the need for better systemic treatments for micrometastatic disease. The positive results from the CheckMate 577 trial[5] established adjuvant nivolumab as standard adjuvant therapy in patients who did not have pathological complete response (pCR) after preoperative CRT. The phase 3 randomized placebo-controlled global study evaluated adjuvant nivolumab or placebo for patients who have esophageal cancer (including SCC and adenocarcinoma) who received neoadjuvant CRT followed by surgery with residual disease (T+ and/or N+; R0 resection).[98] The first report[6] of survival following 24.4 month median follow-up, the median OS for the adjuvant nivolumab arm is numerically superior to the placebo arm, though not reaching statistical significance (51.7 vs 35.3 months; HR, 0.85; 95% CI 0.70-1.03; P = .1064). Long-term follow-up to confirm the survival benefit is ongoing. Nivolumab is approved by FDA for use as adjuvant therapy for patients who have ESCC with residual pathological disease after chemoradiation and resection.[99]

Given the favorable pCR rate (approximately 49%)[5] with CRT in ESCC, definitive CRT (without surgical resection) is considered a standard option for patients who have localized ESCC, or those with or locally advanced disease who are not appropriate surgical candidates.[5,100,101] Decisions regarding surgical appropriateness involve several factors, including but not limited to tumor location, patient age, comorbidities, performance status (PS), and need for laryngectomy. Patients who have T4b disease (tumors invading other adjacent structures, such as aorta, vertebral body, and trachea), tracheoesophageal fistula, or cervical ESCC are not candidates for curative-intent surgery.

Patients who achieve clinical complete response after CRT may choose not to proceed to resection immediately, opting for close monitoring with the goal of avoiding esophagectomy altogether. Salvage esophagectomy at recurrence is associated with similar survival compared with proceeding directly to esophagectomy following completion of chemoRT but has a higher surgical morbidity, including a risk of anastomotic leak of 25% (for salvage esophagectomy) versus 3% if performed shortly after completion of combined-modality therapy.[101,102] Notably, there are ongoing clinical trials evaluating the benefit of immunotherapy in patients treated with definitive CRT for locoregional disease.[103] While the positive CROSS trial established carboplatin and paclitaxel as radiosensitizer of choice to be given concurrently with radiation, fluoropyrimidine plus oxaliplatin (FOLFOX, capecitabine/oxaliplatin) are alternatives for patients who are not candidates for the CROSS regimen.[104-106]

ESOPHAGOGASTRIC ADENOCARCINOMA

In the past, treatment of EGA was driven primarily by tumor location. Historically, patients with esophageal cancers received preoperative chemoRT, whereas patients with gastric cancer were treated with perioperative chemotherapy. For years, management of distal esophageal and GEJ adenocarcinomas has been an area of contention as patients who have tumors arising at GEJ have been included in clinical trials for esophageal cancer (and grouped together with patients with ESCC) as well as in trials for patients who have gastric cancer proper. Therefore, interpreting past data has been challenging.

Until recently, the standard approach to patients who have esophageal adenocarcinoma, including Seiwert I and II GEJ tumors, mirrored those of ESCC. The rationale to support this approach included improved (R0) resection rates with preoperative CRT and improved OS compared with resection alone. The CROSS study with doublet chemotherapy (carboplatin and paclitaxel) was the first stand-alone phase 3 study to support this approach with 75% of patients enrolled having esophageal or GEJ adenocarcinoma (type I or II Siewert tumors) and the other 25% having ESCC. For patients who have esophageal or GEJ adenocarcinoma, the pCR rate was 23% (21% intention to treat), and median OS was 43.2 months with CRT followed by surgery versus 27.1 months with surgery alone. However, the results of the ESOPEC[3] and MATTERHORN[4] trials changed that practice, and the NCCN guideline[79] recommends perioperative systemic chemotherapy as the preferred approach for patients with adenocarcinoma of the esophagus and GEJ who are medically fit for surgery.

The phase 3 randomized ESOPEC trial evaluated perioperative FLOT compared with neoadjuvant ChemoRT with carboplatin and paclitaxel (the CROSS regimen) for patients who have proximal esophageal or GEJ adenocarcinoma.[108] This trial demonstrated a superior 3-year OS for perioperative chemotherapy compared with chemoradiation (57.4% vs 50.7%; HR, 0.70, P = 0.01). The PFS and pathological outcomes were similarly better in the FLOT arm, whereas rates of R0 resection were similar in patients who were treated with radiation and chemotherapy. Notably, patients in the neoadjuvant CRT group did not receive adjuvant nivolumab as the trial was conducted before the results of CheckMate 577 were available.

It is important to acknowledge that not all patients are candidates for triplet FLOT chemotherapy. Dosage modifications should be considered in those who are too frail to tolerate this regimen. Preoperative chemoradiation per CROSS study remains an appropriate approach for patients who are not candidates for intensive chemotherapy and/or surgery, or decline surgery.

Adjuvant nivolumab should be considered for patients who do not achieve complete pathological response following resection based on the positive results from the CheckMate 577 trial described above.

In contrast, patients who have gastric adenocarcinomas are treated with perioperative chemotherapy, and standard treatment consists of perioperative (neoadjuvant and adjuvant) triplet chemotherapy with FLOT (United States,[107] United Kingdom, and much of Europe) or adjuvant chemotherapy alone after D2 resection (Asia).[109] The FLOT regimen is a standard perioperative treatment based on the results of the FLOT4-AIO study.[107] The strategy in the perioperative FLOT4 study was to proceed with four more adjuvant cycles as tolerated. However, it should be noted that, in the perioperative studies, only approximately 50% of patients received all the intended adjuvant chemotherapy.[107,110,111] Despite improvement in outcomes, there are remaining unsettled issues regarding perioperative therapy. It is unclear how to approach patients postoperatively who, on the basis of poor pathological response, did not benefit from neoadjuvant therapy. Further investigation is necessary to better direct an optimal approach in the scenarios of excellent response and poor response to the neoadjuvant component whether it is to continue more FLOT, change to other therapy, or observe only. For now, the standard approach is to complete adjuvant therapy, if possible, in all scenarios (or consider a clinical trial to address these issues).

The use of immune checkpoint inhibitor with perioperative therapy in EGA is established by the positive results from the pivotal MATTERHORN[4] trial. This phase 3 multinational trial randomized resectable gastric or GEJ adenocarcinoma to receive perioperative durvalumab plus FLOT followed by durvalumab for additional 10 cycles versus placebo plus FLOT. The 2-year OS was 75.7% in the durvalumab group versus 70.4% in the placebo group (HR, 0.67 for month 12 onwards; $P < .0001$). The NCCN guideline lists durvalumab plus FLOT as category 1 recommendation for the treatment of resectable GEJ and gastric adenocarcinoma, and category 2A for resectable esophageal adenocarcinoma.

Although neoadjuvant therapy is preferred before surgery in the United States, large studies from Asia have demonstrated the benefit of adjuvant chemotherapy after D2 resection without neoadjuvant treatment.[109,112-114] The Korean CLASSIC study, which included 1,035 patients who had D2-resected stage II or III distal gastric adenocarcinoma, identified adjuvant therapy with CAPOX (capecitabine and oxaliplatin) as superior to surgery alone with substantial improvement in OS.[109] The superior outcomes of patients in Eastern countries are clearly highlighted in the CLASSIC study compared with outcomes in Western countries, but one should not compare perioperative FLOT as studied in the West with adjuvant CAPOX as studied in the East.[107,109] In addition to these individual trials supporting adjuvant chemotherapy, a meta-analysis of 17 trials with 3,838 patients confirmed that adjuvant chemotherapy without radiation therapy after gastric adenocarcinoma resection was associated with a substantial survival benefit.[115] Adjuvant oxaliplatin and fluoropyrimidine is an option for patients who had upfront surgery based on the CLASSIC study. Adjuvant CRT is an option for patients with inadequate surgery, most often the case in patients who have had surgery first in the United States.[116]

EARLY-STAGE MSI-H/DMMR GEJ ADENOCARCINOMA

MSI-H gastric and GEJ adenocarcinoma represent a subtype of tumors with differential biological behavior and response to therapy.[117] A recent meta-analysis demonstrated that MSI-H tumors have a good prognosis compared with microsatellite stable tumors.[118] Importantly, this meta-analysis, including several perioperative phase 3 studies, also demonstrated that patients with MSI-H tumors seem to have a poor outcome with chemotherapy compared with surgery alone, similar to observations in stage II MSI-H colorectal cancer.[117]

The NEONIPIGA phase 2 study evaluated the role of perioperative nivolumab and ipilimumab in 32 patients who have MSI-H, T2-T4, NxM0 resectable gastric adenocarcinoma/GEJ adenocarcinoma.[119] In this study, 29 patients had an R0 resection, and 17 (58.6%; 90% CI 41.8-4.1) had a pCR. The other three patients had a complete clinical response and did not undergo surgery. With a median follow-up of 14.9 months, no patients experienced recurrent disease during this study.

Similar results were seen in the phase 2 INFINITY trial,[120] which enrolled 18 patients. These data demonstrate a potential role for immunotherapy in patients who have MSI-H tumors, but the optimal management of these patients is evolving.

KEY POINTS

- Combined-modality CRT followed by resection is the standard neoadjuvant approach in the treatment of locally advanced ESCC.
- Definitive CRT (without surgery) is a valid treatment option for patients who have ESCC, especially if patients are high-risk surgical candidates.
- One year of adjuvant nivolumab for patients who have esophageal cancer (both SCC and adenocarcinoma) who received neoadjuvant CRT followed by surgery with residual pathological disease (T+ and/or N+; R0 resection) is the standard of care based on the improved DFS observed in CheckMate 577.[95,107]
- The positive results from ESOPEC, FLOT4-AIO, and MATTERHORN established perioperative systemic therapy as the preferred approach for patients with resectable esophageal, GEJ, and gastric cancers who are candidates for surgery and intensive systemic therapy.

- Perioperative FLOT plus durvalumab is a standard for patients with resectable esophageal, GEJ, or gastric cancers who are candidates for surgery.
- Adjuvant nivolumab for 1 year is the standard for patients with resected esophageal or GEJ tumors who received preoperative chemoradiation and have residual pathological disease after surgical resection.
- Adjuvant CAPOX without radiation therapy was superior for tumors with at least muscle invasive (≤T2) and/or node-positive disease (≤N1) in patients with an adequate D2 lymphadenectomy compared with surgery alone based on the CLASSIC study. This should be considered in patients who do not receive preoperative systemic chemotherapy or preoperative chemoradiation.
- Immune checkpoint inhibitor(s) should be considered for patients with resectable MSI-H/mismatch repair (MMR)-deficient esophageal or GEJ adenocarcinoma in either neoadjuvant or perioperative approaches.

TREATMENT OF METASTATIC DISEASE

Unfortunately, many patients present with metastatic disease at initial diagnosis. This risk of recurrence is high after curative-intent therapy; >50% of patients recur within 2.5 to 3 years. There is no role for routine resection of the primary tumor without resection of the metastatic disease even when there is limited single-site metastasis.[121]

As such, the goals of treatment for metastatic GEC are to control the disease, prolong life, and provide palliation while limiting toxicities from therapy. Palliative systemic therapy is associated with improved quality-of-life as well as improved survival. Ancillary support including palliative radiation therapy for symptomatic localized metastases such as bone lesions as well as radiation therapy and/or endoluminal stenting for refractory or symptomatic primary tumors also contributes to improvement in patient outcomes.

SYSTEMIC THERAPY

Many systemic agents have shown anti-cancer activity in GEC, including cytotoxic (eg, fluoropyrimidines, platinum agents, taxanes, irinotecan, and trifluridine and tipiracil), molecularly targeted drugs (eg, trastuzumab, zolbetuximab, and ramucirumab), immune checkpoint inhibitors (ipilumumab, nivolumab, pembrolizumab, and tislelizumab) and antibody-drug conjugates such as trastuzumab deruxtecan.

First-line treatment typically involves doublet chemotherapy as the backbone of combination regimens. The utility of cytotoxic regimens is similar across gastroesophageal subtypes and studies in the West have focused predominantly on EGA due to the higher prevalence in these countries.

Doublet chemotherapy regimens have yielded response rates as high as 40% to 50% and are associated with increased OS when compared with single-agent therapies.[122] Standard contemporary doublet regimens such as FOLFOX and FOLFIRI (5-fluorouracil [5-FU], leucovorin, and irinotecan) achieve similar outcomes with convenient dosing schedules and acceptable toxicity.[123-126] Triplet regimens, using older generation cytotoxics such as epirubicin and cisplatin, in contrast, are not widely used in the United States due to unacceptable toxicity profile and unclear superiority over FOLFOX and FOLFIRI.[127] However, there is an ongoing phase 3 trial AO22102 evaluating FOLFIRINOX compared with FOLFOX chemotherapy in the first-line setting for advanced GEA treatment.[128] The AO22102 trial Alliance[124] cooperative group is ongoing to compare the triplet FOLFIRINOX to doublet FOLFOX regimen (+/− nivolumab) in the first-line treatment of metastatic HER2-negative GEA.[128]

ESOPHAGEAL SQUAMOUS CELL CARCINOMA

First-Line Therapy

Chemo-immunotherapy is the standard as first-line treatment of advanced, metastatic ESCC. The phase 3 randomized, placebo-controlled, global KEYNOTE-590 study evaluated first-line therapy for the treatment of newly diagnosed metastatic esophageal cancer with 5-FU and cisplatin with either pembrolizumab or placebo. Median OS was superior in ESCC with chemotherapy and pembrolizumab versus chemotherapy (median, 12.6 vs 9.8 months; HR, 0.72; 95% CI 0.60-0.88; P = .0006). Median PFS was also significantly longer in patients with ESCC treated with chemotherapy and pembrolizumab as compared with chemotherapy alone (median PFS 6.3 vs 5.8 months; HR, 0.65; 95% CI 0.54-0.78; P < .0001). This benefit was more pronounced in patients who had PD-L1 combined positive score (CPS) ≥10 tumors. Pembrolizumab is currently listed in the NCCN guideline as category 1 recommendation for use in CPS ≥1 tumors in combination with platinum and fluoropyrimidine. The FDA-approved pembrolizumab for all tumors irrespective of histology or PD-L1 level on March 22, 2021.[129] Oxaliplatin may be used interchangeably for cisplatin based upon the findings from the REAL-2 study.[130]

CheckMate 648 tested the role of nivolumab as a component of chemoimmunotherapy in the first-line setting for patients with metastatic ESCC.[131] This phase 3 study randomly assigned patients (N = 970) irrespective of PD-L1 expression to receive treatment with 5-FU and cisplatin alone or in combination with nivolumab (240 mg) every 2 weeks or to a chemotherapy-free combination of nivolumab (3 mg/kg) every 2 weeks and ipilimumab (1 mg/kg) every 6 weeks. The coprimary endpoints were OS and PFS for patients with PD-L1 CPS ≥1% tumors. Median OS in the overall population was 13.2 months with chemotherapy and nivolumab versus 10.7

months with chemotherapy (HR, 0.74; 95% CI 0.61-0.89; *P* = .002). Similarly, the median OS in the overall population was 12.7 months for ipilimumab/nivolumab versus 10.7 months for chemotherapy (HR, 0.78; 95% CI 0.65-0.94; *P* = .01). Median PFS in the overall population was not significantly longer with chemotherapy/nivolumab compared with chemotherapy alone. In the nivolumab and ipilimumab arm, OS was also improved compared with chemotherapy alone (12.7 vs 10.7 months with HR of 0.77). Patient-specific characteristics should be considered during therapy selection, and priority should be given to chemotherapy with nivolumab in the treatment of patients who have bulky disease or with significant symptomatic disease burden. Ipilimumab plus nivolumab, a cytotoxic free regimen, is a reasonable consideration for patients with tumor PD-L1 CPS ≥1 and who are not candidates for combination cytotoxic regimen.

RATIONALE 306 was a double-blind global phase 3 trial in which patients with advanced ESCC with no prior treatment were randomized in a 1:1 manner to chemotherapy (platinum agent combined with either a fluoropyrimidine or paclitaxel plus either tislelizumab or placebo). The addition of tislelizumab to chemotherapy significantly improved OS in both the intent-to-treat population (17.2 vs 10.6 months, HR, 0.66) and in several prespecified subgroups based on the level of PD-L1 expression (tumor area positivity score, TAP ≥ 5). Notably, tislelizumab in patients who have tumors with low PD-L1 level (TAP < 1%) appeared to have a potential detrimental effect with HR of 1.34 on OS. Tislelizumab, in combination with platinum-containing chemotherapy, was approved by FDA on March 4, 2025 for the frontline treatment of patients with unresectable or metastatic ESCC with a tumor PDL1 TAP score ≥1.

The benefit of adding other checkpoint inhibitors to first-line chemotherapy in Asian patients with ESCC has been demonstrated in several phase 3 studies. In the ORIENT-15 study, sintilimab combined with chemotherapy improved OS compared with chemotherapy alone (median, 16.7 vs 12.5 months; HR, 0.63; 95% CI 0.51-0.78; *P* < .001). In the JUPITER-06 study, toripalimab combined with chemotherapy improved OS compared with chemotherapy alone (median, 17.0 vs 11.0 months; HR, 0.58; 95% CI 0.43-0.78; *P* = .0004). In the ESCORT-1 study, the addition of camrelizumab to chemotherapy improved OS compared with chemotherapy alone (median, 15.3 vs 12.0 months; HR, 0.70; 95% CI, 0.56-0.88; *P* = .001). In the RATIONALE-306 study, the addition of tislelizumab to chemotherapy also improved OS compared with chemotherapy alone (median, 17.2 vs 10.6 months; HR, 0.66; 95% CI, 0.54-0.80; *P* < .0001).

In aggregate, these studies established PD-1–based chemoimmunotherapy as the standard first-line therapy for unresectable, metastatic ESCC.

ESOPHAGEAL, GEJ, AND GASTRIC ADENOCARCINOMAS

Biomarker testing, including HER2, PD-L1, Claudin 18.2 (CLDN18.2), and MMR, should be routine and standard when developing treatment plans for patients with unresectable, metastatic esophageal, GEJ, or gastric adenocarcinoma (Table 13.1-1). Next-generation sequencing (NGS) is highly recommended for all cases of advanced-stage disease to identify potentially actionable alterations.

Table 13.1-1 First-line Treatment Options for Advanced Esophago-Gastric Adenocarcinoma

Tumor Characteristics	Treatment
HER2+[a] and PDL1 CPS ≥1	Chemotherapy, trastuzumab, and pembrolizumab
HER2+[a] and PDL1 CPS <1	Chemotherapy and trastuzumab
HER2–[a] and PDL1 CPS ≥1	Chemotherapy and anti-PD1 ab[b]
CLAUDIN 18.2+[c]	Chemotherapy and zolbetuximab
HER2– and PDL1 CPS <1, CLAUDIN 18.2–	Chemotherapy
dMMR/MSI-H	Anti-PD1 ab +/– anti-CTLA4 ab[d] OR chemotherapy + anti-PD1[e]

Abbreviations: CPS, combined positive score; dMMR, deficient DNA mismatch repair; MSI-H, microsatellite instability-high.
[a]HER2+: IHC 3 + or IHC2+/ISH+; HER2-: IHC 1+ or IHC2+/ISH–
[b]Nivolumab, tislelizumab, or pembrolizumab.
[c]Claudin 18.2 moderate or strong expression by IHC in ≥75% tumor cells.
[d]Pembrolizumab, dostarlimab, nivolumab + ipilumumab.
[e]Nivolumab, pembrolizumab.

First-Line Therapy

Since 2021 there have been several regulatory approvals for chemoimmunotherapy in the first-line setting for esophageal, GEJ, and gastric adenocarcinomas.

HER2 Overexpression–Negative Adenocarcinomas

The combination of fluoropyrimidine (5-FU or capecitabine), oxaliplatin, and nivolumab represents the standard of care for HER2 overexpression–negative EGA. The phase 3 randomized open-label global CheckMate 649 study evaluated first-line therapy for newly diagnosed metastatic HER2-negative GEA (gastric cancers, 70%; GEJ cancer, ~17%; and esophageal adenocarcinoma, ~13%) with fluoropyrimidine and oxaliplatin and either nivolumab or placebo. Dual primary endpoints were OS

and PFS in patients with PD-L1 CPS ≥5. A total of 1,581 patients were randomly assigned into these two arms. After a minimum follow-up of 3 years, there was a statistically significant improvement in OS in the chemotherapy and nivolumab arm when compared with the chemotherapy alone arm in patients with PD-L1 CPS ≥5 (median OS, 14.4 vs 11.1 months; HR, 0.70; 95% CI, 0.61-0.81) as well as in all randomly assigned patients (median OS, 13.7 vs 11.6 months; HR, 0.79; 95% CI, 0.71-0.88). There was also an improvement in PFS in patients treated with chemotherapy and nivolumab compared with chemotherapy alone in those with PD-L1 CPS ≥5 (median PFS, 8.3 vs 6.1 months; HR, 0.70; 95% CI, 0.60-0.81) as well as in all randomly assigned patients (median PFS, 7.7 vs 6.9 months; HR, 0.79; 95% CI, 0.71-0.89). Combination fluoropyrimidine/oxaliplatin and nivolumab is currently listed in the NCCN guidelines as a category 1 recommendation for use in CPS ≥5 EGA. It is important to note that, in a subgroup analysis of OS based on CPS score, patients who have PD-L1 CPS <1 (n = 265) experienced no survival benefit with the addition of nivolumab to chemotherapy (median OS, 13.1 months with chemotherapy and nivolumab vs 12.5 months with chemotherapy alone; HR, 0.95; 95% CI, 0.73-1.24).[132-134]

Pembrolizumab is also approved in combination with chemotherapy for patients who have esophageal or GEJ adenocarcinoma tumors based on the KEYNOTE-590 study as described previously.[129] In a subgroup analysis for OS and PFS in adenocarcinoma (approximately 27% of the study population), the arm receiving chemotherapy and pembrolizumab had better OS (11.6 vs 9.9 months; HR, 0.74; 95% CI, 0.55-0.99) and PFS (6.3 vs 5.7 months; HR, 0.61; 95% CI, 0.45-0.84) compared with the chemotherapy alone arm. Pembrolizumab is approved for use in gastric and GEJ adenocarcinoma based on the results of a phase 3 randomized study, KEYNOTE-859, which demonstrated improvement in OS with pembrolizumab in addition to chemotherapy compared with placebo and chemotherapy (median OS, 12.9 vs 11.5 months; HR, 0.78; 95% CI, 0.70-0.87). The NCCN guidelines recommend chemotherapy and pembrolizumab in esophageal, GEJ, and gastric adenocarcinomas with the strongest support for use in patients who have PD-L1 CPS ≥10 tumors.

Tislelizumab, another anti-PD1 antibody, also demonstrated activity in a similar setting, but it is not yet approved for use in the United States. In the phase 3 study, RATIONALE-305, addition of tislelizumab to chemotherapy improved OS (median OS, 17.2 vs 12.6 months; HR, 0.74; 95% CI, 0.59-0.94) and PFS (median PFS, 7.2 vs 5.9 months; HR, 0.67; 95% CI, 0.55-0.83) in PD-L1–positive patients (TAP score of ≥5) As of December 27, 2024, the FDA approved tislelizumab in combination with chemotherapy for first-line treatment of HER2-negative gastric or GEJ adenocarcinoma with PD-L1 1% or greater based on improvement in OS with HR of 0.78 (median OS of 15.0 vs 12.8 months) in patients with TAP 1 or greater.[7,8]

Special note must be made of MSI-H/dMMR GEA tumors. These account for 5% to 20% of all GEAs but show high response rates to checkpoint inhibitors.[135-137] In the CheckMate 649 study, after a minimum follow-up of 24 months, median OS with chemotherapy and nivolumab was significantly longer (38.7 months) than with chemotherapy alone (12.3 months; HR, 0.38; 95% CI, 0.17-0.84) in the MSI-H subgroup of patients. Similarly, ipilimumab/nivolumab significantly prolonged median OS compared with chemotherapy alone in this subgroup of patients (median OS, not reached vs 10 months; HR, 0.28; 95% CI, 0.08-0.92).[132] In a post hoc analysis of the KEYNOTE-062 study, which was a first-line study with three arms (pembrolizumab alone, chemotherapy and pembrolizumab, and chemotherapy), median OS was not reached for both pembrolizumab and chemotherapy and pembrolizumab arms in patients who have dMMR/MSI-H tumors. The 12-month OS rate for the pembrolizumab arm was 79%, and that for chemotherapy and pembrolizumab was 71% (compared with 47% with chemotherapy alone).[138] Based on these data, NCCN guidelines recommend the use of checkpoint inhibitors or chemotherapy and checkpoint inhibitors as first-line treatment of MSI-H GEAs. Recently, zolbetuximab was approved in combination with chemotherapy in the first-line setting as well. Zolbetuximab is a chimeric IgG1 monoclonal antibody (mAB) that binds to the extracellular loop of CLDN18.2, tight junction protein, on the tumor cell surface. Over a third of advanced GEA have upregulated CLDN18.2 expression.[7] In the phase 3 SPOTLIGHT trial, patients with locally advanced, previously untreated, HER2-negative, CLDN18.2-positive GEA (defined as ≥75% of tumor cells showing moderate-to-strong membranous CLDN18 staining) were randomized to either modified 5-FU, leucovorin, and oxaliplatin chemotherapy (mFOLFOX6) plus zolbetuximab or mFOLFOX6 plus placebo.[8] The study met its primary endpoint of median PFS improvement with zolbetuximab addition (10.61 vs 8.67 months, HR, 0.75). Median OS was also significantly improved with zolbetuximab addition (18.23 vs 15.54 months, HR, 0.75). Notably, the objective response rate (ORR) was similar between the two groups. The randomized phase 3 GLOW study had a similar design but used CAPOX as a chemotherapy backbone.[7] Similar to the SPOTLIGHT trial, PFS (8.21 vs 6.80 months, HR, 0.687) and OS (14.39 vs 12.16 months, HR, 0.771) were improved with zolbetuximab in addition to chemotherapy in a biomarker-select patient population. There were no differences in ORR (42.5% in the zolbetuximab arm versus 40.3% in the control arm) in the GLOW trial as well. In both studies, zolbetuximab demonstrated a similar safety profile with nausea and vomiting being the only adverse events (AEs) with more than 10% difference between the treatment arms. These toxicities are likely due to on-target effects of zolbetuximab related to normal expression of CLDN18.2 in gastric mucosa. In both studies, these GI toxicities were more prominent during the first treatment cycle and decreased with subsequent treatments. Based on the results of these trials, the FDA approved zolbetuximab in combination with chemotherapy for the treatment of CLDN18.2 positive GEA in the first-line setting. The infusion-related reactions (IRRs) ranged from 7% to 9% in these trials consisting of flushing, fever, chills and mild hypotension though true hypersensitivity reactions were infrequent. Most IRRs were manageable with anti-emetics and infusion rate adjustments.

KEY POINTS

- The addition of anti-PD1, pembrolizumab, nivolumab, or tislelizumab to combination chemotherapy is considered a standard in the first-line treatment of unresectable, metastatic ESCC. The benefit increases with increasing tumor PD-L1 expression. The NCCN guideline recommends the addition of anti-PD1 to chemotherapy in patients with tumor PD-L1 composite score ≥1.
- In the CheckMate 648 study, ipilumumab plus nivolumab achieved better OS than chemotherapy alone and was numerically shorter than nivolumab plus chemotherapy. Ipilimumab plus nivolumab may be considered for patients with tumor PD-L1 CPS ≥1 who are not candidates for anti-PD1 and chemotherapy combination.
- The CheckMate 649 study established that nivolumab when combined with fluoropyrimidine and platinum improved both PFS and OS compared with chemotherapy alone in patients who have GEAs with pronounced benefit seen in patients with tumors PD-L1 CPS ≥5.
- The KEYNOTE-590 and KEYNOTE-859 studies demonstrated PFS and OS benefit with the addition of pembrolizumab to fluoropyrimidine/platinum chemotherapy when compared with chemotherapy alone in GEAs. This benefit was pronounced in tumors PD-L1 CPS ≥10.
- Zolbetuximab in combination with fluoropyrimidine and platinum-containing chemotherapy is indicated for the treatment of CLDN 18.2 positive, HER-2 negative GEA.

HER2-POSITIVE GEA

HER2 EXPRESSION TESTING

Current clinical diagnostic testing requires evaluation by a combination of immunohistochemistry (IHC; membranous reactivity in >10% of cancer cells in a surgical specimen or a cluster of at least five cells in a biopsy specimen) and fluorescence in situ hybridization (FISH; with an HER2-to-CEP17 ratio ≤2).[139] IHC 0/1$^+$ should be considered negative irrespective of FISH positivity, and IHC3$^+$ is considered positive, whereas IHC2$^+$ requires reflex to FISH assessment. Higher throughput assays, including NGS, have emerged with the potential to refine diagnostic accuracy as well as to assess for other relevant aberrations via multiplexing capability.[140,141] Assessment of amplification by cell-free DNA is also emerging as a potential noninvasive strategy, with additional potential for the serial assessment of HER2 status over time in a noninvasive manner.[142] Intra-patient molecular heterogeneity is becoming a well-recognized phenomenon in these tumors with obvious implications for targeted therapy, including anti-HER2 therapy.[143,144] Consideration of biopsy of a metastatic lesion may assist with optimal targeted-therapy decisions.[143] Similarly, molecular evolution over time after anti-HER2 therapy in the first-line setting may be best identified by repeated testing via tissue or blood biopsy at the time of progression to determine whether HER2 directed therapy in a late line setting remains appropriate.[145]

Approximately 10% to 20% of GEA are HER2-positive GEAs.[146] The first targeted therapy to demonstrate benefit in GEA was trastuzumab, the humanized monoclonal antibody against HER2, added to standard cisplatin and fluoropyrimidine chemotherapy in *ERBB2* gene–amplified and HER2-overexpressing tumors. In the pivotal phase 3 ToGA (trastuzumab for gastric cancer) trial, 584 patients were randomly assigned to receive fluoropyrimidine in combination with 80 mg/m^2 of cisplatin on day 1 with or without trastuzumab.[147] The addition of trastuzumab to cisplatin and a fluoropyrimidine increased the median OS from 11.1 to 13.8 months (P = .0046). In addition, secondary endpoints such as PFS and ORR were also improved in the trastuzumab arm. There were no substantial differences in toxicity between the two treatment arms. An asymptomatic decrease in ejection fraction occurred in 4.6% and 1.1% of patients in the trastuzumab and chemotherapy alone arms, respectively. It is common practice in the United States to use the FOLFOX chemotherapy backbone with trastuzumab, again with routine exclusion of 5-FU bolus, given the better tolerability compared with cisplatin and more convenient 5-FU dosing schedule.[148]

In a randomized phase 3 study, KEYNOTE-811, 698 patients with HER2-positive (IHC 3$^+$ or IHC 2$^+$ and amplified by ISH) GEJ or gastric adenocarcinoma were randomly assigned to fluoropyrimidine (5-FU or capecitabine), platinum (oxaliplatin or cisplatin), or trastuzumab with or without pembrolizumab. In both arms, 85% of the patients were also PD-L1 positive (CPS ≥ 1). The dual primary endpoints were PFS and OS. The ORR favored the pembrolizumab arm (72.6% vs 60.1%). Median PFS was longer in the pembrolizumab arm (10 vs 8.1 months; HR, 0.72; 95% CI, 0.60-0.87; P = .0002). Median OS was improved in the pembrolizumab arm. In patients with PD-L1 CPS ≥1, median OS in the pembrolizumab arm was 20.1 months versus 15.7 months in the placebo arm (HR, 0.79, P = .006). The combination of fluoropyrimidine, platinum, trastuzumab, and pembrolizumab is now FDA approved for first-line treatment of HER2-positive and PD-L1–positive (CPS ≥ 1) EGA. However, there was no survival benefit in PD-L1–negative patients (PD-L1 CPS < 1), and pembrolizumab is not indicated with chemotherapy and trastuzumab for that patient population.

Other attempts to target HER2 in the first-line setting have not been successful. High-dose trastuzumab failed to demonstrate improved survival in comparison with standard dosing in the HELOISE study.[149] In contrast to the positive results observed with trastuzumab in the first-line setting, the addition of oral HER2 inhibitor lapatinib (LOGIC trial) or another anti-HER2 antibody pertuzumab (JACOB trial) to trastuzumab and chemotherapy failed to improve outcomes versus trastuzumab and

chemotherapy.[150,151] Of note, in a single-arm phase 2 study, zanidatamab, a novel bispecific antibody targeting two distinct HER2 epitopes, was studied in combination with first-line fluoropyrimidine/platinum in HER2-expressing GECs. The confirmed ORR was 79%, and the disease control rate was 92%. Median PFS was 12.5 months (95% CI, 7.1 months to not estimable), and median OS has not yet been reached (95% CI, 23.6 months to not estimable). The 12-month OS rate was 88% (95% CI, 73%-95%).

HERIZON-GEA-01 is an ongoing global phase 3 study for patients who have HER2-overexpressing GEA who are randomized between chemotherapy and trastuzumab versus chemotherapy and zanidatamab versus chemotherapy, zanidatamab, and tislelizumab (ClinicalTrials.gov identifier: NCT05152147).

EMERGING TARGETS

FGFR2-β is emerging as another important target in GEA. In a phase 2 study of 155 patients who have tumors selected for FGFR2-β overexpression, FOLFOX and bemarituzumab, a humanized IgG1 monoclonal antibody against FGFR2-β, showed encouraging efficacy with improvement in median PFS and OS in the bemarituzumab arm compared with placebo arms. This agent is currently being evaluated in two large phase 3 trials, FORTITUDE-101 and FORTITUDE-102 (NCT05111626, NCT05052801).

KEY POINTS

- The addition of trastuzumab and pembrolizumab to platinum and fluoropyrimidine is the standard of care in HER2-positive ($IHC3^+$ or $IHC2^+/FISH^+$) and PD-L1–positive (CPS ≥ 1) metastatic GEAs.
- In patients who have tumors that are HER2 positive but PD-L1 negative, the standard treatment is platinum with fluoropyrimidine and trastuzumab.

SECOND-LINE AND SUBSEQUENT THERAPY

ESOPHAGEAL SQUAMOUS CELL CARCINOMA

The phase 3 randomized KEYNOTE-181 sec-line study evaluated the anti-PD-1 antibody pembrolizumab versus paclitaxel for the treatment of esophageal cancer. Substantial improvement in survival was noted only in ESCCs with tumors having a PD-L1 CPS ≥10, which led to FDA approval for this subgroup of patients on July 30, 2019.[152] Within the CPS ≥10 population, median OS was 10.3 versus 6.7 months in favor of pembrolizumab compared with monotherapy taxane/irinotecan, respectively. In contrast, in patients with CPS <10 tumors, median OS was 7.3 versus 7.5 months, respectively. The phase 3 randomized open-label ATTRACTION-3 study, conducted mostly in Asia, compared nivolumab with paclitaxel or docetaxel monotherapy for the treatment of second-line ESCC, which improved median OS to 10.9 months from 8.5 months and led to FDA approval on June 10, 2020. This was not evaluated by PD-L1 CPS scoring.[153]

In the setting of chemoimmunotherapy now being the standard first-line treatment, there is no role for monotherapy checkpoint inhibitor use in subsequent treatment lines for patients who have received initial immunotherapy in first line.

HER2-NEGATIVE ADENOCARCINOMA

Ramucirumab, a VEGFR-2 antibody, demonstrated benefit as monotherapy or in combination with paclitaxel in the second-line setting for advanced or metastatic gastric or GE junction adenocarcinoma.[154,155] In the REGARD trial, 472 patients whose disease had not responded to first-line fluoropyrimidine and platinum therapy were randomly assigned in a 2:1 fashion to receive single-agent ramucirumab or placebo.[154] Median OS was 5.2 months for the ramucirumab group and 3.8 months for the placebo group. Aside from a higher rate of hypertension, no relevant differences were seen in recorded adverse effects between ramucirumab and placebo. Combination ramucirumab and paclitaxel is the standard of care for second-line therapy in adenocarcinomas that do not overexpress HER2 based on the results of the RAINBOW trial. The RAINBOW trial (N = 665) compared second-line therapy with paclitaxel and placebo with paclitaxel and ramucirumab for those in whom disease had progressed after exposure to a platinum and fluoropyrimidine–based regimen.[155] OS was 9.6 months in the ramucirumab arm compared with 7.4 months with paclitaxel alone. Patients in the ramucirumab arm had a substantially higher response rate (28% vs 16%; $P = .001$) and improved PFS (4.4 vs 2.9 months; $P < .0001$) than patients in the paclitaxel and placebo arm.

Despite the activity of ramucirumab seen in these second-line setting therapies in which this was an approved standard option, studies in the first-line setting, including the phase 3 RAINFALL study and others, did not show a benefit to adding ramucirumab to first-line chemotherapy.[156-158] Similarly, the phase 3 AVAGAST study, in which combination bevacizumab and standard chemotherapy was evaluated versus chemotherapy alone in the first-line setting, was negative for OS.[159,160]

In patients who are not candidates for taxanes, combination FOLFIRI and ramucirumab is an acceptable option[161]; retrospective analyses of patients with GEA[162] led to the inclusion of this regimen as a category 2A recommendation in this setting in the NCCN guidelines for gastric cancer and esophageal and GEJ cancers. The RAMIRIS phase 2/3 study of FOLFIRI and ramucirumab versus paclitaxel and ramucirumab reported similar efficacy in the phase 2 part of the study with better efficacy for patients who had prior exposure to taxanes.[163]

Although anti-VEGFR-2 therapy with ramucirumab is the standard of care in second-line treatment, alternative chemotherapy options exist for second-line therapy based on studies evaluating chemotherapy versus best supportive care in which improvement in OS was clearly demonstrated with either irinotecan or taxane after failure of first-line combination fluoropyrimidine and platinum therapy.[164-168] Head-to-head comparison between two commonly used second-line therapies, paclitaxel and irinotecan, demonstrated similar efficacy, and each is a reasonable option.[166,167] There is a drop off in the number of eligible patients proceeding to second-line therapy. Even in modern studies, such as SPOTLIGHT, CheckMate 649, among others, there are only approximately 50% of patients who have preserved PS who remain candidates for continued treatment.[3,9,133,135,169] Similarly, the utility of chemotherapy in third-line and later treatment settings was debatable for the approximately 20% to 30% of patients still otherwise eligible for palliative therapy with preserved PS, but there is now support for continued therapy for these patients. A large phase 3 placebo-controlled randomized study, TAGS, evaluated oral trifluridine/tipiracil versus best supportive care and reported a modest survival advantage (median OS, 3.6-5.7 months) in a third-line (27% of patients) or higher setting (63% of patients); oral trifluridine/tipiracil is an option for therapy in these settings and gained FDA approval on February 25, 2019.[170]

For all patients with advanced disease, NGS testing should be performed in a CLIA-approved laboratory for identification of other biomarkers that can influence treatment selection.

Molecular characterization of EGA has identified mutations and copy-number variations in a number of readily targetable genes, including *ERBB2*, *EGFR*, *FGFR2*, *MET*, and *PI3K*/*mTOR*, along with other oncogenes, biomarkers, and immune oncological checkpoints that may serve as actionable therapeutic targets.[26,27,140,171]

- EGFR monoclonal antibodies added to chemotherapy in unselected patients did not improve patient survival, including in the two first-line GEA studies, EXPAND with cetuximab and REAL-3 with panitumumab, and the COG study of second-line or higher treatment of GEC with gefitinib.[172-174] The consistently negative data from these trials confirm there is no role for EGFR inhibitors in GEC, at least in unselected patients.[175,176]

Similarly, MET tyrosine kinase (hepatocyte growth factor [HGF] receptor) pathway inhibitors were assessed by selecting MET-expressing tumors in two large first-line GEA studies. Each study used different diagnostic antibodies and scoring systems, but both evaluated HGF ligand–blocking antibodies.[177,178] The RILOMET-1 study, in which the combination of the anti-HGF antibody rilotumumab and first-line epirubicin, cisplatin, and 5-fluorouracil (ECF) therapy was evaluated versus ECF and placebo, was negative despite a previous positive randomized phase 2 study.[179] The single-arm METGastric study evaluated the anti-MET antibody onartuzumab, which is another ligand–blocking antibody, and was also negative, confirming the lack of efficacy of this strategy for GEA.[178] Tumors with *MET* gene amplification remain a small subset that may derive benefit from MET-directed therapies, but these require additional investigation.[180]

HER2-POSITIVE ADENOCARCINOMA

Trastuzumab deruxtecan is now FDA approved in second and later lines of therapy for HER2-overexpressing gastric adenocarcinoma based on the results of the DESTINY-GASTRIC01 study. The phase 2 DESTINY-GASTRIC01 study included Asian patients with metastatic HER2-positive GEA who had received two or more prior lines of therapy and were randomly assigned in a 2:1 fashion to receive either trastuzumab deruxtecan (6.4 mg/kg every 3 weeks) or chemotherapy with irinotecan or paclitaxel. The study met its primary endpoint by demonstrating an improved ORR of 51% in the trastuzumab deruxtecan group compared with 14% in the physician's choice chemotherapy group ($P < .001$). Furthermore, OS was longer for patients treated with trastuzumab deruxtecan versus chemotherapy at 12.5 versus 8.4 months (HR, 0.59; 95% CI, 0.39-0.88; $P = .01$). Treatment with trastuzumab deruxtecan was associated with increased grade 3 toxicity bone marrow suppression and trastuzumab deruxtecan–induced interstitial lung disease and pneumonitis. DESTINY-GASTRIC02 was a single-arm study conducted in the Western part of the world that required confirmation of HER2 positivity postprogression during trastuzumab-based treatment before receiving trastuzumab deruxtecan. In the study, 89 patients were enrolled, and the confirmed ORR was 42%. Median PFS was 5.6 months, and median OS was 12.1 months. This drug is FDA approved for patients with HER2-positive GEA as second-line therapy or beyond. Therapy options in the second-line setting and beyond for HER2-negative patients are also used in the HER2-positive setting. Optimal sequencing of therapy remains to be determined.

PALLIATIVE CARE FOR PATIENTS WITH ADVANCED GEC

It is important to monitor and maintain patients' nutritional status in light of weight loss and continued difficulty with alimentation before and during perioperative treatment and surgery, as well as in the advanced metastatic setting. For tumor-related esophageal or gastric outlet obstruction in the advanced setting, several palliative options exist, including radiation therapy, esophageal stents, laser therapy, endoscopic dilation, and/or gastric or jejunal tube feeding. However, >80% of patients derive benefit from systemic palliative chemotherapy. Therefore, chemotherapy could be administered first, followed by radiation therapy. Stenting can be considered when the obstructive symptoms did not improve with chemotherapy and/or radiation.

For refractory bleeding from the primary tumor, endoscopic cautery, interventional radiology embolization, and radiation therapy are all options to address this common issue. Because thromboembolic events are common in advanced disease, balancing anticoagulation and intact primary tumors is often challenging, and clinical discretion as to the more pressing issue is recommended. Oral anticoagulants lead to a higher risk of bleeding compared with subcutaneous low-molecular-weight heparin if the primary tumor is in place, and this should be considered when treating thromboembolic events. Carcinomatosis and ascites are common in GEC, particularly gastric adenocarcinoma, and partial or complete bowel obstruction is frequently experienced by patients with these conditions. Venting gastrostomy tubes, peritoneal drain placement, and somatostatin analogs can be palliative in this subset of patients, particularly if symptoms are refractory to a trial of palliative first-line chemotherapy.[181] Having patients see palliative care physicians to manage the diverse set of these cancer–related symptoms and pain is encouraged as is seeing a nutritionist to assist with dietary issues. Oxaliplatin-induced neuropathy is common, and duloxetine has demonstrated palliative benefit. The OPTIMOX strategy (ie, intermittently adding and stopping oxaliplatin over time to limit cumulative neuropathy) as described in colon cancer is often routinely used for patients with GEA. Recent approvals of immune checkpoint blockade require consideration of all potential toxicities and treatments related to them.

KEY POINTS

- Nivolumab is FDA-approved second-line therapy for all ESCCs based on results from the ATTRACTION-3 study.
- Pembrolizumab is FDA-approved second-line therapy for patients who have metastatic ESCC with PD-L1 expression levels of CPS ≥10 based on results from KEYNOTE-181. In patients who have not received checkpoint inhibitor therapy as part of their first-line treatment, nivolumab or pembrolizumab monotherapy might be a viable option.
- The VEGFR antibody ramucirumab has shown efficacy in second-line phase 3 trials in advanced GEA and is now a standard-of-care option either alone or with paclitaxel therapy, leading to an NCCN guideline listing (category 1). Retrospective and prospective analyses show historically similar efficacy for FOLFIRI and ramucirumab compared with paclitaxel and ramucirumab with a potentially better toxicity profile, particularly for patients previously treated with taxanes, leading to an NCCN guideline listing (category 2A). However, no randomized controlled studies evaluating agents targeting angiogenesis in the first-line setting have shown an OS benefit.
- Approximately 50% of patients have preserved PS and derive benefit from continued treatment with palliative therapy in the second-line setting.
- Third-line chemotherapy has demonstrated a benefit compared with best supportive care or placebo, including with trifluridine and tipiracil (TAS-102), and should be considered for patients with preserved PS after two or more lines of therapy.
- The phase 2 randomized open-label DESTINY-GASTRIC01 study in Asian patients showed an improved ORR as well as PFS and OS for trastuzumab deruxtecan in comparison with chemotherapy as third-line or higher therapy for metastatic HER2-positive GEA, which led to FDA approval on January 15, 2021.

CANCERS OF THE LIVER AND BILIARY TREE

HEPATOCELLULAR CARCINOMA

Epidemiology and Etiology

Primary HCCs represent the highest global incidence of solid-organ tumors and are responsible for approximately 1 million deaths annually; although they are less common in the West, HCC is the cancer with the fastest-growing incidence rate in the United States[182] The risk factors for HCC are well known and include cirrhosis of any etiology. Hepatitis B virus infection accounts for approximately 60% of all liver cancer incidence in developing countries and approximately 23% of liver cancers in developed countries; the corresponding percentages for hepatitis C virus infection are 33% and 20%. Hepatitis B infection can be decreased by vaccination. Effective therapy to eradicate hepatitis C viral infection may lead to fewer cases of HCC in the coming years. The overall incidence of HCC in the Western world has been increasing, mostly as a result of alcohol-related cirrhosis and nonalcoholic steatohepatitis (NASH) associated with obesity. NASH is now referred to as MASH (metabolic dysfunction-associated steatohepatitis) to better reflect its etiology.

Clinical Presentation and Diagnosis

There are a number of presentations of HCC from asymptomatic disease found at screening to decompensated cirrhosis or paraneoplastic syndromes. Guidelines disseminated from several consensus conferences and professional organizations recommend HCC surveillance for patients with cirrhosis who are at high risk of development of HCC.[177] Ultrasound and serum alpha-fetoprotein (AFP) are the most commonly used modalities for HCC surveillance. Data suggest that an elevated subfraction of AFP, the lens culinaris agglutinin-reactive fraction of AFP (AFP-L3%), is a more reliable indicator of the presence of HCC in combination with CT scan or MRI for patients with hepatitis C–related cirrhosis than total AFP.[181] Making an HCC diagnosis with imaging alone versus a confirmatory biopsy has long been deliberated, and debate remains over whether to routinely incorporate biopsy into standard diagnostic practices.[183-185]

HCC is graded as well differentiated, moderately differentiated, and poorly differentiated. The most important pathological issue is the distinction between the fibrolamellar variant and the more traditional HCC. Fibrolamellar cancer is generally seen in younger patients, much more likely to be resectable, and less commonly associated with infection or cirrhosis.[186] In contrast, traditional HCC is found more often in men age >65 years.

Treatment

Localized HCC

The Barcelona Clinic Liver Cancer staging classification and treatment schedule have served as a paradigm on how to stage and treat HCC.[187] The treatment of choice for patients with localized HCC is surgical resection or transplantation. However, resection is not possible in most cases (often because of underlying cirrhosis), and transplantation is limited by organ availability and tumor burden. Fewer than 25% of tumors are resectable, often because of underlying liver disease and inadequate hepatic reserve.[188] HCC commonly presents as unresectable late-stage disease because of the multifocal nature of the disease in the liver, detection late in the disease course, and long asymptomatic latency until diagnosis. Attempts at administration of traditional cytotoxic systemic chemotherapy have been unsuccessful in demonstrating improvement in survival for patients with localized disease. Nonetheless, local ablative options have proven to be useful and have been associated with improved outcomes. Local ablative treatments are generally reserved for unresectable localized disease. In selected patients, local ablative therapy may also be used as bridging for liver transplantation candidates. These approaches include transcatheter arterial chemoembolization (TACE), transarterial radioembolization (TARE), alcohol injection, radiofrequency ablation, microwave ablation, and external-beam radiation therapy or stereotactic body radiation therapy (SBRT). In a recent meta-analysis of three randomized studies, TARE and TACE resulted in similar outcomes in unresectable HCC.[189] Percutaneous ablation achieves complete remission in >80% of tumors <3 cm in diameter but in only 50% of tumors 3 to 5 cm.[190] The single-center randomized phase 2 TRACE study[191] of patients with unresectable HCC treated with TARE or TACE reported prolonged time to progression and OS patients who received TARE; response rates were similar between treatment arms. Although response rates are relatively high, it is unclear whether these techniques result in a significant survival benefit. Meta-analyses[192,193] have supported the superiority of TARE compared to TACE in terms of response to treatment and time to progression, although conclusions regarding potential OS benefit of TARE vary.

Multimodality therapies combining systemic therapy with locally ablative therapies represent evolving therapeutic strategies that are under investigation in multiple studies. The randomized phase 3 NRG/RTOG 1112 study[194,195] demonstrated improvement in PFS and OS with the addition of SBRT to sorafenib treatment, with no significant increase in AEs; the trial was closed due to changes in the HCC treatment landscape. EMERALD-1[196] is a phase 3 randomized placebo-controlled study of TACE combined with durvalumab with or without bevacizumab in patients who have intermediate-stage HCC. The study met its primary endpoint of PFS for superiority of TACE, durvalumab, and bevacizumab versus TACE and placebos with OS data still pending. LEAP-012[197] is another study that combined TACE with systemic treatment in patients with locally advanced HCC. This phase 3 randomized, double-blind study compared patients receiving TACE plus lenvatinib with patients receiving TACE plus placebo. The co-primary endpoint of PFS for superiority of TACE plus lenvatinib over TACE plus placebo was met; however, the study was closed after an interim analysis (https://www.merck.com/news/merck-and-eisai-provide-update-on-phase-3-leap-012-trial-in-unresectable-non-metastatic-hepatocellular-carcinoma/) revealed that the study was unlikely to meet the co-primary OS endpoint. Previous data failed to show a benefit for patients undergoing systemic therapy after resection or ablation. The STORM trial tested whether patients would benefit from sorafenib after resection or ablation; there were no differences in recurrence-free survival or OS.[198] More recently, updated data from the IMbrave 050 trial, a randomized phase 3 study assessing the role of atezolizumab and bevacizumab versus active surveillance in patients with HCC undergoing resection and with a high risk of recurrence (>5 cm, more than three nodules, (micro)vascular invasion, or poorly differentiated), demonstrated that adjuvant treatment did not improve the primary endpoint of relapse-free survival nor did it improve OS.[199] Similarly, a prespecified interim analysis (https://www.merck.com/news/merck-co-inc-rahway-n-j-usa-announces-second-quarter-2025-financial-results/) of the phase 3 KEYNOTE-937 study reported that there was no improvement in the primary endpoint of recurrence-free survival with adjuvant pembrolizumab versus placebo.

Liver transplantation represents the ultimate local therapy for non-metastatic or liver-only unresectable HCC in the presence of liver cirrhosis. In this subgroup of patients, liver transplantation provides an excellent option for early-stage tumors because the procedure is therapeutic for both the cancer and the underlying pathology. Once patients have passed the high-risk peritransplantation phase, the prognosis is similar to that for patients who have had resection of localized disease.[200] Patients with known extrahepatic disease and gross vascular invasion are not candidates for liver transplantation.

Systemic Therapy For Advanced HCC

There seems to be no meaningful role for systemic cytotoxic chemotherapy in HCC although all randomized controlled trials (RCTs) have focused on Child–Pugh class A disease (CPA). Beyond CPA, there have been no clear standard options examined in the RCT setting, and concerns regarding the tolerability and safety of various standard systemic options in HCC remain. Combination

immunotherapy now represents the standard first-line treatment option for eligible patients with advanced HCC with no contraindications for immunotherapy, such as patients undergoing solid-organ transplantation or those with uncontrolled and severe autoimmune disease. Three immunotherapy combinations considered standard in the first-line setting for those eligible include combination atezolizumab and bevacizumab, single tremelimumab regular interval durvalumab (STRIDE), and combination nivolumab and ipilimumab. Atezolizumab plus bevacizumab and STRIDE demonstrated improved OS in comparison with the historical first-line therapy, sorafenib, while nivolumab plus ipilimumab demonstrated improved OS in comparison with investigator's choice of sorafenib or lenvatinib. PFS, however, was improved only with atezolizumab plus bevacizumab and not with STRIDE or nivolumab plus ipilimumab.

Historically, first-line therapy for advanced unresectable HCC with sorafenib was approved by the FDA in 2007 on the basis of results from the SHARP trial.[201] Similar findings were observed in the parallel Asian study.[202] Diarrhea, weight loss, hand-foot skin reaction, and hypophosphatemia were more common in patients receiving sorafenib than in control participants receiving placebo in these studies.

In the last decade, contemporary trials focusing on targeted therapies, including inhibitors of angiogenesis, signal transduction, and immune checkpoint inhibitors in combination, have shown promising results. Interestingly, several other multitargeted tyrosine kinase inhibitors (TKIs) with antiangiogenic activity have failed to achieve superiority to sorafenib in head-to-head studies, including sunitinib,[203] brivanib in the BRISK-FL study,[204] and linifanib.[205] Combinations of sorafenib with erlotinib (an anti-EGFR tyrosine kinase) in the SEARCH study or with everolimus were also negative.[206,207] In the REFLECT study, lenvatinib proved to be noninferior to sorafenib, thus establishing it as another option versus sorafenib.[208] As such, lenvatinib and sorafenib are considered reasonable treatment options for first-line treatment of HCC in patients who are not candidates for immunotherapy.[203,209]

Initial evidence for combination immunotherapy in the management of advanced HCC in the first-line setting was demonstrated in the IMbrave 150 study. IMbrave 150 was an open-label global phase 3 study in which patients with unresectable HCC were randomly assigned at a 2:1 ratio to receive atezolizumab and bevacizumab (n = 336 patients) or sorafenib (n = 165 patients). This study excluded patients who had untreated or incompletely treated esophageal or gastric varices (assessed with esophagogastroduodenoscopy and treated according to local clinical practice) with bleeding or high risk of bleeding. However, this study included patients with main portal vein tumor thrombus (Vp4). The coprimary endpoints were OS and PFS in the intention-to-treat population as assessed at an independent review facility according to Response Evaluation Criteria in Solid Tumors, version 1.1 (RECIST 1.1). The HR for death of atezolizumab and bevacizumab compared with sorafenib was 0.58 (95% CI, 0.42-0.79; $P < .001$),[199] with a 12-month OS rate for atezolizumab and bevacizumab of 67.2% (95% CI, 61.3-73.1) and 54.6% (95% CI, 45.2-64.0) for sorafenib. Median PFS was 6.8 months (95% CI, 5.7-8.3) for atezolizumab and bevacizumab and 4.3 months (95% CI, 4.0-5.6) for sorafenib (HR, 0.59; 95% CI, 0.47-0.76; $P < .001$). The results of this study resulted in FDA approval of the combination of atezolizumab and bevacizumab as first-line therapy in patients with advanced HCC.

The HIMALAYA trial provided the second level of evidence for combined immunotherapy, in this case combining dual immune checkpoint blockade targeting CTLA-4 and PD-L1. This phase 3 study randomly assigned patients who had previously untreated unresectable HCC to receive durvalumab and a single priming dose of tremelimumab (STRIDE regimen; n = 393 patients), durvalumab (n = 389), or sorafenib (n = 389) as first-line therapy. Of note, this study excluded patients with Vp4. The study met its primary endpoint, demonstrating a reduced risk of death in patients treated with the STRIDE regimen compared with sorafenib (HR, 0.78; 95% CI, 0.65-0.092; $P = .0035$). STRIDE-treated patients achieved a median OS of 16.4 versus 13.8 months. The study failed to show an improvement in median PFS, which was similar between the two groups, at 3.8 months for the STRIDE regimen and 4.1 months for sorafenib (HR, 1.02; 95% CI, 0.88-1.99). Serious treatment-related AEs occurred in 17.5% of patients treated with STRIDE, 8.2% of those in the durvalumab arm and 9.4% of those treated with sorafenib. STRIDE treatment-related deaths resulted from immune-mediated toxicity. The results of this study led to FDA approval of the STRIDE regimen for the treatment of unresectable HCC.

In the CheckMate-9DW[11] study first-line combination nivolumab and ipilimumab (NIVO + IPI) improved median OS versus investigator's choice of lenvatinib or sorafenib (LEN/SOR) in patients with untreated unresectable HCC. In total, 668 patients were randomized to NIVO + IPI (n = 335) or LEN/SOR (n = 333); among 325 patients treated in the LEN/SOR arm, 275 (85%) received LEN. After a median (range) follow-up of 35.2 (26.8-48.9) months, median OS was 23.7 months with NIVO + IPI versus 20.6 months with LEN/SOR (HR, 0.79; 95% CI, 0.65-0.96; $P = .0180$) with respective 24-month OS rates (95% CI) of 49% (44-55) versus 39% (34-45). ORR was higher with NIVO + IPI (36%) versus LEN/SOR (13%; $P < .0001$); complete response was observed in 7% of patients with NIVO + IPI versus 2% with LEN/SOR. Median duration of response (DOR) was 30.4 months with NIVO + IPI versus 12.9 months with LEN/SOR. Treatment-related adverse events (TRAEs) were reported in 84% of the NIVO + IPI arm and 91% of the LEN/SOR arm, and grade 3 or 4 TRAEs were 41% and 42%, respectively. Any-grade TRAEs led to treatment discontinuation in 18% of patients receiving nivolumab and ipilimumab and 10% receiving lenvatinib or sorafenib. Combination atezolizumab and bevacizumab, tremelimumab and durvalumab, or ipilimumab and nivolumab are considered first-line therapy for appropriately fit patients with unresectable HCC and preserved liver function. Several phase 3 studies evaluating other

combination therapies in the first-line setting, including atezolizumab in combination with cabozantinib (COSMIC-312)[210] and pembrolizumab in combination with lenvatinib (LEAP-002),[211] showed no improvement over sorafenib and lenvatinib, respectively. CARES-310[212] assessed the role of camrelizumab in combination with rivoceranib, which proved superior to sorafenib; this regimen has not received FDA approval for use in the United States.

With the recent simultaneous approvals of several therapies in the same second-line indication, the optimal sequencing of these therapies post-immunotherapy is not well established. Regorafenib proved superior to placebo in the second-line treatment of patients with advanced HCC who experienced progression during or were intolerant to sorafenib in the RESORCE study.[213] Patients treated with regorafenib experienced a median OS of 10.6 months versus 7.8 months with placebo (HR, 0.63; 95% CI, 0.5-0.79; $P < .0001$), which led to FDA approval on April 27, 2017.[213] The REACH phase 3 study evaluating the efficacy of ramucirumab for patients with HCC whose disease had progressed during prior sorafenib therapy was negative; however, the follow-up REACH-2 phase 3 study confirmed the benefit of ramucirumab for patients with an AFP level ≥400 ng/mL, which led to approval in this indication on May 10, 2019. A pooled analysis of patients with an AFP level ≥400 ng/mL (n = 542) from the REACH and REACH-2 studies demonstrated improved median survival to 8.1 from 5.0 months with placebo (HR, 0.694; 95% CI, 0.571-0.842; $P = .0002$).[214] The CELESTIAL phase 3 study evaluated 707 patients who were randomly assigned (2:1) to receive cabozantinib or placebo, which led to FDA approval of cabozantinib on January 14, 2019.[215] Eligible patients had received previous treatment with sorafenib, had disease progression after at least one systemic treatment of HCC, and could have received up to two previous systemic regimens for advanced HCC. At the second planned interim analysis, median OS was 10.2 months with cabozantinib versus 8.0 months with placebo (HR, 0.76; 95% CI, 0.63-0.92; $P = .005$). Most patients had received only one prior systemic therapy (72%) compared with two prior systemic therapies (27%) with more pronounced OS benefit in the second line (HR, 0.74; 95% CI, 0.59-0.92) compared with the third line (HR, 0.9; 95% CI, 0.63-1.29). The appropriate sequencing of second-line therapy with a TKI or ramucirumab is complicated by the fact that all the studies were conducted after sorafenib failure with no data available post-immunotherapy. Finally, pembrolizumab remains the only anti-PD-1 immune checkpoint inhibitor approved for use in the second-line setting after sorafenib failure. In the follow-up randomized phase 3 KEYNOTE-240 study, pembrolizumab did not significantly improve survival compared with placebo.[216] In that study, 413 patients were randomly assigned at a 2:1 ratio (n = 278 patients received pembrolizumab; n = 135 received placebo). The HR for OS was 0.78, and the HR for PFS was 0.78, in favor of pembrolizumab; however, these differences did not meet significance per the prespecified statistical plan. The double-blind phase 3 KEYNOTE-394[217] study investigated patients from Asia with metastatic HCC who had experienced progression with sorafenib and were randomly assigned to receive pembrolizumab or best supportive care. Pembrolizumab treatment resulted in a 21% reduction in death (HR, 0.79; 95% CI, 0.63-0.99) and median OS of 14.6 months (95% CI, 12.6-18.0) in comparison with 13.0 months (95% CI, 10.5-15.1) for best supportive care. These results support the continued approval for use of pembrolizumab in second-line treatment of HCC although its potential applicable use is complicated by the fact that the first-line landscape has changed dramatically over the years.[218] Conditional FDA approval has been granted for nivolumab and ipilimumab used after first-line TKI therapy in fit patients based on CheckMate 040 (Table 13.1-2).

Table 13.1-2 Current Clinical Trials Paradigm for Hepatocellular Carcinoma

Treatment Line	Outcome	Notes	Study
First			
Sorafenib vs placebo	Superiority study	First approved first-line therapy, December 1, 2007	SHARP study[201]
Lenvatinib vs sorafenib	Noninferiority study	Approved August 16, 2018	REFLECT study[208]
Atezolizumab and bevacizumab vs sorafenib	Superiority study	Approved May 29, 2020	IMbrave 150 study[199]
Durvalumab and tremelimumab vs sorafenib	Superiority study	Approved October 21, 2022	HIMALAYA study[10]
Nivolumab and ipilimumab vs investigator's choice of sorafenib or lenvatinib	Superiority study	Approved April 11, 2025	CheckMate 9DW study[11]
Second			
Regorafenib vs placebo	Superiority study	First approved second-line therapy, April 27, 2017	RESORCE study[213]
Ramucirumab vs placebo	Superiority study	AFP ≥400 ng/mL eligible; approval May 10, 2019	REACH-2 study[219]

Treatment Line	Outcome	Notes	Study
Pembrolizumab		Conditional approval December 17, 2018; has not been removed	KEYNOTE-224 study,[220,221] KEYNOTE-240 study,[216] KEYNOTE-394 study[218]
Nivolumab and ipilimumab		Accelerated approval March 10, 2020	CheckMate 040 study[222]
Second and third			
Cabozantinib vs placebo	Superiority study	Approved January 14, 2019	CELESTIAL study[215]

Abbreviation: AFP, alpha-fetoprotein.
FDA approval of second-line nivolumab is revoked because of lack of efficacy in confirmatory study.

BILIARY CANCERS

Epidemiology, Etiology, and Clinical Presentation

BTCs comprise a diverse group of cancers, including intrahepatic cholangiocarcinoma (IHCC), hilar cholangiocarcinoma, extrahepatic cholangiocarcinoma (EHCC), and gallbladder cancer. Historically, these were considered a uniform entity, but they now are recognized to be quite distinct in terms of etiology, molecular biology, and most recently treatment.[220,224-227] In Western countries, cholangiocarcinoma is associated with metabolic syndrome, inflammatory bowel disease, primary sclerosing cholangitis, and hepatolithiasis, whereas liver fluke and hepatitis B viral infections are important risk factors in Asian countries.[228-231] Cholangiocarcinoma is most common in women age >50 years, and long-term survival is highly dependent on the effectiveness of surgical therapy. A number of risk factors for gallbladder cancer have been described and include the following:[230,231]

- Obesity
- Female sex
- Family history
- Middle age
- Gallstones causing chronic inflammation
- Porcelain gallbladder (ie, hardened gallbladder as a result of calcium deposits)
- Ethnicity (highest in Mexican, Latin American, and Native American individuals)
- Choledochal cysts (ie, bile-filled sacs along the common bile duct)
- Gallbladder polyps
- Abnormalities of the bile ducts causing backflow
- Primary sclerosing cholangitis

Recent molecular studies demonstrate distinct molecular profiles between anatomic sites and geographic or etiologic subsets.[232-235] Cancers of the extrahepatic bile duct and gallbladder are relatively rare with only 12,610 cases diagnosed annually in the United States, resulting in approximately 4,400 deaths annually.[15,236] Approximately 50% of gallbladder cancers are incidental findings on cholecystectomy. Unfortunately, the United States statistics do not provide specific data for IHCC incidence but classify them under hepatobiliary tumors; the actual incidence of biliary cancers as a whole is definitely higher, perhaps approaching the incidence of esophageal cancers, with approximately 15,000 cases per year.[237] Adenocarcinomas of unknown primary site involving the liver are increasingly recognized as primary IHCCs, which has also led to an increase in incidence of the disease.[238]

Typical presentation of cholangiocarcinoma includes jaundice, pain, anorexia, abnormal laboratory test results, or a mass evident on CT scan or ultrasound or visualized endoscopically. Gallbladder cancer often presents as vague postprandial right-upper quadrant pain and is often initially diagnosed as gallstones with incidental finding of gallbladder cancer at the time of resection and/or in the pathology specimen. The location of the primary tumor often dictates which of these symptoms predominantly occur, such as painless jaundice with EHCC, which is quite similar to that seen with pancreatic cancer.

Treatment of Localized Disease

The primary treatment is surgical resection if localized and technically feasible. Because of the location of these tumors, they are frequently difficult to resect; therefore, specialized surgical intervention should always be sought. The cure rate for patients with early-stage disease ranges from 60% to 70%; however, for patients with more advanced-stage disease, the 5-year survival rate is only 10% to 25%.[227,239,240] Prognostic factors associated with decreased relapse-free survival and OS include LN positivity and R1 resection. It is important to note that, when gallbladder cancer is found after laparoscopic cholecystectomy, reresection of the adjacent liver segment and lymphadenectomy are indicated for all disease stages except T1a (limited to the lamina propria).[241,242]

The role of adjuvant therapy continues to be an emerging field with only a few randomized studies. In the phase 3 PRODIGE 12-ACCORD 18 trial, GEMOX (gemcitabine and oxaliplatin) was evaluated and compared with observation in 196 patients randomly assigned after curative-intent resection of BTC, showing no significant difference in relapse-free survival between the two groups.[243] In the BILCAP study,[244] patients with completely resected cholangiocarcinoma or gallbladder carcinoma were randomly assigned to capecitabine at 1,250 mg/m^2 per day (capecitabine administered twice daily on days 1-14 of 21-day cycles) or observation. In the intention-to-treat analysis, median OS was 51.1 months (95% CI, 34.6-59.1) in the capecitabine group compared with 36.4 months (95% CI, 29.7-44.5) in the observation group (adjusted HR, 0.81; 95% CI, 0.63-1.04; *P* = .097). In a protocol-specified sensitivity analysis, adjusting for minimization factors, nodal status, grade, and sex, the OS HR was 0.71 (95% CI, 0.55-0.92; *P* = .010).[244] These data helped establish capecitabine as an acceptable standard for patients with resected cholangiocarcinoma. Additional studies are under way to assess the role of adjuvant gemcitabine and cisplatin with or without immunotherapy in this setting.

The role of radiation therapy in the adjuvant setting is less clear, with an absence of randomized studies evaluating CRT in resected BTCs.[245] The single-arm Intergroup S0809 study evaluated the role of adjuvant chemotherapy comprising four cycles of gemcitabine and capecitabine every 21 days followed by concurrent capecitabine and radiation therapy in EHCC. For all patients, the 2-year survival rate was 65% (95% CI, 53%–74%); it was 67% and 60% for patients who underwent R0 and R1 surgery, respectively. Median OS was 35 months for all patients (R0, 34 months; R1, 35 months). Local, distant, and combined relapses occurred in 14, 24, and 9 patients, respectively. A recent meta-analysis demonstrated that the greatest benefit with adjuvant therapy was in patients with biliary cancers who had LN-positive disease (odds ratio (OR), 0.49; *P* = .004) and in those who had a positive microscopic resection margin (OR, 0.36; *P* = .002).[246] A number of web-based nomograms predicting the benefit of adjuvant chemotherapy and CRT have been developed for BTCs as well as for specific subsets (IHCC, hilar cholangiocarcinoma, EHCC, and gallbladder), which can serve as guidelines in the absence of definitive phase 3 data in this setting.[247-251]

Treatment of Advanced Disease

The efficacy of systemic chemotherapy alone in advanced BTCs has been limited with response rates ranging from 10% to 40% for single-agent and combination chemotherapy regimens.[239] The phase 3 ABC-02 (advanced biliary cancer) trial represented the first RCT assessing the role of systemic therapy in advanced BTC. The study randomly assigned 410 patients who had advanced BTC to receive first-line gemcitabine at 1,000 mg/m^2 on days 1, 8, and 15 every 4 weeks for six cycles or 1,000 mg/m^2 of gemcitabine and 25 mg/m^2 of cisplatin on days 1 and 8 every 3 weeks for eight cycles.[252] The addition of low-dose cisplatin did not result in substantial differences in grade 3 or 4 toxicities. PFS was 8.4 months in the gemcitabine and cisplatin arm and 6.5 months in the gemcitabine only arm (HR, 0.72; 95% CI, 0.57-0.90; *P* = .003). This translated into an OS benefit with a median OS of 11.7 months in the gemcitabine and cisplatin arm compared with 8.3 months in the gemcitabine only arm (HR, 0.70; 95% CI, 0.54-0.89; *P* = .002). AEs were similar in the two groups with the exception of more neutropenia in the cisplatin and gemcitabine group. This trial established combination gemcitabine and cisplatin as a new standard of care in the treatment of advanced biliary cancers. GEMOX has also been studied, and oxaliplatin may be substituted for patients who are not candidates for cisplatin therapy.[253]

The TOPAZ-1 trial established chemoimmunotherapy with durvalumab as a standard first-line treatment of patients with unresectable, recurrent, or metastatic BTC. Six hundred eighty-five previously untreated patients who had unresectable, recurrent, or metastatic BTCs were randomly assigned to receive durvalumab or placebo in addition to gemcitabine and cisplatin.[254] Patients received 1,500 mg of durvalumab every 3 weeks or placebo combined with standard gemcitabine and cisplatin every 3 weeks for up to eight cycles followed by 1,500 mg of durvalumab or placebo every 4 weeks until disease progression. The estimated 24-month OS rate for patients treated with durvalumab and chemotherapy was 24.9% versus 10.4% for chemotherapy alone with an HR for OS of 0.80 (95% CI, 0.66-0.97; *P* = .021), favoring durvalumab and chemotherapy. In addition, there was a significant improvement in PFS (HR, 0.75; 95% CI, 0.63-0.89; *P* = .001) and higher ORR (26.7% vs 18.7%).[254] More recently, another chemoimmunotherapy approach showed benefit in biliary tract tumors. The phase 3 KEYNOTE-966 trial randomly assigned patients with untreated locally advanced or metastatic BTC to receive gemcitabine and cisplatin with pembrolizumab or gemcitabine and cisplatin with placebo.[255] Median OS increased from 10.9 to 12.7 months with the addition of pembrolizumab (HR, 0.83; 95% CI, 0.72-0.95; *P* = .0034). More patients had an ongoing response at 24 months in the pembrolizumab group than in the placebo group (18% vs 6%). In KEYNOTE-966, patients who had IHCC seemed to derive greater survival benefit from pembrolizumab than those who had tumors at other primary locations (HR, 0.76; 95% CI, 0.64-0.91), whereas in TOPAZ-1, the benefit was also seen in EHCC. In both studies, patients who had gallbladder cancer seemed to have less benefit, and there was no significant relationship between higher PD-L1 expression and improved outcomes with chemoimmunotherapy. The results of KEYNOTE-966 support the use of pembrolizumab with gemcitabine and cisplatin as another treatment option for patients who had previously untreated metastatic or unresectable BTC. It is important to note that, in TOPAZ-1 and KEYNOTE-966, PD-L1 expression was not an eligibility criterion and should not be used to select patients for immunotherapy with biliary cancer.

The ABC-06 randomized phase 3 study compared modified FOLFOX chemotherapy versus active symptom control for second-line treatment of BTCs.[256] Median OS was 6.2 months for the chemotherapy arm versus 5.3 months for active symptom control

(adjusted HR, 0.69; 95% CI, 0.50-0.97, P = .031). The role of liposomal irinotecan in the second-line setting of BTC remains unclear. The phase 2b NIFTY trial showed that 5-FU, leucovorin, and liposomal irinotecan had superior outcomes compared with 5-FU and leucovorin in South Korean patients who had disease progression during gemcitabine and cisplatin therapy.[257] However, the recently published phase 2 AIO NALIRICC trial showed that the addition of liposomal irinotecan to FU and leucovorin failed to improve outcomes and worsened toxicity in European patients.[258]

Recently, molecular profiling has revealed targeted therapeutic options for patients with cholangiocarcinoma, particularly IHCC with MSI-H, *FGFR2* fusions (10% of patients with IHCC), *BRAF* V600E mutations (5% of patients), *HER2* amplifications (5% of patients), or *IDH1* mutations (15% of patients with IHCC).[235,259] Thus, molecular profiling of newly diagnosed advanced biliary cancers is essential to ensure potential therapeutic targets are not missed. The randomized phase 3 ClarIDHy study with the IDH1 inhibitor ivosidenib versus placebo for *IDH1*-mutated cholangiocarcinoma met its primary endpoint of PFS and reported improved quality-of-life, leading to FDA approval on August 25, 2021.[260] Targeting *FGFR2* fusions in IHCC has yielded recent accelerated approvals by the FDA.[261,262] First, on the basis of the FIGHT-202 study, pemigatinib obtained accelerated approval for patients with chemorefractory cholangiocarcinoma harboring *FGFR2* fusions on April 20, 2020.[261] The single-arm phase 2 study FOENIX-CCA2 demonstrated the role of futibatinib in FGFR inhibitor–naive patients with unresectable or metastatic *FGFR2* fusion–positive or *FGFR2* rearrangement–positive IHCC who developed disease progression after one or more previous lines of systemic therapy. Treatment with futibatinib demonstrated a response in 43 (42%) of 103 patients (95% CI, 32-52) and was associated with a median PFS of 9.0 months and OS of 21.7 months, leading to the FDA approval of futibatinib. Second-generation FGFR inhibitors such as RLY 4008 are being developed with promising early results.[263,264] The combination of dabrafenib and trametinib has shown activity in patients who have *BRAF* V600E–mutated BTC. In the phase 2 multicenter ROAR (rare oncology agnostic research) basket trial, 43 patients with *BRAF* V600E–mutated BTC were enrolled. Overall response[265] was achieved by 20 (47%) of 43 patients (95% CI, 31.2-62.3). The most common grade ≥3 AE was increased γ-glutamyl transferase in five patients (12%); 17 patients (40%) had serious AEs, and nine (21%) had treatment-related serious AEs, the most frequent of which was pyrexia (eight [19%]). No treatment-related deaths were reported.[266] SGNTUC-019 was an open-label phase 2 basket study evaluating the efficacy and safety of tucatinib and trastuzumab in patients with HER2-altered solid tumors, including a BTC cohort with HER2-overexpressing or *HER2*-amplified (HER2$^+$) tumors. The confirmed ORR was 46.7% (90% CI, 30.8-63.0) with a median DOR and PFS of 6.0 months (90% CI, 5.5-6.9) and 5.5 months (90% CI, 3.9-8.1), respectively. The two most common treatment-emergent AEs were pyrexia (43.3%) and diarrhea (40.0%).[267] A previous study with pertuzumab and trastuzumab suggested similar favorable outcomes.[268]

The phase 2 single-arm HERIZON-BTC-01 assessed the safety and efficacy of zanidatamab, a bispecific antibody targeting two distinct HER2 epitopes, in patients who have unresectable or metastatic *HER2*-amplified BTC who had previously received gemcitabine-based therapy. Patients received zanidatamab 20 mg/kg intravenously every 2 weeks Among patients with HER2-positive disease (IHC 2$^+$ and 3$^+$), confirmed ORR was 41.3%. In the subgroup of IHC 3$^+$, ORR was 51.6%, and median DOR increased to 14.9 months (95% CI, 7.4 not reached). The most common TRAEs included diarrhea (any grade, 36.8%), infusion-related reaction (33.3%), decreased ejection fraction (10.3%), and nausea (9.2%). Based on these results, the FDA granted accelerated approval of zanidatamab in HER2-positive (IHC 3$^+$) advanced BTC on November 20, 2024.[12,269] An open-label randomized phase 3 trial evaluating the addition of zanidatamab to combination treatment with gemcitabine and cisplatin, with or without pembrolizumab or durvalumab, is ongoing (ClinicalTrials.gov ID NCT06282575).

KEY POINTS

- HCC is an important cancer, and global incidence can be reduced by vaccination against hepatitis B virus; treatment of hepatitis C is curative, which may lead to reduced incidence of HCC in the coming years. Alcohol abuse, obesity, and metabolic syndrome represent modifiable risk factors, the moderation of which could also reduce worldwide incidence of the disease.
- The Barcelona Clinic Liver Cancer staging classification and treatment schedule have served as a main paradigm on how to broadly stage and treat HCC.
- Local ablative treatments are generally reserved for intermediate disease. These approaches include TACE, TARE, alcohol injection, radiofrequency ablation, microwave ablation, and external-beam radiation therapy or stereotactic radiation therapy.
- Combination locoregional plus systemic therapy options show promise in the intermediate stage of the disease and require further optimization.
- There is no role for adjuvant treatment in patients with resected HCC.
- The SHARP study established the first standard systemic therapy in HCC with sorafenib.[201]
- The IMbrave 150 study confirmed the benefit of atezolizumab and bevacizumab in first-line treatment compared with sorafenib for advanced HCC.[199]
- The HIMALAYA study demonstrated the role of tremelimumab and durvalumab as a first-line treatment option compared with sorafenib for advanced HCC.[10]

- CHECKMATE 9DW demonstrated the role of ipilimumab and nivolumab as a first-line treatment option compared with investigator's choice of sorafenib or lenvatinib for advanced HCC.[11]
- The REFLECT study confirmed the noninferiority of lenvatinib in first-line treatment compared with sorafenib for advanced HCC.[208]
- The RESORCE study confirmed the benefit of regorafenib in second-line treatment compared with placebo for advanced HCC.[213]
- The CELESTIAL study confirmed the benefit of cabozantinib in second- and third-line treatment compared with placebo for advanced HCC after sorafenib.[215]
- The REACH-2 study confirmed the benefit of ramucirumab in the second-line treatment of patients with AFP level ≥400 ng/mL compared with placebo for advanced HCC.[219,223]
- Immune checkpoint blockade has great promise in HCC with improved response rates and meaningful DOR in select patients with response to anti-PD-1 monotherapy. However, to date, treatment with monotherapy checkpoint blockade has not demonstrated definitive survival benefit in any patients in larger phase 3 randomized studies compared with sorafenib in the first-line setting or placebo in the second-line setting. Biomarker studies to identify those who may derive the most benefit are ongoing.
- The treatment paradigm of advanced HCC is in flux with the addition of all these agents relatively simultaneously without direction on the best sequencing approach.
- Resection, when feasible, is the mainstay of treatment of hepatobiliary tumors.
- The randomized phase 3 BILCAP study of adjuvant capecitabine versus observation in resected BTCs demonstrated improved OS in the prespecified per-protocol analysis and can be considered a standard of care.
- There is limited clinical evidence supporting the adoption of concurrent radiation therapy in the adjuvant setting, but this could be considered for patients who have high risk of relapse, such as patients who have positive LN disease and positive microscopic margins.
- Chemoimmunotherapy comprising durvalumab with gemcitabine and cisplatin as well as pembrolizumab with gemcitabine and cisplatin is a new standard of care option for first-line treatment of patients with advanced BTCs.
- The combination of 5-FU with oxaliplatin represents an appropriate second-line therapy for patients lacking an actionable somatic mutation who have developed progressive disease during gemcitabine and platinum combination therapy based on the ABC-06 trial.
- NGS should be incorporated into routine standard of care for patients who have advanced BTC to identify actionable molecular abnormalities (*FGFR2* fusions, *IDH1* mutations, *HER2* amplification, *BRAF* V600E, and MSI-high).
- The phase 3 ClarIDHy trial with the IDH1 inhibitor ivosidenib versus placebo for *IDH1*-mutated cholangiocarcinoma met its primary endpoint of PFS with the added benefit of improved quality-of-life.
- The FGFR inhibitors pemigatinib and futibatinib have received accelerated FDA approval for the treatment of *FGFR2* fusion–positive or *FGFR2* rearrangement–positive cholangiocarcinoma. The ROAR basket study using the combination of dabrafenib and trametinib showed benefit for patients who have BTC harboring *BRAF* V600E–mutations.
- Zanidatamab is a new bispecific antibody targeting HER2 that has been FDA-approved to treat unresectable or metastatic HER2-positive (IHC3+) BTC previously treated with gemcitabine-based chemotherapy.

PANCREATIC CANCER

EPIDEMIOLOGY AND ETIOLOGY

Pancreatic ductal adenocarcinoma (PDAC) is a substantial health problem in the United States with an annual incidence of 67,440 cases and death occurring in 51,980 patients annually[16] with only 13% surviving 5 years.[270,271] Survival rates are better for those who have localized disease with a 5-year survival rate of >35%, but remain dismal for those with metastatic disease with a 5-year survival of only 3%.[272] The nonhereditary risk factors for pancreatic cancers include older age, long-standing diabetes, chronic pancreatitis, intraductal pancreatic mucinous neoplasms, cigarette smoking, obesity, physical inactivity, and a diet high in saturated fats.[273] Diabetes can also be a paraneoplastic syndrome in pancreatic cancer although in some cases this may simply be a coincident diagnosis. Patients with new-onset diabetes have a fivefold- to eightfold-increased risk of being diagnosed with pancreatic cancer within 1 to 3 years. It is also not uncommon for patients who have well-controlled long-standing diabetes to develop unexplained poor control of their diabetes and subsequently be diagnosed with pancreatic cancer. More recent data suggest pathogenic germline alterations may be present in up to 20% of unselected exocrine pancreatic cancers and have led to the recommendation for universal testing of patients with pancreatic cancer for germline mutations regardless of family history.[274,275] There is no agreed-on approach for screening patients for pancreatic cancer who have an identified germline mutation, but screening typically involves alternating magnetic resonance cholangiopancreatography and EUS procedures. Several ongoing trials are attempting to define the best screening algorithms.

There is no standard surveillance or screening for pancreatic cancer. Pancreatic intraepithelial neoplasias, which are microscopic lesions of the pancreas, and intraductal papillary mucinous neoplasms and mucinous cystic neoplasms, which are both macroscopic lesions often found incidentally during imaging for other reasons, are thought to be precursors of invasive pancreatic cancer, especially those involving the main pancreatic duct.[276,277] The American Gastroenterological Association has issued management guidelines for these lesions.[278] More than 90% of pancreatic cancers harbor activating genetic mutations of the oncogene *KRAS*, which is integrated in signaling pathways of various receptor kinases, such as EGFR and insulin-like growth factor receptor I. In addition, >50% of pancreatic cancers harbor mutations in at least one of three tumor suppressor genes: *p16/CDKN2A*, *TP53*, and *SMAD4*. *BRCA* mutations are less common and found in approximately 5% of pancreatic cancers, but they have recently been found to have therapeutic implications as is discussed in more detail in this section under "First-Line Therapy."[275,277] The advent of drugs targeting these genetic mutations supports the practice of complete germline and somatic genetic analyses of patients upon diagnosis of pancreatic adenocarcinoma (Table 13.1-3).

Table 13.1-3 Germline Mutations Associated With Pancreatic Cancer

Mutated Gene	Syndrome
BRCA1, *BRCA2*	Hereditary breast and ovarian syndrome
ATM	Ataxia-telangiectasia
PALB2	Hereditary breast cancer
PRSS1	Hereditary pancreatitis
STK11	Peutz-Jeghers syndrome
CDKN2A	Familial atypical multiple mole and melanoma syndrome
MLH1, *MLH2*, *MSH6*, *PMS2*	Lynch syndrome

Abbreviations: *ATM*, *ATM* serine/threonine kinase; *BRCA1/2*, *BRCA1/2* DNA repair–associated protein; *CDKN2A*, cyclin-dependent kinase inhibitor 2A; *MLH1/2*, DNA mismatch repair protein *MLH1/2*; *MSH6*, MutS homolog 6; *PALB2*, partner and localizer of *BRCA2*; *PRSS1*, protease, serine 1; *STK11*, serine/threonine protein kinase 11.

CLINICAL PRESENTATION AND DIAGNOSIS

Symptoms associated with pancreatic cancer at the time of presentation commonly include abdominal pain with or without back pain, cachexia, and/or jaundice. Initial symptoms are often vague and can vary based on location with pancreatic head lesions more likely to cause jaundice and tail lesions often asymptomatic and, thus, diagnosed at a later stage. When evaluating patients who have adult-onset diabetes without other risk factors or worsening diabetes without an obvious cause, physicians should consider pancreatic cancer as a possible diagnosis.[275]

The most common diagnostic tests used for pancreatic cancer are triple-phase pancreatic protocol CT scan (so arterial and venous structures are clearly evaluable and differences between enhancement of pancreatic parenchyma and lack of enhancement of tumor are emphasized), MRI, EUS, and endoscopic retrograde cholangiopancreatography. Tissue is best obtained by EUS-guided biopsy and, for those patients presenting with biliary obstruction and for whom immediate surgery is not planned, placement of a biliary stent. Although pancreatic cancer is staged using the standard TNM methodology, in practice, it is often classified as resectable, borderline resectable, locally advanced/unresectable, or metastatic. Degree of vascular involvement, particularly of the superior mesenteric artery and celiac artery, is a criterion in distinguishing resectable and borderline resectable from locally advanced unresectable disease. Additional criteria used in determining unresectability include significant encasement of the common hepatic artery or unreconstructable venous involvement. Levels of serum carbohydrate antigen 19.9 (CA 19-9) may provide limited benefit in predicting resectability and/or surgical outcomes, and should be considered in combination with other criteria when making surgical decisions.[279-282]

TREATMENT

General Principles

The most important component in the management of a patient newly diagnosed with non-metastatic pancreatic cancer is the involvement of a multidisciplinary team at a center with high-volume experience with this cancer. The continuum is complex and often requires the opinions of surgeons and expert radiologists, endoscopists, and radiation oncologists. Although surgery has been the mainstay of treatment of pancreatic cancer and remains an essential component of a curative approach, cure rates with surgery alone remain dismal. This has led to the incorporation of more highly active chemotherapy regimens, such as FOLFIRINOX, into the adjuvant setting and, increasingly, into the neoadjuvant setting. The duration and sequence of these therapies and their role in converting previously unresectable cancers into resectable cancers are the subjects of multiple studies, and the field is rapidly evolving.[283]

Resectable Pancreatic Cancer: Adjuvant Therapy

The appropriate adjuvant treatment of resectable pancreatic cancer has come into clearer focus over the last several years although some controversy remains regarding the role of radiation therapy. A German phase 3 trial (CONKO-001) including 364 patients demonstrated the superiority of adjuvant chemotherapy with gemcitabine compared with surgery alone for patients with resected pancreatic cancer regardless of whether a tumor-free resection margin could be obtained.[284,285] An update of this study demonstrated a substantial improvement in 5-year OS at 20.7% (95% CI, 14.7%–26.6%) for gemcitabine compared with 10.4% (95% CI, 5.9%–15.0%) for surgery alone.[286] Building on CONKO-001, the ESPAC-4 study compared adjuvant gemcitabine with gemcitabine and capecitabine in a large phase 3 study of 732 patients.[287] This study demonstrated a modest improvement in survival with combination adjuvant therapy; median survival was 28.0 versus 25.5 months with gemcitabine alone (HR, 0.82; 95% CI, 0.68-0.98; *P* = .032) with a 5-year OS rate of 29% (95% CI, 22.0%–35.2%) versus 16% (95% CI, 10.2%–23.7%). To date, the most important and practice-changing adjuvant clinical trial was the phase 3 PRODIGE-24 trial,[288] which compared 6 months of adjuvant FOLFIRINOX (5-FU, leucovorin, irinotecan, and oxaliplatin) with gemcitabine therapy; median disease-free survival (DFS) and OS with adjuvant FOLFIRINOX were 21.6 and 53.5 months, respectively. To date, this is the longest median survival seen in a phase 3 trial of adjuvant therapy for pancreatic cancer. As a result, FOLFIRINOX is the preferred adjuvant therapy for patients who are fit enough and have recovered adequately from surgery to receive this regimen.

The phase 3 APACT (adjuvant therapy for patients with resected pancreatic cancer) study compared gemcitabine with gemcitabine plus nab-paclitaxel in the adjuvant setting and did not meet its primary endpoint of improved median DFS; however, long-term follow-up demonstrated persistent improved OS for patients treated with gemcitabine and nab-paclitaxel with median OS of 41.8 versus 37.7 months with gemcitabine alone (HR, 0.80; 95% CI, 0.678-0.947; *P* = .0091).[289] At this point, the role of gemcitabine plus nab-paclitaxel in the adjuvant setting remains unclear.

The role of CRT in the adjuvant treatment setting for pancreatic cancer remains controversial and has been made more difficult by the results seen in the PRODIGE-24 trial described above. The ESPAC-1 study was a complex trial (2 × 2 design) that compared adjuvant chemotherapy and adjuvant CRT each with no such therapy. The trial showed no benefit (and perhaps harm) with CRT but a benefit for chemotherapy.[290] The RTOG 0848 trial of gemcitabine versus gemcitabine and erlotinib followed by either additional chemotherapy or CRT was recently reported at ASCO, 2024.[291] For the entire patient population, there was no benefit to the addition of postoperative radiation therapy. However, in the subset of patients who had node-negative disease, there appeared to be a potential benefit with postoperative radiation therapy. This may be related to less chance of systemic recurrence and greater potential benefit of a local treatment modality. Interestingly, the subgroup of patients who had positive margins (who would be considered at higher risk for local recurrence) did not benefit from postoperative radiation therapy. Whether to offer postoperative radiation therapy to node-negative patients or at all remains controversial.[292,293]

Neoadjuvant Therapy: Resectable and Borderline Resectable Pancreatic Cancers

Several recent trials have shed light on the role of neoadjuvant therapy in this setting: SWOG 1505, ESPAC5, PREOPANC, PREOPANC-2,[294] and ALLIANCE A021501.[295-298] In the resectable pancreatic cancer setting, the SWOG 1505 trial of perioperative mFOLFIRINOX versus gemcitabine and nab-paclitaxel demonstrated no substantial differences in patients who underwent surgery (72%) or in median survival with median OS for mFOLFIRINOX of 23.2 months (95% CI, 17.6-45.9) versus 23.6 months (95% CI, 17.8-31.7) for gemcitabine and nab-paclitaxel.[295] The primary endpoint of achieving a 58% 2-year survival was not met. One cautionary note from this trial, which emphasizes the importance of having these patients evaluated at high-volume centers in a multidisciplinary setting, was that nearly one third of the patients thought to have resectable disease were not deemed to have resectable disease on central review.[299] The ESPAC5 trial compared surgery versus a short course (8 weeks) of several perioperative regimens (CRT, mFOLFIRINOX, and gemcitabine and capecitabine) in the borderline resectable setting.[296] There was no significant difference in R0 resection rates between neoadjuvant therapy groups versus immediate surgery; although 1-year OS rates were higher among the neoadjuvant therapy groups compared to immediate surgery, the trial was not powered for formal comparison of the different neoadjuvant arms.[296]

The Dutch study PREOPANC provides further support for neoadjuvant CRT in patients who have either resectable or borderline resectable disease. Patients were randomly assigned to receive three cycles of neoadjuvant gemcitabine with the addition of radiation therapy at 15 × 2.4 Gy in cycle two followed by surgical resection and four cycles of adjuvant gemcitabine versus up-front surgical resection followed by six cycles of adjuvant gemcitabine. The R0 resection rate was 71% versus 40%, favoring patients receiving neoadjuvant therapy.[297] The updated survival analysis showed that the 5-year OS rate was 20.5% with neoadjuvant CRT and 6.5% with up-front surgery. The beneficial effect of neoadjuvant CRT was consistent across the prespecified subgroups, including resectable and borderline resectable pancreatic cancer.[300] The subsequent phase 3 PREOPANC-2[294] study compared neoadjuvant FOLFIRINOX versus neoadjuvant gemcitabine-based chemoradiotherapy and adjuvant gemcitabine for resectable and borderline resectable pancreatic cancer. There was no significant difference in OS between FOLFIRINOX and gemcitabine-based chemoradiotherapy (median OS 21.9 vs 21.3 months; HR, 0.88; 95% CI 0.69-1.13; *P* = .32). Additionally, there were no significant differences in PFS, (R0) resection percentage, complete pathological response, and adverse event incidence. The authors conclude that both regimens can be considered in the (neo)adjuvant setting for this patient population.

The phase 2 randomized ALLIANCE A021501[301] study compared neoadjuvant FOLFIRINOX with or without hypofractionated radiotherapy. Patients who received neoadjuvant FOLFIRINOX alone reported significant improvements in OS (29.8 vs 17.1 months) and 18-month OS rate (66.7% vs 47.3%) compared to patients who received FOLFIRINOX plus radiotherapy although the radiotherapy arm did not meet target accrual and conclusions regarding efficacy could not be made. We await the results of the phase 3 ALLIANCE A021806 study (ClinicalTrials.gov identifier: NCT04340141), a randomized trial for patients who have resectable pancreatic cancer designed to evaluate the role of perioperative FOLFIRINOX versus up-front resection followed by adjuvant FOLFIRINOX.

Recently, the phase 3 CASSANDRA–PACT-21 trial evaluated neoadjuvant PAXG (cisplatin, nab-paclitaxel, capecitabine, and gemcitabine) versus neoadjuvant mFOLFIRINOX in patients with stage I to III resectable or borderline resectable pancreatic ductal adenocarcinoma. The primary endpoint of event-free survival was met; median event-free survival was 16.0 months for the PAXG arm and 10.2 months for the mFOLFIRINOX arm (HR, 0.64, 95% CI 0.48-0.86, $P = 0.003$); 3-year event-free survival rates were 31% and 13%, respectively. Of note, after patients had received 4 months of neoadjuvant treatment, there was a second randomization event in which patients received either surgery followed by 2 months of the same treatment in the adjuvant setting or two more months of the same neoadjuvant treatment followed by surgery. Consequently, the median duration of neoadjuvant therapy was longer in the PAXG arm compared to the mFOLFIRINOX arm (162 vs 132 days), which may have influenced efficacy outcomes.

Locally Advanced Unresectable Pancreatic Cancer

For patients who have locally advanced unresectable disease, current ASCO guidelines recommend 6 months of initial systemic chemotherapy with a combination regimen with consideration of CRT in those who do not experience progression after induction therapy.[302] As in the case of those with resectable disease, the role of CRT in this setting remains controversial. The international LAP07 phase 3 trial randomly assigned patients with locally advanced unresectable pancreatic cancer to treatment with gemcitabine with or without erlotinib. Patients who had at least stable disease after 4 months were randomly assigned a second time to either continue with the same chemotherapy as in the first phase or proceed to CRT with capecitabine as a radiation sensitizer. This study closed at the first planned interim analysis because of a lack of efficacy. No OS or PFS benefit was observed with the switch from chemotherapy to consolidating CRT. A subsequent analysis to evaluate the effect of radiation therapy on locoregional tumor control found that patients in the radiation therapy arm had substantially less local tumor progression (34% vs 65%; $P < .0001$) and a longer time before reintroduction of chemotherapy (159 vs 96 days; $P = .05$).[303] The NEOLAP trial compared a continuous gemcitabine and nab-paclitaxel regimen with a sequential regimen of gemcitabine and nab-paclitaxel followed by FOLFIRINOX in the preoperative setting. In this trial, roughly two thirds of patients underwent surgical exploration and more than one third had a complete macroscopic resection, much higher than the 4% observed in the LAP07 trial, underscoring the evolution of neoadjuvant chemotherapy and improved surgical expertise.[298] However, no difference in median OS between the two arms was seen in this phase 2 trial, and comparisons between these trials should consider the differences between patient populations, definitions of locally advanced disease, and treatment modalities.[298]

Although previously published studies have not reported a clinical benefit with the addition of radiotherapy, recent prospective and retrospective data suggest that optimization of radiation amounts and administration techniques may be required to significantly improve clinical benefit in this patient population. A retrospective study[304] of 119 patients treated with ablative radiation therapy reported a median OS of 26.8 months, and a single-arm phase 2 trial[305] of 136 patients treated with stereotactic magnetic resonance–guided adaptive radiation therapy reported a median OS of 22.8 months and 2-year OS rate of 53.6%. Ongoing randomized trials include LAP100 (ClinicalTrials.gov ID NCT06958328) and LAPSTAR (ClinicalTrials.gov ID NCT06272162). While both trials are investigating modified radiotherapy (dose-escalated radiotherapy in LAP100 and stereotactic magnetic resonance–guided radiotherapy in LAPSTAR), the primary endpoint for LAP100 is OS; in contrast, LAPSTAR's primary endpoint is health-related quality-of-life deterioration-free survival, with OS as a secondary endpoint. LAPSTAR's choice of primary outcome serves as a reminder that prolonged survival at the cost of significantly impaired quality-of-life may not be acceptable to patients, and their goals of treatment should be considered in trial design and treatment planning.

The recently published phase 3 PANOVA-3[306] trial investigated the use of tumor treating fields (TTFields) in combination with gemcitabine and nab-paclitaxel versus gemcitabine and nab-paclitaxel alone. This is the first trial to demonstrate improved OS over gemcitabine and nab-paclitaxel alone in patients with locally advanced unresectable pancreatic cancer. Median OS for TTFields plus gemcitabine/nab-paclitaxel was 16.2 months versus 14.2 months for gemcitabine/nab-paclitaxel alone (HR, 0.82, 95% CI 0.68-0.99, $P = 0.039$); median 1-year survival rates were 68.1% and 60.2%, respectively. A premarket approval application has been submitted to the FDA, with a decision expected in the second half of 2026 (https://www.businesswire.com/news/home/20250820419511/en/Novocure-Submits-Premarket-Approval-Application-to-FDA-for-Tumor-Treating-Fields-Therapy-in-Locally-Advanced-Pancreatic-Cancer).

In general, after completion of planned chemotherapy, patients should be reevaluated by a multidisciplinary team with high-volume expertise in pancreatic cancer to determine whether they could be candidates for surgical resection. If the disease is deemed non-metastatic at that time, then CRT should be considered.

PRESENTING CASE STUDY

A 66-year-old woman presents to the oncology clinic for management of her recently diagnosed metastatic pancreatic cancer. Her medical history includes obesity, hypertension, hypercholesterolemia, and a bilateral hip replacement. She was diagnosed with diabetes mellitus approximately 2 years ago that has become difficult to control over the last 6 months, resulting in a 30-pound (13.6-kg) unintentional weight loss and gnawing post-prandial discomfort that lasts for a few hours. Subsequent imaging reveals numerous liver and lung lesions and a mass in the pancreas tail. Biopsy of a liver lesion confirms moderately differentiated adenocarcinoma. The patient's family history is notable for ovarian cancer in a maternal aunt; germline testing identifies a pathogenic *BRCA2* mutation. The patient's family has observed functional decline over several years; her Eastern Cooperative Oncology Group (ECOG) PS is 2.

How would this patient's comorbidities, ECOG PS, and *BRCA2* mutation status inform your decisions regarding first-line treatment?

This patient has metastatic pancreatic cancer with a confirmed germline *BRCA2* mutation. Results from the pivotal POLO trial support the use of maintenance olaparib monotherapy for individuals with an ECOG PS of 0 or 1 who have achieved disease response or stability after at least 16 weeks of induction platinum-based chemotherapy.[307] Most study subjects received 5-fluorouracil, leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX) variants, while a very small minority were treated with gemcitabine and cisplatin. The US Food and Drug Administration has approved olaparib for first-line maintenance in patients with germline BRCA-mutated metastatic pancreatic cancer following 16 weeks of platinum-based chemotherapy.

As such, platinum-containing chemotherapy should be considered for this patient, followed by olaparib maintenance should she achieve disease stabilization/benefit following induction chemotherapy. However, she has multiple comorbidities and an intermediate ECOG PS of 2. The treatment recommendation should be personalized after discussing the risks and benefits. The intensive triplet therapy FOLFIRINOX and variant is highly likely to result in unacceptable toxicities and should be avoided. Platinum doublets (eg, gemcitabine and cisplatin, 5-fluorouracil, leucovorin, and oxaliplatin [FOLFOX]) may be more appropriate with cautious monitoring and support during treatment. To mitigate the risk of toxicities during initial treatment, one approach includes starting with gemcitabine alone and adding the platinum agent if she tolerates monotherapy with an improvement in PS.

TREATMENT OF METASTATIC PANCREATIC CANCER

First-Line Therapy

All patients who have metastatic pancreatic cancer should be considered for early referral to a palliative care specialist if available. Because these patients often have symptoms that are due to direct involvement of the celiac plexus, biliary obstruction, and gastric outlet obstruction, involvement of specialists in interventional pain management and interventional endoscopy is also often required (Fig. 13.1-1).

Historically, single-agent gemcitabine was considered the standard of care for patients who have metastatic pancreatic cancer when it was approved by the FDA in 1997.[308,309]

A present standard of care in the treatment of metastatic pancreatic cancer was defined in 2011 by the results of the French PRODIGE trial of 342 patients comparing gemcitabine with FOLFIRINOX.[310] Median OS was an unprecedented 11.1 months in the FOLFIRINOX group compared with 6.8 months in the gemcitabine group (HR, 0.57; 95% CI, 0.45-0.73; $P < .001$); median PFS was 6.4 months in the FOLFIRINOX group and 3.3 months in the gemcitabine group (HR, 0.47; 95% CI, 0.37-0.59; $P < .001$), and the ORR was 31.6% for FOLFIRINOX compared with 9.4% for gemcitabine ($P < .001$). More AEs were noted in the FOLFIRINOX group, but despite this, overall quality-of-life scores were superior in the FOLFIRINOX arm. These results established FOLFIRINOX as the new standard of care for patients who have advanced pancreatic cancer, good PS, absence of biliary obstruction, and no infectious complications. It should be noted that the trial excluded patients who had an ECOG PS of ≥2 and patients aged >75 years. More recent trials with FOLFIRINOX in pancreatic cancer have modified the original regimen by eliminating the 5-FU bolus and reducing the irinotecan dose from 180 to 150 mg/m^2 without seeming to compromise effectiveness. This mFOLFIRINOX regimen was used in the practice-changing PRODIGE-24 adjuvant study.[311] An alternative first-line therapy for advanced pancreatic cancer was established in 2013 when the addition of nab-paclitaxel to gemcitabine was found to be superior to gemcitabine alone in the phase 3 MPACT trial.[312] In this study, median OS was 8.5 months in the nab-paclitaxel and gemcitabine group compared with 6.7 months in the gemcitabine alone group (HR, 0.72; 95% CI, 0.62-0.83; $P < .001$); the response rate, according to independent

review, was 23% compared with 7% ($P < .001$). Rates of neutropenia, febrile neutropenia (3% vs 1%), neuropathy, and fatigue were substantially higher in the nab-paclitaxel arm. Notably, unlike the FOLFIRINOX study, the nab-paclitaxel and gemcitabine trial included patients with ECOG PS of 2 and older patients.

More recently, the NAPOLI-3 trial evaluated the role of NALIRIFOX (triplet 5-FU, liposomal irinotecan, and oxaliplatin) compared with gemcitabine and nab-paclitaxel. This open-labeled randomized phase 3 study assigned 770 treatment-naive patients who had de novo metastatic pancreatic adenocarcinoma to receive NALIRIFOX versus nab-paclitaxel and gemcitabine. Median OS was 11.1 months with NALIRIFOX versus 9.2 months with nab-paclitaxel and gemcitabine (HR, 0.83; 95% CI, 0.70-0.99; $P = .036$). The most common grade 3 to 4 treatment-emergent AEs were neutropenia, diarrhea, and hypokalemia in the NALIRIFOX group and neutropenia, anemia, and peripheral neuropathy in the nab-paclitaxel and gemcitabine group. The FDA approved the NALIRIFOX regimen for first-line treatment of metastatic PDAC.[12]

In the POLO study,[313] 154 patients with metastatic pancreatic cancer and a germline *BRCA1* or *BRCA2* mutation who had received, but not experienced progression during, at least 16 weeks of a platinum-containing regimen were randomly assigned to receive maintenance therapy with the PARP inhibitor olaparib or placebo. Median PFS was substantially longer in the olaparib group than in the placebo group (7.4 vs 3.8 months; HR, 0.53; 95% CI, 0.35-0.82; $P = .004$).[313] The final OS data did not demonstrate a benefit for olaparib treatment (median, 19.0 vs 19.2 months; HR, 0.83; 95% CI, 0.56-1.22; $P = .3487$). Olaparib has received FDA approval for metastatic germline *BRCA*-mutated pancreatic adenocarcinoma as maintenance therapy without disease progression on at least 16 weeks of platinum-based chemotherapy. For patients with germline *BRCA* or *PALB2* mutations, the combination of cisplatin and gemcitabine demonstrated high response rates as initial therapy for advanced disease in a phase 2 study. The addition of a PARP inhibitor to cisplatin/gemcitabine did not improve outcomes further. The combination of maintenance PARP inhibition with immune checkpoint blockade is a promising avenue of ongoing investigation.

mFOLFIRINOX, NALIRIFOX, and gemcitabine/nab-paclitaxel are appropriate initial treatment options for patients who have metastatic pancreatic cancer. Platinum-based regimens, which also include gemcitabine/cisplatin, are preferred options for patients with *BRCA1/2* or *PALB2* mutations. We caution against the tendency for cross-trial comparisons in general given potential differences in the underlying populations. Decisions regarding first-line treatment, therefore, depend on patient factors and clinician preferences. It could be reasonable to establish a three-tiered approach toward metastatic pancreatic cancer; otherwise healthy, medically fit patients with good ECOG PS (0 or 1) and those with a germline *BRCA1/2* mutation could preferentially be treated with FOLFIRINOX or NALIRIFOX as first-line therapy. A small randomized phase 2 trial also suggested that first-line gemcitabine and cisplatin could be an effective regimen for patients who have germline *BRCA* or *PALB2* mutations with a median OS of 16.4 months and 3-year OS rate of 17.8%.[314] Patients who have poor PS, advanced age, and substantial comorbidities could still be considered candidates for single-agent gemcitabine or 5-FU therapy. In between these extremes, given that NALIRIFOX improved outcomes compared with gemcitabine/nab-paclitaxel, lies a group of patients who could be considered for nab-paclitaxel and gemcitabine as first-line therapy.

Second-Line Therapy and Beyond

There is no agreed-on standard-of-care regimen for patients who experience progression during first-line treatment of metastatic pancreatic cancer. In general, the treatment choice for the second line is often based on the first-line regimen, PS, and organ function. These patients should always be considered for enrollment in a clinical trial. The NAPOLI-1 trial evaluated nanoliposomal irinotecan for patients with metastatic pancreatic cancer refractory to gemcitabine.[315] Patients in the combination nanoliposomal irinotecan with 5-FU and leucovorin arm had a substantially improved OS compared with patients in the 5-FU and leucovorin arm at 6.1 months compared with 4.2 months (HR, 0.67; 95% CI, 0.49-0.92; $P = .012$). Second-line therapy continues to be characterized by poor outcomes and short median survivals.

Neuregulin 1 (*NRG1*) fusions have been shown to enhance HER2/HER3 dimerization and downstream activation. Therefore, targeting HER2 and HER3 in patients with *NRG1* fusions may be beneficial. Zenocutuzumab[14] is a first-in-class bispecific antibody targeting HER2 and HER3. The phase 2 eNRGy study evaluated zenocutuzumab in patients with *NRG1* fusion–positive solid tumors, including 36 patients with pancreatic cancer. Of note, all 36 patients had *KRAS* wild-type disease. Objective responses were observed in 16 of 36 patients per BICR; the ORR (95% CI) was 44% (28-62) and the DCR (95% CI) was 81% (64-92). Median PFS (95% CI) was 7.4 months (5.5-10.2); median DOR was 9.1 months. On December 4, 2024, the FDA granted accelerated approval (https://www.fda.gov/drugs/resources-information-approved-drugs/fda-grants-accelerated-approval-zenocutuzumab-zbco-non-small-cell-lung-cancer-and-pancreatic) for the use of zenocutuzumab-zbco in patients with advanced pancreatic adenocarcinoma with an *NRG1* gene fusion with disease progression during or after prior systemic therapy.

Additional rare alterations in pancreatic cancer include rearranged during transfection (*RET*) fusions, V-RAF murine sarcoma viral oncogene homolog B1 (*BRAF*) V600E mutations, neurotrophic tropomyosin kinase receptors (*NTRK*) fusions, and MSI-high.

On September 21, 2022, the FDA granted accelerated approval for the use of selpercatinib[316] in patients with locally advanced or metastatic pancreatic adenocarcinoma with an *RET* gene fusion with disease progression during or after prior systemic therapy. This accelerated approval was based on data from the LIBRETTO-1[317] phase 1/2 open-label basket trial, which included 11 patients with *RET* fusion–positive pancreatic cancer. The ORR was 54.5%, and the median DOR was not reached.

Dabrafenib plus trametinib received accelerated approval by the FDA (https://www.fda.gov/drugs/resources-information-approved-drugs/fda-grants-accelerated-approval-dabrafenib-combination-trametinib-unresectable-or-metastatic-solid) on June 22, 2022, for patients with advanced solid tumors with a *BRAF* V600E mutation who had progressed on prior systemic therapy. Of note, of the two trials used as evidence for this accelerated approval, ROAR[265] and NCI-MATCH Subprotocol H,[318] ROAR did not include patients with pancreatic cancer; NCI-MATCH included two patients with pancreatic adenocarcinoma, of whom only one was included in efficacy analyses.

The tropomyosin receptor kinase inhibitors larotrectinib and entrectinib are two FDA-approved treatment options for patients with advanced solid tumors with a *NTRK* gene fusion and no known acquired resistance mutations. A pooled analysis of three phase 1 or 2 studies[319] (LOXO-TRK-14001, SCOUT, and NAVIGATE) in 55 pediatric and adult patients treated with larotrectinib reported an overall response rate (95% CI) of 75% (61-85); one patient with pancreatic cancer was included and achieved a partial response to treatment. Long-term efficacy and safety data of an expanded 150-patient cohort[320] reported an ORR (95% CI) of 57% (50-65). Seven adult patients with pancreatic cancer were included; of six evaluable patients, one patient achieved a partial response.

FDA approval of entrectinib was based on a pooled analysis of three phase 1 or 2 clinical trials[321] (ALKA-372-001, STARTRK-1, and STARTRK-2). Of 121 patients total, the efficacy-evaluable population included four patients with pancreatic cancer. The ORR for this subgroup was 75%, with a median PFS of 12.8 months and median OS of 22.0 months; these statistics are comparable to those of the total study population, which reported an ORR of 74%, median PFS of 13.8 months, and median OS of 33.8 months.

Among patients with MSI-high disease, the FDA has approved the immune checkpoint inhibitor pembrolizumab for patients with advanced MSI-high solid tumors who have progressed on prior systemic therapy. The phase 2 KEYNOTE-158[322,323] study enrolled 22 patients with pancreatic cancer and reported an ORR of 18.2% (one complete response and three partial responses). Although the median DOR was not reached, PFS and OS remained low (2.1 and 3.7 months, respectively).

EMERGING THERAPIES

The acquisition of activating mutations in *KRAS* is the single most common genetic abnormality associated with pancreatic adenocarcinoma, accounting for >95% of patients. The recent development of KRAS inhibitors represents a new area of promise for treating patients with this disease. Initial evidence of the promise of this approach was observed in *KRAS* G12C–mutated pancreatic adenocarcinoma, which accounts for 1% to 2% of pancreatic cancers. The KRYSTAL-1 study treated 63 patients who had *KRAS* G12C–mutated cancer with adagrasib, 21 of whom had pancreatic cancer. Seven (33.3%) of 21 evaluable patients achieved a partial response. Median PFS was 5.4 months (95% CI, 3.9-8.2), and median OS was 8.0 months (95% CI, 5.2-11.8).[324]

The CodeBreaK study was a phase 1/2 study of the KRAS G12C inhibitor sotorasib for patients who have *KRAS* G12C–mutated pancreatic cancer. Thirty-eight patients were treated in the study with 21% having a confirmed objective response (95% CI, 10-37). Median PFS was 4.0 months (95% CI, 2.8-5.6), and median OS was 6.9 months (95% CI, 5.0-9.1).

Daraxonrasib has received FDA breakthrough designation (https://ir.revmed.com/news-releases/news-release-details/revolution-medicines-announces-fda-breakthrough-therapy) for patients with previously treated metastatic cancer with *KRAS* G12 mutations. This approval is based on data from the ongoing phase 1 RMC-6236-001 trial.[325] The phase 3 RASolute 302[326] trial of daraxonrasib versus investigator's choice of standard of care chemotherapy in patients with metastatic PDAC who experienced disease progression on first-line chemotherapy (5-FU–based or gemcitabine-based) is ongoing, with results expected in 2026. Together, these data demonstrate promise for *KRAS* mutation–targeted therapy in this disease.[327]

KEY POINTS

- Exocrine pancreatic cancer is an aggressive disease with an incidence nearly equaling the mortality rate and a 5-year survival rate of 13%.
- Several lifestyle risk factors are associated with the risk of pancreatic cancer.
- Genetic testing for inherited mutations is recommended for any patient with confirmed pancreatic cancer, using comprehensive gene panels for hereditary cancer syndromes.
- Best surveillance screening for affected relatives continues to be the subject of ongoing trials, and family members should be referred to centers with expertise in this area.
- Presenting symptoms of pancreatic cancer are vague but often include abdominal or back pain, jaundice, and cachexia.
- Staging should include CT scans of chest, abdomen, and pelvis with appropriate arterial phasing to assess the abdominal vasculature.
- Pathologic diagnosis is best obtained by EUS biopsy for patients who have localized disease, and patients who have biliary obstruction for whom immediate surgery is not planned should undergo biliary stenting.
- Although formal TNM staging exists, in practice, tumors are best classified as resectable, borderline resectable, locally advanced unresectable, and metastatic disease.
- Six months of modified FOLFIRINOX (mFOLFIRINOX) treatment is the standard of care for fit patients with resected pancreatic cancer.

- For those patients not felt to be candidates for mFOLFIRINOX, 6 months of treatment with gemcitabine and capecitabine or gemcitabine alone can be considered.
- The optimal preoperative regimen for patients with pancreatic cancer remains debated. For patients with resectable pancreatic cancer, resection followed by adjuvant chemotherapy or perioperative chemotherapy are both appropriate and being compared in an ongoing trial.
- For borderline resectable patients, initial chemotherapy with either FOLFIRINOX or gemcitabine/nab-paclitaxel are reasonable options with reevaluation for resection.
- For locally advanced unresectable patients, initial chemotherapy with either FOLFIRINOX or gemcitabine/nab-paclitaxel is reasonable with reevaluation for local radiation therapy in select patients. There are numerous active studies testing neoadjuvant chemotherapy and CRT for resectable and borderline resectable pancreatic cancers, and although the data are early and based on relatively small trials, there is a suggestion of a survival advantage with a neoadjuvant approach compared with surgery and adjuvant chemotherapy in the borderline resectable pancreatic cancer population.
- Although the exact definition of locally advanced unresectable disease differs by guideline, contraindications to successful surgical resection often include: >180° encasement of the superior mesenteric artery or portal vein or direct involvement of the celiac axis or common hepatic artery deemed unreconstructable.
- Determination of unresectability must be made in conjunction with a multidisciplinary team at a high-volume pancreatic cancer center.
- Treatment should include initial multiagent chemotherapy with consideration of CRT in those who do not experience progression. The exact duration of therapy is not well defined.
- After definitive therapy, the patient should be reevaluated by the multidisciplinary team to determine if the cancer is now potentially resectable.
- All patients with metastatic pancreatic cancer should be referred to a palliative care specialist if available.
- mFOLFIRINOX, NALIRIFOX, and gemcitabine/nab-paclitaxel are considered appropriate first-line regimens. Choice should be based on the patient's PS, underlying organ dysfunction, and presence or absence of germline *BRCA1/2* mutations.
- Patients with *BRCA1/2* germline mutations who do not experience progression during at least 16 weeks of a platinum-containing regimen could be considered for olaparib maintenance therapy. A less toxic gemcitabine and cisplatin chemotherapy regimen can also be considered for initial chemotherapy in these patients.
- Second-line treatment should be based on first-line treatment and the patient's overall functional status. These patients should be considered for a clinical trial if available. Liposomal irinotecan and 5-FU can be considered for those who experience progression with gemcitabine and nab-paclitaxel based on the NAPOLI-1 data.

HIGH-YIELD TAKEAWAYS

- Common presenting symptoms for GEC include dysphagia, anorexia, early satiety, nausea, dyspepsia, pain, bleeding, and hematemesis. Individuals who carry a germline *CDH1* mutation are at substantial lifetime risk of developing gastric cancer and should undergo risk-reducing prophylactic gastrectomy as early as in their 20s. Nivolumab is a standard-of-care adjuvant treatment of patients with esophageal and GEJ adenocarcinoma with residual disease after preoperative chemoradiation.
- Perioperative FLOT chemotherapy is the standard treatment of patients with resectable microsatellite stable esophageal, GEJ, and gastric adenocarcinoma.
- Patients with advanced E/GEJ/G adenocarcinoma should have their tumor tested for the following biomarkers for optimal first-line treatment selection: HER2, PD-L1 CPS, CLAUDIN 18.2, and MMR expression/microsatellite status.
- Immunotherapy-based regimens are standard of care first-line systemic treatment for patients with HCC.
- Chemoimmunotherapy comprising gemcitabine and cisplatin with either durvalumab or pembrolizumab is a new standard of care option for first-line treatment of patients with advanced BTCs regardless of PD-L1 expression.
- NGS should be incorporated into routine standard of care of patients with advanced BTC to identify actionable molecular abnormalities (*FGFR2* fusions, *IDH1* mutations, *HER2* amplification, *BRAF* V600E, and *MSI*-high).
- mFOLFIRINOX, NALIRIFOX, and gemcitabine/nab-paclitaxel are considered appropriate first-line regimens for patients with metastatic pancreatic cancer. Choice should be based on the patient's PS, underlying organ dysfunction, and presence or absence of germline *BRCA1/2* mutations, for which platinum-containing regimen is preferred.
- Patients with pancreatic cancer and *BRCA1/2* germline mutations who do not experience progression on a platinum-containing regimen could be considered for olaparib maintenance therapy.

Acknowledgments

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

UPPER GASTROINTESTINAL CANCERS 13.1

CHAPTER SUMMARY GUIDE

KEY POINTS

- Beyond known histopathologic and epidemiological distinctions, molecular features differentiate ESCC from esophageal adenocarcinoma with SCC resembling SCCs of other organs more than it does esophageal adenocarcinoma, whereas esophageal adenocarcinoma predominantly resembles the CIN type found in gastric adenocarcinoma.
- The Cancer Genome Atlas project proposed a molecular classification dividing esophageal and GEJ adenocarcinomas and gastric adenocarcinoma (together, gastroesophageal adenocarcinoma (GEA)) into four subtypes: tumors positive for Epstein–Barr virus, MSI-H unstable tumors, genomically stable tumors, and tumors with CIN.
- Individuals who carry a germline *CDH1* mutation are at substantial lifetime risk of developing gastric cancer and should undergo risk-reducing prophylactic gastrectomy as early as in their 20s.
- All patients with *H. pylori* infection should undergo treatment.
- Common presenting symptoms for GEC include dysphagia, anorexia, early satiety, nausea, dyspepsia, pain, bleeding, and hematemesis.
- Cross-sectional imaging including PET, EUS, and laparoscopic staging for patients with gastric and Siewert III GEJ tumors are critical to determine the location and stage of the tumor.
- Combined-modality CRT followed by resection is the standard neoadjuvant approach in the treatment of locally advanced ESCC.
- Definitive CRT (without surgery) is a valid treatment option for patients who have ESCC, especially if patients are high-risk surgical candidates.
- One year of adjuvant nivolumab for patients who have esophageal cancer (both SCC and adenocarcinoma) who received neoadjuvant CRT followed by surgery with residual pathological disease (T+ and/or N+; R0 resection) is the standard of care based on the improved DFS observed in CheckMate 577.[95,107]
- The positive results from ESOPEC, FLOT4-AIO, and MATTERHORN established perioperative systemic therapy as the preferred approach for patients with resectable esophageal, GEJ, and gastric cancers who are candidates for surgery and intensive systemic therapy.
- Perioperative FLOT plus durvalumab is a standard for patients with resectable esophageal, GEJ, or gastric cancers who are candidates for surgery.
- Adjuvant nivolumab for 1 year is the standard for patients with resected esophageal or GEJ tumors who received preoperative chemoradiation and have residual pathological disease after surgical resection.
- Adjuvant CAPOX without radiation therapy was superior for tumors with at least muscle invasive (≤T2) and/or node-positive disease (≤N1) in patients with an adequate D2 lymphadenectomy compared with surgery alone based on the CLASSIC study. This should be considered in patients who do not receive preoperative systemic chemotherapy or preoperative chemoradiation.
- Immune checkpoint inhibitor(s) should be considered for patients with resectable MSI-H/mismatch repair (MMR)-deficient esophageal or GEJ adenocarcinoma in either neoadjuvant or perioperative approaches.
- The addition of anti-PD1, pembrolizumab, nivolumab, or tislelizumab to combination chemotherapy is considered a standard in the first-line treatment of unresectable, metastatic ESCC. The benefit increases with increasing tumor PD-L1 expression. The NCCN guideline recommends the addition of anti-PD1 to chemotherapy in patients with tumor PD-L1 composite score ≥1.
- In the CheckMate 648 study, ipilumumab plus nivolumab achieved better OS than chemotherapy alone and was numerically shorter than nivolumab plus chemotherapy. Ipilimumab plus nivolumab may be considered for patients with tumor PD-L1 CPS ≥1 who are not candidates for anti-PD1 and chemotherapy combination.
- The CheckMate 649 study established that nivolumab when combined with fluoropyrimidine and platinum improved both PFS and OS compared with chemotherapy alone in patients who have GEAs with pronounced benefit seen in patients with tumors PD-L1 CPS ≥5.
- The KEYNOTE-590 and KEYNOTE-859 studies demonstrated PFS and OS benefit with the addition of pembrolizumab to fluoropyrimidine/platinum chemotherapy when compared with chemotherapy alone in GEAs. This benefit was pronounced in tumors PD-L1 CPS ≥10.

- Zolbetuximab in combination with fluoropyrimidine and platinum-containing chemotherapy is indicated for the treatment of CLDN 18.2 positive, HER-2 negative GEA.
- The addition of trastuzumab and pembrolizumab to platinum and fluoropyrimidine is the standard of care in HER2-positive ($IHC3^+$ or $IHC2^+/FISH^+$) and PD-L1–positive (CPS ≥ 1) metastatic GEAs.
- In patients who have tumors that are HER2 positive but PD-L1 negative, the standard treatment is platinum with fluoropyrimidine and trastuzumab.
- Nivolumab is FDA-approved second-line therapy for all ESCCs based on results from the ATTRACTION-3 study.
- Pembrolizumab is FDA-approved second-line therapy for patients who have metastatic ESCC with PD-L1 expression levels of CPS ≥10 based on results from KEYNOTE-181. In patients who have not received checkpoint inhibitor therapy as part of their first-line treatment, nivolumab or pembrolizumab monotherapy might be a viable option.
- The VEGFR antibody ramucirumab has shown efficacy in second-line phase 3 trials in advanced GEA and is now a standard-of-care option either alone or with paclitaxel therapy, leading to an NCCN guideline listing (category 1). Retrospective and prospective analyses show historically similar efficacy for FOLFIRI and ramucirumab compared with paclitaxel and ramucirumab with a potentially better toxicity profile, particularly for patients previously treated with taxanes, leading to an NCCN guideline listing (category 2A). However, no randomized controlled studies evaluating agents targeting angiogenesis in the first-line setting have shown an OS benefit.
- Approximately 50% of patients have preserved PS and derive benefit from continued treatment with palliative therapy in the second-line setting.
- Third-line chemotherapy has demonstrated a benefit compared with best supportive care or placebo, including with trifluridine and tipiracil (TAS-102), and should be considered for patients with preserved PS after two or more lines of therapy.
- The phase 2 randomized open-label DESTINY-GASTRIC01 study in Asian patients showed an improved ORR as well as PFS and OS for trastuzumab deruxtecan in comparison with chemotherapy as third-line or higher therapy for metastatic HER2-positive GEA, which led to FDA approval on January 15, 2021.
- HCC is an important cancer, and global incidence can be reduced by vaccination against hepatitis B virus; treatment of hepatitis C is curative, which may lead to reduced incidence of HCC in the coming years. Alcohol abuse, obesity, and metabolic syndrome represent modifiable risk factors, the moderation of which could also reduce worldwide incidence of the disease.
- The Barcelona Clinic Liver Cancer staging classification and treatment schedule have served as a main paradigm on how to broadly stage and treat HCC.
- Local ablative treatments are generally reserved for intermediate disease. These approaches include TACE, TARE, alcohol injection, radiofrequency ablation, microwave ablation, and external-beam radiation therapy or stereotactic radiation therapy.
- Combination locoregional plus systemic therapy options show promise in the intermediate stage of the disease and require further optimization.
- There is no role for adjuvant treatment in patients with resected HCC.
- The SHARP study established the first standard systemic therapy in HCC with sorafenib.[201]
- The IMbrave 150 study confirmed the benefit of atezolizumab and bevacizumab in first-line treatment compared with sorafenib for advanced HCC.[199]
- The HIMALAYA study demonstrated the role of tremelimumab and durvalumab as a first-line treatment option compared with sorafenib for advanced HCC.[10]
- CHECKMATE 9DW demonstrated the role of ipilimumab and nivolumab as a first-line treatment option compared with investigator's choice of sorafenib or lenvatinib for advanced HCC.[11]
- The REFLECT study confirmed the noninferiority of lenvatinib in first-line treatment compared with sorafenib for advanced HCC.[208]
- The RESORCE study confirmed the benefit of regorafenib in second-line treatment compared with placebo for advanced HCC.[213]
- The CELESTIAL study confirmed the benefit of cabozantinib in second- and third-line treatment compared with placebo for advanced HCC after sorafenib.[215]
- The REACH-2 study confirmed the benefit of ramucirumab in the second-line treatment of patients with AFP level ≥400 ng/mL compared with placebo for advanced HCC.[219,223]
- Immune checkpoint blockade has great promise in HCC with improved response rates and meaningful DOR in select patients with response to anti-PD-1 monotherapy. However, to date, treatment with monotherapy checkpoint blockade has not demonstrated definitive survival benefit in any patients in larger phase 3 randomized studies compared with sorafenib in the first-line setting or placebo in the second-line setting. Biomarker studies to identify those who may derive the most benefit are ongoing.

- The treatment paradigm of advanced HCC is in flux with the addition of all these agents relatively simultaneously without direction on the best sequencing approach.
- Resection, when feasible, is the mainstay of treatment of hepatobiliary tumors.
- The randomized phase 3 BILCAP study of adjuvant capecitabine versus observation in resected BTCs demonstrated improved OS in the prespecified per-protocol analysis and can be considered a standard of care.
- There is limited clinical evidence supporting the adoption of concurrent radiation therapy in the adjuvant setting, but this could be considered for patients who have high risk of relapse, such as patients who have positive LN disease and positive microscopic margins.
- Chemoimmunotherapy comprising durvalumab with gemcitabine and cisplatin as well as pembrolizumab with gemcitabine and cisplatin is a new standard of care option for first-line treatment of patients with advanced BTCs.
- The combination of 5-FU with oxaliplatin represents an appropriate second-line therapy for patients lacking an actionable somatic mutation who have developed progressive disease during gemcitabine and platinum combination therapy based on the ABC-06 trial.
- NGS should be incorporated into routine standard of care for patients who have advanced BTC to identify actionable molecular abnormalities (*FGFR2* fusions, *IDH1* mutations, *HER2* amplification, *BRAF* V600E, and MSI-high).
- The phase 3 ClarIDHy trial with the IDH1 inhibitor ivosidenib versus placebo for *IDH1*-mutated cholangiocarcinoma met its primary endpoint of PFS with the added benefit of improved quality-of-life.
- The FGFR inhibitors pemigatinib and futibatinib have received accelerated FDA approval for the treatment of *FGFR2* fusion–positive or *FGFR2* rearrangement–positive cholangiocarcinoma. The ROAR basket study using the combination of dabrafenib and trametinib showed benefit for patients who have BTC harboring *BRAF* V600E–mutations.
- Zanidatamab is a new bispecific antibody targeting HER2 that has been FDA-approved to treat unresectable or metastatic HER2-positive (IHC3+) BTC previously treated with gemcitabine-based chemotherapy.
- Exocrine pancreatic cancer is an aggressive disease with an incidence nearly equaling the mortality rate and a 5-year survival rate of 13%.
- Several lifestyle risk factors are associated with the risk of pancreatic cancer.
- Genetic testing for inherited mutations is recommended for any patient with confirmed pancreatic cancer, using comprehensive gene panels for hereditary cancer syndromes.
- Best surveillance screening for affected relatives continues to be the subject of ongoing trials, and family members should be referred to centers with expertise in this area.
- Presenting symptoms of pancreatic cancer are vague but often include abdominal or back pain, jaundice, and cachexia.
- Staging should include CT scans of chest, abdomen, and pelvis with appropriate arterial phasing to assess the abdominal vasculature.
- Pathologic diagnosis is best obtained by EUS biopsy for patients who have localized disease, and patients who have biliary obstruction for whom immediate surgery is not planned should undergo biliary stenting.
- Although formal TNM staging exists, in practice, tumors are best classified as resectable, borderline resectable, locally advanced unresectable, and metastatic disease.
- Six months of modified FOLFIRINOX (mFOLFIRINOX) treatment is the standard of care for fit patients with resected pancreatic cancer.
- For those patients not felt to be candidates for mFOLFIRINOX, 6 months of treatment with gemcitabine and capecitabine or gemcitabine alone can be considered.
- The optimal preoperative regimen for patients with pancreatic cancer remains debated. For patients with resectable pancreatic cancer, resection followed by adjuvant chemotherapy or perioperative chemotherapy are both appropriate and being compared in an ongoing trial.
- For borderline resectable patients, initial chemotherapy with either FOLFIRINOX or gemcitabine/nab-paclitaxel are reasonable options with reevaluation for resection.
- For locally advanced unresectable patients, initial chemotherapy with either FOLFIRINOX or gemcitabine/nab-paclitaxel is reasonable with reevaluation for local radiation therapy in select patients. There are numerous active studies testing neoadjuvant chemotherapy and CRT for resectable and borderline resectable pancreatic cancers, and although the data are early and based on relatively small trials, there is a suggestion of a survival advantage with a neoadjuvant approach compared with surgery and adjuvant chemotherapy in the borderline resectable pancreatic cancer population.
- Although the exact definition of locally advanced unresectable disease differs by guideline, contraindications to successful surgical resection often include: >180° encasement of the superior mesenteric artery or portal vein or direct involvement of the celiac axis or common hepatic artery deemed unreconstructable.
- Determination of unresectability must be made in conjunction with a multidisciplinary team at a high-volume pancreatic cancer center.

- Treatment should include initial multiagent chemotherapy with consideration of CRT in those who do not experience progression. The exact duration of therapy is not well defined.
- After definitive therapy, the patient should be reevaluated by the multidisciplinary team to determine if the cancer is now potentially resectable.
- All patients with metastatic pancreatic cancer should be referred to a palliative care specialist if available.
- mFOLFIRINOX, NALIRIFOX, and gemcitabine/nab-paclitaxel are considered appropriate first-line regimens. Choice should be based on the patient's PS, underlying organ dysfunction, and presence or absence of germline *BRCA1/2* mutations.
- Patients with *BRCA1/2* germline mutations who do not experience progression during at least 16 weeks of a platinum-containing regimen could be considered for olaparib maintenance therapy. A less toxic gemcitabine and cisplatin chemotherapy regimen can also be considered for initial chemotherapy in these patients.
- Second-line treatment should be based on first-line treatment and the patient's overall functional status. These patients should be considered for a clinical trial if available. Liposomal irinotecan and 5-FU can be considered for those who experience progression with gemcitabine and nab-paclitaxel based on the NAPOLI-1 data.

CHAPTER TABLES AND IMAGES

Table 13.1-1 First-line Treatment Options for Advanced Esophago-Gastric Adenocarcinoma

Tumor Characteristics	Treatment
HER2+[a] and PDL1 CPS ≥1	Chemotherapy, trastuzumab, and pembrolizumab
HER2+[a] and PDL1 CPS <1	Chemotherapy and trastuzumab
HER2−[a] and PDL1 CPS ≥1	Chemotherapy and anti-PD1 ab[b]
CLAUDIN 18.2+[c]	Chemotherapy and zolbetuximab
HER2− and PDL1 CPS <1, CLAUDIN 18.2−	Chemotherapy
dMMR/MSI-H	Anti-PD1 ab +/− anti-CTLA4 ab[d] OR chemotherapy + anti-PD1[e]

Abbreviations: CPS, combined positive score; dMMR, deficient DNA mismatch repair; MSI-H, microsatellite instability-high.
[a]HER2+: IHC 3 + or IHC2+/ISH+; HER2-: IHC 1+ or IHC2+/ISH−
[b]Nivolumab, tislelizumab, or pembrolizumab.
[c]Claudin 18.2 moderate or strong expression by IHC in ≥75% tumor cells.
[d]Pembrolizumab, dostarlimab, nivolumab + ipilumumab.
[e]Nivolumab, pembrolizumab.

Table 13.1-2 **Current Clinical Trials Paradigm for Hepatocellular Carcinoma**

Treatment Line	Outcome	Notes	Study
First			
Sorafenib vs placebo	Superiority study	First approved first-line therapy, December 1, 2007	SHARP study[201]
Lenvatinib vs sorafenib	Noninferiority study	Approved August 16, 2018	REFLECT study[208]
Atezolizumab and bevacizumab vs sorafenib	Superiority study	Approved May 29, 2020	IMbrave 150 study[199]
Durvalumab and tremelimumab vs sorafenib	Superiority study	Approved October 21, 2022	HIMALAYA study[10]
Nivolumab and ipilimumab vs investigator's choice of sorafenib or lenvatinib	Superiority study	Approved April 11, 2025	CheckMate 9DW study[11]
Second			
Regorafenib vs placebo	Superiority study	First approved second-line therapy, April 27, 2017	RESORCE study[213]
Ramucirumab vs placebo	Superiority study	AFP ≥400 ng/mL eligible; approval May 10, 2019	REACH-2 study[219]
Pembrolizumab		Conditional approval December 17, 2018; has not been removed	KEYNOTE-224 study,[220,221] KEYNOTE-240 study,[216] KEYNOTE-394 study[218]
Nivolumab and ipilimumab		Accelerated approval March 10, 2020	CheckMate 040 study[222]
Second and third			
Cabozantinib vs placebo	Superiority study	Approved January 14, 2019	CELESTIAL study[215]

Abbreviation: AFP, alpha-fetoprotein.
FDA approval of second-line nivolumab is revoked because of lack of efficacy in confirmatory study.

Table 13.1-3 **Germline Mutations Associated With Pancreatic Cancer**	
Mutated Gene	**Syndrome**
BRCA1, *BRCA2*	Hereditary breast and ovarian syndrome
ATM	Ataxia-telangiectasia
PALB2	Hereditary breast cancer
PRSS1	Hereditary pancreatitis
STK11	Peutz-Jeghers syndrome
CDKN2A	Familial atypical multiple mole and melanoma syndrome
MLH1, *MLH2*, *MSH6*, *PMS2*	Lynch syndrome

Abbreviations: *ATM*, *ATM* serine/threonine kinase; *BRCA1/2*, *BRCA1/2* DNA repair–associated protein; *CDKN2A*, cyclin-dependent kinase inhibitor 2A; *MLH1/2*, DNA mismatch repair protein *MLH1/2*; *MSH6*, MutS homolog 6; *PALB2*, partner and localizer of *BRCA2*; *PRSS1*, protease, serine 1; *STK11*, serine/threonine protein kinase 11.

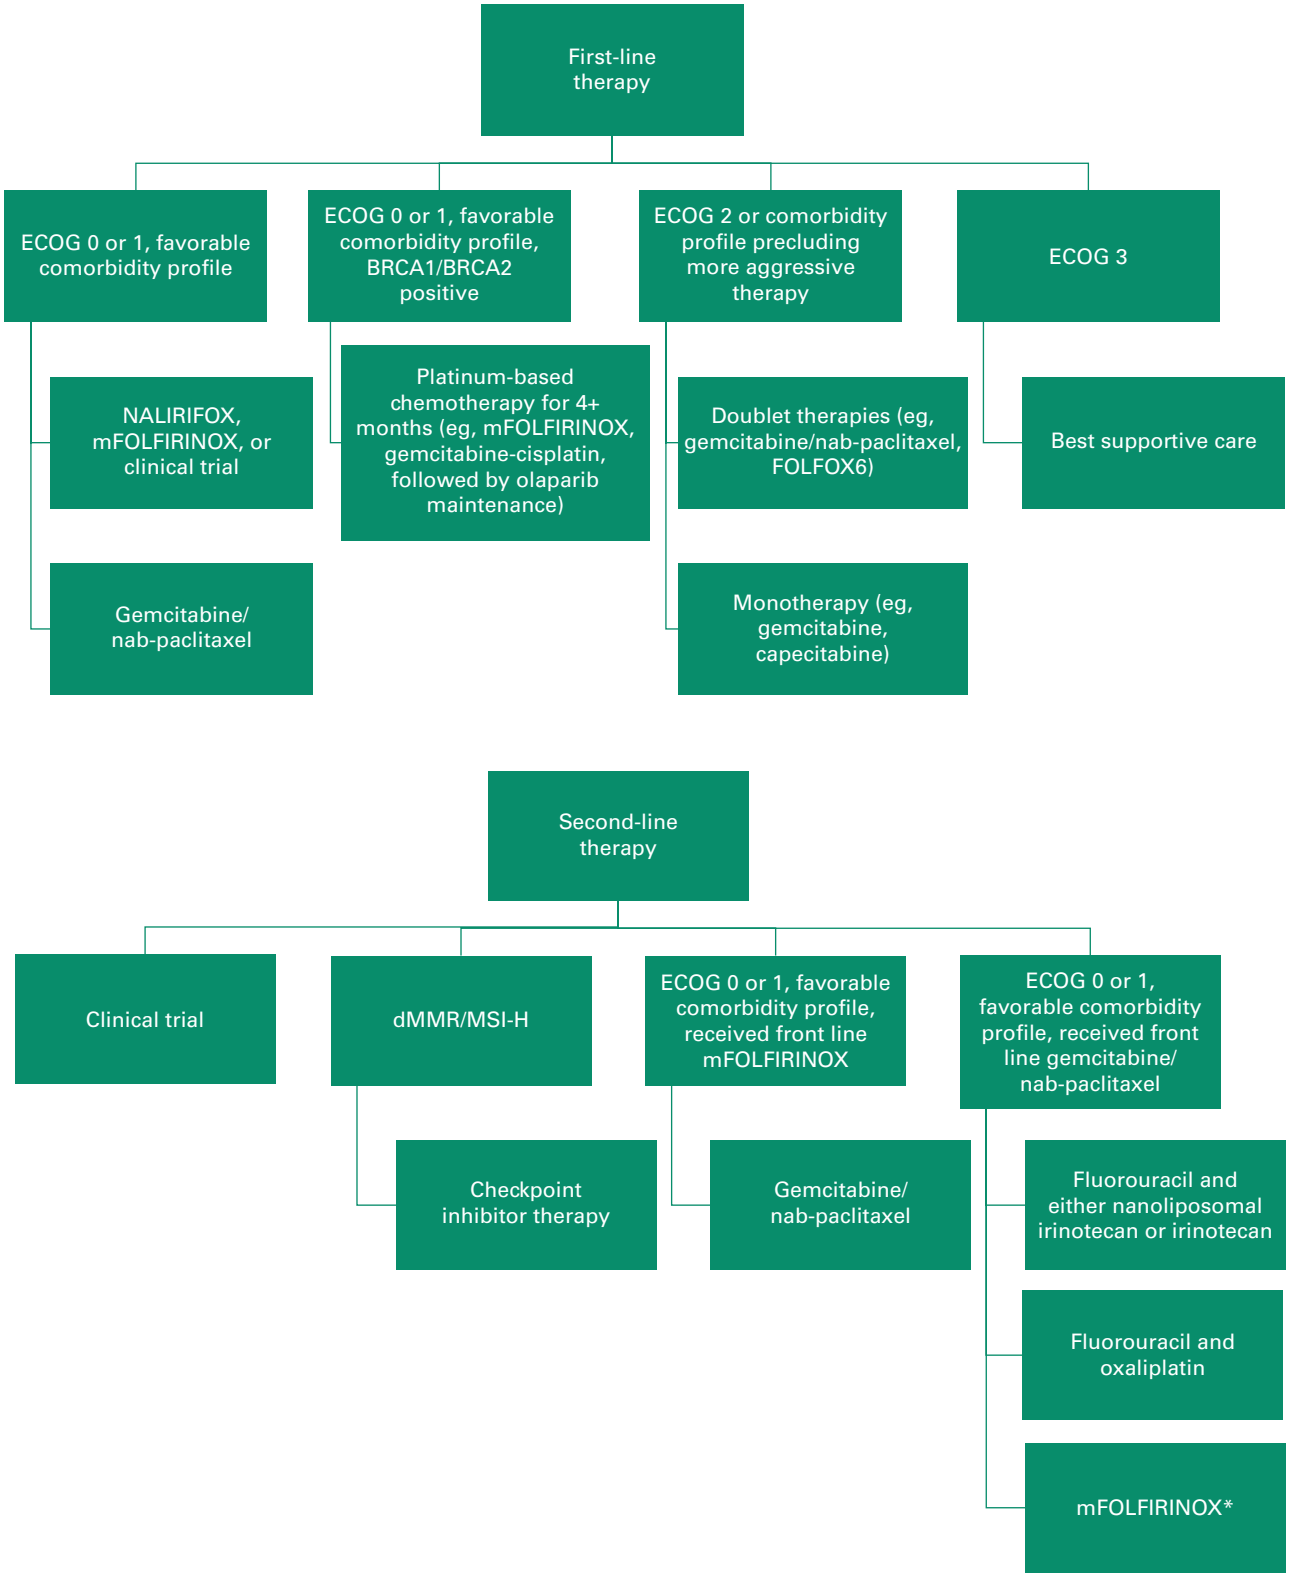
Figure 13.1-1 Treatment Algorithm for Metastatic Pancreatic Cancer



Abbreviations: dMMR, mismatch repair deficient; ECOG, Eastern Cooperative Oncology Group; FOLFOX6, 5-fluorouracil, leucovorin, and oxaliplatin; mFOLFIRINOX, modified regimen of leucovorin, fluorouracil, irinotecan, and oxaliplatin; MSI-H, microsatellite instability high; NALIRIFOX, liposomal irinotecan, 5-fluorouracil, leucovorin, and oxaliplatin.
*Only for those patients deemed medically fit.

LOWER GASTROINTESTINAL CANCERS 13.2

Steven J. Cohen, MD, and Katrina S. Pedersen, MD, MS

RECENT UPDATES

Colorectal Cancer

- In the ALASCCA randomized clinical trial, 626 patients with stage 1 to 3 rectal cancer or stage 2 to 3 colon cancer with alterations in the PI3K pathway were randomized to receive aspirin 160 mg or placebo for 3 years. For the primary outcome measure, the use of aspirin was associated with a significantly decreased risk of colorectal cancer recurrence whether the tumor had a *PIK3CA* exon 9/20 mutation (3-year recurrence 7.7% vs 14.1%, HR, 0.49, P = 0.044) or other PI3K pathway alteration (3-year recurrence 7.7% vs 16.8%, HR, 0.42, P = .013). For the secondary outcome measure of 3-year disease-free survival, the use of aspirin was also associated with an improvement in the other PI3K pathway group (89.1% vs 78.7%, HR = 0.51, P = .017). These data have been incorporated into guidelines, with implications for testing all early-stage colorectal cancer tumors for alterations in the PI3K pathway.[328]
- Exercise has long been associated with improved colon cancer-specific survival. The Canadian Cancer Trials Group (CCTG) CO.21 CHALLENGE trial was the first randomized trial to evaluate whether a structured exercise program could improve colon cancer survival. In this trial, 889 patients primarily from Canada or Australia with resected stage 3 or high-risk stage 2 colon cancer after 2-6 months of adjuvant therapy were randomized to a 3-year structured exercise program and given health education materials or only given health education materials. The goal of the structured exercise program was to increase physical activity by 10 MET/hours/week above baseline, with 1 hour of brisk walking equivalent to 4 MET-hours. The primary endpoint of 3-year disease-free survival (DFS) was improved in the structured exercise arm from 73.9% to 80.3%, HR 0.72, P = 0.017. The secondary endpoint of 8-year overall survival (OS) was also improved, from 83.2% to 90.3%, HR, 0.63, P = .022. While there are questions about the applicability in everyday practice, these data support recommendations to colorectal cancer survivors for increasing physical activity.[329]
- *BRAF* V600E mutations are present in 5% to 10% of metastatic colorectal cancer and have been associated with poor prognosis. The BREAKWATER built upon demonstration of benefit of the encorafenib/cetuximab combination in second-line therapy from the BEACON trial and investigated encorafenib/cetuximab (EC) plus mFOLFOX6 (modified FOLFOX regimen: 5-fluorouracil, leucovorin, and oxaliplatin) versus standard of care chemotherapy as initial therapy for untreated metastatic *BRAF* V600E colorectal cancer. The initial report demonstrated that EC + mFOLFOX6 had increased ORR, 60.9% versus 40.0% with SOC chemotherapy. Median duration of response was 13.9 versus 11.1 months. A subsequent presentation and manuscript extended the analysis and follow-up, reporting a statistically significant improvement in progression-free survival for the addition of EC (median, 12.8 vs 7.1 months; hazard ratio for progression or death, 0.53; 95% confidence interval [CI], 0.41 to 0.68; P < .001). An interim analysis also demonstrated improved OS with the addition of EC to FOLFOX (median, 30.3 vs 15.1 months; hazard ratio for death, 0.49; 95% CI, 0.38-0.63; P < .001). Side effects were modestly increased but consistent with known profiles of these agents. These data highlight the importance of testing for *BRAF* mutations with initial diagnosis of metastatic disease.[330] As a result of this trial, NCCN guidelines were updated as well as the FDA approval for encorafenib and cetuximab in combination with mFOLFOX6 for treatment of patients with metastatic colorectal cancer (CRC) with a *BRAF* V600E mutation.

Anal Squamous Cell Cancer

- For many years, there was no standard treatment for recurrent or metastatic anal squamous cell cancer (ASCC). This changed with the presentation and publication of the POD1UM-303/InterAACT 2 trial, which was a phase 3,

double-blind, controlled trial. The trial enrolled and randomized 303 patients with treatment-naive locally recurrent or metastatic ASCC to receive either first-line carboplatin, paclitaxel, and a placebo or carboplatin, paclitaxel, and retifanlimab, a PD-1 inhibitor In this study, patients were randomly assigned to six cycles of standard-dosage carboplatin and paclitaxel plus placebo (P arm) or retifanlimab (PD-1 inhibitor) 500 mg q4w (R arm) for up to 1 year with possibility of crossover. The trial met its primary endpoint with the median progression-free survival (PFS) improving from 7.4 months in the placebo arm to 9.30 months in patients receiving retifanlimab (HR, 0.63 [95% CI], 0.63 [0.47-0.84]; *P* = .0006). Follow-up remains immature, though currently suggests retifanlimab with chemotherapy despite crossover is trending toward improved mOS (29.2 vs 23.0 months, HR, 0.70 [95% CI, 0.49-1.01]. As a result of these data, in May 2025, the FDA approved carboplatin/paclitaxel/retifanlimab for first-line treatment of advanced, anal squamous cell cancer, and is the current standard of care for patients eligible to receive immunotherapy.

OVERVIEW

The management of lower gastrointestinal cancers has evolved significantly, increasingly leveraging molecular profiling to guide clinical decision-making. For colorectal cancer (CRC), adjuvant therapy in stage II disease requires risk stratification and shared decision-making; notably, patients with stage IIA dMMR/MSI-H tumors have an excellent prognosis and do not require adjuvant chemotherapy. For stage III colon cancer, 6 months of FOLFOX or CAPOX remains a standard, though 3 months of CAPOX is a reasonable alternative for T1–3 and N1 disease to reduce neurological toxicities. In the metastatic setting, treatment is guided by extended *RAS*, *BRAF*, *MSI*, and *HER2* mutation testing. First-line management for MSI-H/dMMR metastatic CRC is centered on immunotherapy, such as single-agent pembrolizumab or the combination of nivolumab and ipilimumab. For *BRAF* V600E–mutated metastatic CRC, current standards support the use of encorafenib and cetuximab in combination with mFOLFOX6. Circulating tumor DNA (ctDNA) is also emerging as a highly specific prognostic tool for monitoring minimal residual disease (MRD), which may soon refine adjuvant therapy intensity.

For anal squamous cell cancer (ASCC), definitive chemoradiation remains the standard for localized disease. As of May 2025, the FDA-approved regimen of carboplatin, paclitaxel, and retifanlimab serves as the standard of care for first-line treatment of advanced ASCC in patients eligible for immunotherapy. Regarding neuroendocrine tumors (NETs), management is dictated by tumor site, histological grade, and functional status. Somatostatin analogs like octreotide and lanreotide are utilized as first-line therapy for advanced well-differentiated NETs. Peptide receptor radionuclide therapy (PRRT) with ^{177}Lu is indicated for progressive disease, with recent data supporting its activity in the first-line setting for specific grade 2 and 3 tumors. Targeted options for pancreatic NETs include sunitinib, everolimus, and cabozantinib, with cabozantinib also approved for extrapancreatic GI NETs. Surgical resection remains the primary curative approach for isolated or oligometastatic disease, necessitating multidisciplinary evaluation.

Regarding rectal cancer, current treatment of locally advanced rectal cancer (LARC) is centered on total neoadjuvant therapy (TNT) strategies, in which chemotherapy and radiation therapy are used neoadjuvantly before total mesorectal excision (TME). Selected patients who achieve a clinical complete response after TNT or immunotherapy may be considered for nonoperative management (NOM) with "watch & wait" surveillance.

COLORECTAL CARCINOMA

EPIDEMIOLOGY AND ETIOLOGY

In 2025, colorectal cancer (CRC) was estimated to affect approximately 154,270 patients in the United States.[331] Among all cancers, it is the second leading cause of death in the United States (n = 52,900) and affects men and women equally (second only to lung cancer).[254] The incidence of CRC is higher in developed countries than in developing countries. In the last two decades, there have been decreases in the incidence and mortality rate of CRC in the United States in the overall population, likely due to improved adherence to screening recommendations.[22] Findings from epidemiologic studies indicate that, during the last two decades, the anatomic distribution of CRC may have shifted from the distal to the proximal colon, but alarmingly, there has also been a particularly sharp increase in the incidence of distal colon and rectal cancers among persons under 50 years (early-onset) that are mostly not associated with germline mutations and high inherited cancer risk.[332] These results indicate strong environmental associations for CRC. For colorectal cancer as a whole, data from prospective interventional studies indicating an association among dietary fiber, calcium, fat intake, and CRC are not clear.[333,334] Additional environmental factors include the intake of alcohol and tobacco, antibiotics, hormone replacement in women (protective), total calorie consumption, and physical activity as it relates to obesity.[335]

FAMILIAL SYNDROMES

The two most common inherited forms of CRC are those associated with Lynch syndrome and the familial adenomatous polyposis (FAP) syndrome. These two recognized genetic syndromes are distinct in their molecular biology and clinical characteristics.

FAP Syndrome

The first syndrome to be recognized was familial adenomatous polyposis (FAP) (Fig. 13.2-1). FAP syndrome is caused by an inherited germline mutation in the adenomatous polyposis coli (*APC*) gene, a key regulator of the Wnt signaling pathway. Mutations in the *APC* gene lead to the formation of a dysfunctional protein, which cannot bind to β-catenin; thus, β-catenin can then activate the transcription of various oncogenes. Patients who have a germline *APC* mutation have hundreds to thousands of colonic polyps, predisposing them to malignant tumors at a young age. Although FAP represents a small percentage (~0.5%-1%) of the overall number of cases of CRC, somatic *APC* (or β-catenin) mutations activating the Wnt signaling pathway have been found in a majority (80%-85%) of sporadic CRCs. Additional gene expression studies along the adenoma-to-carcinoma sequence (Fig. 13.2-2) provide an important genetic model in which specific genetic mutations, leading to invasive CRCs, have been clearly elucidated.[336]

Lynch Syndrome

Lynch syndrome (previously known as hereditary nonpolyposis colorectal cancer [HNPCC]) is an inherited autosomal dominant disease with high penetrance. It is the most common hereditary colorectal syndrome, accounting for approximately 5% of CRCs (Table 13.2-1). CRC generally develops at an early age in these patients (median age, 45 years) and most commonly in the proximal colon. Other malignancies associated with the genetic syndrome include endometrial, ovarian, pancreatic, breast, biliary, gastric, bladder, prostate, cutaneous squamous cell carcinomas, and small bowel adenocarcinomas. Although the Amsterdam and Bethesda criteria have traditionally been used to identify patients who should be considered for genetic testing, there is a push for universal germline testing in all patients diagnosed with CRC. Due to its prevalence and now the predictive nature of high microsatellite instability in the immunotherapeutic treatment of colorectal cancers, all newly diagnosed colorectal cancers should have at least DNA mismatch repair (MMR) genes assessed via IHC, or microsatellite instabity established by PCR or NGS.

Table 13.2-1 Clinical Criteria to Determine Likelihood of Lynch Syndrome

Amsterdam II criteria (all criteria must be met)
At least three relatives with Lynch syndrome–associated cancer (CRC, cancer of endometrium, small bowel, ureter, or renal pelvis)
One relative should be a first-degree relative of the other two
Malignancies should include at least two successive generations
At least one family member should have been diagnosed at age <50 years
Familial adenomatous polyposis is excluded
Tumors should be verified by pathological examination
Revised Bethesda criteria to identify patients with CRC who should undergo pathological examination for Lynch syndrome (any criterion is sufficient)
Synchronous or metachronous CRC or associated with another Lynch syndrome–associated tumor (ie, endometrial, stomach, small intestine, ovarian, pancreatic, biliary tract, ureter or renal pelvis, brain, sebaceous gland adenoma, or keratoacanthoma)
Pathological features of MSI-H cancer (eg, tumor-infiltrating lymphocytes, Crohn-like lymphocytic reaction, mucinous/signet-ring differentiation, medullary growth pattern) in patient age <60 years
Development of CRC in individual who has a first-degree relative with CRC and/or Lynch syndrome–related extracolonic cancer and/or colorectal adenoma, with one of the cancers diagnosed before the patient reaches age 50 years or an adenoma diagnosed at age <40 years
CRC in two or more first- or second-degree relatives with Lynch syndrome–related tumors, regardless of age

Abbreviations: CRC, colorectal cancer; MSI-H, microsatellite instability-high.

Lynch syndrome is caused by mutations in a group of genes that code for DNA MMR enzymes, including *MSH2*, *MLH1*, *PMS2*, *MSH6*, and *EPCAM* (deletion causes loss of expression of MSH2).[337] The defect in MMR allows spontaneous genetic mutations to accumulate in the colonic mucosa, which predispose to the development of dysplasia and, eventually, for invasive cancers. Tumor testing can be performed in one of two ways, and this often creates confusion in terminology. Microsatellite instability (MSI) designation is derived from a polymerase chain reaction–based tumor test in which a panel of microsatellite markers (so-called Bethesda markers) is used to test for MSI, and tissue is classified as microsatellite instability-high (MSI-H) if two or more of five core markers show instability. A second, and now more common, test is to perform IHC analysis of the four MMR proteins listed at the beginning of this paragraph. If any one of them is not expressed on IHC, the tumor is classified as dMMR (mismatch repair deficient). Although dMMR and MSI-H are often used interchangeably, this is technically not accurate.

Approximately 20% of patients with dMMR or MSI-H CRC have Lynch syndrome (ie, germline mutations); the rest have sporadic alterations in the MMR mechanism confined to the tumor. Approximately 10% to 15% of sporadic colon cancers have aberrations in the MMR enzymes, and the prevalence is approximately 15% in stage II, 8% in stage III, and 4% to 5% in stage IV CRCs.[338] These sporadic cases are generally caused by epigenetic silencing of *MLH1*.[339] These patients also often lack expression of PMS2 and usually have a mutation in *BRAF*.

Regardless of whether universal germline screening is performed for patients with CRC, routine testing for dMMR by IHC or for MSI by polymerase chain reaction should be performed on the tumors of all patients with CRC (Fig. 13.2-3) because this has implications for the treatment of early-stage cancers and is the basis of the FDA approval of checkpoint inhibitor use in both early-stage and more advanced-stage disease.

OTHER POLYPOSIS AND COLORECTAL CARCINOMA SYNDROMES

There are other polyposis and CRC syndromes. Inflammatory bowel disease (IBD), particularly ulcerative colitis, is associated with an increased risk of colon cancer, estimated to be 5% to 10% by 20 years after the time of diagnosis of IBD. IBD is also associated with a high incidence of synchronous cancers, affecting 10% to 20% of cases. Crohn's disease also may have a role in increasing the risk of CRC, particularly cancer in the ileocolic region. However, in the absence of colonic involvement by Crohn's disease, there is no increased risk of colon cancer. The risk of developing a subsequent cancer is 3% for patients who have a history of adenomatous polyps.

COLORECTAL CARCINOMA GENETIC ABERRATIONS

CRC is driven by three key carcinogenic pathways, including chromosomal instability (CIN), MSI, and CpG island methylator phenotype (CIMP). The CIN pathway is characterized by early mutations in key genes, including *APC*, *TP53*, and *KRAS*, and constitutes most CRCs (85%).[340] The CIMP pathway involves hypermethylation of promoter regions of tumor suppressor genes such as *MGMT* and may overlap with MSI through hypermethylation of *MMR* genes such as *MLH1*.[341] The MSI pathway is the result of loss of function of MMR genes, resulting in instability of lengths of microsatellites, which are short sequences of DNA distributed throughout the genome. In 2015, a consensus statement was released evaluating data from 18 colorectal data sets, including the TCGA and other public and proprietary sources. Four consensus molecular subtypes (CMSs) were described: CMS1 (MSI immune, 14%) with hypermutated MSI and strong immune activation, CMS2 (canonical, 37%) with marked WNT and MYC activation, CMS3 (metabolic, 13%) with metabolic dysregulation, and CMS4 (mesenchymal, 23%) with transforming growth factor-β activation and angiogenesis.[342] With the exception of CMS1, which has clear prognostic and predictive implications for cancer treatment, as is discussed later in this section, the other three CMSs have not yet been incorporated into clinical decision making but form the basis for continued attempts to personalize therapy for CRC.

SCREENING

Screening recommendations from the US Preventive Services Task Force (see also Chapter 1: Epidemiology and Prevention) are in alignment with the American Cancer Society recommendations, which propose starting screening for CRC in average-risk individuals at age 45 years instead of 50 years. Fecal immunochemical test (FIT) or fecal DNA tests for screening is now included as an option for patients every 1 to 3 years.[3] The sensitivity for detecting CRC is 92.3% with fecal DNA testing and 73.8% with FIT ($P = .002$). The sensitivity for detecting advanced precancerous lesions is 42.4% with fecal DNA testing and 23.8% with FIT ($P < .001$) and represents a weakness in potentially preventing evolution of precursor lesions, including adenomatous polyps, into invasive colorectal adenocarcinomas. Direct visualization tests included in the guidelines are colonoscopy, CT colonography, and flexible sigmoidoscopy, with emphasis that, for average-risk patients, colonoscopy every 10 years or CT colonography every 5 years have greater estimated life years gained than flexible sigmoidoscopy every 5 years.[343,344]

Screening should occur at shortened intervals for patients at high risk, including those who have inherited syndromes, IBD, previous adenomatous polyps or CRC, and strong family history of CRC. Individuals who have Lynch syndrome should have screening by total colonoscopy every 1 to 3 years beginning between ages 20 and 25 years because of the lack of a visible premalignant lesion in this population and the higher risk of right-sided colon cancers.[345] Individuals who have FAP should start screening colonoscopies as early as age 10 years. If colon cancer or severe dysplasia is found for patients with IBD, the general recommendation is for near total or subtotal colectomy because of the high incidence of synchronous and metachronous cancers in this population.[346] Surgery can be less extensive for patients who have sporadic cancers. For patients who have Lynch syndrome, more extensive surgery can be recommended, particularly for women beyond childbearing age, for whom hysterectomy and oophorectomy should be considered. Finally, patients with a strong family history (one first-degree relative diagnosed before age 60 years or two first-degree relatives diagnosed at any age) of colon cancer or advanced adenomatous polyps (>1 cm or high-grade dysplasia [HGD] or with villous elements) should start screening with colonoscopy no later than age 40 years or 10 years younger than the youngest first-degree relative and should undergo screening every 5 years. Several blood-based biomarkers for screening are under development, but their role is unclear; none are approved by the FDA, and currently, none are included in any major consensus guidelines.

KEY POINTS

- Screening for CRC is underutilized. Screening colonoscopy and fecal DNA/FIT reduce CRC-associated death over the long term.
- All individuals who have CRC should have their tumors evaluated for MMR or MSI status. Those with dMMR/MSI-H tumors suggestive of germline origin should be referred for genetic screening.
- If universal screening for germline mutations is not performed in all patients who have colon cancer, clinicians should follow the revised Bethesda criteria to determine who should be recommended for germline genetic testing.
- Early-onset CRC patients are more likely to have cancer-associated germline mutations compared to standard-onset patients, but the rapidly increasing incidence of CRC in young-adults (<50 years old) is not associated with genetic causes but rather yet-to-be-identified environmental hazards.

STAGING

In the eighth edition of the AJCC manual (2017), important areas to note that are included in the seventh and eighth editions but differ from the sixth edition are the T4b category (invasion or adherence to other organs or structures) and the N1c category (tumor deposits in subserosa, mesentery, or nonperitonealized pericolic and perirectal tissues without regional lymph nodes [LNs]). In effect, T4b places a patient in the very high-risk IIC or IIIC category, depending on nodal status, and N1c (recorded as present or absent and not counted) is considered a risk equivalent to that of N1 LNs (one to three regional LNs). The eighth edition also includes nodal micrometastases (tumor clusters >0.2 mm in diameter) as being LN positive and has added the M1C category (peritoneal metastases), creating a stage IVC category. Proposed changes to the forthcoming AJCC version 9 staging criteria were previewed at the ASCO 2025 Annual Meeting and will likely place greater emphasis on tumor deposits in assigning stage.[347]

TREATMENT OF COLORECTAL CARCINOMA

Early-Stage Colon Cancer (Stages 0 and 1)

Nearly all patients who have stage 0 disease (carcinoma in situ or intramucosal cancer) are cured by endoscopic resection alone; note, however, that LNs are not adequately assessed by this technique. The primary treatment of virtually all invasive nonmetastatic CRCs is surgery. For stage I cancers, surgical resection alone is often recommended and frequently curative. For select T1 cancers without other high-risk features (low grade, no angiolymphatic invasion, and negative margin) diagnosed in a polyp, endoscopic resection alone may be sufficient.[348]

Stage II Colon Cancer

For patients who have stage II disease, the role of adjuvant chemotherapy remains controversial because of the heterogeneity of this disease stage. ASCO recommendations suggest that routine adjuvant chemotherapy is not recommended for most patients who have stage II tumors A discussion should be held with patients about their individual benefit-to-risk ratio when using adjuvant chemotherapy in stage II colon cancer.[349] The identification of prognostic factors might help distinguish patients at high risk of relapse and identify patients who have high-risk stage II disease who may be more likely to benefit from adjuvant treatment. In addition to T4 status, all major groups (ASCO, NCCN, and European Society of Medical Oncology) consider inadequate LN sampling (<12 or 13 nodes), lymphovascular invasion, perineural invasion, and clinical obstruction or perforation to be high-risk stage II disease that may warrant chemotherapy. Poorly differentiated tumors must be evaluated in the context of their MSI/dMMR status.

Apart from the aforementioned clinical risk factors, molecular determinants of prognosis such as MSI have been evaluated. Remarkably consistent results from retrospective analyses of large adjuvant trials and pooled data sets confirm that patients with

stage IIA colon cancers that are dMMR/MSI-H have excellent prognosis (>95% long-term DFS) and may be harmed from treatment with single-agent fluoropyrimidine adjuvant chemotherapy.[349-353] For patients who have dMMR/MSI-H stage IIB, stage IIC, or stage III disease, adjuvant therapy with a fluoropyrimidine, oxaliplatin, and immunotherapy should be considered. Duration of such treatment is discussed in more detail in the following paragraphs. Efforts to develop a molecular profile of predictive variables that could potentially guide adjuvant treatment decisions in stage II colon cancer have not proven useful clinically.[350,354,355] These tests include gene expression signatures, such as Oncotype DX Colon[356] and ColoPrint,[354] as well as molecular detection assays of micrometastases in morphologically unaffected LNs.[355] At this time, none of these assays is routinely recommended for use in clinical practice as a decision tool for adjuvant therapy in stage II colon cancer because they remain prognostic tests but are not able to predict which patients derive benefit from chemotherapy.

Emerging Role of Circulating Tumor DNA

Circulating tumor DNA (ctDNA) comprises fragments of DNA that are 130- to 150-bp long released into circulation by cancer cells undergoing apoptosis or necrosis or via secretion with a short half-life of up to 2.5 hours.[357] Given the short half-life, ctDNA is a real-time marker of tumor burden and is rapidly emerging as a prognostic tool across the continuum of cancer care, including in CRC. In the adjuvant setting, the detection of ctDNA after completion of curative-intent treatment—that is, minimal residual disease (MRD)—is highly specific and has high positive predictive value (90% to 100% for both) for occult micrometastatic disease that may result in eventual clinical recurrence. For instance, in the observational GALAXY trial (n = 3,034 stage II-IV resectable CRC), ctDNA positivity postsurgery was associated with higher risk of recurrence (HR, 15.75; $P < .0001$). In MRD-positive patients who received adjuvant therapy, 73% had ctDNA clearance. However, with longer follow-up, only 54% had sustained ctDNA clearance with much better outcomes compared with those with transient clearance (HR, 32.57; $P < .0001$).[358] Because the sensitivity of detection of ctDNA directly correlates with the underlying tumor volume, the sensitivity of such assays for detecting MRD is limited but improving over time and currently provides a median lead time of nearly 8 to 9 months.[356,359-361] Ongoing trials are aiming to establish the clinical utility of postoperative ctDNA-defined MRD in determining the intensity of adjuvant therapy. These trials are evaluating the role of adjuvant therapy for patients with clinically low-risk but MRD-positive stage II disease and also escalation/de-escalation of standard-of-care adjuvant therapy for patients who have stage III disease depending on postoperative MRD status.[361-363] The DYNAMIC trial randomly assigned 455 patients who had stage II colon cancer 2:1 to adjuvant therapy guided by either ctDNA results or standard clinicopathological features with a primary endpoint of recurrence-free survival at 2 years and showed that ctDNA-guided management was noninferior to standard management (93.5% and 92.4%, respectively; absolute difference, 1.1 percentage points; 95% CI, −4.1 to 6.2; noninferiority margin, −8.5 percentage points). A key secondary endpoint was adjuvant chemotherapy use with the results showing that a lower percentage of patients in the ctDNA-guided group than in the standard management group received adjuvant chemotherapy (15% vs 28%; relative risk, 1.82; 95% CI, 1.25-2.65). Thus, the utilization of ctDNA as opposed to traditional pathological features could spare nearly half of patients from receiving unnecessary chemotherapy and is being increasingly utilized in clinical practice for stage 2 colon cancer. In the phase 2/3 COBRA trial, patients who had resected stage II colon cancer without high-risk features deemed appropriate for surveillance were randomly assigned to observation versus ctDNA assay–guided therapy (a blood-only assay evaluating mutations and methylation changes); patients who were MRD-positive were treated with 6 months of adjuvant chemotherapy. The trial was stopped early because it crossed the futility boundary for the phase 2 endpoint of ctDNA clearance, likely related to the specificity of the assay.[364]

KEY POINTS

- Stage II colon cancer is a heterogeneous disease, and there is no one-size-fits-all answer for which patients should receive chemotherapy.
- The role of adjuvant therapy in stage II colon cancer should involve risk stratification and shared decision making.
- Patients who have stage IIA colon cancer that is dMMR/MSI-H have an excellent prognosis and do not require adjuvant therapy.
- Patients who have stage IIB or IIC dMMR/MSI-H colon cancer should be considered for adjuvant oxaliplatin-based therapy and potentially immunotherapy.
- Patients who have stage IIA disease without any risk factors do not typically benefit from adjuvant chemotherapy and should be counseled about the low absolute benefit of chemotherapy.
- Patients who have stage IIA disease and high-risk features and those who have stage IIB (T4a) or IIC disease should be counseled regarding their higher risk of tumor recurrence and the potential benefit of fluoropyrimidine and oxaliplatin-based chemotherapy.
- Accumulating data suggest that, for patients with resected colon cancer, postoperative ctDNA-defined MRD status is strongly prognostic, and prospective trials show that ctDNA-guided management is noninferior to standard-of-care management and that it also results in lesser use of adjuvant therapy. While awaiting additional data from ongoing trials, whether to incorporate ctDNA into adjuvant therapy decisions for stage II colon cancer outside of clinical trials should be a shared discussion between patients and their providers.

Stage III Colon Cancer

Adjuvant Chemotherapy

The initial trial presented in the early 1990s that established adjuvant chemotherapy as a standard of care in stage III colon cancer used a combination of 5-FU and levamisole administered for 12 months.[365] A 10% to 20% absolute improvement in 5-year survival was documented for patients receiving postoperative adjuvant 5-FU–based chemotherapy. Evidence from subsequent trials demonstrated that 5-FU combined with leucovorin provides superior outcomes with 6 months of therapy being adequate to achieve this survival benefit.[366] For more than a decade, the standard in adjuvant therapy remained unchanged because of the lack of novel agents with relevant activity in CRC. This changed when oxaliplatin, irinotecan, and the oral 5-FU prodrug capecitabine were used for the treatment of advanced CRC with combination regimens of 5-FU and either irinotecan or oxaliplatin demonstrating high antitumor efficacy.

Worldwide, six phase 3 trials were conducted to evaluate the value of these three novel chemotherapeutic agents in the adjuvant setting. The results of the pivotal MOSAIC (Multicenter International Study of Oxaliplatin/5-FU/Leucovorin in the Adjuvant Treatment of Colon Cancer) trial clearly demonstrated that FOLFOX is superior to 5-FU with leucovorin in terms of 3-year DFS and ultimately OS with longer follow-up.[367] Results of the National Surgical Adjuvant Breast and Bowel Project C-07 trial and XELOXA trial confirmed the role of oxaliplatin and intravenous or oral 5-FU–based regimens in adjuvant therapy for colon cancer.[368,369]

Although irinotecan- and oxaliplatin-based regimens are thought to be equally effective as palliative therapy for advanced CRC, for unknown reasons, none of the three phase 3 trials using combination regimens of irinotecan, 5-FU, and leucovorin demonstrated substantially superior efficacy regarding 3-year DFS when compared with 5-FU and leucovorin alone.[370-372] Similarly, despite their activity in the metastatic setting, several trials examining the addition of bevacizumab in an unselected population and cetuximab in a *KRAS* wild-type (WT) population did not show benefit when adding these agents to standard 6-month 5-FU– and oxaliplatin-based regimens.[373-376]

To mitigate the long-term neurotoxic adverse effects of oxaliplatin-based adjuvant therapy (10%-15% of patients can develop grade 3 neuropathy, resulting in, for example, an inability to button shirts or walk without difficulty), the IDEA (International Duration Evaluation of Adjuvant Chemotherapy) collaboration was established to prospectively combine and analyze data from six randomized trials conducted around the world to answer the question of whether a 3-month course of oxaliplatin-based adjuvant therapy is noninferior to the current standard 6-month treatment in patients with stage III colon cancer.[377] The final combined published analysis included 12,834 patients from 12 countries. The primary endpoint of noninferiority overall was not met (HR, 1.07; 95% CI, 1.00-1.15); however, the absolute difference in 3-year DFS was only 0.9% (75.5% vs 74.6%). Importantly, grade ≤ 2 neurotoxicity during therapy and in the month after treatment was substantially lower in the 3-month group than in the 6-month group. Preplanned subgroup analyses included specific tumor penetration, nodal status groups, and chemotherapy regimen (FOLFOX or capecitabine and oxaliplatin [CAPOX]).[378] For patients who have stage III colon cancer, after a median follow-up of 72 months, updated DFS results confirmed prior findings (HR, 1.08; 95% CI, 1.02-1.15) but with minimal 5-year OS differences: 82.4% (95% CI, 81.4-83.3) with 3 months of therapy and 82.8% (95% CI, 81.8-83.8) with 6 months of therapy (HR, 1.02; 95% CI, 0.95-1.11). The 5-year OS results according to the regimen were as follows (3 vs 6 months of therapy): CAPOX, 82.1% (95% CI, 80.5-83.6) vs 81.2% (95% CI, 79.2-82.9; HR, 0.96; 95% CI, 0.85-1.08) and FOLFOX, 82.6% (95% CI, 81.3-83.8) vs 83.8% (95% CI, 82.6-85.0; HR, 1.07; 95% CI, 0.97-1.18).

Current ASCO clinical guidelines recommend that patients who have T4 or N2 disease receive 6 months of therapy and that, for all other patients, either 6 months of adjuvant chemotherapy or a shorter duration of 3 months may be offered on the basis of a potential reduction in AEs and no substantial difference in DFS with the 3-month regimen.[379] On the basis of the subgroup analyses, many expert panels, including the NCCN, favor CAPOX over FOLFOX if 3 months of therapy is chosen. The ASCO guideline panel also favored CAPOX over FOLFOX but chose not to make it a formal recommendation. Data presented at the ASCO 2019 Annual Meeting revealed the same findings of 3 versus 6 months for stage II cancers with high-risk features when an oxaliplatin regimen was chosen.[380] These results were reaffirmed in the subsequent publication, which included high-risk stage II patients from 4 of the 6 IDEA studies.[381] Five-year DFS was 80.7% for 3 months of therapy and 83.9% for 6 months of therapy, HR 1.17, *P* for noninferiority .39). While a formal test of interaction by chemotherapy regimen (FOLFOX vs capeox) was negative, the duration effect did appear related to choice of regimen and for this reason and convenience most favor 3 months of capeox for the high-risk stage 2 adjuvant pMMR population for whom chemotherapy is selected. Additional analyses regarding early therapy discontinuation (ETD; <75% of planned doses) or early oxaliplatin discontinuation (EOD) for patients with stage III disease initially intending to receive 6 months of therapy revealed worse outcomes with ETD for both DFS and OS (HR, 1.40; 95% CI, 1.23-1.58; $P < .001$ and HR, 1.51; 95% CI, 1.31-1.74; $P < .001$, respectively) but not with EOD (HR, 1.10; 95% CI, 0.77-1.58; $P = .6$ and HR, 0.97; 95% CI, 0.62-1.52; $P = .9$, respectively). Overall, these data suggest that, for patients treated with 6 months of therapy, it is reasonable to discontinue oxaliplatin while continuing fluoropyrimidine in individuals who have significant neurotoxicity having received >50% of the planned 6-month chemotherapy. These data indicate that fluoropyrimidines remain the mainstay of adjuvant chemotherapy.[382]

The ATOMIC trial randomized patients with dMMR/MSI-H stage 3 colon cancer to 6 months of FOLFOX chemotherapy alone or with 1 year of the checkpoint inhibitor atezolizumab.[383] The addition of atezolizumab improved 3-year disease-free survival (primary endpoint) from 76.6% to 86.4%, HR, 0.5, $P < 0.0001$. Whether these results can be extrapolated to higher risk stage

II dMMR colon cancer is unclear, but in practice this is a reasonable approach. The other key unanswered question from the ATOMIC trial is whether checkpoint inhibitor therapy alone would result in similar benefit in this patient population, as the relative benefit of chemotherapy for dMMR colon cancer is significantly less.

A further emerging area of investigation for patients with dMMR primary colon cancer is whether neoadjuvant immunotherapy may be beneficial in a similar manner to the dMMR rectal cancer paradigm described below. Theoretical benefits include enhanced efficacy of immunotherapy in the preoperative setting (when target antigens are present with the intact primary tumor) and the potential to downstage cancers. It remains less clear whether this may potentially create opportunities to pursue nonoperative management. In a phase 2 single-arm NICHE-2 study, investigators treated 115 patients with clinical stage 2/3 dMMR locally advanced colon cancer with one dose of ipilimumab/nivolumab followed 2 weeks later with one dose of nivolumab monotherapy followed by surgical resection 2 to 4 weeks after the second immunotherapy dose. Impressively, approximately two-thirds of patients (68%) had a complete pathological response (pCR) and no tumor recurrences had been detected at a median follow-up of over 2 years.[384] While encouraging, challenges in implementing neoadjuvant immunotherapy strategies include a need to change cancer referral patterns (so that medical oncologists see localized colon cancer preoperatively), the need for timely MMR testing on initial colonoscopy biopsies, and the limitations of preoperative radiographic staging leading to potential overtreatment of some patients with reactive rather than malignant LNs, which are commonly seen in dMMR colon cancers.

SURVIVORSHIP

In addition to adjuvant chemotherapy, recent data demonstrate the benefit of intensive exercise programs and aspirin use for patients whose tumors have alterations in the *PIK3CA* pathway. The CHALLENGE Trial was the first randomized trial to evaluate whether a structured exercise program could improve colon cancer survival. In this trial, 889 patients primarily from Canada or Australia with resected stage III or high-risk stage II colon cancer after 2 to 6 months of adjuvant therapy were randomized to a 3-year structured exercise program and given health education materials, or only given health education materials. The goal of the structured exercise program was to increase physical activity by 10 MET/hours/week above baseline, with 1 hour of brisk walking equivalent to 4 MET-hours. The primary endpoint of 3 year disease-free survival was improved in the structured exercise arm from 73.9% to 80.3%, HR, 0.72, $P = 0.017$. The secondary endpoint of 8 year overall survival was also improved, from 83.2% to 90.3%, HR 0.63, $P = 0.022$. While there are questions about the applicability of this intense approach to exercise in everyday practice, these data support recommendations to colorectal cancer survivors for increasing physical activity.[329]

Alterations in PI3K pathway genes are noted in approximately one-third of colorectal cancers. Aspirin has been demonstrated to reduce the rate of colonic adenomas and cancers among high-risk patients and there have been suggestions of improved outcomes among patients with resected colorectal cancers with *PIK3CA* mutations. In the ALASCCA randomized clinical trial, 626 patients with stage 1-3 rectal cancer or 2-3 colon cancer with alterations in the PI3K pathway were randomized to receive aspirin 160 mg or placebo for 3 years. For the primary outcome measure, the use of aspirin was associated with a significantly decreased risk of colorectal cancer recurrence whether the tumor had a *PIK3CA* exon 9/20 mutation (3-year recurrence 7.7% vs 14.1%, HR 0.49, $P = .044$) or other PI3K pathway alteration (3-year recurrence 7.7% vs 16.8%, HR 0.42, $P = .013$). For the secondary outcome measure of 3-year disease-free survival, the use of aspirin was also associated with an improvement in the other PI3K pathway group (89.1% vs 78.7%, HR = 0.51, $P = .017$). These data have been incorporated into guidelines, with implications for testing all early-stage colorectal cancer tumors for alterations in the PI3K pathway.[328]

KEY POINTS

- By strict scientific criteria, 6 months of adjuvant CAPOX or FOLFOX remains a standard of care for stage III colon cancer.
- Emerging clinical consensus suggests 3 months of adjuvant therapy, particularly with capeox, is a reasonable alternative for patients who have T1-3 and N1 disease given the small absolute difference in DFS and the substantial decrease in clinically substantial neurological and other toxicities. The data are also similar for high-risk stage III colon cancer.
- If 3 months of therapy is chosen, many expert panels favor CAPOX over FOLFOX.
- Six months of therapy with FOLFOX or 3 to 6 months with CAPOX are recommended for those with T4 or N2 disease. It is reasonable to discontinue oxaliplatin while continuing fluoropyrimidine in individuals with significant neurotoxicity having received >50% of the planned 6-month chemotherapy.
- For dMMR (MSI-H) stage 3 colon cancer, the addition of atezolizumab to adjuvant chemotherapy improves outcome. Whether this can be extrapolated to high-risk stage 2 dMMR(MSI-H) colon cancer is unknown but a reasonable extension.
- For patients with stage 2/3 colorectal cancer, data now support a focus and recommendation for exercise the intensity of which should likely be individualized.
- For patients with stage 2/3 colorectal cancer with alterations in the PIK3CA pathway, after adjuvant therapy, the use of low-dose aspirin for 3 years is now recommended.
- Irinotecan, anti-VEGF agents such as bevacizumab, and anti-EGFR antibodies such as cetuximab, regardless of *RAS* status, should not be used in the adjuvant setting.

Figure 13.2-4 Treatment Algorithm for Metastatic Colorectal Cancer

ADVANCED COLORECTAL CARCINOMA (STAGE IV)

Stage IV CRC (colon and rectal cancers are managed similarly in the metastatic setting) is generally not considered curable with the exception of a small subset of patients who have isolated sites of metastasis (see the section "Oligometastatic CRC" later in the chapter). For decades, standard first-line therapy consisted of 5-FU and leucovorin with a response rate of approximately 20% and median survival of approximately 1 year. In the late 1990s and early 2000s, the addition of oxaliplatin and irinotecan to the backbone of 5-FU and leucovorin resulted in an improvement in median OS to nearly 24 months when patients received active first- and second-line treatment. The introduction of biological agents, such as bevacizumab, ziv-aflibercept, ramucirumab, cetuximab, and panitumumab, has further enhanced the efficacy of systemic medical therapy. The emphasis of current advances in medical therapy is on the development of predictive biomarker signatures, which can help guide treatment decisions for specific patient subpopulations.

The availability of various active agents for the treatment of mCRC has resulted in an abundance of therapeutic options that now demand a goal-oriented strategic approach to therapy to maximize patient benefit (Fig. 13.2-4). When treating a patient who has mCRC, the first determination is whether stage IV disease is potentially curable by surgical resection of metastases either at the time of diagnosis or after downsizing initially unresectable metastases by neoadjuvant chemotherapy. This will guide the choice and timing of chemotherapy because, in this scenario, the most appropriate treatment is conceivably the one that generates the highest response rate and carries the greatest potential to downsize metastases. If the patient's disease does not seem potentially curable, the main goals of systemic chemotherapy are to extend the duration of the patient's life and to maintain quality of life for as long as possible. In this scenario, treatment regimens that offer the longest PFS and OS as well as a favorable toxicity profile are preferred.

Irinotecan and Oxaliplatin

In the late 1990s and early 2000s, several trials established the benefit of oxaliplatin- and irinotecan-containing regimens in the first-line metastatic setting (eg, FOLFOX, FOLFIRI [5-fluorouracil, leucovorin, and irinotecan], IFL [irinotecan, bolus 5-FU, and leucovorin], and CAPOX).[382,385-392] The main lessons learned over time were that an infusional or oral fluoropyrimidine-based regimen was superior to a bolus 5-FU–based regimen, especially when combined with irinotecan, and that oxaliplatin was ineffective as a single agent and needed to be combined with other chemotherapy agents such as a fluoropyrimidine or irinotecan.

In the 2000s, several trials established the superiority of FOLFOX and FOLFIRI over bolus 5-FU regimens in the metastatic setting, and smaller trials suggested an equivalency between FOLFOX and FOLFIRI.[393-395] The choice between FOLFOX and FOLFIRI in the clinic should be based mainly on the expected adverse effect profile although recently published work using tumor molecular profiling, clinical data, and artificial intelligence suggests that an algorithm may be used to determine who is most likely to benefit from up-front FOLFOX chemotherapy.[396] These results still must be validated in a prospective fashion. Because the benefit of subsequent-line therapy in CRC has been well established, patients should receive all active cytotoxic drugs in the course of their therapy to optimize outcome.[397]

Bevacizumab

Bevacizumab, a recombinant humanized monoclonal antibody to VEGF-A, demonstrates clinical efficacy in the treatment of mCRC. In a large, phase 3 placebo-controlled trial with 813 patients, the IFL protocol was compared with IFL and bevacizumab (5 mg/kg every 2 weeks) as first-line therapy for advanced CRC.[398] The addition of the anti-VEGF antibody led to a substantially increased response rate (45% vs 35%; $P = .0036$), PFS (10.6 vs 6.2 months; HR, 0.54; $P < .00001$), and median OS (20.3 vs 15.6 months; HR, 0.66; $P = .00004$). This trial was the first phase 3 validation of an antiangiogenic agent as an effective treatment option in a human malignancy. Subsequently, bevacizumab was also shown to enhance the efficacy of oxaliplatin-based regimens in first- and second-line treatment as well as in combination with 5-FU and leucovorin alone or with irinotecan.[399-401] It also improved survival when administered with trifluridine-tipiracil in the SUNLIGHT trial in patients who received up to 2 prior chemotherapy regimens (10.8 months vs 7.5 months for trifluridine-tipiracil alone).[402]

It is important to note that bevacizumab does not seem to have substantial single-agent activity in mCRC.[403]

The main adverse effects observed with bevacizumab consist of hypertension (a class effect of all agents targeting VEGF signaling), bleeding, GI perforations (1.5%-2% of patients), and poor wound healing as well as arterial thrombotic events in approximately 4%-5% of patients.[403] In addition to arterial thrombotic events, a meta-analysis identified a 33% higher incidence of venous thrombotic events for patients receiving bevacizumab compared with the nonbevacizumab control arm in randomized trials[404] although another more recent analysis refuted this claim.[405] Bevacizumab should be used with extreme caution, if at all, for patients who have a strong history of a recent arterial thrombotic event. Bevacizumab should also be used with caution for patients who have recent surgery or for whom surgery is planned (at least 4 weeks between bevacizumab and surgery is recommended if possible) and those who have obstructing primary tumors. History of a venous thromboembolic event is not considered an absolute contraindication to bevacizumab therapy and patients on stable therapeutic anticoagulation can also receive bevacizumab without an increase in severe bleeding risk.[406]

On the basis of its well-documented efficacy and relative moderate toxicity, bevacizumab has emerged as a standard component of first-line chemotherapy for advanced CRC. Its use in right- versus left-sided tumors is discussed in the section titled "Head-to-Head Comparison between EGFR Monoclonal Antibodies and Bevacizumab."

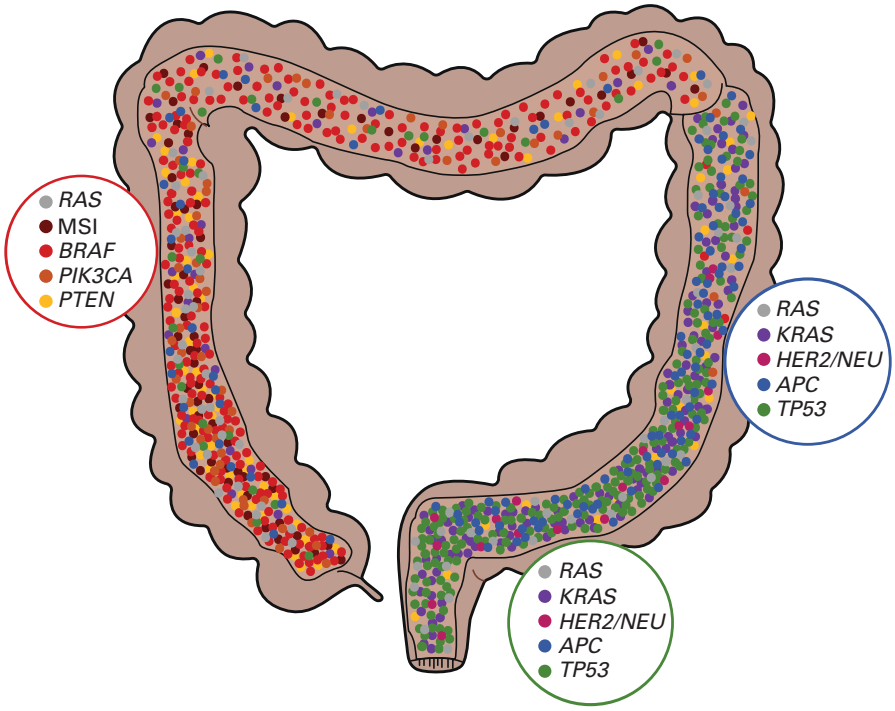
Anti-EGFR Antibodies: Cetuximab and Panitumumab

Data from various clinical trials and translational studies have opened the door to individualized treatment approaches in CRC by identifying patients who are most likely to benefit from monoclonal antibodies against EGFR, namely, cetuximab and panitumumab. It is increasingly clear that patients who have advanced CRC must have a tumor that is WT for *KRAS* exons 2, 3, and 4 and *NRAS* exons 2, 3, and 4 (referred to as extended RAS) for EGFR monoclonal antibodies to be effective.[407-412] Mutations in *RAS* (~55% of tumors) result in constitutively active signaling downstream from EGFR, thereby negating the effect of blocking the receptor. The CRYSTAL trial was a large phase 3 trial of 1198 patients with untreated metastatic colon cancer that compared FOLFIRI and cetuximab with FOLFIRI alone. In patients with pan-*RAS* WT tumors, response rate (57% vs 40%), median PFS (9.9 vs 8.4 months), and OS (23.5 vs 20 months) were all improved with the addition of cetuximab.[411] The PRIME trial of FOLFOX with or without panitumumab yielded similar results. NCCN guidelines call for expanded *RAS* mutation testing before EGFR monoclonal antibodies are used in patients with CRC, and all patients who have metastatic colon cancer should have extended *RAS* and *RAF* testing performed at the time of diagnosis if active therapy is being considered.[412] Use of either agent with either chemotherapy backbone (FOLFOX or FOLFIRI) is an acceptable standard of care for the first-line treatment of extended *RAS* WT tumors. Additional negative predictive biomarkers for first-line anti-EGFR therapy include *BRAF* V600E–mutated and *HER2*-amplified tumors as well as right-sided tumors.

The main toxic effects of anti-EGFR monoclonal antibodies are acneiform skin rash, hypomagnesemia, diarrhea, and hypersensitivity reactions, the latter of which is particularly relevant for the chimeric antibody cetuximab. Prophylactic treatment of the skin rash with oral doxycycline and topical corticosteroids was investigated in the randomized phase 2 STEPP trial,[413] and skin toxicities were reduced from 62% in the reactive group to 29% in the preemptive group. Preemptive therapy should be considered for all patients receiving anti-EGFR therapies. Recent ESMO guidelines for prevention and treatment of dermatologic toxicity from EGFR antibodies have been published.[414]

Initial reports suggested synergistic activity when bevacizumab was combined with cetuximab in salvage therapy.[415] Results of subsequent larger randomized first-line trials, however, demonstrated an antagonistic effect of the combination of EGFR monoclonal antibodies with bevacizumab in the context of concurrent chemotherapy.[416,417] Therefore, combinations of bevacizumab and EGFR monoclonal antibodies should generally not be used in clinical practice outside of a clinical trial at this time.

Figure 13.2-5 Molecular Alterations by Tumor Sidedness in Colorectal Cancer



Abbreviation: MSI, microsatellite instability.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

The choice of anti-EGFR therapy versus bevacizumab in the first-line metastatic setting for patients with extended *RAS* WT tumors has been addressed by several phase 3 trials. The FIRE-3 trial randomly selected 592 patients who had conventionally assessed *KRAS* exon 2 WT CRC to receive FOLFIRI and cetuximab or FOLFIRI and bevacizumab. The primary endpoint of investigator-assessed response rate was not reached. In addition, no difference in PFS was noted (10.0 vs 10.3 months); in fact, the PFS curves were almost completely superimposable. Surprisingly, however, a statistically substantial difference was found in OS with a difference in median OS of 3.7 months in favor of FOLFIRI and cetuximab.[418] An updated analysis that accounted for additional mutations in *KRAS* and *NRAS* demonstrated an even larger difference in median OS (33.1 vs 25.0 months; HR, 0.70; $P = .0059$), again without a statistically substantial difference in response rate or PFS.[418]

The US Intergroup study CALGB/SWOG 80405 compared investigator's choice of chemotherapy (FOLFOX or FOLFIRI) with cetuximab or bevacizumab as first-line therapy for 1,137 patients who had *KRAS* exon 2 WT mCRC.[419] In contrast to the FIRE-3 trial, no difference in OS was noted between the two treatment arms, not even when any *RAS*-mutated cancers were excluded. Both treatment arms showed long median OS: 31.2 months for chemotherapy and bevacizumab and 32.0 months for chemotherapy and cetuximab (HR, 0.9; $P = .40$). Note that the outcome parameters of FIRE-3 and CALGB/SWOG 80405 were more similar than different with the exception of poor performance in the bevacizumab arm in FIRE-3.

Colorectal tumors present with substantial heterogeneity in molecular features, which is strongly associated with tumor location (Fig. 13.2-5). Left-sided tumors (splenic flexure to rectum) often present with WT *BRAF*, *KRAS* point mutations (codons 12, 13, and 61), and extensive copy-number alterations as well as other structural genomic aberrations, including CIN and loss of heterozygosity. Right-sided tumors (cecum to hepatic flexure) are enriched for *BRAF* V600E point mutations; are WT for *KRAS*; and have a diploid copy number, MSI, DNA hypermutation, and extensive DNA hypermethylation associated with the CIMP phenotype.

On the basis of these molecular differences, left- and right-sided colon tumors are now becoming increasingly recognized as two unique cancer types that may benefit from different therapeutic strategies. A post hoc analysis of the CALGB 80405 data found sidedness to be prognostic; median survival of patients with left- versus right-sided tumors was 31.4 versus 24.2 months, respectively ($P = .01$).[420,421] The trial also suggested that sidedness was predictive of response to cetuximab versus bevacizumab ($P_{int} = .05$) with cetuximab having an OS advantage for left-sided tumors ($P = .01$) and a suggestion of improved survival with bevacizumab for right-sided tumors ($P = .08$). An analysis of the CRYSTAL and FIRE-3 studies similarly showed a survival advantage for chemotherapy and cetuximab over chemotherapy alone or chemotherapy and bevacizumab for left-sided tumors.[422] The PARADIGM trial randomly assigned 802 patients who had *RAS* WT metastatic CRC (604 with left-sided tumors) to first-line mFOLFOX6 with bevacizumab or panitumumab with OS as the endpoint to be tested hierarchically in left-sided tumors followed by the full analysis set (FAS) population. These results showed that panitumumab substantially improved OS in both groups: left-sided (HR, 0.82; 95.798% CI, 0.68-0.99; $P = .031$, which crossed the boundary of significance [.042]) and in the overall population (HR, 0.84; 95% CI, 0.72-0.98; $P = .030$, with <.05 as the boundary). Although PFS was comparable between the arms, response rates (80.2%; 95% CI, 75.3-84.5% vs 68.6%; 95% CI, 62.9-74.0) were higher with panitumumab. NCCN and ESMO guidelines currently recommend either anti-EGFR therapy or bevacizumab as the biological choice in combination with chemotherapy for left-sided extended *RAS* WT tumors; anti-EGFR antibodies should not be used as first-line therapy for patients with right-sided extended *RAS* WT tumors. Data on response to EGFR antibodies for patients with transverse colon (hepatic to splenic flexure) primaries are currently lacking.

5-Fu, Oxaliplatin, and Irinotecan Regimens

The FOLFIRINOX regimen (5-fluorouracil, leucovorin, irinotecan, and oxaliplatin; also called FOLFOXIRI) has high activity but also increased toxicity. The largest trial evaluating FOLFIRINOX in this setting was the TRIBE trial, in which FOLFIRINOX and bevacizumab were compared with FOLFIRI and bevacizumab alone.[423] The triplet combination improved median OS (29.8 vs 25.8 months; HR, 0.8; 95% CI, 0.65-0.98; $P = .03$), and 5-year survival was doubled to 25% vs 12.5%. There was also a suggestion that patients with *BRAF*-mutated tumors had improved median OS (19 vs 10.7 months; HR, 0.54; 95% CI, 0.24-1.20) that did not reach statistical significance, likely secondary to the small number of patients with this mutation (n = 28). A subsequent phase 2 trial, OLIVIA, testing FOLFIRINOX with bevacizumab versus FOLFOX with bevacizumab also showed higher response rates and longer PFS and improved rates of liver resection.[424] Another phase 3 trial, STEAM, confirmed the benefit of the triplet regimen for PFS and liver resection rates, and the TRIBE2 study of FOLFIRINOX with bevacizumab versus FOLFOX with bevacizumab suggested an OS advantage with early results.[425,426] The TRIPLETE study compared FOLFOX versus FOLFIRINOX in combination with panitumumab for patients who have advanced *RAS* and *BRAF* WT mCRC (88% left-sided) and failed to show an improvement in the primary endpoint of ORR (76% vs 73%; OR, 0.87; 95% CI, 0.56-1.34; $P = .526$) or secondary endpoint of PFS (median PFS, 12.3 vs 12.7 months; HR, 0.88; 95% CI, 0.70-1.11; $P = .277$). Given the increased efficacy at the cost of potentially increased toxicities, the triplet regimen may be a potential option for patients with aggressive tumors (eg, right-sided tumors, *BRAF* V600E mutated) or in those needing rapid clinical response but with overall excellent clinical status.

Stop-and-Go Strategies

Because the treatment-limiting toxicity of oxaliplatin-based first-line therapy is cumulative neurotoxicity, proactive strategies must be used to maximize treatment duration for patients who start palliative therapy with fluoropyrimidine and oxaliplatin.

Initial trials such as OPTIMOX1 and CONCePT, which randomly assigned patients to continuous versus intermittent oxaliplatin therapy while continuing fluoropyrimidine, showed lower toxicity for intermittent dosing, especially for peripheral neuropathy.[427,428] However, subsequent trials, such as OPTIMOX-2 and MRC COIN, suggested that complete discontinuation of therapy without careful patient selection may be detrimental.[428,429] The results of these trials have paved the way toward the current approach of induction maintenance with a limited number of oxaliplatin-containing treatment cycles up front and maintenance therapy with a fluoropyrimidine and targeted agent combination now considered standard of care. Maintenance therapy with a fluoropyrimidine and bevacizumab is supported by several prospective trials and most prominently by the Dutch CAIRO3 study.[430] In this trial, 558 patients who had achieved at least stable disease after 18 weeks (six cycles) of induction therapy of capecitabine and oxaliplatin with bevacizumab were randomly assigned to a completely chemotherapy-free interval or maintenance therapy with low-dose continuous capecitabine (625 mg/m^2 twice daily) and bevacizumab (7.5 mg/kg every 3 weeks). All prospectively defined outcome parameters in this strategy trial were in favor of the maintenance therapy arm with a strong trend toward improvement in OS. Similarly, in eligible patients who are started on oxaliplatin and anti-EGFR monoclonal antibody regimens, maintenance therapy with a fluoropyrimidine and anti-EGFR monoclonal antibody is recommended over either single agent. In the TRIBE 2 trial, patients were randomly assigned to receive two different strategies: first-line FOLFOX plus bevacizumab (bev) followed by FOLFIRI plus bev after disease progression (arm A, standard treatment) or first-line FOLFIRINOX plus bev followed by reintroduction of FOLFIRINOX plus bev after disease progression (arm B, experimental strategy). All treatments are administrated up to eight cycles followed by 5-FU/LV plus bev randomized to receive two different strategies: first-line FOLFOX plus bev followed by FOLFIRI plus bev after disease progression (arm A, standard treatment) or first-line FOLFIRINOX plus bev followed by reintroduction of FOLFIRINOX plus bev after disease progression (arm B, experimental strategy). All treatments are administrated up to eight cycles followed by 5-FU/LV plus bev maintenance until disease progression or unacceptable adverse events. In this study, up-front FOLFIRINOX plus bevacizumab followed by the reintroduction of the same regimen after disease progression seems to be a preferable therapeutic strategy to sequential administration of chemotherapy doublets in combination with bevacizumab. The phase 2 VALENTINO study showed inferior outcomes in the primary endpoint of 10-month PFS with maintenance panitumumab (49%) versus 5-FU and leucovorin with panitumumab (59%) after induction with FOLFOX and panitumumab (HR, 1.51; 95% CI, 1.11-2.07. A combination maintenance approach in this setting was also supported by the phase 3 PANAMA study. After induction with FOLFOX and panitumumab, this trial randomly assigned patients to maintenance therapy with 5-FU versus 5-FU and panitumumab and showed improvement in PFS with the combination (8.8 vs 5.7 months; HR, 0.72. Therefore, an induction maintenance approach with a limited duration of oxaliplatin-based therapy and prolonged fluoropyrimidine and monoclonal antibody therapy may be considered an option to minimize toxicity for patients who have advanced CRC. Importantly, these and other trials established that oxaliplatin could be reintroduced at the time of progression and still yield acceptable response rates as demonstrated in the OPTIMOX1 trial.

Benefit in Older Patients

Although most patients who have mCRC tolerate and receive bevacizumab in the context of an irinotecan- or oxaliplatin-based combination regimen, it is unclear whether specific subgroups such as older patients benefit from a bevacizumab and fluoropyrimidine combination alone. This question was addressed in the AVEX phase 3 trial.[431] In this study, 280 patients age ≥ 70 years (median age, 76 years) who were not deemed to be candidates for oxaliplatin- or irinotecan-based first-line chemotherapy regimens were randomly selected to receive capecitabine alone or bevacizumab and capecitabine every 3 weeks. PFS, the primary endpoint, was substantially longer with bevacizumab and capecitabine than with capecitabine alone (median, 9.1 vs 5.1 months; HR, 0.53; 95% CI, 0.41-0.69; $P < .0001$). Although the study was underpowered to demonstrate a statistically significant improvement in OS, the median survival in the bevacizumab arm of 20.7 months (compared with 16.8 months for capecitabine alone) is remarkable given the age of the patient population and the limited postprogression therapies patients received. The combination of fluoropyrimidine and bevacizumab can be considered an acceptable standard of care for older patients who are not eligible for irinotecan or oxaliplatin but have no contraindication to receiving bevacizumab.

KEY POINTS

- All patients with metastatic colon cancer being considered for multiagent chemotherapy should have their tumors undergo extended *RAS* and *BRAF* mutation testing. In addition, all tumors should be tested for dMMR/MSI-H status and should undergo HER2 testing for overexpression or amplification as this may be a marker of resistance to anti-EGFR therapy as well as a potential target for therapies discussed subsequently.
- Either FOLFOX or FOLFIRI with a biological agent is an appropriate first-line chemotherapy backbone for patients who have mCRC.
- Eventual exposure to all appropriate agents is what is most important. Triplet regimens (FOLFIRINOX) with bevacizumab may be an option for patients who have aggressive tumors.

- For patients who have left-sided extended *RAS* WT tumors, anti-EGFR therapy should be preferentially considered, and anti-EGFR therapy should be avoided as initial therapy for patients who have right-sided tumors for which bevacizumab is preferred.
- Induction maintenance approaches with a limited number of oxaliplatin-containing treatment cycles up front and maintenance therapy with a fluoropyrimidine and bevacizumab combination can be considered standard of care. Those whose disease progresses during maintenance therapy can still have oxaliplatin reintroduced.
- For patients who are not candidates for either oxaliplatin- or irinotecan-containing regimens, the combination of a fluoropyrimidine and bevacizumab can be considered an acceptable standard of care.

ANTI-VEGFR ANTIBODY THERAPY BEYOND FIRST-LINE PROGRESSION

It has been suggested that prolonged inhibition of the VEGF-mediated proangiogenic system is required to maximize the treatment benefit for patients who are receiving anti-VEGF therapy, particularly because the mechanism and onset of secondary resistance could differ between chemotherapy and bevacizumab.[432] Additional evidence supporting the concept of prolonged VEGF inhibition as an optimized treatment approach in CRC comes from the ML18147 phase 3 trial, which tested the efficacy of bevacizumab beyond progression added to chemotherapy in mCRC.[433] A total of 820 patients who had received first-line palliative therapy with a bevacizumab-based combination were randomly assigned at progression to either continue bevacizumab with another standard chemotherapy backbone or stop bevacizumab. The primary endpoint of the study, improvement in OS, was reached with an HR of 0.81 (95% CI, 0.69-0.94) and median improvement of 1.4 months (11.2 vs 9.8 months; $P = .0062$). This effect was confirmed in all evaluated subgroups and supported by the PFS results, which demonstrated superiority for the bevacizumab beyond progression arm (HR, 0.68; median, 5.7 vs 4.1 months; $P < .0001$). No increase in response rate was seen in the bevacizumab beyond progression group, and the response rates seen in both arms in second-line therapy were low, approximately 4% to 5%. No new or unexpected safety issues emerged for bevacizumab. Confirmatory results were seen with two alternative anti-VEGF therapies: ziv-aflibercept (formerly known as VEGF-Trap), a VEGF receptor decoy fusion protein, and ramucirumab, a human monoclonal antibody directed against VEGFR-2.[154,434] It should be noted that there is no role for bevacizumab as a single agent as either maintenance or subsequent-line therapy. Further support for the efficacy of bevacizumab in patients who have previously received bevacizumab is provided by the randomized SUNLIGHT clinical trial which demonstrated improved survival for the addition of bevacizumab to trifluridine-tipiracil in previously treated patients. Approximately 3/4 of patients in both treatment arms had received prior bevacizumab. While a subgroup analysis of overall survival demonstrated what appeared to be a greater benefit to the addition of bevacizumab in the group who hadn't received bevacizumab compared to those who had (0.4 and 0.72 respectively), the benefit was statistically significant in both groups.[402]

Oral Agents in Salvage Therapy for CRC

Regorafenib, a small-molecule inhibitor of multiple cell-signaling kinases (eg, VEGFR-1 to -3, KIT, RET, FGFR1-2, PDGFR-β, and BRAF), has documented efficacy as salvage therapy in advanced CRC. Regorafenib was investigated in a placebo-controlled randomized phase 3 trial in a salvage therapy setting. Efficacy results of the trial demonstrated a benefit in OS for patients receiving regorafenib compared with placebo (6.4 vs 5.0 months).[435] The activity of regorafenib was also reflected in an improvement of PFS (1.9 vs 1.7 months). The most common severe toxicities observed with regorafenib were hand-foot syndrome, fatigue, diarrhea, and hypertension. Regorafenib is FDA approved as a salvage therapy option for patients with advanced CRC who have previously been treated with fluoropyrimidine, oxaliplatin, irinotecan, a VEGF inhibitor, and, if pan-*RAS* WT, an anti-EGFR monoclonal antibody. Given that approximately two-thirds of patients assigned to regorafenib in the pivotal required dose modification due to toxicity, and that clinical practice generally deemed the 160 mg daily dose approved by the FDA as intolerable for many patients, the randomized phase 2 ReDOS trial was performed.[436] Toxicities necessitating dose modification were primarily dermatologic, gastrointestinal, and constitutional. The ReDOS trial ultimately compared a starting dose of 80 mg/day and dose increases as tolerated versus a starting dose of 160 mg/day. The primary endpoint of essentially making it to start cycle 3 was met, with 43% in the dose escalation group versus 26% in standard dosing. Thus, in clinical practice, a ReDOS strategy is generally recommended for regorafenib use.

Trifluridine and tipiracil (TAS-102) comprise a novel oral anticancer agent consisting of trifluorothymidine as the antitumor component, which is incorporated into and retained in the DNA of cancer cells, and tipiracil hydrochloride, which prevents the degradation of trifluorothymidine. An international phase 3 study of 800 patients was launched in the same setting with random assignment at a 2:1 ratio favoring trifluridine and tipiracil.[437] The primary endpoint of the trial was met with an improvement in OS (median OS, 7.1 vs 5.3 months) with trifluridine/tipiracil compared with placebo. The most common grade 3 to 4 AE was neutropenia, seen in approximately 40% of patients with 4% having febrile neutropenia. Trifluridine and tipiracil received FDA approval in September 2015 for the treatment of patients with mCRC who have previously been treated with fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy, an anti-VEGF biological product, and an anti-EGFR monoclonal antibody, if pan-*RAS* WT. Trifluridine and tipiracil and regorafenib have distinctly different adverse effect profiles (trifluridine and tipiracil,

myelosuppression; regorafenib, hand-foot skin reaction and fatigue) but similar efficacy data. A phase 2 trial of 93 patients with refractory mCRC randomly assigned to trifluridine and tipiracil with or without bevacizumab showed improvement in the primary endpoint of PFS (median PFS, 4.6 vs 2.6 months). The follow-up phase 3 SUNLIGHT trial randomly selected patients with pretreated mCRC in the third-line setting to receive trifluridine and tipiracil with or without bevacizumab and showed an improvement in the primary endpoint of OS from 7.5 to 10.8 months (HR, 0.61; 95% CI, 0.49-0.77) and improvement in PFS from 2.4 to 5.6 months (HR, 0.44; 95% CI, 0.36-0.54) with the combination of trifluridine/tipiracil and bevacizumab, and this combination is included as an option in NCCN guidelines.[438]

Fruquintinib is a selective inhibitor of VEGFR-1, -2, and -3. It was evaluated in the placebo-controlled phase 3 FRESCO trial conducted in China for patients who have pretreated CRC (≤2 lines) that showed improvement in the primary endpoint of OS (9.3 vs 6.6 months; HR, 0.65; 95% CI, 0.51-0.83; $P < .001$), which led to its approval in China in the third- or later-line setting. The FRESCO-2 trial was a global placebo-controlled phase 3 trial that randomly selected 691 patients with refractory CRC, including prior trifluridine and tipiracil and/or regorafenib, that showed an improvement in the primary endpoint of OS (7.4 vs 4.8 months; HR, 0.66; 95% CI, 0.55-0.80; $P < .001$). The most common grade 3+ adverse events in the pivotal trials were hypertension, asthenia, and hand/foot syndrome. This drug gained FDA approval in November 2023.

With the approvals of trifluridine/tipiracil, regorafenib, and fruquintinib, these serve as reasonable subsequent treatment options for patients with metastatic colon cancer who have received prior fluoropyrimidine, oxaliplatin, irinotecan, bevacizumab, and anti-EGFR inhibitor if RAS/RAF wild-type. The key missing data are direct comparisons between the agents. Thus, in practice, selection of an oral agent is often based on prior toxicities experienced by patients as well as patient preferences as the dose schedules differ as well.

PD-1/PD-L1 Immune Checkpoint Inhibitors in CRC

Immune checkpoint inhibitors targeting the PD-1 pathway by binding to PD-1 or its ligand (PD-L1 or PD-L2) have shown proof of efficacy in various malignancies since 2014, and several antibodies targeting this system have already received FDA approval in noncolorectal malignancies, such as melanoma and non-small-cell lung cancer.[439] PD-1/PD-L1 inhibitors allow the patient's immune system to recognize cancer cells by blocking immunosuppressive mechanisms generated by tumor cells, particularly when these tumor cells carry a high DNA mutational burden with consecutive expression of many neoantigens. MSI-H/dMMR CRCs carry 10 to 100 times as many somatic mutations as microsatellite stable/MMR-proficient (pMMR) tumors.[440] In addition, MSI-H/dMMR colon cancers are commonly characterized by dense lymphocytic infiltrates, indicating a potential activation of the host's immune system.[441] On the basis of these observations, a pivotal pilot study was initiated that investigated the role of pembrolizumab, an antibody against PD-1, in heavily pretreated patients with advanced CRC, with cohorts identified by their MSI status (MSI-H/dMMR vs microsatellite stable/pMMR).[442] In addition, a cohort of patients who have MSI-H/dMMR non-CRC was included in the study. Single-agent pembrolizumab showed remarkable activity only in patients who have MSI-H/dMMR cancer, independent of histological origin. In MSI-H/dMMR CRCs, patients experienced a response rate >60% and a disease control rate >90% with some experiencing durable response for >1 year.[443] These findings led to the initiation of several studies with PD-1/PD-L1 antibodies, targeting the approximately 4% to 5% of mCRCs characterized as MSI-H/dMMR. Furthermore, for the first time, the FDA granted organ site–agnostic approval of pembrolizumab for any dMMR solid tumor. For CRC, pembrolizumab was approved for MSI-H/dMMR tumors after prior treatment with a fluoropyrimidine, oxaliplatin, and irinotecan.

Similarly, the FDA approved both nivolumab and combination nivolumab and ipilimumab for the treatment of patients with metastatic colon cancer with MSI-H/dMMR tumors. This was based on the results of the CheckMate 142 study, which showed an ORR of 34% (complete response [CR], 9%) and disease control rate of 62% in the single agent nivolumab arm.[444] In the 119 patients treated with the combination of ipilimumab and nivolumab, the ORR was 55% and disease control rate was 80%.[445] The two arms were not randomly assigned, so caution is required when comparing the results. At this point, there is no specific guidance on which PD-1 inhibitor should be used or whether it should be used in combination with ipilimumab or as a single agent.

The landmark phase 3 KEYNOTE-177 study randomly assigned patients who had first-line treatment-naive metastatic MSI-H/dMMR CRC to pembrolizumab or investigator's choice of chemotherapy; crossover to pembrolizumab was allowed at disease progression for patients in the chemotherapy arm. Median PFS was 16.5 months for pembrolizumab versus 8.2 months for chemotherapy (HR, 0.60; 95% CI, 0.45-0.80). The 24-month PFS rate was 48% for pembrolizumab versus 19% for chemotherapy. Overall response was 43.8% for pembrolizumab versus 33.1% for chemotherapy with 11% of patients in the pembrolizumab arm achieving a CR ($P = .0275$). In an updated analysis, after a median follow-up of 44.5 months, although the HR for OS favored pembrolizumab, it did not reach statistical significance (HR, 0.74; 95% CI, 0.53-1.03; $P = .0359$). This likely was related to 60% of patients in the chemotherapy arm subsequently receiving anti–PD-1/PD-L1 therapies on or off study.[446] This study, however, established pembrolizumab as the standard-of-care first-line therapy for patients with MSI-H/dMMR tumors and is now FDA approved for this indication. Additional trials are examining combinations with CTLA-4 inhibitors and combinations of chemotherapy with immunotherapy. CheckMate 8HW, which is a randomized phase 3 study comparing nivolumab and ipilimumab with nivolumab or chemotherapy in patients with MSI-H/dMMR mCRC, initially reported results only for the nivolumab and ipilimumab arm. This arm demonstrated superior PFS versus chemotherapy in previously untreated patients who have MSI-H/

dMMR mCRC.[447] The trial subsequently reported data for the comparison between combination ipilimumab/nivolumab and nivolumab monotherapy across all lines of therapy.[448] There was a statistically significant improvement in PFS (median 54.1 months vs 18.4 months, HR 0.64 [0.52-0.79], with a 13% increase in response rate (58%-71%, $P = .0011$). Of equal importance, treatment-related adverse events of grade 3/4 were only modestly increased from 14 to 22%, with 9% discontinuing the combination due to adverse events compared to 4% with nivolumab monotherapy. Based on these data, combination therapy with ipilimumab/nivolumab may be considered the standard initial therapy for patients with dMMR/MSI-H metastatic colorectal cancer with good performance status. Single-agent checkpoint inhibitor therapy can also be considered in select patients. It is reasonable to consider dual immunotherapy for patients who have progressed on single-agent checkpoint inhibitor, although data addressing the degree of benefit (if any) are lacking. It must be emphasized again that, for all of the immunotherapy trials discussed in this section, these agents should not be used in patients who have pMMR tumors outside of a clinical trial.

BRAF-Mutated Tumors

BRAF encodes a protein GTPase, downstream of RAS. *BRAF* V600E mutations can be found in approximately 5% to 10% of patients with advanced CRC.[449] They are mutually exclusive with *RAS* mutations and have been consistently found to be associated with a poor prognosis.[411,450,451] Even in the era of modern combination therapy, median survival of patients with *BRAF*-mutated stage IV CRC is only 12 to 14 months.[411] Whether activating *BRAF* mutations can be considered negative predictive markers for the activity of anti-EGFR antibodies has long been unclear because of their strong negative prognostic effect and their low prevalence. A meta-analysis of nine phase 3 trials and one phase 2 trial, which all randomly assigned patients to treatment with or without EGFR inhibitors, showed no benefit for the use of EGFR antibodies with regard to PFS, OS, or response rate.[452] Therefore, the use of EGFR inhibitors (without combining with a BRAF inhibitor) for patients with tumors containing activating *BRAF* mutations should not be considered a first choice if at all.

The phase 3 BEACON trial evaluated second- or third-line cetuximab and the BRAF inhibitor encorafenib with or without the MEK inhibitor binimetinib compared with irinotecan (with or without 5-FU) and cetuximab.[453] Both experimental arms showed improved efficacy over the control, but the doublet regimen of cetuximab and encorafenib showed lower toxicity rates. Updated results of this trial showed improvement in median OS for triplet over control (9.3 vs 5.9 months; HR, 0.60; 95% CI, 0.47-0.75) and for doublet over control (9.3 months; HR, 0.61; 95% CI, 0.48-0.77). Confirmed response rates were 26.8% (95% CI, 21.1-33.1) for triplet, 19.5% (95% CI, 14.5-25.4) for doublet, and 1.8% (95% CI, 0.5%-4.6%) for control. Based on these encouraaging second-line data, the phase 3 BREAKWATER trial investigated encorafenib/cetuximab (EC) plus mFOLFOX6 versus standard-of-care chemotherapy for untreated metastatic BRAFV600E colorectal cancer.[454] The initial report demonstrated that EC + mFOLFOX6 had increased ORR, 60.9% versus 40.0% with SOC chemotherapy. Median duration of response was 13.9 versus 11.1 months. A subsequent presentation and manuscript extended the analysis and follow-up, reporting a statistically significant improvement in progression-free survival for the addition of EC (median, 12.8 vs 7.1 months; hazard ratio for progression or death, 0.53; 95% confidence interval [CI], 0.41 to 0.68; $P < .001$). An interim analysis also demonstrated improved OS with the addition of EC to FOLFOX (median, 30.3 vs 15.1 months; hazard ratio for death, 0.49; 95% CI, 0.38 to 0.63; $P < .001$). Side effects were modestly increased but consistent with known profiles of these agents. These data highlight the importance of testing for *BRAF* mutations with initial diagnosis of metastatic disease.[370] As a result of this trial, NCCN guidelines were updated as well as the FDA approval for encorafenib and cetuximab in combination with mFOLFOX6 for treatment of patients with metastatic CRC with a *BRAF* V600E mutation. In practice, many substitute panitumumab for cetuximab. It also should be noted that nearly all patients in the BREAKWATER trial had MSS cancers. While patients with dMMR (MSI-H) tumors and concomitant *BRAF* V600E mutations would technically be eligible for encorafenib/cetuximab combination therapy, most would favor initial immunotherapy given the degree and durability of benefit, and reserving BRAF-targeted therapy for progression.

Non-V600E mutations in *BRAF* (atypical *BRAF* mutations) represent a rare subset (2%-3% of all patients with CRC) and are divided into classes II (RAS independent; intermediate to high kinase activity) and III (RAS dependent; low kinase activity); such patients may have limited response to anti-EGFR antibodies.[455] Other studies show that their OS may be better than that of patients with *BRAF* V600E–mutated or *BRAF* WT tumors.[456]

HER2 Overexpression/Amplification

HER2 is overexpressed in approximately 5% of metastatic colon cancers and this overexpression occurs more in left-sided tumors. The HERACLES trial treated patients with mCRC with *KRAS* WT/*HER2*-amplified disease (IHC 3^+ or IHC 2^+ with FISH ratio >2.0) with trastuzumab and lapatinib. Despite 74% of these patients receiving more than four lines of therapy, the ORR was 30%, and the disease control rate was 60%.[456] Similar findings were seen in the MyPathway trial, in which patients who had HER2-positive disease were treated with trastuzumab and pertuzumab therapy.[457] In the 37 patients who had colon cancer, most of whom had received more than four prior therapies, 38% had tumor response, and the disease control rate was 49% with a median DOR of >11 months. The MOUNTAINEER trial treated 84 patients who had *RAS* WT/*HER2*-amplified disease with tucatinib and trastuzumab and showed an ORR of 38%, (95% CI, 28-49); median DOR was 12.4 months (95% CI, 8.5-20.5).[458] Based on these data, the FDA granted accelerated approval of tucatinib in combination with trastuzumab for *RAS* WT/*HER2*-amplified unresectable

or metastatic colorectal cancer that has progressed after fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy. The ongoing phase 3 MOUNTAINEER-03 trial is comparing tucatinib, trastuzumab, and mFOLFOX6 versus mFOLFOX6 with or without bevacizumab or cetuximab in the first-line setting for these patients. The DESTINY-CRC02 trial of the antibody-drug conjugate trastuzumab-deruxtecan (T-DXd) was conducted in two stages. In stage 1, 80 patients were randomly assigned 1:1 to 5.4 (n = 40) or 6.4 mg/kg (n = 40) of T-DXd once every 3 weeks. In stage 2, an additional 42 patients received 5.4 mg/kg of T-DXd. The confirmed ORR was 37.8% (95% CI, 27.3%-49.2%) in the 5.4 mg/kg arm and 27.5% (95% CI, 14.6%-43.9%) in the 6.4 mg/kg arm. Grade ≥ 3 TEAEs were observed in 41 (49.4%) of 83 patients and 23 (59.0%) of 39 patients in the 5.4 and 6.4 mg/kg arms, respectively. Serious AEs were observed in 20 (24.1%) of 83 patients and 12 (30.8%) of 39 patients in the 5.4 and 6.4 mg/kg arms, respectively. Independently adjudicated drug-related interstitial lung disease occurred in seven (8.4%) of 83 patients with 5.4 mg/kg of T-DXd and five (12.8%) of 39 patients with 6.4 mg/kg of T-DXd. This study suggests that the 5.4 mg/kg dose may be preferable over the 6.4 mg/kg dose with similar efficacy but an improved toxicity profile. Additionally, antitumor efficacy was observed irrespective of *RAS* mutation status at 5.4 mg/kg of T-DXd and in those with prior anti-HER2 therapy although no meaningful activity was observed in those with low HER2 expression.[459] Thus in practice, the MOUNTAINEER regimen of tucatinib/trastuzumab may be preferred for patients with *HER2* amplified, RAS wild-type cancers and is not approved for patients whose tumors have *RAS* mutations. Trastuzumab-deruxtecan is preferred for patients with HER2-positive (HER2 3+) cancers and concomitant *RAS* mutations.

KRAS G12C–Mutated Tumors

Although *KRAS* mutations have been long thought to be undruggable, recently developed small molecules that covalently bind to the mutant cysteine in the *KRAS* switch II binding pocket of *KRAS* G12C have shown activity. *KRAS* G12C mutations are seen in 3% to 4% of CRCs and are associated with worse survival outcomes than other *KRAS* mutations in retrospective studies. The nonrandomized phase 1 to 2 KRYSTAL study assigned 44 heavily pretreated patients who had *KRAS* G12C–mutated CRC to receive adagrasib and 32 to receive combination therapy of adagrasib and panitumumab. Both the response rate (19% vs 46%) and median response duration seemed to be higher with the combination (4.3 vs 7.6 months). Updated data on 94 patients receiving adagrasib and cetuximab with a median follow-up of 11.9 months suggested an ORR of 34.0%, disease control rate of 85.1%, and median duration of response of 5.8 months (95% confidence interval [CI], 4.2-7.6). Median progression-free survival was 6.9 months (95% CI, 5.7-7.4), and median overall survival was 15.9 months (95% CI, 11.8-18.8). Treatment-related adverse events (TRAEs) occurred in all patients; grade 3-4 in 27.7% and no grade 5. No TRAEs led to adagrasib discontinuation. This combination was provided an accelerated approval by the FDA in June 2024.[460] Sotorasib, another *KRAS* G12C inhibitor, was evaluated as a single agent in 62 patients in the phase 2 CODEBREAK trial and in combination with cetuximab in 40 patients in the CODEBREAK101 trial. Although the single agent seemed to have modest activity with a response rate of 9.7%, the combination showed better results with a response rate of 30%. The combination of sotorasib and panitumumab was ultimately evaluated in a phase 3 randomized trial at one of two doses of sotorasib (960, 240 mg) or investigator's choice of lonsurf or regorafenib in patients with previously treated metastatic colorectal cancer with a *KRAS* G12C mutation.[461] After a median follow-up of 7.8 months (range, 0.1-13.9), the median progression-free survival was 5.6 months (95% confidence interval [CI], 4.2-6.3) and 3.9 months (95% CI, 3.6-5.7) in the 960-mg sotorasib–panitumumab and 240-mg sotorasib–panitumumab groups, respectively, compared with 2.0 months (95% CI, 1.9-3.9) in the standard-care group. The hazard ratio for disease progression or death in the 960-mg sotorasib–panitumumab group compared with the standard-care group was 0.48 (95% CI, 0.30-0.78; $P = .005$), and the hazard ratio in the 240-mg sotorasib–panitumumab group was 0.59 (95% CI, 0.37-0.95; $P = .036$). The objective response was 26.4% (95% CI, 15.3-40.3), 5.7% (95% CI, 1.2-15.7), and 0% (95% CI, 0.0-6.6) in the 960-mg sotorasib–panitumumab, 240-mg sotorasib–panitumumab, and standard-care groups, respectively. In the era of G12C-targeted therapy, it is of utmost importance to recognize the specific *RAS* mutation that may be present in each patient's tumor.

KEY POINTS

- Continuing anti-VEGF therapy beyond first-line progression with bevacizumab and second-line chemotherapy is supported by data.
- Patients who have *BRAF* V600E–mutated tumors should be considered for encorafenib/cetuximab/mFOLFOX6 for the front line or, in the second line and beyond, treatment with the doublet regimen of encorafenib and anti-EGFR antibody.
- For patients who have MSI-H/dMMR tumors, the use of single-agent pembrolizumab or the combination of nivolumab/ipilimumab is considered a preferred standard of care over multiagent chemotherapy as first-line therapy based on the KEYNOTE-177 trial and CheckMate 8HW, respectively.
- Patients who have *HER2*-amplified or HER2-overexpressed colorectal cancers should be considered for treatment with agents directed against HER2 after initial therapy with consideration of RAS status.
- Patients with colorectal cancer with *KRAS* G12C mutations should be considered for targeted therapy after initial chemotherapy with sotorasib or adagrasib alone or with anti-EGFR antibody therapy.

- Regorafenib, fruquintinib, or trifluridine/tipiracil with or without bevacizumab should be considered for patients who have disease refractory to all other approved agents. The decision of how to best sequence these agents is based on the adverse effect profile and individual preferences.

PRESENTING CASE STUDY

A 55-year-old man presents with a 10-pound unintentional weight loss over a few months and newly discovered iron-deficiency anemia. Subsequent evaluation with colonoscopy identifies a mass in the ascending colon; biopsy confirms invasive adenocarcinoma of the colon. Staging imaging reveals numerous metastatic lesions in both lobes of the liver and the right lung and periportal and retroperitoneal lymphadenopathy. Hepatic lesion biopsy confirms adenocarcinoma of likely colonic origin. Baseline carcinoembryonic antigen level is 278 ng/mL. The patient has well-controlled hyperlipidemia and is otherwise in good health. His Eastern Cooperative Oncology Group performance status is 1. Further testing of the biopsy samples shows that the tumor is RAS and BRAF wild type with proficient mismatch repair proteins. HER2 is not overexpressed. He visits the oncology clinic to discuss systemic treatment.

How would this patient's symptoms, primary tumor site, baseline comorbid conditions, and RAS/BRAF status inform your choice of initial front-line systemic therapy?

For patients with previously untreated metastatic colon cancer, the site of the primary tumor, presenting symptoms and baseline comorbid conditions, and the RAS/BRAF status influence the choice of biological agent added to chemotherapy in the front line.

Cumulative data from randomized trials indicate that right-sided tumors that are RAS and BRAF wild type derive relatively more benefit when standard-of-care chemotherapy (eg, FOLFOX (5-fluorouracil, leucovorin, and oxaliplatin), FOLFIRI (5-fluorouracil, leucovorin, and irinotecan), or FOLFIRINOX) is combined with bevacizumab. On the other hand, patients with left-sided tumors that are similarly RAS and BRAF wild type derive relatively more benefit when chemotherapy is combined with epidermal growth factor receptor inhibitors (eg, cetuximab and panitumumab). In general, bevacizumab may need to be approached with caution on initial cycle(s) if there is threatened obstruction, recent surgery or radiation, active GI bleeding, or other relative contraindications that may improve on subsequent treatment dates. Thus, chemotherapy plus bevacizumab would be the most appropriate initial treatment selection for this patient.

OLIGOMETASTATIC CRC

All patients who have potentially resectable metastatic disease, most frequently presenting with few lesions limited to liver and/or lung, should be evaluated by a multidisciplinary team at a center with high-volume expertise in treating oligometastatic disease. If there is any question about potential resectability, a referral is appropriate. When pooling data for all patients who have a hepatic resection, the average 5-year survival rate is approximately 30% with a less favorable prognosis for patients with multiple lesions, a short interval between the diagnosis of the primary tumor and recurrence, and the presence of stage 3 disease at the time of initial diagnosis.[462-464]

Preoperative chemotherapy can be used to downsize initially unresectable metastases to increase potential resectability. Patients who undergo successful neoadjuvant therapy with subsequent R0 resection of liver metastases may achieve a median OS approaching that of patients with initially resectable metastases.[462,465] Therefore, the initial therapeutic approach for a patient who has limited metastatic disease should always include consideration of a potentially curative option.

The benefit of chemotherapy in the setting of clearly resectable hepatic disease either in the adjuvant or the neoadjuvant setting is low with no clear survival advantage. In a European phase 3 trial of resectable liver-limited mCRC, 364 patients were randomly assigned to either proceed directly to surgery or receive FOLFOX chemotherapy for 3 months followed by resection and then followed by three additional months of FOLFOX.[466] Patients meeting the eligibility criteria of the trial who received perioperative chemotherapy had a significant improvement in 3-year PFS compared with patients in the surgery alone arm (36.2% vs 28.1%; HR, 0.77; $P = .041$). After a median follow-up of 8.5 years, no difference in OS was seen in this study.[467] It is important to note that 5-year survival in this group of patients with resectable metastatic disease was approximately 50%, which is significantly better than historically expected for all-comers with stage IV colorectal cancer. The small phase II/phase III JCOG 0603 study examined the role of observation alone versus adjuvant FOLFOX for 6 months after resection of colorectal liver metastases in approximately 300 total patients (280 deemed eligible after randomizing). The study similarly found that, while DFS improved (HR, 0.67; 95% CI, 0.5-0.9), OS did not (HR, 1.25; 95% CI, 0.78-2.00) in the adjuvant chemotherapy cohort after nearly 5 year

median follow-up. Notably, patients in the adjuvant FOLFOX cohort did not start treatment until 56 to 84 days after hepatectomy, which is generally considered a window of significantly less adjuvant benefit in earlier cancer stages,[468,469] and of 146 FOLFOX patients deemed eligible, only 91 patients completed chemotherapy.[470]

The role of biological agents (eg, EGFR and VEGF inhibitors) in the context of preoperative or perioperative therapy for potentially resectable liver metastases is unclear. Initial data suggest some benefit with the addition of cetuximab to chemotherapy (FOLFOX or FOLFIRI) in this setting,[471] but later results from the randomized new EPOC trial conducted in the United Kingdom suggested an unexplained detrimental effect on OS when cetuximab was added to perioperative FOLFOX or FOLFIRI, though initially the study did not exclude *RAS*-mutated cancers, but was amended to include only KRAS wild type tumors beginning 1 year into the 5 years of enrollment to this study, by which point 12 *RAS/RAF*-mutated cancers had been enrolled in each arm.[472] No randomized trial, to our knowledge, has tested the role of chemotherapy with or without bevacizumab in the context of liver resection. If bevacizumab is used in the preoperative setting, it must be discontinued approximately 6 to 8 weeks before planned abdominal surgery to reduce the risk of wound-healing complications.[473]

Colorectal oligometastasis to only the lung has been associated with better progression free and overall survival compared to colorectal cancer liver metastasis (CRCLM). It is important to note that there are substantial data to support disease resection outside of the liver with the lung being the next most common site for secondary resection.[474]

The randomized TransMet trial recently assessed the role of liver transplantation plus chemotherapy compared to palliative chemotherapy alone in select patients with unresectable liver-only metastases. Patients aged 18 to 65 years, with unresectable colorectal liver metastases from resected *BRAF*-nonmutated colorectal cancer responsive to systemic chemotherapy (≥3 months, ≤3 lines), and no extrahepatic disease were eligible for enrollment. Patients were randomized to liver transplantation plus chemotherapy or chemotherapy alone. In the intention-to-treat population, 5-year OS was 56.6% (95% CI, 43.2-74.1) for liver transplantation plus chemotherapy and 12.6% (5.2-30.1) for chemotherapy alone (HR, 0.37 [95% CI, 0.21-0.65]; *P* = .0003) and 73.3% (95% CI, 59.6-90.0) and 9.3% (3.2-26.8), respectively, for the per-protocol population. Serious adverse events occurred in 32 (80%) of 40 patients who underwent liver transplantation (from either group), and 69 serious adverse events were observed in 45 (83%) of 54 patients treated with chemotherapy alone.[474]

Liver-Directed Therapies

Hepatic arterial infusion pumps have been evaluated in multiple prospective trials. Although excellent response rates and control of hepatic metastases have been achieved, a meta-analysis of 10 randomized trials enrolling >1000 patients found no differences in OS.[475] Similarly, radioembolization using ^{90}Y and systemic chemotherapy was evaluated in three parallel multinational trials for patients with CRCLM, and despite improved response rates and liver-specific PFS, no improvement in OS, PFS, or hepatic resection rates was seen.[476] The recent phase III COLLISION[477] trial compared overall survival between patients receiving surgical metastasectomy versus thermal ablation for liver metastases ≤3 cm. While median OS has not yet been reached for either group, the study found survival outcomes for ablation were noninferior to surgery. Combinations of surgical resection and radiofrequency ablation are used at some specialty centers as is external-beam stereotactic radiation therapy (RT). Histotripsy, a device used to sonicate liver lesions, was cleared by the FDA in 2023 for use with liver metastases from any primary site on the basis of reasonably safe application in small early HOPE4LIVER trials[478] (n = 44); however, there are no trials specific to CRCLM, no long-term survival outcomes, nor comparative trials against other liver-directed modalities to determine if this should be utilized over other established options. This again emphasizes the importance of evaluation at centers with high-volume expertise in treating such patients.

Peritoneal-Only Metastases

An older randomized Dutch trial that compared cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) with systemic 5-FU chemotherapy for patients with CRC with peritoneal-only disease reported improved survival for the cytoreductive surgery and HIPEC group.[479] The relevance of the trial was questioned because of the use of the older, less aggressive systemic chemotherapy (ie, 5-FU alone) and because the relative value of HIPEC added to cytoreductive surgery could not be determined. The results from the PRODIGE-7-ACCORD-15 trial comparing the outcomes between patients with peritoneal-only colorectal metastases who were randomly assigned to either CRS with 6 months of systemic chemotherapy, or the same with HIPEC using oxaliplatin, showed no difference in OS between the two groups with a median OS of >41 months in both groups and a 5-year survival rate of 40%.[480] Overall, this did represent better than expected mOS for patients in both cohorts compared to mOS in all-comers with stage IV CRC, suggesting CRS itself may improve mOS. Subgroup analyses found a trend toward HIPEC survival benefit in those with intermediate-volume peritoneal disease. CAIRO6 is a phase 3 trial, presented at ASCO Annual Meeting 2025, that randomized 358 patients with treatment-naive CRC with peritoneal-only metastases, to receive CRS-HIPEC alone versus perioperative doublet-chemotherapy (CAPOX, FOLFOX, or FOLFIRI) with CRS-HIPEC, to determine if perioperative chemotherapy improved OS from CRS-HIPEC at 3 years.[481] While there was numeric improvement of mOS and OS-3 year in the perioperative group compared to the CRS-HIPEC only cohort, this was not statistically significant. At this time, HIPEC, at least that with oxaliplatin, which does not traditionally exhibit systemic single-agent activity in CRC, cannot be universally recommended

for patients who have CRC with peritoneal-only metastases. CRS is an option, but patients should be seen at centers with specialization in assessing patients for this type of procedure.

KEY POINTS

- All patients who have isolated metastatic disease should be considered for surgical resection or other locoregional therapies, and discussion should take place in a multidisciplinary setting conducted at a center with high-volume expertise in treating these cancers.
- Patients who have initially unresectable disease can be considered for conversion therapy with multiagent neoadjuvant chemotherapy.
- The benefit of neoadjuvant, perioperative, or adjuvant chemotherapy for patients who have clearly resectable metastatic disease, although often used, has not been substantiated by randomized clinical trials to improve OS.
- Liver-directed therapies with either intrahepatic chemotherapy or radioembolization have not shown a survival advantage in multi-institution trials and should not be considered standard of care outside of careful patient selection in experienced centers.
- Liver transplantation is an option for highly select patients with permanently unresectable liver-only metastases and where the primary tumor was previously resected.
- Patients who have peritoneal-only CRC should be evaluated at specialized centers for cytoreductive surgery, but HIPEC remains controversial.

NONMETASTATIC RECTAL CANCER

Cancers arising in the rectum are associated with a higher overall risk of recurrence than those associated with similar stages of colon cancer. The reason for local recurrence in rectal cancer is believed to be the anatomic location of the rectum and the challenge this presents to the surgeon to achieve clear circumferential resection margins. Traditionally, clinical stage II and III rectal cancers, unlike colon cancer, are treated with trimodality therapy of chemotherapy, radiation therapy, and surgery, though a number of recent trials have been shifting the treatment paradigm.

STAGING

Staging of rectal cancer consists of either rectal MRI or transrectal ultrasound (TRUS) to determine clinical tumor (T) and N (lymph node) staging. Both are considered appropriate, but more recent data suggest more information can be gleaned from rectal MRI, including more precise T staging and better evaluation of the likely circumferential resection margin.[482] Both approaches are contingent on the technical competence of the endoscopist or the reading radiologist and on the availability of modern MRI equipment. Cross-sectional imaging, preferably with CT of the chest and abdomen (contrast-enhanced), should be performed to rule out metastatic disease. There is no role for routine PET scan in the staging of rectal cancer. DNA mismatch repair (MMR) IHC or microsatellite instability (MSI) PCR/NGS testing needs to be conducted on the initial biopsy tissue confirming malignancy, as subsequent treatment may vary significantly depending on whether the cancer is pMMR/microsatellite stable (MSS) or deficient (dMMR)/microsatellite instability-high (MSI-H).

TREATMENT

There is increasing evidence to suggest that local excision (ie, transanal endoscopic microdissection [TEM]) should be restricted to patients who have stage T1 rectal cancer without high-risk factors.[483] For all other stages, total mesorectal excision (TME) has emerged as the preferred surgical technique. This technique honors natural tissue planes alongside the mesorectal fascia (MRF) and decreases the chances of local seeding and subsequent recurrence.[484] TME is most frequently performed as a sphincter-preserving low anterior resection (LAR) in mid-to-proximal rectal tumors, or as permanent sphincter excision with an anterior peritoneal resection (APR) in distal rectal cancers that arise too closely to the anorectal junction. In combination with preoperative (neoadjuvant) or postoperative (adjuvant) chemoradiation therapy (CRT), 5-year local recurrence rates of less than 5% to 10% can be achieved.[485-488]

Due to significant morbidity and higher disease-specific mortality associated with local relapse, neoadjuvant and adjuvant pelvic radiation strategies were designed to reduce local recurrence in locally advanced (stage II and stage III). Two different approaches have been used in this regard: short-course, high-dose radiation therapy commonly delivered as 5 Gy daily for 5 days (5 × 5) or long-course combined-modality CRT with radiosensitizing systemic chemotherapy (ie, capecitabine, 5-FU) administered concurrently with radiation therapy to a total dose of 50.4 Gy (45 + 5.4 Gy local boost) over 5 to 5.5 weeks (25-28 fractions), followed by an 8- to 10-week treatment break before curative surgery.[486,488,489]

Of note, only the longer CRT approach has repeatedly been demonstrated to downstage tumors, which might allow sphincter preservation. Both treatment approaches, however, have been associated with a decrease in locoregional failure. Prevention of

local recurrence has not uniformly been associated with improved OS. However, one Swedish trial, in which 1,168 patients were randomly assigned to either short-course RT (5 Gy × 5 days to 25 Gy) in the week before surgery versus surgery alone, demonstrated both a reduction in local recurrences (11% vs 27%; $P < .001$) and a survival advantage at 5 years (58% vs 48%; $P = .004$) for those receiving neoadjuvant RT.[488] A subsequent Dutch trial, using the same short-course RT regimen in combination with quality-controlled TME surgery, confirmed a low rate of local recurrence (at 2 years, 2.4% vs 8.4%; $P < .001$) but did not demonstrate a survival benefit.[486] Of note, however, the local recurrence rate of tumors >10 cm above the anal verge was not significantly improved, suggesting more proximal/upper rectal tumors may not all benefit from radiation.

Although the short-course neoadjuvant RT strategy is most commonly used in Scandinavia and other European countries, most US oncologists have historically preferred neoadjuvant or adjuvant combined long-course CRT. Findings from two studies of adjuvant CRT demonstrated that combination 5-FU-based chemotherapy and RT were more effective than RT or surgery alone in preventing both local and distant recurrences.[490,491] Results from NSABP R-01 showed that 5-FU in a continuous IV infusion (CIVI) was superior to 5-FU bolus administration during adjuvant radiation therapy, providing a 3-year DFS advantage.[492] This finding confirms that protracted delivery of chemotherapy-sensitizing agents concomitant with long-course RT regimens is the best option for CRT. Two randomized phase 3 studies confirmed the noninferiority of oral capecitabine (825 mg/m^2 twice daily on days of RT) as a radiosensitizer compared with 5-FU CIVI during neoadjuvant therapy in rectal cancer.[493,494] Clinically, either 5-FU CIVI or capecitabine is an acceptable choice to administer with RT, and the choice depends on patient preferences for convenience and the clinical team's determination of potential adverse effects and whether the patient is likely to adhere to an oral regimen.

The long-standing question about whether neoadjuvant or adjuvant CRT results in improved outcomes was definitively answered by the results of a large German randomized trial that compared standard long-course CRT with 5-FU CIVI either before or after quality-controlled TME.[488] Patients undergoing neoadjuvant CRT had a lower rate of local recurrence (6% vs 13% at 5 years), a lower rate of acute and chronic toxicities, and a significantly higher rate of sphincter preserving TME compared with those receiving adjuvant CRT ($P = .006$), but there was no survival advantage to the neoadjuvant approach. This trial established neoadjuvant CRT with 5-FU CIVI as a new standard of care for stage II and III rectal cancers. It is important to note that, for those patients who undergo up-front surgery (because of clinical stage I disease) and are found to have pathological stage II or III disease, postoperative chemotherapy and CRT should be considered.

Subsequent studies have tried to further improve the local control rate by incorporating additional radiosensitizing agents, such as oxaliplatin, and biological agents into the preoperative treatment phase.[495-498] Data call into question the potential role of oxaliplatin as a radiosensitizer when added to fluoropyrimidines in neoadjuvant CRT for rectal cancer.[499-501] Consistent results from Italian, French, and US phase 3 trials have shown the addition of oxaliplatin to fluoropyrimidine (5-FU or capecitabine) as a component of neoadjuvant CRT does not increase the rate of pCR with the use of oxaliplatin, but it significantly increases toxic effects, mainly diarrhea. Only a German trial, which used a slightly different schedule of oxaliplatin administration, showed superiority in the oxaliplatin arm in terms of pathological response.[497] However, the overwhelming body of evidence at this time suggests oxaliplatin should not be used as part of neoadjuvant CRT for rectal cancer outside of a clinical trial.

Two smaller phase 3 trials (Polish I, TTOG 01.04) compared neoadjuvant CRT, following the German rectal protocol, with short-course radiation therapy (5 × 5 Gy) as neoadjuvant treatment of localized rectal cancer. The two trials demonstrated that both treatment approaches are valid options in the preoperative setting of rectal cancer with similar rates of local recurrence and OS.[502,503] The more complex Chinese STELLAR trial enrolled 599 patients with mid/distal clinical stage II or III rectal cancer to receive either neoadjuvant treatment with short-course RT and consolidation CAPOX x4 cycles or long-course CRT with capecitabine.[504] In both groups, this followed by surgery (though this was not pursued in 63 patients in each cohort) and adjuvant CAPOX for either two cycles in the short-course group (erroneously labeled "TNT" in the study paper, as patients were intended to receive adjuvant therapy), or six cycles in the long-course CRT group. Despite this more heterogeneous treatment course in both cohorts and more prevalent severe acute toxicity during neoadjuvant therapy (26.5% vs 12.6%, $P < .01$), DFS at 3 years was noninferior (64.5% vs 62.2%, $P < .01$ for noninferiority) and OS at 3 years was improved (86.5% vs 75.1%, $P = .33$) in the short-course group.

Role of Adjuvant Chemotherapy

The role of adjuvant chemotherapy, particularly after neoadjuvant radiation therapy, has been disputed by the results of individual trials and by a meta-analysis of four studies.[505] The meta-analysis included subgroups of patients from trials, two of which were completed a decade ago. The trials used 5-FU-based adjuvant chemotherapies administered according to outdated regimens no longer considered standard of care, such as the Mayo Clinic regimen (5-FU/LV) and its variations. Neoadjuvant therapy was heterogeneous and included CRT and radiation therapy alone. The authors found no difference in distant relapse or OS associated with the use of adjuvant therapy. A consistent problem in many of these studies and in clinical practice is that it is difficult for patients to complete chemotherapy after surgery; completion rates of ≤50% are often seen. The more recent Korean ADORE trial randomly assigned patients who had received neoadjuvant CRT and had pathological stage II or III cancer to either adjuvant bolus 5-FU/LV or FOLFOX for 4 months (16 weeks). The 6-year DFS rate was 68.2% in the FOLFOX arm versus 56.8% in

the bolus 5-FU arm (HR, 0.63; 95% CI, 0.43-0.93; $P = .018$).[506] Although some experts advocate that those who achieve a pathological complete response (pCR) following neoadjuvant CRT do not need adjuvant chemotherapy, this is not standard of care, and NCCN guidelines currently recommend all such patients receive adjuvant chemotherapy, though this clinical scenario is becoming uncommon in the era of TNT.

Total Neoadjuvant Therapy (TNT) Approach

Currently, the most widely used treatment for locally advanced rectal cancer is TNT, in which all intended systemic chemotherapy and CRT (or short-course RT) are completed before surgery. The theoretical advantage to this approach is that micrometastatic disease is treated earlier, tumor downstaging is enhanced, and delivery of the full chemotherapy regimen (ie, FOLFOX for 4 months) may be increased in the absence of patients having complications from surgery or reduced drug tolerance after surgery, leading to greater dose intensity of treatment.

In one phase II trial, 108 patients were randomly assigned to CRT with CAPOX followed by TME followed by four cycles of adjuvant CAPOX or assigned to a TNT approach of four cycles of neoadjuvant CAPOX followed by CRT with CAPOX followed by surgery. pCR rates did not differ between the groups, but grade 3 toxicity was much lower in the TNT arm (19% vs 54%), and compliance with all four cycles of chemotherapy was higher with TNT (94% vs 57%).[507]

The multicenter "Timing" trial included 259 patients who were administered neoadjuvant CRT with 5-FU CIVI followed by sequential assignment to cohorts receiving either zero, two, four, or six cycles of FOLFOX before TME. Patients who received six cycles of neoadjuvant FOLFOX (ie, TNT) experienced 38% pCR, significantly greater than the 18% pCR experienced by the group receiving standard CRT alone ($P = .0036$).[470] Chemotherapy was also completed by 98% of the patients in the six-cycle group.

Two phase II trials have examined the sequencing order of neoadjuvant modalities, with chemotherapy being given either before (induction) or after (consolidation) CRT. CAO/ARO/AIO-12, a randomized phase II trial, compared patients receiving CRT with either induction or consolidation neoadjuvant FOLFOX chemotherapy, who then went on to TME. The study found increased pCR rates in the consolidation chemotherapy arm (25% vs 17% in the induction group).[508] The OPRA trial also examined the question of optimal sequence of chemotherapy in the TNT approach in a randomized fashion, but additionally allowed "nonoperative management" with close "watch & wait" for patients who achieved a clinical complete response (cCR) to TNT.[509] This trial demonstrated that the 3-year TME-free survival rate was 41% (95% CI, 33-50) in the induction group and 53% (95% CI, 45-62) in the consolidation group. The three-year DFS rates did not seem to be compromised by this nonoperative approach compared to historical controls, though DFS was the same whether patients received either induction or consolidation chemotherapy.

On the question of long-course CRT versus short-course RT having the best outcomes with TNT, several randomized phase III trials have been performed. The Polish II trial randomized 541 patients to receive either neoadjuvant short-course RT with FOLFOX4 x3 cycles or long-course CRT (bolus 5-FU/LV on weeks 1 and 5 with or without weekly oxaliplatin x5 weeks) followed by surgical resection, though the trial was subsequently amended during enrollment to allow omission of oxaliplatin in both groups.[510,511] While this makes the study more difficult to contextualize, those on the short-course TNT regimen had significantly less acute toxicity and improved OS rate at 3 years (73% vs 65%, $P = 0.046$), though no improvement in R0 resection rates (77% vs 71%, $P = 0.07$), pCR rates (16% vs 12%, $P = 0.17$), local failure (22% vs 21%, $P = 0.82$), or DFS rates at 3 years (53% vs 52%, $P = 0.85$). The European RAPIDO trial (n = 920) compared short-course RT followed by consolidation CAPOX or FOLFOX for 4.5 months followed by TME versus CRT, TME, and optional adjuvant FOLFOX or CAPOX chemotherapy strictly in rectal cancers with one or more high-risk features for metastasis (ie, cT4, cN2, MRF+, EMVI+, pelvic sidewall LN+).[512] The results demonstrated a significantly higher pCR rate with the TNT approach (28% vs 14%; $P < .001$) and a lower rate of distant metastases at 3 years (20% vs 27%; $P = .005$). No difference in OS was seen. However, after longer follow-up, the short-course radiation therapy arm had higher rates of locoregional failure particularly at the anastomosis and presacral space (10% vs 6%; $P = .027$) that has dampened uptake of short-course RT in the United States, especially in the high-risk tumors that were included on RAPIDO, but has not reduced enthusiasm for TNT.[513]

Optimal drug combinations for neoadjuvant chemotherapy are also being investigated. The phase III PRODIGE 23 trial examined CRT followed by 3 months of neoadjuvant mFOLFIRINOX and TME followed by 3 months of adjuvant FOLFOX or CAPOX versus the standard-of-care approach of CRT followed by TME and adjuvant chemotherapy for 6 months. The experimental arm showed improvement in pCR rate (27.5% vs 11.7%), 3-year DFS (HR, 0.69; 95% CI, 0.49-0.97; $P = .034$), and metastasis-free survival (HR, 0.64; 95% CI, 0.44-0.93; $P < .02$). OS data are not yet mature.[514] Triplet versus doublet TNT chemotherapy superiority is currently being evaluated in the JANUS trial, though results will not be mature for several years.

Removing a Modality of Therapy in Locally Advanced Rectal Cancer

Retrospective and prospective data have prompted the question of whether all patients who have locally advanced rectal cancer (LARC) need surgery and whether all need radiation therapy. In terms of nonoperative management (NOM), data from Brazil suggest high rates of rectal preservation and excellent DFS and OS in patients who have a cCR to neoadjuvant therapy compared with a population of patients who have pCR who underwent surgery.[515] These findings were confirmed in a meta-analysis of 23 studies[516] including 867 patients and in the large multicenter International Watch & Wait (IWW) registry, which suggested

local regrowth rates of 15% to 25% in the NOM group, most of which could be successfully treated with salvage resection.[517] A subsequent analysis of this registry showed that the probability of two additional years of local recurrence-free survival after remaining disease free for 1, 3, and 5 years was 88.1%, 97.3%, and 98.6%. For distant (metastatic) recurrence-free survival, these proportions were 93.8%, 97.8%, and 96.6%, respectively. Together, these data suggest that recurrence risk is highest in the first two years, supporting enhanced posttreatment surveillance during this period though studies have not been performed to inform the optimal schedule and currently mostly follow the protocol used in the OPRA trial (Table 13.2-2).

Table 13.2-2 Surveillance Survivorship for Colorectal Cancer

	Recommendations	
	Resected (Standard)	**Unresected (NOM)[#]**
Testing schedule	H&P with laboratory tests including CEA every 3 months for 2 years, then every 6 months for years 3-5 from surgical resection	H&P and labs with CEA every 4 months for 2 years, then every 6 months years 3-5 from end of treatment and cCR determination
	CT CAP every 12 months for 5 years	Rectal MRI every 6 months and CT CAP every 12 months for 2 years, then CT CAP and rectal MRI once every 12 months for years 3-5
	Colonoscopy 1 year after initial diagnosis, then at 3 years if findings are normal, and then every 5 years for life if findings remain normal	Flexible sigmoidoscopy and digital rectal examination every 4 months for 2 years and every 6 months years 3-5 (consider switching one endoscopic evaluation for colonoscopy annually years 0-2, then as indicated per standard schedule)
	In families without an identified familiar risk syndrome, all first-degree relatives should undergo screening colonoscopy starting 10 years younger than when the patient was diagnosed but no later than age 40 years and should undergo screening colonoscopy every 5 years	
	Chemo prophylaxis	ALASCCA and consideration daily ASA for 3 years for PI3K altered rectal cancer
Lifestyle changes	• Increased exercise after diagnosis and avoidance of a Western-style diet; diets with a low glycemic load are associated with a reduced risk of cancer recurrence and improved OS[287,518,519] • Patients with class II or III obesity (BMI >35 kg/m^2) have a modestly increased risk of recurrence[332] • Lower serum vitamin D levels have been associated with an increased risk of recurrence, but prospective studies are lacking to show that increasing vitamin D to normal levels can improve outcomes in the adjuvant setting[363]	

Abbreviations: BMI, body mass index; CEA, carcinoembryonic antigen; CT CAP, computed tomography of chest, abdomen, pelvis; H&P, history and physical examination; OS, overall survival.
[#]Surveillance regimen per OPRA trial[509] as published in Scott et al.[520]

Another approach being tested is whether radiation therapy can be eliminated in a subset of patients with LARC. The phase 3 PROSPECT trial assessed a primary endpoint of DFS and randomized >1,100 patients with cT2N$^+$ or cT3N$^{+/-}$ (provided ≤4 mesorectal lymph nodes were >1 cm in short-axis diameter) rectal cancer eligible for sphincter-sparing surgery (ie, LAR) to receive either neoadjuvant CRT followed by surgery and adjuvant FOLFOX or CAPOX (given to 77.9% for up to 4 months) or to receive neoadjuvant FOLFOX for 3 months with selective CRT only if the primary tumor decreased <20%, followed by TME and optional adjuvant FOLFOX for 3 months, of which 79.5% of patients opted in. In the neoadjuvant FOLFOX arm, only 10.5% received CRT (9% preoperatively; 1.5% postoperatively). Five-year DFS was noninferior with FOLFOX despite the omission of CRT for the majority of patients (HR, 0.92; 90% CI, 0.74-1.14), and OS and local recurrence were similar in both groups.[521] The NCCN guidelines recommend this approach as an alternative to CRT for patients without cT4 disease and who are eligible for sphincter-sparing surgery. Also, the phase 3 FOWARC trial conducted in China compared FOLFOX alone with FOLFOX and radiation therapy or 5-FU and radiation therapy followed by surgery and demonstrated similar rates of local recurrence, 3-year DFS, and OS.[522]

Role of Immunotherapy in dMMR/MSI-H Rectal Tumors

Approximately 1% to 5% of rectal adenocarcinomas are MSI-H/dMMR, and retrospective studies have suggested that they respond poorly to chemotherapy regimens. Several studies show the activity of immunotherapy for patients who have localized tumors. A single-institution phase 2 study of dostarlimab, a PD-1 inhibitor, in 47 patients with locally advanced dMMR tumors, 100% of patients who completed all 6 months of immunotherapy had a clinical complete response (cCR) with a median follow-up of >12 months.[523,524] Based on these and other data showing the efficacy of immunotherapy in dMMR tumors, the preferred neoadjuvant therapy for locally advanced dMMR rectal cancer is currently checkpoint inhibitor monotherapy for up to 6 months with those achieving a cCR being appropriate for surveillance without further chemotherapy, radiation, or surgery.[523] Ongoing studies are exploring the utility of doublet immunotherapy in MSI-H LARC, as well as attempting to reproduce the single-institution dostarlimab trial in a global population (AZUR-1).

Role of Biologics

Several studies have sought to enhance the efficacy of preoperative radiation therapy by adding biological agents to a fluoropyrimidine backbone. Results with bevacizumab suggest improved response rates in some studies but at the cost of perineal wound and anastomotic healing complications.[525,526] Results with anti-EGFR therapy (cetuximab and panitumumab) have been disappointing with respect to pCR rates and toxicity.[527,528] As a result, adding a biological to fluoropyrimidine chemotherapy during radiation therapy is not recommended.

KEY POINTS

- Rectal cancer should be staged preferably with rectal MRI or in certain cases with endorectal ultrasound (ERUS) on the basis of local availability and technical competence of the endoscopist or reading radiologist.
- Imaging of chest and upper abdomen should also be performed to rule out metastatic disease. There is no role for routine PET scan in the staging of rectal cancer.
- Neoadjuvant CRT using either infusional 5-FU or capecitabine followed by TME and adjuvant FOLFOX or CAPOX is the historical standard treatment approach for stage II and III rectal cancers.
- Current treatment of LARC (clinical stage II or III rectal cancer) is centered on TNT strategies, in which chemotherapy and radiation therapy (in either order) are used neoadjuvantly before TME. Although short-course RT is a reasonable alternative to long-course CRT, it may be associated with higher risk of local recurrence in patients with high-risk disease.
- A subset of patients who have non-cT4 disease who are eligible for sphincter-sparing surgery may be treated with neoadjuvant FOLFOX with selective use of CRT in those who have ≤ 20% tumor regression. Adjuvant chemotherapy was offered in the trial.
- Selected patients who have a complete clinical response after TNT or immunotherapy may be considered for nonoperative management with watch & wait surveillance in lieu of surgery.
- Patients with dMMR/MSI-H locally advanced rectal cancer may be considered for TNT with PD-1 immune checkpoint inhibitor treatment for 6 months and avoid surgery, radiation, and chemotherapy if cCR is achieved.
- Oxaliplatin, bevacizumab, cetuximab, or panitumumab should not be added to the CRT backbone for patients with rectal cancer.

ANAL SCC

EPIDEMIOLOGY AND ETIOLOGY

Cancers of the anus are relatively uncommon in the United States. The male-to-female ratio is approximately 2:3.5. The clearest causal relationship for anal cancer is infection with HPV (mainly HPV-16); >90% of anal cancers are associated with HPV infection.[529] One large study found a strong positive correlation between the amount of sexual activity and the risk of anal cancer.[530] The association between HIV infection and anal cancer has been known for some time, but the exact etiologic relationship has not been elucidated. The incidence of anal cancer in patients infected with HIV is increased >40 times compared with the general population and, unlike other HIV-associated cancers, has not decreased since the introduction of highly active antiretroviral therapy (HAART).[531] Additional risk factors for anal cancer are smoking, immunosuppression, chronic inflammation or fistulas in the context of IBD, and extramammary Paget's disease in the perianal region (adenocarcinoma).

The efficacy of a quadrivalent HPV vaccine (HPV-6, -11, -16, and -18) against anal intraepithelial neoplasia was prospectively investigated in a double-blind randomized study of 602 healthy homosexual men aged 16 to 26 years.[532] The rate of grade 2 or 3 anal intraepithelial neoplasia related to infection with HPV-6, -11, -16, or -18 was reduced by 54.2% (95% CI, 18.0%-75.3%) in the intention-to-treat population and by 74.9% (95% CI, 8.8%-95.4%) in the per-protocol efficacy population. These intriguing findings, which could lead to a decrease in the incidence of anal cancer through HPV vaccination, prompted the Advisory Committee on Immunization Practices (ACIP) to recommend routine HPV vaccination for girls aged 11 to 12 and catch up

vaccination for women through age 26 years since 2007 and routine HPV vaccination in boys aged 11 to 12 years with catch up vaccination in men up to age 21 and high-risk populations through age 26 since October 2011.[533] Catch up vaccination was amended in 2019 to include all persons through 26 years, and suggested consideration with shared medical decision making in all adults aged 27 to 45 years.

Most anal cancers are squamous cell carcinomas (ASCC) or cloacogenic cancers, and the rare anal adenocarcinomas should be treated as rectal cancers. Inguinal lymph nodes (LNs) are locoregional in ASCC and may be involved in as many as 63% of cases. The most important prognostic factors are tumor (T) stage (T1, <2 cm; T2, 2-5 cm; T3, >5 cm; T4, invasion into adjacent organs) and lymph node (N) status. In a pooled analysis of four randomized trials with a total of 644 patients, tumor diameter >5 cm and LN involvement were associated with poorer 5-year DFS ($P < .0001$) and 5-year OS ($P = .0001$). In stratified analyses, LN involvement had more adverse influence on DFS and OS than did tumor diameter. Patients with tumors >5 cm and LN metastases had the worst DFS (only 30% at 3 years compared with 74% for the best group, which had <5 cm primary and N0 status) and OS (only 48% at 4 years compared with 81% for the best group, which had <5 cm primary and N0 status). Men had worse DFS ($P = .02$) and OS ($P = .016$).[534]

STAGING

In general, staging involves physical examination and biopsy to determine the size of the primary and the presence of inguinal lymphadenopathy. Cross-sectional (ie, CT) imaging of the chest and abdomen should be performed to rule out metastatic disease, especially in those with T3 to T4 or N+ disease, as well as CT or MRI of the pelvis in all patients to assess regional LNs. PET-CT scan should be strongly considered for anal cancer because a meta-analysis suggested PET imaging changed nodal staging in nearly 30% of the patients.[535] Because the presence of inguinal or pelvic LNs change the radiation therapy strategy, information provided by PET is important in treatment planning. Women with anal cancer should also be evaluated for cervical cancer, which is also mostly induced by HPV infection with oncogenic viral strains.

TREATMENT OF LOCALIZED DISEASE

In the distant past, treatment of patients who have anal cancers was surgical, entailing an abdominal perineal resection (APR). This treatment option was curative for only approximately 50% of patients and was associated with a high morbidity rate. Today, the standard approach to treatment of ASCC is definitive CRT. Local excision is reserved for patients with small node-negative tumors (T1N0) that are well differentiated. Even here, long-term efficacy data are lacking.

In initial CRT trials, combinations of 5-FU and mitomycin C with RT, still referred to today as the "Nigro protocol" after Dr. Norman Nigro who developed the definitive approach in the 1970s, yielded high response rates, including pCR.[531,536] Eventually, it was recognized that surgical resection was not necessary for many patients, and APR is used today only as salvage therapy for patients who have local recurrence after CRT. The expectation is that the cCR rate with combined-modality CRT therapy will be between 70% and 80% with a 5-year OS rate >65%, but this is highly dependent on stage at diagnosis. More recently, capecitabine with mitomycin has been explored and appears to be well tolerated across several prospective trials and one retrospective report with one small trial reporting a cCR of 100% and treatment failure rate of 90% at 3 years.[537-539] Overall, though, a substantial number of patients still experience either local recurrence or metastatic disease.

Strategies to improve survival outcomes on the existing 5-FU/mitomycin CRT standard beyond the likely equivalent shift from 5-FU CIVI to capecitabine, have not been successful. The phase III RTOG 98-11 trial (n = 682 patients) assessed an intensified regimen with induction 5-FU/cisplatin followed by CRT with 5-FU/cisplatin compared against the standard CRT with 5-FU/mitomycin C.[540] Both the 5-year locoregional recurrence rate (25% vs 33%) and the distant metastasis rate (15% vs 19%) trended in favor of the mitomycin-based (Nigro) treatment. The cumulative rate of colostomy was significantly better for mitomycin C–based than for cisplatin-based therapy (10% vs 19%; $P = .02$). An updated analysis with long-term follow-up identified the standard mitomycin C–based arm as significantly superior in OS.[541] Results of a more recent phase 3 ACT II 2 × 2 randomized trial comparing between 5-FU/mitomycin or 5-FU/cisplatin with RT with second randomization to receive either no further treatment or "maintenance" treatment with two subsequent weeks (weeks 11 and 14) of 5-FU/cisplatin chemotherapy found no substantial difference in outcome,[542] so the inferior results of the RTOG 98-11 intensified arm could be related to the delay in RT because of the initial induction chemotherapy component. The ACT II trial also did not show the benefit of post-RT maintenance 5-FU/cisplatin chemotherapy; therefore, neither induction nor consolidation chemotherapy has a role in locally advanced anal cancer. Currently, clinical research (ie, EA2165) is investigating the role of immune checkpoint inhibitors in locoregional ASCC after activity was recently shown in the metastatic setting, though data awaits maturation.

As described above, the well-established definitive combined-modality approach using 5-FU/mitomycin/RT remains the standard of care. Mitomycin C carries an FDA black-box warning for severe bone marrow suppression that is often delayed (nadir occurs often at 4 weeks) and can be prolonged. Patients' blood cell counts should be carefully monitored during and after the completion of therapy, including CD4 T cell levels in patients with HIV+ who despite HAART adherence may experience CD4 nadirs that require prophylaxis for opportunistic infections until recovery. Combination cisplatin and 5-FU can be used

for patients with contraindications to mitomycin C, usually those related to baseline bone marrow deficiency, though should be applied with caution due to enhanced toxicity seen in recent 5-FU/cisplatin trials.

Intensity-modulated radiation therapy (IMRT) for anal cancer is being evaluated in an effort to reduce short- and long-term toxicities from radiation therapy.[385] Intensity-modulated radiation therapy should only be used by radiation oncologists experienced in delivering this therapy for anal cancer to avoid undertreatment of the cancer (ClinicalTrials.gov identifier: NCT04166318). EA2182 (DECREASE), an ongoing randomized phase 2 clinical trial is comparing standard of care versus lower dosage CRT in early (cT1-2N0) anal cancer, has completed accrual though results are maturing.

The treatment of anal cancer for patients with HIV+ is somewhat more complex. Standard aggressive combined-modality therapies should be used for patients who have a CD4 count >200 × 10^9/mm^3 who have no signs or symptoms of other HIV-related diseases. For patients who have more severe HIV-related problems, reduced doses of radiation, chemotherapy, or both should be considered to maintain local disease control.[543]

FOLLOW-UP AFTER TREATMENT

Evaluation of ASCC response to treatment too early after the completion of CRT can result in premature declaration of treatment failure and unnecessary APRs. The most recent data from the aforementioned ACT II trial suggest tumor regression can be seen up to 26 weeks after therapy completion[544]; therefore, persistent disease before 26 weeks should not be deemed a treatment failure as long as the tumor does not appear to be progressing (Table 13.2-3).

Table 13.2-3 Anal Cancer Follow-Up

Years	Tests	Interval	Patients
0-5	Digital rectal examination	Every 3-6 months starting 12 weeks after completion of chemoradiation therapy	All
	Anoscopy		
	History and physical examination with inguinal LN palpation		
	CBC with differential at least until count recovery. Consider CD4 T cell levels in HIV+ patients until count recovery		
0-3	CT scan of chest, abdomen, and pelvis	Annually	cT3/T4 disease or cN+ disease or with positive disease on 12 week examination

Abbreviation: LN, lymph node.

TREATMENT OF RECURRENT AND METASTATIC DISEASE

For those patients who have locally recurrent disease at the 26-week post-CRT evaluation or progressive nonmetastatic disease at any time after end of treatment, surgical resection is preferred with evidence of 5-year survival rates of nearly 50%.[545]

Patients with newly diagnosed metastatic disease are currently recommended to receive first-line carboplatin/paclitaxel based palliative chemotherapy (CT CAP every 3 months in patients with non progressing incomplete responders until cCR is achieved or progression is confirmed). Prior to the phase 2 InterAACT trial, 5-FU/cisplatin was the standard first-line recommendation, primarily on the basis of the regimen's activity in other squamous cell carcinomas. InterAACT randomized 91 patients with untreated advanced anal cancer to either 5-FU/cisplatin or carboplatin/paclitaxel with a pick-the-winner design and primary endpoint of ORR. Although ORR was not different between the regimens (57% vs 59%), combination 5-FU/cisplatin was associated with significantly more serious adverse effects (62% vs 36%; $P = .016$). Furthermore, carboplatin/paclitaxel achieved higher median PFS (8.1 vs 5.7 months) and OS (20 vs 12.3 months; HR, 2; $P = .014$). These results provide strong evidence for the use of carboplatin and paclitaxel as first-line treatment of patients with metastatic anal cancer.[546]

Recently published and ongoing studies also suggest a role for immunotherapy in metastatic ASCC. In NCI9673, originally a single-arm second- or later-line trial of 37 patients treated with nivolumab, results showed ORR 24%, including two patients achieving CR, disease control rate (DCR) 70%, median PFS 4.1 months, and median OS 11.5 months.[534] This led to a part B expansion of the original NCI9673 study to the randomized phase II cohorts of nivolumab +/− ipilimumab in 100 patients with refectory metastatic ASCC that showed ipilimumab/nivolumab did not significantly improve outcomes compared to nivolumab alone (mPFS 3.7 vs 2.9 months ($P = .16$), ORR 21.5% vs 17.4% ($P = .89$), DCR 47.7% vs 43.5%, mOS 20.0 vs 15.4 months ($P = .59$)).[547] Currently, dual immunotherapy targets are not recommended for refractory metastatic ASCC.

The activity of checkpoint inhibitors in later-line palliative treatment led to first-line chemo/immunotherapy investigations. POD1UM-303/InterAACT 2 was a phase 3, double-blind, controlled trial that randomized 303 patients with treatment-naive locally recurrent or metastatic ASCC to receive either first-line carboplatin/paclitaxel/placebo or carboplatin/paclitaxel/retifanlimab, a PD-1 inhibitor, with possibility of crossover. The trial met its primary endpoint with the median PFS improving from 7.4 months in the placebo arm to 9.3 months in patients receiving retifanlimab (HR 0.63 [95% CI, 0.47, 0.84]; $P = .0006$). Follow-up remains immature, though currently suggests retifanlimab with chemotherapy despite crossover is trending toward improved mOS (29.2 vs 23.0 months, HR 0.70 [95% CI 0.49, 1.01]. As a result of this data, in May 2025, the FDA approved carboplatin/paclitaxel/retifanlimab for first-line treatment of advanced ASCC, and is the current standard of care for patients eligible to receive immunotherapy. Results from EA2176, the randomized phase 3 trial (ClinicalTrials.gov identifier: NCT04444921) evaluating carboplatin/paclitaxel with or without nivolumab for patients with newly diagnosed metastatic anal cancer, are awaited.

KEY POINTS

- HPV vaccination reduces the incidence of anal intraepithelial neoplasia and will, it is hoped, reduce the incidence of anal cancer as well.
- Combination 5-FU/mitomycin with RT remains the standard approach for localized anal squamous cell cancers, but 5-FU/cisplatin or capecitabine/mitomycin C can be considered for those at risk for bone marrow or other toxicity.
- Responses to definitive CRT can be seen up to and occasionally beyond 26 weeks after treatment completion, so early declaration of failure should be avoided.
- Salvage surgery (APR) is the treatment of choice for those with locally recurrent or progressive disease at or beyond the 26-week evaluation.
- There is no role for induction or consolidation chemotherapy in locally advanced disease.
- Standard chemotherapy for first-line treatment of metastatic anal cancer is carboplatin and paclitaxel per the InterAAct study.
- Retifanlimab added to carboplatin and paclitaxel represents a new standard of care option in the first-line treatment of locally recurrent/metastatic ASCC.
- In the refractory metastatic setting, treatment with nivolumab or pembrolizumab can be considered. CTLA-4 inhibitors have not shown significant additive benefit.

APPENDICEAL MUCINOUS NEOPLASMS, ADENOCARCINOMAS, AND GOBLET CELL ADENOCARCINOMAS

Appendiceal mucinous neoplasms and cancers and goblet cell adenocarcinoma (GCA, formerly goblet cell ex carcinoid) have their own terminology and a recently updated WHO diagnostic grading system (Table 13.2-4).[548,549] AJCC recently updated their staging guidelines to version 9 for appendiceal malignancies, with a significantly enhanced importance given to tumor grade.[550] These malignancies most frequently metastasize along peritoneal surfaces with cellular lesions (ie, peritoneal carcinomatosis) more frequently seen in higher grade appendiceal cancers, or with acellular mucinous deposits (ie, pseudomyxoma peritonei (PMP)) that is frequently seen in low-grade mucinous histologies. Patients who have appendiceal neoplasms, adenocarcinomas, or goblet cell adenocarcinomas, should have tumor pathology reviewed by expert pathologists and should be seen by multidisciplinary teams specializing in these cancers.

Table 13.2-4 **Appendicular Mucinous Cancers and Goblet Cell Carcinoids**

Diagnostic Terminology	Histological Criteria
Serrated polyp with or without dysplasia	Serrated crypt profiles confined to the mucosa with intact muscular is mucosae; when present, dysplasia can be classified as low or high grade
Low-grade appendiceal mucinous neoplasm (LAMN)	Mucinous neoplasm with low-grade cytology and any of the following:
	Loss of lamina propriety and muscular is mucosae
	Fibrosis of submucosa
	Pushing diverticulum-like growth into the wall
	Dissection of acellular mucin in the wall
	Mucin and/or neoplastic cells outside of appendix
High-grade appendiceal mucinous neoplasm (HAMN)	Mucinous neoplasm with high-grade cytology present (at least focally) and lacking infiltrative invasion

Diagnostic Terminology	Histological Criteria
Mucinous adenocarcinoma	Mucinous neoplasm with infiltrative invasion; patterns of infiltrative invasion include:
	Infiltrative glands, incomplete glands, or single infiltrative tumor cells associated with extracellular mucin and desmoplastic stroma
	Small cellular mucin pool pattern characterized by small dissecting pools of mucin containing floating nests, glands, or single neoplastic cells
	Grade assessment is based on AJCC criteria
Mucinous adenocarcinoma with signet-ring cells	Mucinous neoplasm with signet-ring cell component accounting for ≤50% of tumor cells
	Mucinous neoplasm with signet-ring cell component accounting for >50% of tumor cells

Abbreviations: AJCC, American Joint Committee on Cancer; HAMN, high-grade appendicular mucinous neoplasm; LAMN, low-grade appendicular mucinous neoplasm.

Recent molecular characterization suggests unique patterns of genomic alterations are seen across the low- to high-grade histological spectrum of appendiceal malignancies.[551] This includes *GNAS* and *KRAS* being mutated in the majority of patients with low-grade mucinous appendiceal adenocarcinomas and PMP, whereas high grade adenocarcinomas (ie, signet ring) and GCA most frequently appear driven by *TP53* mutations. Unsurprisingly in a disease characterized by peritoneal patterns of metastatic spread, circulating tumor DNA (ctDNA) is less frequently detected from appendiceal adenocarcinoma (38% detectable) compared to other GI adenocarcinomas.[552] These observations suggest potential roles for targeted therapies, particularly against GNAS and KRAS alterations.

Treatment usually consists of surgical cytoreduction (CRS) with consideration of HIPEC, although the use of HIPEC is not universally accepted, it appears to have more impact in lower grade, mucinous histologies and several expert groups have recommendations on how to apply CRS/HIPEC for appendiceal malignancies. Systemic therapy, primarily extrapolated from colorectal cancer studies, is usually recommended for high-grade and poorly differentiated tumors, although prospective clinical trials are lacking to guide therapy. One small observational study (n = 20) assessing patients with PMP (60% low grade, 40% high grade) receiving FOLFOX4 after progression from prior CRS/HIPEC found ORR 20%, DCR 65%, median duration of response 14.2 months, mPFS 8 months with 6 month PFS rate 50%, and median OS 26.3 months.[553] A more recent attempt at a randomized trial of patients with low-grade appendiceal adenocarcinoma to observation for 6 months followed by investigator's choice of chemotherapy for 6 months versus upfront chemotherapy followed by observation unfortunately closed early due to slow accrual (n = 24, enrollment goal had been 30 patients), but suggest from the data available that there was no benefit in either tumor response or bowel obstructions in patients on fluoropyrimidine-based chemotherapy phases compared to observation phases.[554] Intriguingly, despite the historical approach to treating appendiceal adenocarcinomas as colorectal cancers, recent retrospective data leveraged knowledge of infrequent APC alterations in appendiceal adenocarcinoma, and found that taxane-based chemotherapy given to a small number of patients (n = 13) in the metastatic refractory setting, was associated with ORR 30%, DCR 50%, and an mOS 8.3 months.[555] Compare this to multiple taxane-based trials in metastatic CRC that have consistently shown no responses, and it appears that trials dedicated to the various appendiceal malignancies are of urgent need to improve outcomes of patients with these rare cancers.

Two recent trials have explored the efficacy of targeted therapy or immunotherapy in patients with advanced appendiceal malignancies. This includes the small (n = 16), single-institution, single-arm phase II trial of the CDK4/6 tyrosine kinase inhibitor, palbociclib, in patients with *GNAS*-mutated peritoneal mucinous carcinomatosis.[556] The primary endpoint was CEA biomarker reduction and was achieved in 13 of 16 patients, and DCR at 12 months was 50% with mOS not reached after median follow-up of 17.6 months. Atezolizumab/bevacizumab was studied in a small (n = 16), single institution, single arm with synthetic case-matched historical cohort, phase II study as well, though in any-grade appendiceal adenocarcinoma patients.[557] Despite the biological heterogeneity, atezo/bev achievied DCR 100%, mPFS 18.3 months, mOS not reached after median follow-up of 40 months. This was compared to the synthetic control cohort of mPFS 4.4 months (P = .041). While these treatments require further prospective validation before entering standard of care globally, they again further highlight the need to focus research on orphan diseases or risk continued suboptimal outcomes.

GASTROENTEROPANCREATIC NETS

EPIDEMIOLOGY, CLASSIFICATION, AND STAGING

The gastroenteropancreatic (GEP) NET incidence rate is 3.56 per 100,000 individuals in the United States and has increased substantially over the last >40 years as has median OS. Five-year survival rates for metastatic grade 1 and 2 GEP NETs range from 28% for rectal to 69% for small-intestine NETs.[255] Although there are many different historical classification systems for GEP NETs, in practice and in the recent clinical trial literature, they tend to be divided between pancreatic and extrapancreatic

NETs. They are then additionally classified into low-, intermediate-, and high-grade tumors on the basis of either mitotic rate per 10 high-power fields or Ki-67 labeling. A recent change in the 2017 WHO classification system for pancreatic NETs created a category of well-differentiated grade 3 tumors, which are tumors that have a high-grade proliferation index but a more well-differentiated appearance on histology. They are treated more in line with the well-differentiated than the poorly differentiated small cell and large cell subtypes. Staging is slightly different for each location but follows general TNM AJCC principles.

CLINICAL GENETICS

Although most pancreatic NETs are sporadic, they have been clearly associated with multiple endocrine neoplasia type 1 (MEN1), von Hippel–Lindau disease (VHL), neurofibromatosis 1 (NF1), and tuberous sclerosis.

CLINICAL PRESENTATION AND WORKUP

A majority of NETs are nonfunctional; therefore, patients often exhibit few symptoms, and the NETs are often found incidentally at the time of imaging for unrelated reasons. Workup for metastatic GEP NETs typically involves dotatate PET (gallium [^{68}Ga] or copper [^{64}Cu]) imaging, which has largely replaced somatostatin receptor scintigraphy (octreotide scan) because of its superior sensitivity and specificity. CT imaging with arterial phase (multiphase) contrast for improved liver visualization of what are typically hyperenhancing metastases (compared to metastatic GEP adenocarcinomas that tend to have hypoenhancing liver lesions) or MRI with gadoxetate disodium is the preferred anatomic imaging. If the primary is not identified with these modalities, then upper and lower endoscopy, pancreatic EUS, and/or CT or MRI enterography can be used to better identify pancreatic, gastric, or small-bowel (duodenal, jejunal, ileal) origin. Laboratory workup can include measuring 24-hour urine 5-hydroxyindoleacetic acid (HIAA) or serum chromogranin A levels, but these are often nonspecific or prone to artifact. In pancreatic NETs, additional functional markers, such as glucagon, gastrin, vasoactive intestinal peptide (VIP), and insulin levels, can be determined depending on the clinical presentation. Pathological findings should be reviewed by pathologists with expertise in evaluating these tumors and should include degree of tumor differentiation (ie, well vs poorly differentiated), tumor grade (G1-G3), and either Ki-67 labeling (preferred) and/or mitotic rate per 10 high-power fields.

TREATMENT

Locoregional Therapies

Surgery is the primary treatment of patients who have nonmetastatic tumors. There is no role for adjuvant therapy in these patients. For patients who have advanced disease, palliative cytoreductive surgery (debulking) is controversial and may be considered for patients who have refractory hormone-producing tumors (decreasing the amount of hormone-producing tissue). Such surgery includes hepatic resection or resection of other intra-abdominal and thoracic metastases. Surgical palliation of bowel obstruction from tumor masses or mesenteric fibrosis associated with carcinoid tumors may substantially improve quality of life.

Liver-directed therapy, such as transarterial chemoembolization (TACE), transarterial radioembolization (TARE), and radiofrequency ablation (RFA), are particularly useful for reducing symptoms caused by local growth of the tumor or by hormone production and should be regarded as nonsurgical debulking. These procedures are also associated with a greater likelihood of prolonged tumor regression.

Somatostatin Analogs

Somatostatin analogs have been used for many years to control the secretion of 5-HIAA and other peptides.[558,559] Although octreotide has long been used and is indicated for the palliation of symptoms related to excess hormone secretion, more recently, the analogs have been assessed for their antitumor activity despite their poor tumoricidal effect, resulting in few regressions. In the PROMID study, a prospective placebo-controlled randomized trial of 85 patients with midgut NETs, the use of long-acting octreotide (30 mg intramuscular injection monthly) was associated with substantial delay in tumor progression and a trend toward improvement in OS.[560] An alternative long-acting somatostatin analog, lanreotide, was evaluated in the randomized, placebo-controlled CLARINET trial of advanced NETs.[561] In contrast to the PROMID study, which included mainly patients who had low-grade midgut NETs, CLARINET enrolled 204 patients who had NETs from the pancreas, midgut, hindgut, or unknown origin, that were well-differentiated or moderately differentiated and had a Ki-67 <10%. PFS was not reached in the lanreotide arm, compared with PFS 18 months in the placebo arm (HR, 0.47; 95% CI, 0.30-0.73; $P < .001$). The 2-year PFS rates were 65.1% and 33.0% for the lanreotide and placebo arms, respectively. OS was not different between the arms, likely because crossover was allowed in the study and because of potential differences in subsequent treatments. Lanreotide was approved by the FDA in December 2014. The excellent PFS of 18 months in the placebo group should be noted from the CLARINET study as should the finding that lanreotide was associated with increased rates of diarrhea, abdominal pain, and cholelithiasis. This argues that, in asymptomatic patients with a low burden of metastatic disease, watchful waiting is an appropriate option.

Somatostatin analogs are the first-line therapy for all patients who have advanced well-differentiated NETs in need of systemic therapy. The indication to start therapy in asymptomatic patients is not well defined but should be strongly considered in those who have progressive disease on interval imaging or those who have a large baseline burden of disease.

Treatment of Carcinoid Syndrome

In addition to the use of surgical and nonsurgical debulking and somatostatin analogs for carcinoid syndrome, patients who have carcinoid syndrome symptoms refractory to standard therapy may benefit from telotristat etiprate, which targets an enzyme involved in excess serotonin production, tryptophan hydroxylase. In a phase 3 trial, patients with carcinoid syndrome uncontrolled by somatostatin analog treatment experienced a 35% reduction in the number of bowel movements with telotristat etiprate compared with placebo (17%; $P < .001$).[562] Patients in the telotristat etiprate arm also had a lower frequency of flushing episodes and less intense abdominal pain compared with those receiving placebo although these differences were not statistically significant.

Radioligand Therapy

^{177}Lu-DOTA0-Tyr3-octreotate (^{177}Lu) is a peptide receptor radionuclide therapy (PRRT) that has been available in Europe since 2000 and was approved by the FDA in 2018. This therapy was tested in the randomized phase 3 trial NETTER-1, in which patients who had progressive somatostatin receptor–positive midgut well-differentiated NETs with Ki67 <20% were randomly assigned to receive four doses of ^{177}Lu every 8 weeks followed by 30 mg of octreotide compared with octreotide alone at 60 mg every 28 days.[563] With a median follow-up of 30 months, median PFS was not reached in the ^{177}Lu/octreotide arm and was 8.4 months in the octreotide alone arm (HR, 0.21; 95% CI, 0.13-0.34; $P < .0001$). Serious AEs include renal failure, irreversible myelotoxicity, a 2% to 3% rate of myelodysplastic syndrome, and a 0.5% rate of acute leukemia. Acute events include nausea related to the amino acid infusion required for renal protection, which has improved with new amino acid formulations. Updated results show that median PFS was 28.4 and 8.4 months (HR, 0.21; 95% CI, 0.14-0.33) and median OS was 48 and 36.3 months (HR, 0.84; $P = .30$) in the ^{177}Lu arm and the octreotide arm, respectively. The OS difference was likely not substantial in large part because of the 36% crossover from the octreotide to the ^{177}Lu arm.[564] PRRT was approved by the FDA for all patients with well-differentiated GEP NETs based on these data in conjunction with retrospective data from the Netherlands.[565] The recently reported phase 3 NETTER-2 trial randomly assigned patients with GEP NETs with Ki-67 10% to 55% diagnosed within 6 months to receive either ^{177}Lu for 4 doses once every 8 weeks followed by 30 mg of monthly octreotide versus monthly octreotide monotherapy at 60 mg. The primary endpoint of PFS improved from 8.5 to 22.8 months (HR, 0.28; 95% CI, 0.18-0.42) along with improvement in response rate (43% vs 9.3%) with the addition of ^{177}Lu compared to monthly depot octreotide alone.[566] Ongoing trials are evaluating novel radioligands, including those with alpha particle emitters, such as ^{225}Ac and ^{212}Pb.

Additional Systemic Treatment of Pancreatic NETs

Pancreatic NETs (pNETs) are more sensitive to cytotoxic chemotherapy compared with other GEP NETs and respond to alkylating agents such as streptozocin, dacarbazine, and temozolomide. Single-arm studies with temozolomide-based regimens show response rates up to 50%.[567-569] In an important phase 2 trial by the ECOG-ACRIN group (study E2211), 144 patients who had metastatic or unresectable pNETs were randomly assigned to temozolomide alone or capecitabine/temozolomide (CAPTEM) combination. Median PFS was 22.7 months in the combination arm versus 14.4 months in the temozolomide arm (HR, 0.58; 95% CI, 0.36-0.93) with a response rate of 33% in the combination arm.[570]

Novel biologics, including VEGF inhibitors, such as sunitinib, and signal transduction inhibitors, such as mTOR inhibitors, also show efficacy in pNETs.[571] Data from a placebo-controlled phase 3 trial with sunitinib (37.5 mg per day) versus best supportive care for 169 patients who had advanced pancreatic NETs, all of whom had experienced progression in the last 12 months,[571] demonstrated that PFS increased from 5.5 months with placebo to 11.4 months in the sunitinib group (HR, 0.42; 95% CI, 0.26-0.66; $P < .001$). Median OS favored sunitinib but was not statistically significant (38.6 vs 29.1 months).[572] In a parallel placebo-controlled phase 3 trial of 410 patients with advanced low- to intermediate-grade pNETs, the mTOR inhibitor everolimus (10 mg per day) likewise improved median PFS from 4.6 to 11.0 months (HR, 0.35; 95% CI, 0.27-0.45; $P < .001$).[573] OS data showed a nonsignificant improvement in median OS of 44.0 months in the everolimus arm and of 37.7 months in the placebo arm (HR, 0.94; 95% CI, 0.73-1.20; $P = .300$).[574] These trials also show that the ORR with these agents are low at approximately 5%. Based on these positive trial results, sunitinib and everolimus gained FDA approval in 2011 for the treatment of pancreatic NETs. The placebo-controlled phase 3 SANET-p trial of surufatinib conducted in China in 264 patients with pNETs showed improvement in the primary endpoint of PFS from 3.7 to 10.9 months (HR, 0.49; 95% CI, 0.32-0.76; $P = .0011$).[575] The randomized placebo-controlled phase 3 CABINET trial enrolled 290 patients with progressive well-differentiated NETs during at least one prior therapy other than somatostatin analogs into two separate cohorts: pNETs and extrapancreatic NETs (epNETs). Patients were randomly assigned 2:1 to receive cabozantinib versus placebo in both cohorts, with a primary endpoint of PFS. The study was stopped early after an interim analysis and showed significant PFS benefit with cabozantinib in both cohorts (11.4 vs 3 months; HR, 0.25; 95% CI, 0.12-0.54 in the pNET cohort).[111]

Multiple systemic therapy options now exist for patients who have metastatic pNETs. The correct sequencing of these agents remains unknown at this time and will require shared decision making regarding the differing toxicities and response rates associated with each of the agents. For instance, for patients who have a need for radiographic response, temozolomide-based regimens would be reasonable given the high rates as noted above.

EXTRAPANCREATIC GI NETs

Everolimus added to octreotide initially demonstrated only modest activity for patients with epNETs with only a borderline statistically significant improvement in PFS.[576] The RADIANT-4 study was a randomized phase 3 trial of everolimus versus placebo for patients who have advanced progressive well-differentiated nonfunctional lung and GI epNETs.[577] Patients in the everolimus arm had a median PFS of 11.0 months compared with 3.9 months with placebo ($P < .001$). There were few partial responses (2% and 1% for everolimus and placebo, respectively). OS favored everolimus but this was not significant (HR, 0.73; 95% CI, 0.48-1.11). Based on these results, the FDA approved everolimus for these tumors in February 2016. The epNET cohort from the abovementioned CABINET showed improved PFS with cabozantinib to 8.3 months compared with 3.2 months with placebo (HR, 0.45; 95% CI, 0.30-0.66).[111] As a result of the CABINET findings, the FDA approved cabozantinib for use in epNETs in March 2025.

Unlike pNETs, well-differentiated grade 1 nonpancreatic GEP tumors are not as responsive to cytotoxic chemotherapy. For patients whose disease is refractory to somatostatin analogs, the clinician has the choice among everolimus, cabozantinib, or ^{177}Lu. Many are choosing ^{177}Lu because of its long PFS, but this is not based on clear level I evidence. As mentioned, shared decision making regarding the different toxicities and costs of these agents is needed.

POORLY DIFFERENTIATED GEP NETs

For patients who have poorly differentiated or for many well-differentiated grade 3 GEP tumors, the selection of chemotherapy is similar to that for small-cell lung cancer with the most consistent regression observed using combination etoposide and platinum agents.[578,579] A trial comparing CAPTEM with platinum/etoposide for these tumors was stopped because of a lack of CAPTEM benefit based on an interim futility analysis, and should be reserved for more medically frail patients who are likely unable to tolerate platinum/etoposide. The success of immunotherapy in small-cell lung cancers has led to an interest in these poorly differentiated tumors as well. Ongoing trials are evaluating the role of adding anti–PD-1/PD-L1 agents to first-line chemotherapy; other trials suggest modest activity for dual checkpoint inhibitor regimens in the salvage setting.[578]

KEY POINTS

- GEP NETs are a heterogeneous group of tumors leading to a variable course of illness depending on stage, site of origin, and histological grade based on Ki-67 index labeling and/or mitotic rate.
- Surgery is the primary treatment of tumors amenable to resection. There is no role for adjuvant therapy in patients undergoing complete surgical resection.
- The oral tryptophan hydroxylase inhibitor telotristat ethyl is an option for patients who have somatostatin-refractory carcinoid syndrome–related diarrhea.
- For asymptomatic patients who have metastatic low-grade tumors and low tumor burden, a watch-and-wait strategy may be appropriate.
- Somatostatin analogs octreotide and lanreotide are standard first-line treatment options for most well or moderately differentiated NETs that exhibit uptake on functional imaging.
- PRRT with ^{177}Lu dotatate is an approved treatment of patients with GEP NETs whose disease has progressed with somatostatin analogs, and recent data also suggest robust activity in first-line therapy for patients with GEP NETs with Ki-67 10-55%.
- Combination capecitabine and temozolomide is a systemic chemotherapy option for patients who have pancreatic NETs. Nonpancreatic NETs do not seem to be as responsive to cytotoxic chemotherapy.
- Everolimus, cabozantinib, and sunitinib are targeted therapy options in pancreatic NETs, and everolimus and cabozantinib are approved for extrapancreatic GI NETs. Recent data show that cabozantinib has activity in patients with NETs irrespective of primary site. The optimal sequencing of these agents, however, has not been established.

HIGH-YIELD TAKEAWAYS

- The role of adjuvant therapy in stage II colon cancer should involve risk stratification and shared decision making.
- Three months of adjuvant therapy is a reasonable alternative for patients with pMMR stage III T1-3 N1 disease given the small absolute difference in DFS and the substantial decrease in neurological and other toxicities with 3 months. If 3 months of therapy is chosen, many expert panels favor CAPOX over FOLFOX.

- All patients with localized colorectal cancer should have tumor testing for MMR/MSI and consideration of testing for PI3K pathway mutations (ie, PIK3CA, PIK3R1, loss of PTEN).
- All patients with metastatic CRC being considered for multiagent chemotherapy should have their tumors tested for extended *RAS* and *BRAF* mutations, dMMR/MSI-H and *HER2* amplifications.
- FOLFOX, FOLFIRI, or FOLFIRINOX with a biological agent is an appropriate first-line chemotherapy backbone for patients with pMMR, BRAF wild type mCRC.
- For patients with left-sided extended *RAS* WT tumors, anti-EGFR therapy may be preferentially considered, and anti-EGFR therapy should be avoided with initial chemotherapy for patients with right-sided tumors, for which bevacizumab is preferred, or in combination with FOLFOXIRI/FOLFIRINOX.
- For patients with newly diagnosed pMMR, *BRAF* V600E–mutated mCRC, the new standard of care for first-line therapy is FOLFOX + encorafenib + cetuximab (panitumumab) due to superior mOS compared to first-line combination chemotherapy and later-line encorafenib/cetuximab.
- For patients with newly diagnosed dMMR mCRC, the first-line standard of care is immunotherapy only (ipilimumab + nivolumab, or anti-PD1 monotherapy).

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

LOWER GASTROINTESTINAL CANCERS 13.2

CHAPTER SUMMARY GUIDE

KEY POINTS

- Screening for CRC is underutilized. Screening colonoscopy and fecal DNA/FIT reduce CRC-associated death over the long term.
- All individuals who have CRC should have their tumors evaluated for MMR or MSI status. Those with dMMR/MSI-H tumors suggestive of germline origin should be referred for genetic screening.
- If universal screening for germline mutations is not performed in all patients who have colon cancer, clinicians should follow the revised Bethesda criteria to determine who should be recommended for germline genetic testing.
- Early-onset CRC patients are more likely to have cancer-associated germline mutations compared to standard-onset patients, but the rapidly increasing incidence of CRC in young-adults (<50 years old) is not associated with genetic causes but rather yet-to-be-identified environmental hazards.
- Stage II colon cancer is a heterogeneous disease, and there is no one-size-fits-all answer for which patients should receive chemotherapy.
- The role of adjuvant therapy in stage II colon cancer should involve risk stratification and shared decision making.
- Patients who have stage IIA colon cancer that is dMMR/MSI-H have an excellent prognosis and do not require adjuvant therapy.
- Patients who have stage IIB or IIC dMMR/MSI-H colon cancer should be considered for adjuvant oxaliplatin-based therapy and potentially immunotherapy.
- Patients who have stage IIA disease without any risk factors do not typically benefit from adjuvant chemotherapy and should be counseled about the low absolute benefit of chemotherapy.
- Patients who have stage IIA disease and high-risk features and those who have stage IIB (T4a) or IIC disease should be counseled regarding their higher risk of tumor recurrence and the potential benefit of fluoropyrimidine and oxaliplatin-based chemotherapy.
- Accumulating data suggest that, for patients with resected colon cancer, postoperative ctDNA-defined MRD status is strongly prognostic, and prospective trials show that ctDNA-guided management is noninferior to standard-of-care management and that it also results in lesser use of adjuvant therapy. While awaiting additional data from ongoing trials, whether to incorporate ctDNA into adjuvant therapy decisions for stage II colon cancer outside of clinical trials should be a shared discussion between patients and their providers.
- By strict scientific criteria, 6 months of adjuvant CAPOX or FOLFOX remains a standard of care for stage III colon cancer.
- Emerging clinical consensus suggests 3 months of adjuvant therapy, particularly with capeox, is a reasonable alternative for patients who have T1-3 and N1 disease given the small absolute difference in DFS and the substantial decrease in clinically substantial neurological and other toxicities. The data are also similar for high-risk stage III colon cancer.
- If 3 months of therapy is chosen, many expert panels favor CAPOX over FOLFOX.
- Six months of therapy with FOLFOX or 3 to 6 months with CAPOX are recommended for those with T4 or N2 disease. It is reasonable to discontinue oxaliplatin while continuing fluoropyrimidine in individuals with significant neurotoxicity having received >50% of the planned 6-month chemotherapy.
- For dMMR (MSI-H) stage 3 colon cancer, the addition of atezolizumab to adjuvant chemotherapy improves outcome. Whether this can be extrapolated to high-risk stage 2 dMMR(MSI-H) colon cancer is unknown but a reasonable extension.
- For patients with stage 2/3 colorectal cancer, data now support a focus and recommendation for exercise the intensity of which should likely be individualized.
- For patients with stage 2/3 colorectal cancer with alterations in the PIK3CA pathway, after adjuvant therapy, the use of low-dose aspirin for 3 years is now recommended.
- Irinotecan, anti-VEGF agents such as bevacizumab, and anti-EGFR antibodies such as cetuximab, regardless of *RAS* status, should not be used in the adjuvant setting.
- All patients with metastatic colon cancer being considered for multiagent chemotherapy should have their tumors undergo extended *RAS* and *BRAF* mutation testing. In addition, all tumors should be tested for dMMR/MSI-H status and

should undergo HER2 testing for overexpression or amplification as this may be a marker of resistance to anti-EGFR therapy as well as a potential target for therapies discussed subsequently.

- Either FOLFOX or FOLFIRI with a biological agent is an appropriate first-line chemotherapy backbone for patients who have mCRC.
- Eventual exposure to all appropriate agents is what is most important. Triplet regimens (FOLFIRINOX) with bevacizumab may be an option for patients who have aggressive tumors.
- For patients who have left-sided extended *RAS* WT tumors, anti-EGFR therapy should be preferentially considered, and anti-EGFR therapy should be avoided as initial therapy for patients who have right-sided tumors for which bevacizumab is preferred.
- Induction maintenance approaches with a limited number of oxaliplatin-containing treatment cycles up front and maintenance therapy with a fluoropyrimidine and bevacizumab combination can be considered standard of care. Those whose disease progresses during maintenance therapy can still have oxaliplatin reintroduced.
- For patients who are not candidates for either oxaliplatin- or irinotecan-containing regimens, the combination of a fluoropyrimidine and bevacizumab can be considered an acceptable standard of care.
- Continuing anti-VEGF therapy beyond first-line progression with bevacizumab and second-line chemotherapy is supported by data.
- Patients who have *BRAF* V600E–mutated tumors should be considered for encorafenib/cetuximab/mFOLFOX6 for the front line or, in the second line and beyond, treatment with the doublet regimen of encorafenib and anti-EGFR antibody.
- For patients who have MSI-H/dMMR tumors, the use of single-agent pembrolizumab or the combination of nivolumab/ipilimumab is considered a preferred standard of care over multiagent chemotherapy as first-line therapy based on the KEYNOTE-177 trial and CheckMate 8HW, respectively.
- Patients who have *HER2*-amplified or HER2-overexpressed colorectal cancers should be considered for treatment with agents directed against HER2 after initial therapy with consideration of RAS status.
- Patients with colorectal cancer with *KRAS* G12C mutations should be considered for targeted therapy after initial chemotherapy with sotorasib or adagrasib alone or with anti-EGFR antibody therapy.
- Regorafenib, fruquintinib, or trifluridine/tipiracil with or without bevacizumab should be considered for patients who have disease refractory to all other approved agents. The decision of how to best sequence these agents is based on the adverse effect profile and individual preferences.
- All patients who have isolated metastatic disease should be considered for surgical resection or other locoregional therapies, and discussion should take place in a multidisciplinary setting conducted at a center with high-volume expertise in treating these cancers.
- Patients who have initially unresectable disease can be considered for conversion therapy with multiagent neoadjuvant chemotherapy.
- The benefit of neoadjuvant, perioperative, or adjuvant chemotherapy for patients who have clearly resectable metastatic disease, although often used, has not been substantiated by randomized clinical trials to improve OS.
- Liver-directed therapies with either intrahepatic chemotherapy or radioembolization have not shown a survival advantage in multi-institution trials and should not be considered standard of care outside of careful patient selection in experienced centers.
- Liver transplantation is an option for highly select patients with permanently unresectable liver-only metastases and where the primary tumor was previously resected.
- Patients who have peritoneal-only CRC should be evaluated at specialized centers for cytoreductive surgery, but HIPEC remains controversial.
- Rectal cancer should be staged preferably with rectal MRI or in certain cases with endorectal ultrasound (ERUS) on the basis of local availability and technical competence of the endoscopist or reading radiologist.
- Imaging of chest and upper abdomen should also be performed to rule out metastatic disease. There is no role for routine PET scan in the staging of rectal cancer.
- Neoadjuvant CRT using either infusional 5-FU or capecitabine followed by TME and adjuvant FOLFOX or CAPOX is the historical standard treatment approach for stage II and III rectal cancers.
- Current treatment of LARC (clinical stage II or III rectal cancer) is centered on TNT strategies, in which chemotherapy and radiation therapy (in either order) are used neoadjuvantly before TME. Although short-course RT is a reasonable alternative to long-course CRT, it may be associated with higher risk of local recurrence in patients with high-risk disease.
- A subset of patients who have non-cT4 disease who are eligible for sphincter-sparing surgery may be treated with neoadjuvant FOLFOX with selective use of CRT in those who have ≤ 20% tumor regression. Adjuvant chemotherapy was offered in the trial.
- Selected patients who have a complete clinical response after TNT or immunotherapy may be considered for nonoperative management with watch & wait surveillance in lieu of surgery.

- Patients with dMMR/MSI-H locally advanced rectal cancer may be considered for TNT with PD-1 immune checkpoint inhibitor treatment for 6 months and avoid surgery, radiation, and chemotherapy if cCR is achieved.
- Oxaliplatin, bevacizumab, cetuximab, or panitumumab should not be added to the CRT backbone for patients with rectal cancer.
- HPV vaccination reduces the incidence of anal intraepithelial neoplasia and will, it is hoped, reduce the incidence of anal cancer as well.
- Combination 5-FU/mitomycin with RT remains the standard approach for localized anal squamous cell cancers, but 5-FU/cisplatin or capecitabine/mitomycin C can be considered for those at risk for bone marrow or other toxicity.
- Responses to definitive CRT can be seen up to and occasionally beyond 26 weeks after treatment completion, so early declaration of failure should be avoided.
- Salvage surgery (APR) is the treatment of choice for those with locally recurrent or progressive disease at or beyond the 26-week evaluation.
- There is no role for induction or consolidation chemotherapy in locally advanced disease.
- Standard chemotherapy for first-line treatment of metastatic anal cancer is carboplatin and paclitaxel per the InterAAct study.
- Retifanlimab added to carboplatin and paclitaxel represents a new standard of care option in the first-line treatment of locally recurrent/metastatic ASCC.
- In the refractory metastatic setting, treatment with nivolumab or pembrolizumab can be considered. CTLA-4 inhibitors have not shown significant additive benefit.
- GEP NETs are a heterogeneous group of tumors leading to a variable course of illness depending on stage, site of origin, and histological grade based on Ki-67 index labeling and/or mitotic rate.
- Surgery is the primary treatment of tumors amenable to resection. There is no role for adjuvant therapy in patients undergoing complete surgical resection.
- The oral tryptophan hydroxylase inhibitor telotristat ethyl is an option for patients who have somatostatin-refractory carcinoid syndrome–related diarrhea.
- For asymptomatic patients who have metastatic low-grade tumors and low tumor burden, a watch-and-wait strategy may be appropriate.
- Somatostatin analogs octreotide and lanreotide are standard first-line treatment options for most well or moderately differentiated NETs that exhibit uptake on functional imaging.
- PRRT with ^{177}Lu dotatate is an approved treatment of patients with GEP NETs whose disease has progressed with somatostatin analogs, and recent data also suggest robust activity in first-line therapy for patients with GEP NETs with Ki-67 10-55%.
- Combination capecitabine and temozolomide is a systemic chemotherapy option for patients who have pancreatic NETs. Nonpancreatic NETs do not seem to be as responsive to cytotoxic chemotherapy.
- Everolimus, cabozantinib, and sunitinib are targeted therapy options in pancreatic NETs, and everolimus and cabozantinib are approved for extrapancreatic GI NETs. Recent data show that cabozantinib has activity in patients with NETs irrespective of primary site. The optimal sequencing of these agents, however, has not been established.

CHAPTER TABLES AND IMAGES

Table 13.2-1 **Clinical Criteria to Determine Likelihood of Lynch Syndrome**
Amsterdam II criteria (all criteria must be met)
At least three relatives with Lynch syndrome–associated cancer (CRC, cancer of endometrium, small bowel, ureter, or renal pelvis)
One relative should be a first-degree relative of the other two
Malignancies should include at least two successive generations
At least one family member should have been diagnosed at age <50 years
Familial adenomatous polyposis is excluded
Tumors should be verified by pathological examination
Revised Bethesda criteria to identify patients with CRC who should undergo pathological examination for Lynch syndrome (any criterion is sufficient)
Synchronous or metachronous CRC or associated with another Lynch syndrome–associated tumor (ie, endometrial, stomach, small intestine, ovarian, pancreatic, biliary tract, ureter or renal pelvis, brain, sebaceous gland adenoma, or keratoacanthoma)
Pathological features of MSI-H cancer (eg, tumor-infiltrating lymphocytes, Crohn-like lymphocytic reaction, mucinous/signet-ring differentiation, medullary growth pattern) in patient age <60 years
Development of CRC in individual who has a first-degree relative with CRC and/or Lynch syndrome—related extracolonic cancer and/or colorectal adenoma, with one of the cancers diagnosed before the patient reaches age 50 years or an adenoma diagnosed at age <40 years
CRC in two or more first- or second-degree relatives with Lynch syndrome–related tumors, regardless of age

Abbreviations: CRC, colorectal cancer; MSI-H, microsatellite instability-high.

Table 13.2-2 **Surveillance Survivorship for Colorectal Cancer**		
	Recommendations	
	Resected (Standard)	**Unresected (NOM)[#]**
Testing schedule	H&P with laboratory tests including CEA every 3 months for 2 years, then every 6 months for years 3-5 from surgical resection	H&P and labs with CEA every 4 months for 2 years, then every 6 months years 3-5 from end of treatment and cCR determination
	CT CAP every 12 months for 5 years	Rectal MRI every 6 months and CT CAP every 12 months for 2 years, then CT CAP and rectal MRI once every 12 months for years 3-5
	Colonoscopy 1 year after initial diagnosis, then at 3 years if findings are normal, and then every 5 years for life if findings remain normal	Flexible sigmoidoscopy and digital rectal examination every 4 months for 2 years and every 6 months years 3-5 (consider switching one endoscopic evaluation for colonoscopy annually years 0-2, then as indicated per standard schedule)
	In families without an identified familiar risk syndrome, all first-degree relatives should undergo screening colonoscopy starting 10 years younger than when the patient was diagnosed but no later than age 40 years and should undergo screening colonoscopy every 5 years	
	Chemo prophylaxis	ALASCCA and consideration daily ASA for 3 years for PI3K altered rectal cancer
Lifestyle changes	• Increased exercise after diagnosis and avoidance of a Western-style diet; diets with a low glycemic load are associated with a reduced risk of cancer recurrence and improved OS[287,518,519] • Patients with class II or III obesity (BMI >35 kg/m^2) have a modestly increased risk of recurrence[332] • Lower serum vitamin D levels have been associated with an increased risk of recurrence, but prospective studies are lacking to show that increasing vitamin D to normal levels can improve outcomes in the adjuvant setting[363]	

Abbreviations: BMI, body mass index; CEA, carcinoembryonic antigen; CT CAP, computed tomography of chest, abdomen, pelvis; H&P, history and physical examination; OS, overall survival.
[#]Surveillance regimen per OPRA trial[509] as published in Scott et al.[520]

Table 13.2-3 **Anal Cancer Follow-Up**			
Years	**Tests**	**Interval**	**Patients**
0-5	Digital rectal examination	Every 3-6 months starting 12 weeks after completion of chemoradiation therapy	All
	Anoscopy		
	History and physical examination with inguinal LN palpation		
	CBC with differential at least until count recovery. Consider CD4 T cell levels in HIV+ patients until count recovery		
0-3	CT scan of chest, abdomen, and pelvis	Annually	cT3/T4 disease or cN+ disease or with positive disease on 12 week examination

Abbreviation: LN, lymph node.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 13.2-4 **Appendicular Mucinous Cancers and Goblet Cell Carcinoids**

Diagnostic Terminology	Histological Criteria
Serrated polyp with or without dysplasia	Serrated crypt profiles confined to the mucosa with intact muscular is mucosae; when present, dysplasia can be classified as low or high grade
Low-grade appendiceal mucinous neoplasm (LAMN)	Mucinous neoplasm with low-grade cytology and any of the following:
	Loss of lamina propriety and muscular is mucosae
	Fibrosis of submucosa
	Pushing diverticulum-like growth into the wall
	Dissection of acellular mucin in the wall
	Mucin and/or neoplastic cells outside of appendix
High-grade appendiceal mucinous neoplasm (HAMN)	Mucinous neoplasm with high-grade cytology present (at least focally) and lacking infiltrative invasion
Mucinous adenocarcinoma	Mucinous neoplasm with infiltrative invasion; patterns of infiltrative invasion include:
	Infiltrative glands, incomplete glands, or single infiltrative tumor cells associated with extracellular mucin and desmoplastic stroma
	Small cellular mucin pool pattern characterized by small dissecting pools of mucin containing floating nests, glands, or single neoplastic cells
	Grade assessment is based on AJCC criteria
Mucinous adenocarcinoma with signet-ring cells	Mucinous neoplasm with signet-ring cell component accounting for ≤50% of tumor cells
	Mucinous neoplasm with signet-ring cell component accounting for >50% of tumor cells

Abbreviations: AJCC, American Joint Committee on Cancer; HAMN, high-grade appendicular mucinous neoplasm; LAMN, low-grade appendicular mucinous neoplasm.

GENITOURINARY CANCERS 14

David Einstein, MD, and Daniel Fein, MD

RECENT UPDATES

Prostate Cancer

- In June 2025, darolutamide with androgen deprivation therapy (ADT) was FDA approved for patients with metastatic castration-sensitive prostate cancer (mCSPC). This was approved based on a progression-free survival (PFS) benefit compared to ADT + placebo demonstrated in the ARANOTE study.[1] Darolutamide, enzalutamide, apalutamide, and abiraterone + prednisone with ADT are now all FDA-approved options for treatment of mCSPC.
- In March 2025, lutetium Lu 177 vipivotide tetraxetan (Lu177PSMA) was FDA approved for patients with prostate-specific membrane antigen (PSMA)-positive metastatic castration-resistant prostate cancer (mCRPC) who previously received an androgen receptor pathway inhibitor (ARPI). Previously, this radioligand was approved only for patients who had received ARPI and docetaxel chemotherapy, but it is now approved for patients who have not yet received docetaxel and are considered appropriate to delay taxane-based chemotherapy. This was based on the PSMAfore study,[2] which demonstrated a PFS benefit with Lu177PSMA compared to switching to an alternative ARPI.
- The combination of Radium-223 and enzalutamide was shown in the PEACE-3 study to improve PFS compared to enzalutamide alone for patients receiving first-line therapy for mCRPC with no prior ARPI exposure.[3]

Bladder Cancer

- In March 2025, the combination of neoadjuvant gemcitabine, cisplatin, and durvalumab, followed by adjuvant durvalumab after cystectomy, was FDA approved for patients with muscle-invasive bladder cancer (MIBC). This was approved based on the NIAGARA trial,[4] which demonstrated improvements in event-free survival and overall survival (OS) for the combination compared to standard perioperative cisplatin-based chemotherapy. The option of "sandwich" chemo-immunotherapy with gemcitabine, cisplatin, and durvalumab or cisplatin-based chemotherapy followed by risk-adapted adjuvant PD-1 immunotherapy is now a preferred option for perioperative systemic therapy for MIBC.
- The FDA approved two additional local therapies for the treatment of Bacillus Calmette-Guérin (BCG)–refractory non-muscle-invasive bladder cancer: the gemcitabine instillation system TAR-200 device (based on the SUNRISE-01 study[5]) and nogapendekin alfa inbakicept-pmln in combination with BCG (based on the QUILT-3.032 study).
- EV-303 demonstrated an OS benefit with perioperative enfortumab vedotin + pembrolizumab compared to cystectomy alone in cisplatin-ineligible patients with MIBC, resulting in FDA approval.[6]

Renal Cancer

- Long-term results from CheckMate-214 confirmed the benefit of ipilimumab/nivolumab over sunitinib across subgroups, including favorable International Metastatic Renal-Cell Carcinoma Database Consortium risk.[7]
- Long-term results from Keynote-564 confirmed the benefit of adjuvant pembrolizumab across all subgroups.

OVERVIEW

Genitourinary malignancies, including cancers of the prostate, bladder, ureters, kidneys, testes, and penis, are a heterogeneous group of tumors with major public health implications.[8] Prostate cancer is the second most common cancer among men worldwide and the fourth most common cancer overall. Bladder cancer incidence is increasing in developing nations, reflecting increased rates of tobacco smoking decades ago. In this chapter, we discuss the medical oncologist's approach to genitourinary malignancies. We discuss risk stratification and, in some cases of low-risk cancers, active surveillance (AS) instead of intervention. In more advanced settings, we discuss established treatment protocols as well as emerging biomarkers and therapies. The spectrum of treatments for genitourinary malignancies is wide and includes not only chemotherapy but also hormonal therapies, molecularly targeted therapies, and immunotherapies, in addition to local therapies, such as surgery and radiation therapy (RT).

EPIDEMIOLOGY OF PROSTATE CANCER

Approximately one in eight American men will be diagnosed with prostate cancer during his lifetime, and it is the most common cancer in American men other than skin cancer.[9] It has been estimated that approximately 15% to 17% of men older than age 50 years harbor occult prostate cancer, and this percentage increases with each decade of advancing age.[10] Autopsy series show that nearly 70% of men older than age 80 years have occult prostate cancer.[11] Only approximately 1 in 41 will die as a result of prostate cancer, but this incidence still makes it the second leading cause of death resulting from cancer in American men. In the United States in 2023, there were an estimated 288,300 new cases of prostate cancer and 34,700 associated deaths.[12] The 8:1 ratio of incidence to mortality demonstrates that, although the disease is lethal for some men, a majority of men with prostate cancer die of other causes. These data highlight the variable biology and clinical course of prostate cancer. Many prostate cancers do not require immediate intervention because the risk of death from non–cancer related causes exceeds that from the cancer; other prostate cancers require multimodality approaches to both eradicate the tumor locally and eliminate micrometastases.

Although the frequency of histological cancers at autopsy is similar throughout the world, the clinical incidence is significantly higher in Western countries, suggesting a role for environmental factors. High consumption of dietary fats, in particular the fatty acid α-linoleic acid, is believed to increase risk by two-fold to three-fold. Several potentially protective dietary factors for prostate cancer incidence have been proposed, including tomatoes (which contain lycopene), cruciferous vegetables, carotenoids, fish, long-chain marine omega-3 fatty acids, soy, and polyphenols. The association with dietary animal fat intake is most robust.

KEY POINT

- Prostate cancer is a common diagnosis, and although metastatic disease develops in only a small percentage of affected patients, this translates into a large absolute number of deaths resulting from prostate cancer.

PROSTATE CANCER: FAMILY HISTORY AND HEREDITY

Prostate cancer is among the most heritable human cancers.[13] Several population-based studies, including a Nordic twin study and others, have shown family history of prostate or breast cancer, especially in a first-degree relative, is a strong risk factor.[14-17] Although family history is a strong risk factor, not all familial cancers are correlated with inheritable germline pathogenic mutations. One study found that, among patients with prostate cancer with a first-degree relative with prostate cancer, approximately 12% of cases are hereditary with germline pathogenic mutations in DNA-repair genes.[18] An interesting finding was that the frequency of this mutation was the same (12%) for those without a first-degree relative with prostate cancer. This observation suggests that approximately 90% of all prostate cancers are sporadic without detectable germline pathogenic mutations, and family history is not an enriching factor for detecting germline pathogenic mutations, at least in DNA-repair genes.[19]

Examples of germline alterations in prostate cancer are the following:

- A rare but recurrent mutation (G84E) in *HOXB13* (rs138213197), a homeobox transcription factor, is strongly associated with early-onset familial prostate cancer, suggesting that rare genetic variants exist that contribute to familial clustering of prostate cancer.
- Germline alterations in DNA-repair genes (*BRCA2*, *BRCA1*, and *MSH2*) are more common and are especially enriched in metastatic disease.

The Prostate Cancer Consensus Conference discussed the role and implementation of genetic testing for inherited prostate cancer risk.[20] Based on these findings, along with available therapeutic options (eg, PARP inhibitors for *BRCA1*, *BRCA2*, or other homologous recombination repair [HRR] gene mutations and PD-L1/PD-1 inhibitors for mismatch repair [MMR]-deficient solid tumor, including in patients with Lynch syndrome), National Comprehensive Cancer Network (NCCN) prostate cancer guidelines recommend routine germline testing in patients with a personal history of prostate cancer in the following scenarios[21,22]:

1. By the patient's prostate cancer stage/risk group:
   a. Any patient with metastatic or node-positive prostate cancer
   b. Any patient with a very high-risk or high-risk disease
   c. May be considered for a patient with intermediate-risk prostate cancer with intraductal/cribriform histology or a patient diagnosed at age ≤55 who would otherwise not meet criteria for testing.
2. By family history/ancestry:
   a. Ashkenazi Jewish ancestry
   b. One or more first-, second- or third-degree relative with ANY:

i. Breast cancer at age ≤50
ii. Male breast cancer
iii. Ovarian cancer
iv. Pancreatic cancer
v. Metastatic, node-positive, or very high-risk or high-risk prostate cancer

c. Three or more first-, second-, or third-degree relatives with prostate cancer (any grade) and/or breast cancer on the same side of the family, including the patient with prostate cancer.
d. A first- or second-degree blood relative who meets any of the criteria above.

KEY POINTS

- Prostate cancer is one of the most hereditary cancers. Clinicians should take a full history of malignancies in the family and be familiar with the link between prostate cancer and germline alterations in *BRCA2* and MMR genes, which are enriched among men with metastatic prostate cancer.
- Clinicians should offer genetic counseling for all patients with high-risk or very high-risk localized, regional node-positive, or metastatic prostate cancer, regardless of family history; those with localized prostate cancer and strong family history as outlined in the preceding paragraphs; and those with alterations in DNA damage repair or MMR genes identified from tumor sequencing.

ANATOMY OF PROSTATE CANCER

The peripheral zone is palpable by digital rectal examination (DRE) and is the site of origin of 70% of prostate cancers. The transition zone surrounds the urethra and cannot be assessed by DRE. Up to 20% of all prostate cancers develop in the transition zone; however, benign prostatic hypertrophy is more common than prostate cancer in the transition zone. The anterior portion of the prostate gland is especially important because this area is generally not biopsied as part of a routine prostate needle biopsy. It should be evaluated by either MRI or targeted directed biopsy in cases in which the prostate-specific antigen (PSA) level continues to rise in the setting of continued negative biopsy specimens, often harboring, in these circumstances, high-grade cancers.

When counseling men considering treatment options with either a surgical approach or RT, the anatomic location of the positive biopsy specimen is instructive. In the standard 12-core biopsy, generally two biopsy cores are obtained from the base of the gland, the midportion, and the apical regions. The possibility of seminal vesicle involvement with a preponderance of positive biopsy specimens in the base of the gland is a concern, especially because the base is in the anatomic region of the seminal vesicle. Therefore, a clinician should carefully review the MRI of the prostate, if available, to look for seminal vesicle involvement if the bulk of positive biopsy specimens are from the base. If seminal vesicle involvement is suspected, primary RT and androgen deprivation therapy (ADT) are typically used in lieu of prostatectomy.

Likewise, apical disease poses the problem of having a higher rate of positive surgical margins, harboring an anterior tumor (not necessarily biopsied during a standard biopsy procedure), and incontinence resulting from the necessity of creating an anastomosis between the bladder neck and the penile urethra, near the external urinary sphincter. Therefore, patients with a bulk of positive biopsy specimens from the apex may not be optimal candidates for prostatectomy. In addition, the possibility of an anterior tumor in this instance may prompt an MRI to investigate for undersampled disease via standard transrectal ultrasound (TRUS) biopsy. These considerations may aid decision-making regarding the initial treatment approach.

Although TRUS biopsy has been the most widely used method, a transperineal approach may reduce the chances of biopsy-related infection, although data have been mixed. Typically, this approach is done in an operating room instead of an office setting, potentially limiting accessibility, although some centers are now offering this in the office. The transperineal approach may be preferred for patients with anterior and apical tumors not easily accessible by TRUS, or for those at higher risk of infection.

ROLE OF MULTIPARAMETRIC MRI IN DIAGNOSTIC WORKUP IN SUSPECTED PROSTATE CANCER

There is mounting evidence to support the use of multiparametric MRI and multiparametric MRI-guided biopsy combined with systematic TRUS biopsy in men with suspected prostate cancer. For decades, a TRUS-guided 12-core prostate biopsy has been used as a standard procedure to ensure that biopsy specimens encompass all portions of the gland. However, there are several limitations with TRUS biopsy, including undersampling of anterior tumors and the detection of clinically insignificant prostate cancer.

Multiparametric MRI provides detailed visualization of the prostate gland and potentially significant prostate cancer, and facilitates direct targeting of suspicious lesions during biopsy and to select patients who may not need a prostate biopsy.

A study called PRECISION accrued 500 men with elevated PSA who had not yet undergone biopsy.[23] Men with suspected prostate cancer were randomly assigned to undergo MRI, with or without targeted biopsy, or standard TRUS-guided 10 to 12 core biopsy. Men in the MRI-targeted biopsy group underwent a targeted biopsy without standard biopsy cores if the MRI was

suggestive of prostate cancer. Men whose MRI results were not suggestive of prostate cancer were not offered a biopsy. The investigators found that when MRI was used for guidance, there was higher detection of clinically significant cancer (38% vs 26% with TRUS biopsy) and a lower chance of detecting low-grade cancers that were not clinically significant. In addition, 28% of patients could avoid biopsy given the absence of MRI abnormalities.

Similarly, The PAIREDCAP study and other large trials show that while MRI-targeted biopsies detect more cancer per core than systematic biopsies, the overall detection rates are similar when each is used alone (about 52%-60%). Combining MRI-targeted and systematic approaches, however, provides the highest detection rate (around 62%-70%), ensures fewer clinically significant cancers are missed (about 9% if MRI-guided biopsy alone without systematic biopsies), and reduces upgrading at prostatectomy (3.5% vs 8.7% with MRI and 16.8% with systematic alone).

These data are prompting the increased use of MRI as the first diagnostic step in the evaluation of PSA-suspected prostate cancer, but longer follow-up is needed to determine the safety of eliminating standard template biopsies based on MRI and to determine the cost-effectiveness of this strategy.

Most recently, the PRIME study[24] investigated the utility of a "Bi-parametric" prostate MRI (ie, MRI without gadolinium contrast) in comparison to the standard multiparametric MRI for initial diagnosis. The investigators found that biparametric MRI was non-inferior to the multiparametric MRI for the detection of clinically significant prostate cancer. This data may lead to a change in the standard of care to allow for more biparametric MRI use, which could allow for greater MRI availability for patients and reduce worldwide healthcare costs.

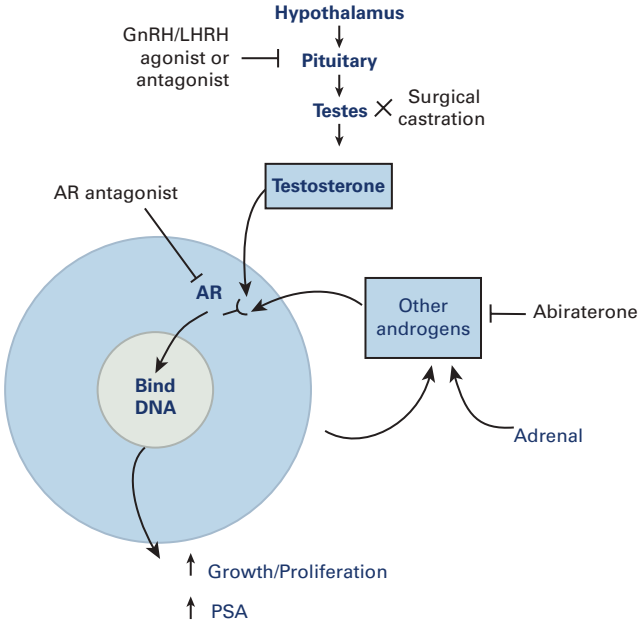
KEY POINTS

- Prostate cancer is typically diagnosed via TRUS or transperineal biopsy using a standard 12-core template to sample the posterior peripheral zone. MRI-guided biopsy combined with a standard TRUS biopsy has been shown to lessen the likelihood of missing clinically significant cancers and should be used when available.
- Among men undergoing evaluation for elevated PSA, a prebiopsy multiparametric or biparametric MRI may help triage those who require biopsy, limiting biopsies to those with a greater likelihood of clinically significant cancer. Anatomic location can help predict the pattern of spread and treatment-related risks. Disease near the base of the gland may extend into the seminal vesicles. Disease in the apex may increase the risk of positive surgical margins and urinary incontinence.

PROSTATE CANCER PATHOLOGY AND MOLECULAR PATHOGENESIS

Androgens are the primary drivers of prostate cancer cell growth and proliferation. Prostate cancer rarely develops in castrated men or in those who have hypopituitarism before the age of 40 years.[25] The androgen receptor (AR), located on chromosome Xq11-13, is a member of a superfamily of ligand-dependent transcription factors that have a similar structure with different

Figure 14-1 Basic Schematic of Androgen Receptor–Directed Therapies



Abbreviations: AR, androgen receptor; GnRH, gonadotropin-releasing hormone; LHRH, luteinizing hormone-releasing hormone; PSA, prostate-specific antigen.

functional domains. The development of prostate cancer involves a multistep process in which AR signaling plays a key role (Fig. 14-1). The cornerstone of systemic therapy is inhibition of AR signaling, which can be accomplished through direct inhibition of AR with AR antagonists, and/or depleting androgen ligands. Androgens include testicular testosterone, which can be inhibited with ADT, and androgens synthesized in the adrenal glands and/or intratumorally, which can be blocked with abiraterone. Collectively, AR antagonists and abiraterone are referred to as androgen receptor pathway inhibitors (ARPIs) in this chapter, although elsewhere they may also be referred to as androgen signaling inhibitors (ASIs), androgen receptor signaling inhibitors (ARSIs), androgen receptor inhibitors (ARIs), or novel hormonal agents (NHAs).

Specific genetic changes have been identified in tumors representing different clinical states. Gene expression profiling has identified numerous molecular abnormalities that may differ between primary, metastatic, and castration-resistant prostate cancers (CRPCs). As such, the targets relevant for the treatment of early-stage disease may not be the same as those for late-stage tumors.

The typical immunohistochemistry profile of prostate cancer is as follows:

- Negative for cytokeratins 7 and 20
- Positive for AR and PSA
- Positive for the NKX 3.1 homeobox protein

Figure 14-2 Gleason Scoring

A

A Gleason score is assigned by adding the two most common grades of prostate cancer cells in a tissue sample.

How is it calculated?

Formula for Gleason scoring

Primary pattern (>50%) + Secondary pattern (<50%) = GS

Example:

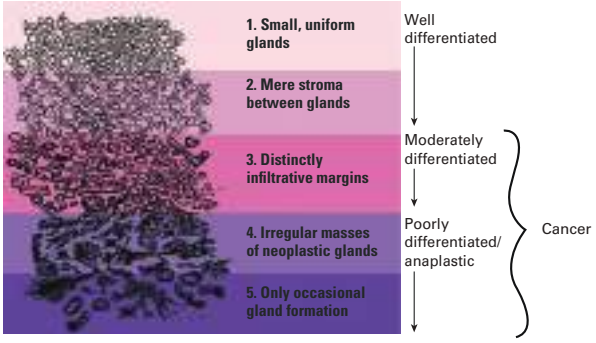
Primary pattern = 3

Secondary pattern = 4

Total GS = 7

This means that most of the tumor is grade 3 (aka dominant pattern), and a smaller portion is grade 4.

B



C

Gleason score Formula: GS = Primary pattern (>50%) + Secondary pattern (<50%)	ISUP Grade Groups derived from GS; Cancer grading
6 (</3 + 3)	Grade Group I (GS = </6)
7 (3 + 4)	Grade Group II
7 (4 + 3)	Grade Group III
8 (4 + 4)	Grade Group IV
9 (4 + 5)	Grade Group V
9 (5 + 4)	Grade Group V
10 (5 + 5)	Grade Group V

The Gleason score is a scale that helps with the staging of prostate cancer (by aggressiveness and prognosis) based on the microscopic examination of the sample tissue in the prostate biopsy. The grades in the score compare the pattern of the cancerous tissue with that of normal tissue in regard to aspects including shape, disposition, and spread. There are two grades that are awarded, each on a scale from 1 to 5. The primary grade is given to the most commonly observed type of cancerous cell; the secondary grade is given to the second most commonly observed type of cancerous cell.

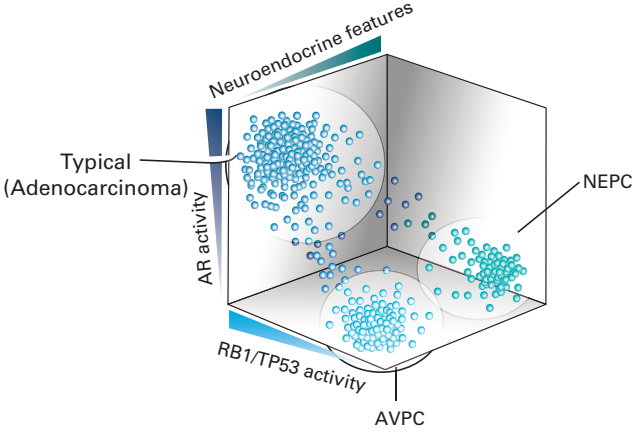
NKX 3.1 positivity is retained even in some advanced treatment-resistant prostate cancers that have lost AR and/or PSA expression (although loss in neuroendocrine prostate cancer, discussed subsequently, can occur). In cases of a mass involving both prostate and bladder, this profile can help differentiate prostate cancer from urothelial cancer, which is typically positive for cytokeratins 20 and (usually) 7 as well as GATA3 and negative for PSA and NKX 3.1 (and typically, but not always, negative for AR). The Gleason grading system is used to describe the morphology of adenocarcinomas of the prostate. It can be applied to prostate biopsies (each core graded separately) or entire radical prostatectomy specimens; it should not be applied to metastatic biopsies or after preceding hormone therapy. In general, the higher the Gleason pattern, the less well differentiated (gland-forming) the histology (Fig. 14-2).

During the 2014 International Society of Urological Pathology Consensus Conference, a new prostate grade system was developed.[25] This new system provides more accurate stratification with simplified grading categories. Many experts believe that this stratification helps patients understand the risk of their cancer and limits overtreatment. As shown in Figure 14-2, the new system assigns grade groups from 1 through 5, derived from the Gleason score. This new system has been validated in two separate studies.[26] Both studies found that grade groups predicted the risk of recurrence after primary treatment.[27]

Prostatic intraepithelial neoplasia is an epithelial cellular proliferation within benign-appearing glands and acini. Approximately 50% of men with prostatic intraepithelial neoplasia, as demonstrated in prostate biopsy specimens, will be diagnosed with prostate cancer in 5 years, depending on the frequency of biopsy procedures. More than 99% of prostate cancers are adenocarcinomas; <1% are pure ductal and mucinous variants. Other histological subtypes include small-cell carcinoma and rare mesenchymal tumors (ie, rhabdomyosarcomas in younger patients and leiomyosarcomas in older patients). Urothelial carcinomas of the prostate are confined to the periurethral ducts and are more common among patients who have been successfully treated for non-muscle-invasive bladder cancer (NMIBC). Though cases are rare, lymphomas and leukemias may occur in the prostate gland.

During the course of treatment of advanced prostate cancer, multiple genomic and transcriptomic alterations can occur as mechanisms of treatment resistance. Despite resistance to castration and ARPIs, most prostate cancers remain dependent on AR signaling, but a subset may become androgen-independent and are generally characterized by alterations in *RB1*, *PTEN*, and *p53* (Fig. 14-3).[28] According to a multi-institutional prospective series of 202 consecutive patients with metastatic castration-resistant prostate cancer (mCRPC), 17% of patients with mCRPC developed treatment-associated small-cell/neuroendocrine histology on metastatic tumor biopsies.[29] Some, but not all, of these tumors may exhibit neuroendocrine differentiation with positive synaptophysin and/or chromogranin A staining. The extreme of neuroendocrine differentiation is small-cell morphology. A patient with rapid visceral progression in the absence of significant PSA change should prompt rebiopsy to exclude the emergence of a neuroendocrine or aggressive variant histology.

Figure 14-3 Relationship Between AR Signaling, Tumor-Suppressor Genes, and Neuroendocrine Features in Metastatic Castration-Resistant Prostate Cancer



This depicts a conceptual representation of the spectrum of profiles that include AR signaling, loss of tumor-suppressor genes, and development of neuroendocrine features during prostate cancer progression. Individual dots represent hypothetical patients, but different subclones may also be present within one individual.

Abbreviations: AR, androgen receptor; AVPC, aggressive variant prostate cancer; NEPC, neuroendocrine prostate cancer.

KEY POINTS

- Prostate cancer can be characterized by its typical immunohistochemistry profile: cytokeratin 7/20 negative, PSA positive, AR positive, and NKX 3.1 positive.
- As treatment resistance occurs, different phenotypes may emerge. Most CRPCs are still driven by AR signaling even after developing resistance to subsequent AR-directed therapies.
- Some advanced CRPCs may become androgen-independent, often harboring alterations in *RB1*, *PTEN*, and *p53.* These may be admixed with AR-driven tumors. A subset of these cases may have neuroendocrine features, with the most extreme exhibiting small-cell morphology.
- There are two kinds of small-cell/neuroendocrine prostate cancer: (1) de novo small-cell prostate cancer, which is a very rare disease subset and presents admixed with adenocarcinoma (more common) or pure, (2) treatment-associated small-cell/neuroendocrine prostate cancer, which occurs in about 15% to 20% of patients who have mCRPC. Small-cell/neuroendocrine prostate cancer should be suspected in patients with a rapid radiographic progression or new hepatic metastases without PSA increase. It is characterized primarily by morphology, but it can also be positive for synaptophysin and/or chromogranin A staining.

PROSTATE CANCER PREVENTION

A number of chemoprevention strategies have been studied in prostate cancer, including the Prostate Cancer Prevention Trial (PCPT)[9] and REDUCE trials, both using 5-α reductase inhibitors.[30]

In 2011, a US Food and Drug Administration (FDA) advisory committee analysis of both trials confirmed a relative reduction of approximately 25% in the overall incidence of prostate cancer. The authors of the analysis noted, however, that this reduction was limited to tumors with a modified Gleason score of 6 or below and that many of the detected cancers were diagnosed by prostate biopsy in response to an elevated PSA level or an abnormal DRE. The reassessment of the PCPT and REDUCE trials confirmed a significantly increased incidence of high-grade prostate cancers, and the committee estimated that the use of a 5-α reductase inhibitor for the prevention of prostate cancer would result in one additional high-grade cancer to avert three to four potentially clinically relevant lower-grade cancers. The advisory committee concluded that finasteride and dutasteride do not have a favorable risk–benefit profile for chemoprevention of prostate cancer in healthy men. In a recent population-based cohort study, the all-cause and prostate cancer–specific mortality rates were increased in patients treated with 5-α reductase inhibitors, possibly related to a delay in diagnosis resulting from the decrease in PSA level that occurs with treatment; importantly, PSA is expected to fall by approximately one-half on 5-α reductase inhibitors, so more stringent criteria must be used to trigger a workup for cancer.[29]

Trials of vitamin supplementation have also not demonstrated benefit in reducing the risk of prostate cancer, and the Selenium and Vitamin E Cancer Prevention (SELECT) trial actually demonstrated a 17% increased risk of prostate cancer in the vitamin E group but not in the selenium and vitamin E group, suggesting that vitamin E supplementation at 400 IU daily significantly increases the risk of prostate cancer development.[31,32]

PROSTATE CANCER SCREENING AND EARLY DETECTION

PSA is a single-chain glycoprotein that functions as a kallikrein-like serine protease, causing liquefaction of seminal coagulum. It is prostate-specific, but not prostate cancer–specific, and an elevated PSA concentration may occur as a result of prostatitis, nonmalignant enlargement of the gland, biopsy of the prostate, ejaculation, and prostate cancer. A DRE does not alter PSA levels appreciably. The half-life of PSA is estimated to be 2 to 3 days, and levels should remain undetectable if the prostate has been removed.[33]

A screening procedure, by definition, is intended to be performed in asymptomatic patients with no signs or symptoms of the organ being evaluated. The PSA blood test was first introduced in the early 1990s as a screening test for prostate cancer. Three large randomized controlled trials failed to demonstrate any overall survival (OS) benefit conferred by PSA with or without DRE screening, and cancer–specific survival benefit has been inconsistent and modest at best. However, there are methodological issues, including significant "contamination" of the control arm of one trial, and benefits on prevention of distant metastatic disease have been observed in some trials.

- A PSA level >4 ng/mL has predictive value for the diagnosis of prostate cancer; however, lower PSA values may also be associated with prostate cancer as well as with high-grade cancers, as demonstrated in the PCPT.[10]
- For men with a PSA value between 4 and 10 ng/mL, a PSA velocity of at least 0.75 ng/mL per year is suspicious for cancer.

PSA measurements should be made on at least three to four consecutive occasions, usually separated by 6 months over at least 12 to 18 months because of variability.

- A variety of additional modifications to PSA testing have been developed to help improve its sensitivity and specificity, especially when PSA values are between 4 and 10 ng/mL. The proportion of free/bound PSA can help suggest a higher chance of cancer if <10%. PSA density (value divided by volume of gland) >0.15 is associated with prostate cancer. The SelectMDx, Prostate Health Index, and 4K scores are commercially available platforms that have been proposed to help decide whether to biopsy, but may be increasingly superseded by prebiopsy MRI.

US PREVENTIVE SERVICES TASK FORCE GUIDELINE

In 2018, the US Preventive Services Task Force issued a grade C evaluation (balance of risks and benefits is too close to make a recommendation) of prostate cancer screening in average-risk men aged 55 to 69 years, revised from a grade D recommendation previously (harms outweigh benefits) in light of increasing use of active surveillance to decrease harms and not from any new known benefits. Men at higher risk by virtue of family history, African ancestry, or known germline predisposition may be more strongly advised to undergo screening, but not based on any high-level data. If screening is beneficial in these patients, it is likely to be in younger men (eg, 40-45 years of age), and screening is generally unlikely to be beneficial in older populations (eg, 75 years of age and older), given the natural history of prostate cancer.

The US Preventive Services Task Force summarized the risks and benefits of PSA testing for the early diagnosis of prostate cancer as follows[34]:

Benefits

- In men aged 55 to 69 years, PSA testing may prevent approximately 1.3 deaths resulting from prostate cancer over approximately 13 years per 1,000 men screened.
- Screening may prevent approximately three cases of metastatic prostate cancer per 1,000 men screened.

Harms

- Erectile dysfunction, urinary incontinence, and bowel symptoms are associated with definitive therapies, and occasionally, some erectile dysfunction is associated with biopsies.
- Harms of screening in men older than 70 years of age are at least moderate and greater than in younger men.

KEY POINTS

- There are no universally accepted protocols for prostate cancer prevention or screening.
- Two 5-α reductase inhibitors (eg, finasteride and dutasteride) were evaluated in large phase 3 chemoprevention trials. Although these agents decreased the overall incidence of prostate cancer by approximately 25%, this decrease was limited to low-grade tumors. The use of these agents was associated with a significantly increased incidence of high-grade prostate cancer.
- PSA-based prostate cancer screening has shown, at most, a small reduction in prostate cancer–specific mortality rate and no convincing effect on overall mortality. Screening could be more effective if targeted to men with a higher risk and to the age groups most likely to benefit (ie, younger men rather than older men), but additional studies evaluating this possibility are underway. DRE for screening does not significantly add to PSA.

PROSTATE CANCER STAGING

The American Joint Committee on Cancer (AJCC) *Cancer Staging Manual, 8th Edition* (2017), TNM system describes the extent of the primary tumor (T), status of the regional nodes (N), and presence or absence of T4 distant metastases (M).[33,35,36] For more information, visit https://www.cancer.org/cancer/types/prostate-cancer/detection-diagnosis-staging/staging.html.

Clinical T stage is assigned by DRE. Radiographic evidence of extracapsular extension is not formally part of the staging guidelines, but clinicians may opt to intensify therapy for patients with radiographically advanced tumors. As discussed in the earlier section above, there has been increased use of multiparametric MRI in staging, which incorporates T2-weighted, diffusion-weighted, and dynamic contrast–enhanced MRI imaging for the detection, staging, and management of prostate cancer. The Prostate Imaging Reporting and Data System (PI-RADS) assessment uses a 5-point scale based on the multiparametric MRI findings to determine the likelihood of a clinically significant cancer (International Society of Urological Pathology grade 2+) in the prostate gland; importantly, higher PI-RADS scores do not indicate higher-grade disease. MRI can also provide a likelihood of extraprostatic extension (EPE), sometimes graded from 0 to 3, where 3 is frank EPE (closest to clinical T3 staging by digital rectal exam), whereas 1 to 2 indicate some probability of microscopic EPE.

Pathological T stage is assigned based on examination of a radical prostatectomy specimen for patients who undergo surgery. Margin positivity, which is influenced by surgical technique and the anatomic extent of disease, should be specified in the pathology report. Nodal involvement can also be assessed.

Tumors detected in a biopsy specimen based on an elevated PSA level, and no palpable disease detected by DRE are designated T1c. T2 disease is confined to the prostate (pathological substaging to T2a, T2b, or T2c is no longer performed). In T3 disease, the tumor extends through the prostate capsule (T3a) or invades the seminal vesicles (T3b), whereas tumors are considered T4 if they invade adjacent structures or organs.

RISK STRATIFICATION

Localized prostate cancer is clinically heterogeneous. Many groups have developed prognostic models based on the combination of the initial T stage, Gleason score, and baseline PSA level. These algorithms are used to predict disease extent (ie, organ-confined versus non-organ-confined), node status (negative or positive), and the probability of success using a PSA-based definition of failure specific to the local therapy under consideration. Specific nomograms have been developed for radical prostatectomy, external-beam radiation therapy (EBRT), and brachytherapy (ie, radioactive seed implantation). The eighth edition of the *AJCC Cancer Staging Manual* includes prognostic groupings that incorporate anatomic stage and PSA.[36]

Using T stage, Gleason score, and PSA value, discrete risk categories have been defined and form the basis for treatment decision-making (Fig. 14-4).[35] ASCO guidelines differ slightly from NCCN criteria but are broadly similar. Historically, patients were categorized as low, intermediate, or high risk. However, these categories have been subdivided in more recent updates using additional factors, such as PSA density and the number of involved cores.

There are several tissue-based molecular biomarkers (genomic risk classifiers) that have been developed to refine clinical risk stratification, although none have been prospectively validated to improve decision-making. In 2019, ASCO published a guideline with recommendations for these tissue-based assays to help clinicians select patients for active surveillance versus definitive therapy and to choose between adjuvant RT versus surveillance/salvage RT (although adjuvant RT is increasingly not used outside of pathological node positivity).[37] The Decipher test may have a role in determining the benefit of ADT in combination with salvage RT for patients with low PSAs, as is increasingly common in modern practice, although this is still being prospectively validated. In the future, pathology artificial intelligence platforms may be used in some of these settings.

ROLE OF IMAGING IN STAGING

Prostate cancers spread by local extension through the capsule and seminal vesicles, the lymphatic system to regional nodes, or hematogenously to bone and visceral sites. Imaging studies play a key role in staging. Generally, evaluation of the extent of the local disease is done by a combination of DRE and multiparametric MRI. Although there is no consensus on which patients should undergo MRI, multiparametric MRI is commonly used in centers with available resources. See "Role of Multiparametric MRI in Diagnostic Workup in Suspected Prostate Cancer" section for further reading.

For all men with unfavorable intermediate-, high-, or very high-risk disease, the ASCO, the American Urological Association/American Society for Radiation Oncology/Society of Urologic Oncology, and the NCCN recommend cross-sectional imaging with CT or MRI and conventional ^{99m}Tc methylene diphosphonate bone scan to evaluate regional and distant metastases. No routine staging imaging study is recommended for low-risk or favorable intermediate-risk patients.

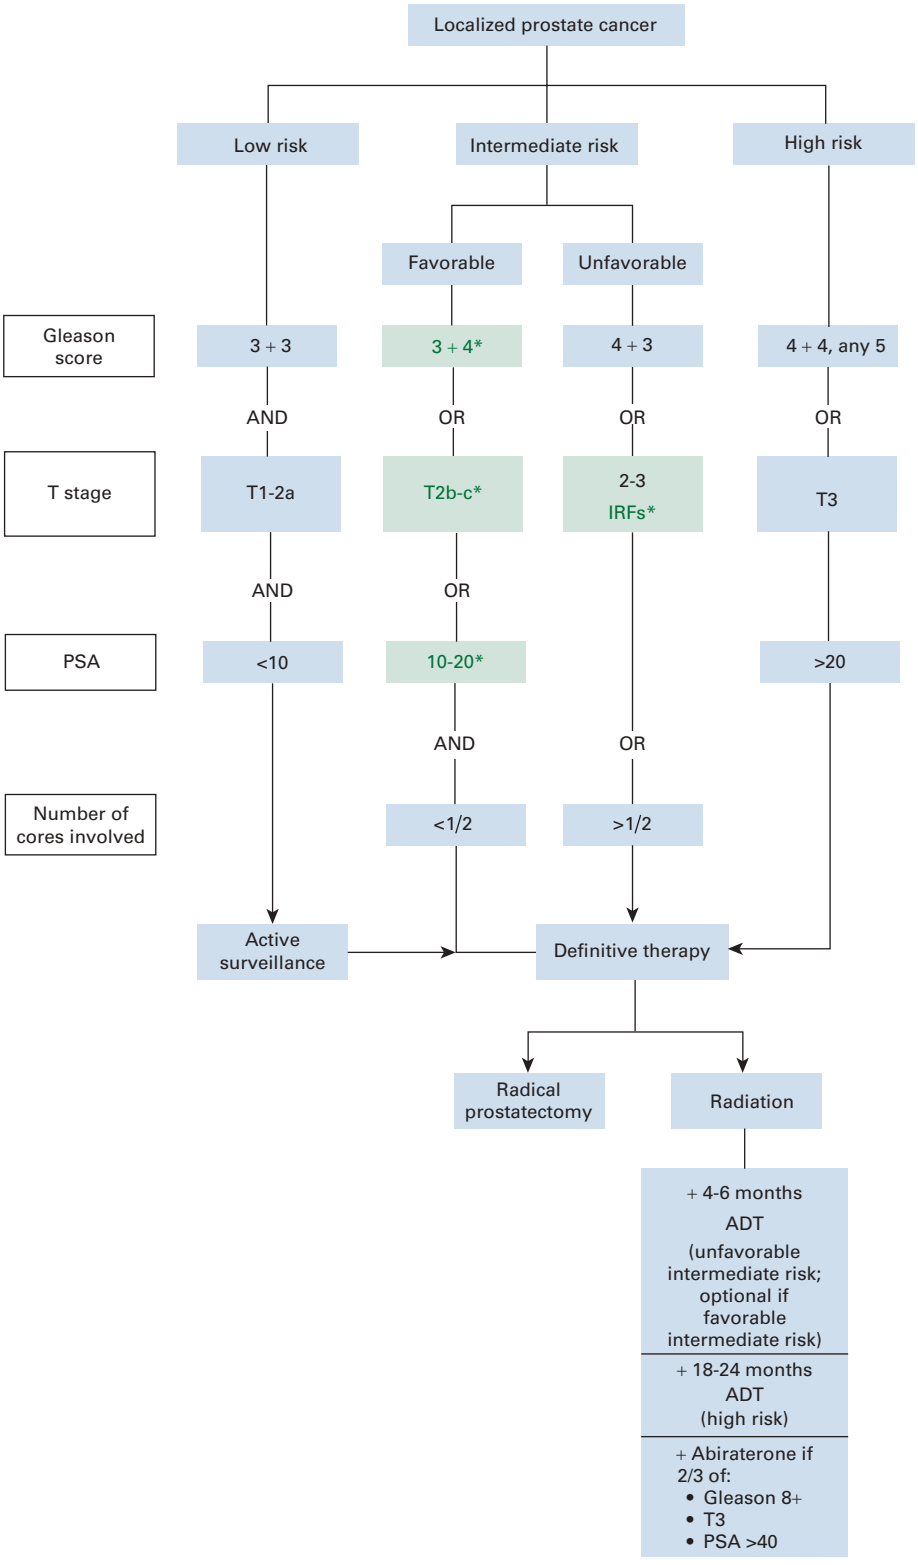
There are emerging roles of next-generation imaging with PET scan using prostate cancer–specific tracers such as ^{18}F fluciclovine,^{11}Ccholine, ^{68}Ga PSMA-11, and ^{18}F piflufolastat.[38] Although all four of these are FDA approved for evaluation of biochemically recurrent prostate cancer, the last two are also FDA approved for initial staging in men who have high-risk or very high-risk prostate cancer with suspected metastases. The trials that led to the approval of ^{68}Ga PSMA-11 and piflufolastat tracers as initial staging for newly diagnosed high-risk prostate cancer showed a sensitivity of 40% and specificities of 95% and 98% for detecting pelvic lymph node metastases.[36,38] Importantly, specificity is higher than sensitivity; thus, negative scans do not exclude nodal metastases, but positive scans are likely to represent true nodal metastases and provide valuable information that may affect management decisions. To date, there are no prospective data supporting a validated approach for changing the treatment of these patients compared with those who undergo staging using conventional imaging. Nevertheless, the use of prostate-specific membrane antigen (PSMA) PET/CT scans is recommended for staging of men with high- and very high-risk disease. Some data also suggest the use of PSMA PET/CT in unfavorable intermediate-risk patients, although the yield is likely lower, and this is a controversial area.

MANAGEMENT OF PROSTATE CANCER BY RISK

Localized prostate cancers are those confined to the prostate gland without nodal involvement or metastases. Treatment selection considers whether the disease can be eradicated by a treatment directed solely at the prostate, whether a combined local and systemic approach is necessary for cure, or whether therapy is not needed or can be deferred because of a low risk of progression. In general, therapy is aimed at complete local control to decrease the potential for recurrence while preserving optimal bowel, bladder, and sexual function.

Tumors confined to the prostate are generally managed by radical prostatectomy, RT, or, in some cases, AS. An assessment of the patient's life expectancy, overall health status, and tumor characteristics should be undertaken before a treatment decision

Figure 14-4 Approach to Treatment Options in Newly Diagnosed Localized Prostate Cancer According to Risk Stratification



Various forms of radiation are discussed in the text. Short course of ADT (4–6 months) is recommended for intermediate-risk category (especially if unfavorable) and long course (18–24 months) for high-risk category.
Abbreviations: ADT, androgen deprivation therapy; EBRT, external-beam radiation therapy; IRF, intermediate risk factor; PSA, prostate-specific antigen.

is made. Life expectancy can be estimated with nomograms, including one from the Social Security database. Patients with a life expectancy of <5 years do not benefit from treatment of low-risk prostate cancer and therefore should undergo watchful waiting and additional workup only if the patient becomes symptomatic.

The general approach to treatment of prostate cancer by risk category is described here, with further details of the treatment modalities of radical prostatectomy and radiation described in the following sections.

LOW RISK

For patients with very low-risk localized prostate cancer, AS is the preferred management option. AS is also generally preferred for patients with low-risk localized prostate cancer, but depending on patient preferences, interstitial prostate brachytherapy, EBRT, and radical prostatectomy can also be offered. Prostate brachytherapy should not be offered to men who have significant lower urinary tract symptoms or who have had repeated episodes of prostatitis or urinary infections, because brachytherapy may be more likely to exacerbate these symptoms. The American Urological Association symptom score index for assessment of urinary symptoms (developed to assess urinary symptoms of benign prostatic hyperplasia) or the EPIC-26 instrument can be used to quantify the current symptom burden a patient is experiencing. This information can then be incorporated into initial therapy decisions for men opting for localized treatment with EBRT or prostatectomy, and these instruments can be used to track changes in symptoms after treatment. Subtotal approaches such as focal ablation or high-intensity focused ultrasound are still being evaluated and may not have a favorable risk/benefit profile pending longer-term results but can sometimes be offered for patients with very focal, low- or intermediate-grade disease with the understanding that recurrences are still possible and may be more difficult to manage with conventional definitive therapy and that quality of life is not necessarily improved.

INTERMEDIATE AND HIGH RISK

For patients with intermediate-, high-, or very high-risk localized prostate cancer, definitive therapy with either prostatectomy or RT (+/− ADT, dependent on risk category) is recommended as long as the patient's life expectancy is 10 years or more (intermediate risk) or 5 years or more (high and very high risk) or if the patient is symptomatic. Patients with favorable intermediate-risk prostate cancer may be considered for active surveillance, especially those with small proportions of Gleason pattern 4 disease. The rate of subsequent upgrading may be increased for favorable intermediate-risk patients compared with low-risk patients under active surveillance, but it is not clear whether OS or cancer–specific survival is affected.

With few randomized trials, comparisons among treatments have been limited by selection bias and differences in outcome reporting with respect to both cancer control and quality of life. The best available data suggest that long-term cancer control is equivalent between surgery and radiation. This is supported by the ProtecT study, which was a large phase 3 trial in the UK that randomized patients with newly diagnosed localized prostate cancer to undergo (1) active monitoring, (2) surgery, or (3) radiation for first-line treatment. At 15 years of follow-up, the risk of metastasis was similar between intervention groups and was higher in the inactive monitoring group, but the overall prostate cancer mortality risk was low regardless of treatment group assigned (61% of patients in the active monitoring group eventually received treatment).[39] Given this apparent equipoise, the treatment decision is guided primarily by adverse effect profiles.

- Overall, prostatectomy is primarily associated with urinary incontinence and erectile dysfunction, with the incontinence typically improving in the months after surgery and erectile function dependent on baseline function as well as surgical approach (nerve-sparing versus non–nerve-sparing surgery).
- Radiation therapy is more associated with irritative urinary and bowel symptoms in the days/weeks after treatment (acute) or months to years later (chronic).[40]

Reported complication rates for each modality vary widely in the literature. The differences are related to the different definitions used, whether the patient or physician is reporting, and the time from treatment to assessment of symptoms. Health-related quality of life studies are more accurately defining patient satisfaction with the different treatments for localized prostate cancer. For example, in one study, adjuvant hormone therapy was associated with worse quality of life outcomes among patients receiving brachytherapy or external RT; prostatectomy was associated with worse urinary incontinence, but urinary irritation and obstruction improved, particularly in patients with a large prostate.[35] Thus, prostatectomy may be the preferred modality in patients with significant baseline urinary obstructive symptoms; RT may worsen obstructive symptoms in the short term.

Erectile dysfunction can occur as a result of both RT and radical prostatectomy. The risk is generally greater with radical prostatectomy. Of note, all patients experience decreases in erectile function over time related to reasons other than prostate cancer treatment. This was observed in the ProtecT study as referenced above. These analyses have led to the development of health-related quality of life nomograms that may help guide treatment choice in an individual patient with localized prostate cancer.

ROLE OF ADT WITH RADIATION FOR LOCALIZED PROSTATE CANCER

ADT has a clearly established role for use with radiation for the treatment of localized prostate cancer. It does not yet have an established role in the perioperative setting for patients undergoing surgery, but this is currently under investigation.

Common modalities of ADT with radiation include luteinizing hormone-releasing hormone (LHRH) agonists (leuprolide, goserelin, triptorelin) and LHRH antagonists (relugolix, degarelix). ADT is typically started approximately 2 months before RT, although earlier or later timing of RT relative to ADT does not seem to affect long-term outcomes. It is uncertain whether the addition of bicalutamide to ADT improves outcomes for localized prostate cancer, but based on analyses in more advanced disease (see "Therapy for Metastatic Prostate Cancer" section), some clinicians will add bicalutamide for the first 4 to 6 months of ADT or until after RT is completed.

For patients with intermediate-risk disease, the addition of 4 to 6 months of ADT to RT has been shown to improve biochemical-free survival and progression-free survival (PFS) in several trials.[41-43] Importantly, the addition of ADT here has not been shown to improve OS for intermediate-risk disease. A secondary analysis of the RTOG 9408 study found that patients categorized with "unfavorable" intermediate-risk disease receiving ADT had a reduction in distant metastases and prostate cancer–specific mortality. This benefit was not seen for patients categorized to have "favorable" intermediate-risk disease. Based on these data, NCCN guidelines support a short course of ADT for 4 to 6 months together with RT for patients with "unfavorable" intermediate-risk prostate cancer.

In contrast to intermediate risk disease, the addition of ADT to radiation in high-risk disease has been clearly demonstrated to improve OS in addition to prostate cancer–specific mortality. The optimal duration of ADT with EBRT for high-risk disease has been evaluated in several randomized, controlled trials.[44-48] Longer ADT courses resulted in improved long-term survival, with an optimal duration in the range of 18 to 24 months. Two studies showed superiority of prolonged ADT, whereas one showed comparable outcomes with medium-course versus prolonged ADT (although not powered as a noninferiority study). The recommended duration can be customized depending on patient tolerability and comorbidities.

For patients with very high-risk disease and those with regional lymph node involvement, the addition of an AR pathway inhibitor (such as abiraterone) to ADT for 2 years should be considered, based on data from the STAMPEDE protocol described below. This is endorsed by the NCCN guidelines. The role of adding docetaxel to ADT and RT in this setting has been evaluated in several clinical trials, but is not recommended as it has not shown a definitive OS benefit.[38,49,50]

- A meta-analysis of pooled data from two randomized controlled trials of the STAMPEDE protocol indicated metastasis-free survival (MFS) and OS benefit from the addition of 2 years of abiraterone to ADT and standard-of-care RT for men with newly diagnosed "high-risk" or relapsing with high-risk features non-metastatic prostate cancer.[51] Newly diagnosed high-risk non-metastatic prostate cancer was defined as node positive (Tx N1) or, if node negative, having at least two of the following: tumor stage T3 or T4, Gleason score of 8 to 10, and PSA concentration of 40 ng/mL or more. Notably, these are not the same as NCCN high-risk criteria but instead represent a particularly high-risk subset. The results of similar studies with second-generation AR antagonists are awaited.

REGIONAL RISK PROSTATE CANCER (CN1) (STAGE IVA)

Some aggressive local tumors may have already metastasized to pelvic lymph nodes at the time of diagnosis. These may be diagnosed clinically, by suspicious appearance on a CT scan, MRI, and/or PSMA PET/CT. The treatment of patients with positive lymph nodes found at the time of prostatectomy with lymph node dissection (ie, surprise positive lymph nodes) is discussed under the "Pathologic Node-Positive Disease" section of the chapter. Suspicious nodes located above the aortic bifurcation are considered outside of the pelvis and, therefore, are staged as M1 disease (stage IVB) rather than N1 (stage IVA).

Some nodes may be borderline. In this case, the clinician may choose to obtain a biopsy specimen for clarification. Alternatively, treatment with neoadjuvant ADT may be started before planned definitive RT. Then, if a repeated CT scan or MRI after approximately 3 months of ADT shows that any suspicious nodes have decreased in response to ADT, this strongly implies the presence of prostate cancer and may be treated as such. Finally, PSMA PET may be helpful, although, as noted, negative results do not rule out nodal involvement.

Men with clinical evidence of regional lymph node metastases (stage IVA) without distant metastases are not necessarily precluded from definitive (ie, curative-intent) therapy. Although no randomized trials have established the role of definitive local therapy in men with regional lymph node metastases, retrospective analyses[52] from the National Cancer Database,[53] the SEER database,[54] have suggested a survival benefit from definitive EBRT to prostate and pelvic nodes with ADT in men with clinical node-positive prostate cancer.

The meta-analysis of two randomized controlled trials of the STAMPEDE protocols, which included patients with TxcN1M0, showed the MFS and OS benefited from adding 2 years of abiraterone to ADT and standard-of-care EBRT and ADT.[55] Currently, the NCCN recommends EBRT plus ADT plus 2 years of abiraterone for regional lymph node-positive prostate cancer. Alternatively, prostatectomy and extended lymphadenectomy may be performed, but with a likely plan for adjuvant RT and ADT after surgery (trimodality therapy) for selected patients. The increased toxicity of trimodality therapy may only be justified if a patient has significant obstructive urinary symptoms that could actually be palliated by surgery.

KEY POINTS

- Patients with localized prostate cancer can be risk-stratified based on three clinical factors: T stage, Gleason score, and PSA level. Genomic testing of the cancer specimen may provide additional information about risk and progression, but this has not yet been prospectively validated for decision-making.
- Patients with low-risk disease may be offered active surveillance, which uses serial PSA measurements, DREs, and biopsy specimens to detect any presence of higher-risk disease, at which point definitive therapy can be offered. Sequential MRI may also be helpful. This strategy results in less treatment-associated morbidity and similar long-term cancer survival compared with immediate therapy.
- Patients with intermediate- or high-risk disease typically should receive definitive therapy, assuming a life expectancy of at least 5 (high risk) to 10 (intermediate risk) years (or if symptomatic). Definitive therapies include radical prostatectomy and RT. Long-term cancer survival is similar with either strategy, but adverse effect profiles differ.
- For patients who have intermediate- or high-risk disease undergoing RT, the addition of ADT improves biochemical disease-free survival (DFS) (intermediate risk) and OS (high risk). Duration is typically 4 to 6 months for unfavorable intermediate-risk disease and 18 to 24 months for high-risk disease.
- Patients with clinical evidence of pelvic lymph node involvement (cN1) are typically treated with definitive RT to the prostate and pelvis with long-course ADT. Although no randomized data exist, prostatectomy followed by adjuvant RT and ADT may also be an option.
- For patients who are very high-risk or regional risk (cN1) undergoing definitive EBRT and ADT, the addition of 2 years of abiraterone has been shown to improve MFS and OS.

PROSTATE CANCER TREATMENT MODALITIES

WATCHFUL WAITING AND ACTIVE SURVEILLANCE

Watchful waiting is a policy of no therapeutic intervention after a diagnosis has been established until symptomatic disease progression is evidenced by changes in symptoms, local tumor growth, or development of symptomatic metastases. In contrast with active surveillance, watchful waiting involves no monitoring of PSA levels or scheduled serial biopsies. Watchful waiting is most appropriate for men with limited life expectancy based on age and/or comorbid conditions. The approach evolved from studies of predominantly older men who had well-differentiated tumors in whom tumor progression occurred over a protracted time, and among whom, during the follow-up interval, a substantial proportion died as a result of illnesses unrelated to prostate cancer.

Active surveillance (with delayed intention to treat) is a recommended option for men with low-risk prostate cancer; no immediate treatment interventions are initiated in an effort to reduce overtreatment and the resulting adverse effects of therapy. These protocols include scheduled PSA testing, DREs, and periodic repeated prostate needle biopsies (or more recently, use of repeat multiparametric MRIs after the initial prostate biopsies). Most protocols require a repeated biopsy at 1 year to account for the sampling error of a 12-core biopsy. Treatment is offered if or when changes in Gleason score, volume of tumor, or serum PSA suggest increasing disease activity.

The largest randomized trial to evaluate immediate versus delayed primary therapy was the ProtecT trial, as referenced earlier, which randomized a population of mostly low-risk patients in the United Kingdom to active monitoring (no serial biopsies mandated, unlike AS), radical prostatectomy, or EBRT with or without ADT. Overall, there was no OS advantage to immediate definitive therapy, and there was an adverse effect of definitive therapies on several quality of life metrics. There was a slight increase in distant metastases. Importantly, some higher-risk patients who would not otherwise be offered AS by current guidelines were included, and approximately half of the active monitoring group eventually did receive primary therapy. Thus, this trial was not a study of doing "nothing" versus "something."

RADICAL PROSTATECTOMY

The goal of radical prostatectomy is to completely excise the cancer while maintaining urinary control and preserving potency. After the prostate has been removed, PSA should decline to undetectable levels; any detectable or increasing PSA levels after prostatectomy are an indication of recurrent or residual cancer. Cancer control is assessed by PSA relapse-free survival, time to objective progression (local or systemic), cancer–specific survival, and OS.

Robotic prostatectomy has become common, with a majority of procedures using robot-assisted laparoscopic prostatectomy rather than the historically more common open or laparoscopic radical prostatectomy. Despite initial enthusiasm and widespread acceptance of this technique by community and academic urological centers, few data exist to suggest improvements in oncological or functional outcomes when compared with the more traditional approaches. In fact, the skill of the operating surgeon in the surgeon's specific modality should be a major determinant in which approach is selected.

Management of Erectile Dysfunction

As discussed earlier, most men will experience erectile dysfunction after radical prostatectomy, even in settings where one neurovascular bundle is spared during surgery. Less frequent loss of erectile function may occur when both neurovascular bundles are spared. Methods for treating this include the use of PDE-5 inhibitors (eg, sildenafil and tadalafil), sometimes administered in the immediate postoperative period to help minimize penile shortening. Some experts advocate daily doses ("penile rehab") with increases in dosing before anticipated sexual activity, although data supporting this practice are limited. Use of vacuum pumps is often effective, but these must be judiciously used, especially in the immediate postoperative period, because disruption of the bladder neck–penile anastomosis can occur. Direct injections of alprostadil or insertion of drug pellets containing alprostadil into the penis or penile urethra may result in more effective erections. When regaining, erectile function is not achieved by these methods, patients may be considered for implantation of a penile prosthesis, of which several varieties are available, each with advantages and disadvantages. Patients will find it helpful to understand these potential options before surgery and set appropriate expectations, because this adverse effect is likely to occur and can be irreversible without intervention.

Management of Urinary Incontinence

Development of urinary incontinence after radical prostatectomy is an adverse effect that can more commonly result in patient-reported poorer quality of life and regret. Performing Kegel exercises of the pelvic floor muscles can speed recovery if routinely practiced. Most of the improvement after prostatectomy tends to happen within the first year, with typically no major changes after that point. After prostatectomy, many men use a male diaper to maintain their current lifestyle without being limited by incontinence. Surgical approaches to reduce incontinence should be considered when the difficulty tolerating symptoms is high, as a result of leakage itself or urinary odor, which can be particularly bothersome to patients. Procedures include bulbourethral sling surgery, which may have only modest and temporary effects, and the implantation of an artificial urinary sphincter, often more effective than a sling if the amount of urinary leakage is interfering with normal daily activities and is not controllable with diapers or pads, or is accompanied by urinary odor. As with erectile dysfunction, urinary incontinence must be recognized as a potential complication before surgery to ensure that patient expectations are aligned with possible outcomes.

RADIATION THERAPY

Radiation therapy can be administered using external-beam techniques, an implant of radioactive seeds, or a combination of the two. Contemporary EBRT incorporates three-dimensional conformal treatment planning with intensity modulation to maximize the administered dose to the tumor while minimizing the exposure of surrounding normal structures. These techniques allow for the safe administration of higher doses, which, in turn, have resulted in improved outcomes. Most EBRT protocols involve approximately 5 to 8 weeks of treatment, five times per week. Stereotactic radiosurgery (eg, CyberKnife) offers a more condensed schedule of only five treatments (hypofractionation) and otherwise seems comparable with standard EBRT.[56] Protons are heavier than the photons emitted by standard EBRT and, therefore, discharge their energy over a shorter distance, thereby limiting damage to surrounding normal tissue (ie, a narrow Bragg peak). In theory, this would optimize delivery of radiation to the tumor and prevent toxicity to nearby organs, but the technique has not improved clinical outcomes or quality of life[57] and is significantly more costly.

Radiation therapy administered to pelvic lymph nodes in addition to the prostate can be considered for patients with a substantial risk of lymph node involvement, although including nodes in the radiation field was not associated with superior outcomes in two randomized trials. For patients with radiographically evident lymph node involvement, the radiation field should include the pelvic lymph nodes and may still offer a chance of long-term disease control or, at a minimum, decreased chance of symptomatic local relapse.

The use of interstitial radiation or implantation of radioactive seeds, also known as brachytherapy, is typically used either as monotherapy for gland-confined, low- to intermediate-risk disease or as a boost together with EBRT for gland-confined, high-risk disease. An acute toxicity associated with implantation is irritative urinary symptoms, including urinary frequency. Long-term complications, including stricture and irritative symptoms, can be bothersome, especially in men who had symptoms of lower urinary tract symptoms before receiving treatment. Four prospective randomized trials have demonstrated that RT doses <70 Gy are inadequate for the curative treatment of clinically localized prostate cancer, and doses of 78 to 79 Gy provide improved cancer control. Studies that have evaluated the addition of ADT to RT (with or without a brachytherapy boost) suggest some improvements in local control and biochemical freedom from relapse.

Compared with surgery, RT is associated with a higher frequency of bowel complications, mainly loose stools and diarrhea, as well as irritative urinary symptoms, but lower rates of urinary incontinence and sexual dysfunction. Because urinary symptoms may worsen with RT, patients with significant baseline urinary obstructive symptoms may be better candidates for

prostatectomy; if they do undergo RT, symptoms can be improved with a combination of several months of neoadjuvant ADT, standard therapies such as α-blockers, and transurethral resection of the prostate in refractory cases.

Management of Proctitis

The development of rectal proctitis commonly occurs throughout the lifetime of patients who have had curative doses of radiation for prostate cancer. Proctitis can be accompanied by sporadic rectal bleeding, which can occur months to years after completion of RT and is often self-limited in duration. Increased dietary fiber or fiber supplements can help in mild, clinically suspected cases. Endoscopic findings include telangiectasias in the distal rectum that are often cauterized at the time of endoscopic examination using argon plasma coagulation. Administration of rectal suppositories containing steroids or mesalamine can also lessen the effects of proctitis. For refractory cases, hyperbaric oxygen or formalin injections can be used. Judicious evaluations of the distal rectal mucosa should be performed routinely, especially because a small but finite increase in the incidence of rectal cancers after RT has been observed.

Management of Radiation Cystitis

Cystitis can manifest as hematuria and/or dysuria. It can be diagnosed symptomatically and treated with nonsteroidal anti-inflammatories in mild cases; in more severe cases, a cystoscopy may be indicated. Intractable cases may respond to the use of hyperbaric oxygenation. Suspicion for urothelial cancer should be raised in the setting of persistent hematuria and urinary irritative symptoms, and cystoscopy and urine cytology should be strongly considered if these symptoms develop after the first few months to years after RT.

KEY POINTS

- Prostatectomy, RT, and ADT have unique adverse effect profiles. Prostatectomy can lead to urinary incontinence and erectile dysfunction, but it can help improve significant obstructive symptoms.
- Short-term side effects of RT include irritative urine and bowel symptoms. Radiation cystitis or proctitis may occur months to years after the completion of prostate RT. Endoscopic evaluation is warranted if the symptoms persist to rule out a second malignancy (eg, urothelial carcinoma) or telangiectasias.
- Patients with preexisting urinary symptoms should avoid brachytherapy and may experience symptomatic benefit from radical prostatectomy.
- There is little to no advantage to treatment with robotic prostatectomy versus other surgical approaches or to treatment with proton therapy versus conventional RT for clinically localized prostate cancer.

THERAPY FOR RECURRENT OR ADVANCED PROSTATE CANCER

PATHOLOGICAL NODE-POSITIVE DISEASE (PN1)

This section refers to a clinical scenario in which patients undergo radical prostatectomy and pelvic lymph node dissection for a localized prostate cancer and are found to have pathological nodal involvement (pN1) and undetectable PSA (<0.1 ng/mL) post-prostatectomy.

The risks of biochemical and radiographic recurrence are high for this group of patients. Adjuvant ADT is an option justified by a small multi-institutional randomized trial demonstrating improved OS and prostate cancer–specific survival in patients with positive lymph nodes at the time of prostatectomy and lymphadenectomy.[58,59] Unfortunately, this OS benefit of immediate over delayed ADT for pN1 patients could not be confirmed by another similar phase 3 study trial, EORTC 30846,[60] population-based study,[61] and meta-analysis.[62] In fact, the ASCO practice guideline in 2007 did not recommend immediate ADT for pathologically node-positive prostate cancer.[62] Adjuvant RT is often considered. However, only retrospective data are available on the use of adjuvant RT combined with ADT in such patients.[63-65] Alternatively, salvage EBRT with ADT at the time of biochemical recurrence (BCR) is an alternative option.

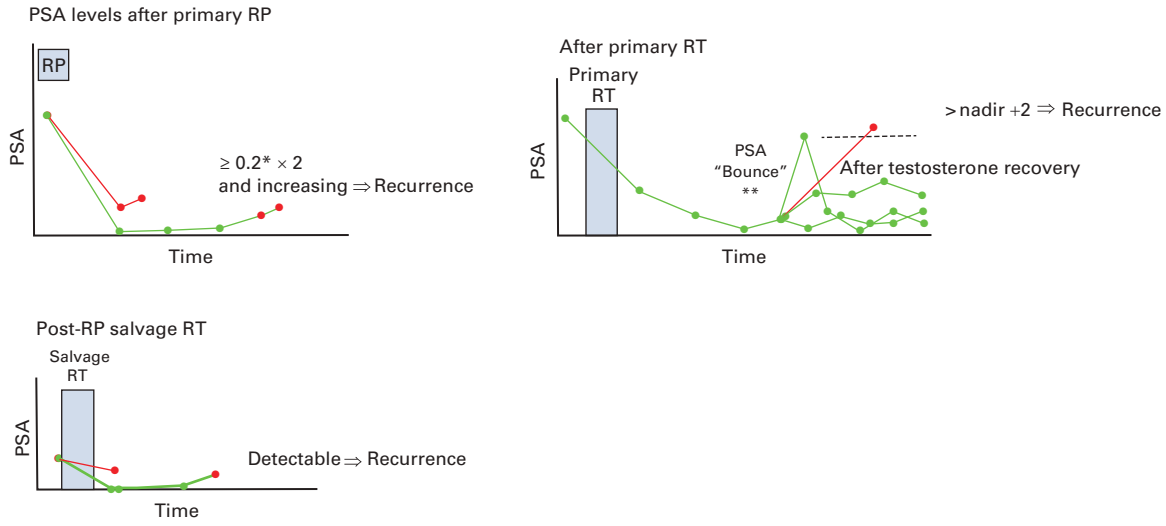
BIOCHEMICAL RECURRENCE

BCR refers to the disease status in which patients have rising PSA levels only without radiographic evidence of recurrence or metastatic disease after radical prostatectomy, RT, or both (Fig. 14-5). It does not refer to an increase in PSA level for patients in whom the disease is managed by watchful waiting. BCR is generally defined by the absence of metastases on conventional imaging (eg, CT scans and Tc99 bone scan) with either of the following:

- In patients who received primary radical prostatectomy (regardless of adjuvant or salvage RT), serum PSA 0.2 ng/mL or more, which is confirmed by a second determination (American Urological Association definition). Although a successful radical prostatectomy should remove the source of PSA from both the cancer and the normal prostate tissue, some patients may have a persistently detectable PSA <0.2 ng/mL, particularly when an ultrasensitive PSA immunoassay is used.

- In patients who received primary RT, a serum PSA level that has increased by 2 ng/dL above the nadir PSA value after RT (Phoenix criteria). Of note, PSA level may transiently increase after RT because of recovery of testosterone after ADT and/or the so-called "PSA bounce" that may be induced by prostate inflammation in the months after RT (18-24 months). Issues in management include whether the increasing PSA value represents local recurrence that could be eliminated with additional treatment to the prostate bed, metastatic disease, or both.

Figure 14-5 PSA Outcomes After Primary Therapies for Localized Prostate Cancer-Defining Biochemical Recurrence



Abbreviations: PSA, prostate-specific antigen; RP, radical prostatectomy; RT, radiation therapy.
*Ultrasensitive PSA assays define biochemical recurrence as any measurable PSA value after radical prostatectomy.
**PSA "bounce" observed only in the absence of ADT.

In most cases, an increasing PSA level represents micrometastatic disease that is not detectable on conventional imaging studies. The time to the development of metastases is highly variable. Prostate-specific antigen doubling time (PSADT), time to biochemical progression, and Gleason score can be used to prognosticate regarding time to development of metastases. PSADTs of <3 to 6 months are generally associated with development of metastases within months, whereas PSA doubling times of 1.5 to 2 years are generally associated with many years of MFS. Therefore, treatment is often targeted to those with the short PSA doubling times (<3-6 months), although it is not clear that these prognostic markers can be used to predict benefit from treatment versus surveillance (Figs. 14-6 and 14-7).

Figure 14-6 Management Options After Primary Therapy for Prostate Cancer

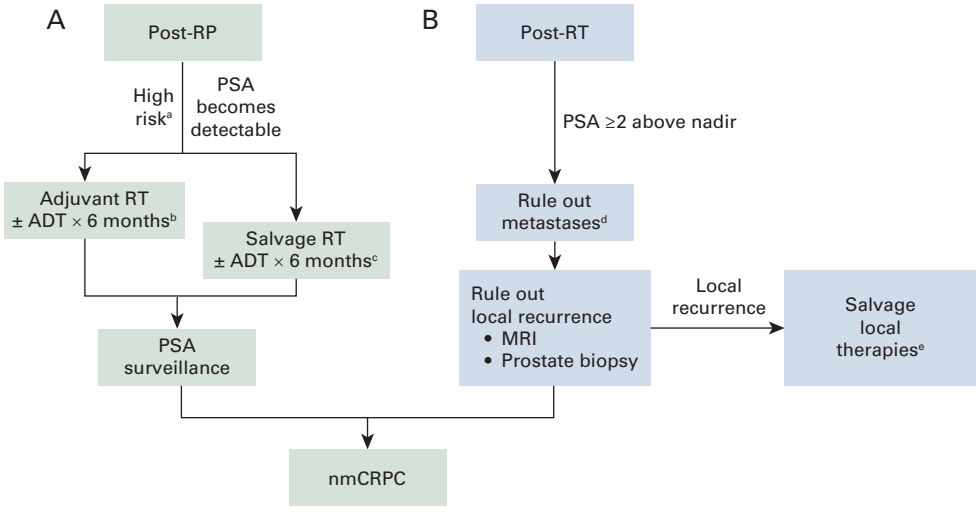

Figure 14-6 Continued

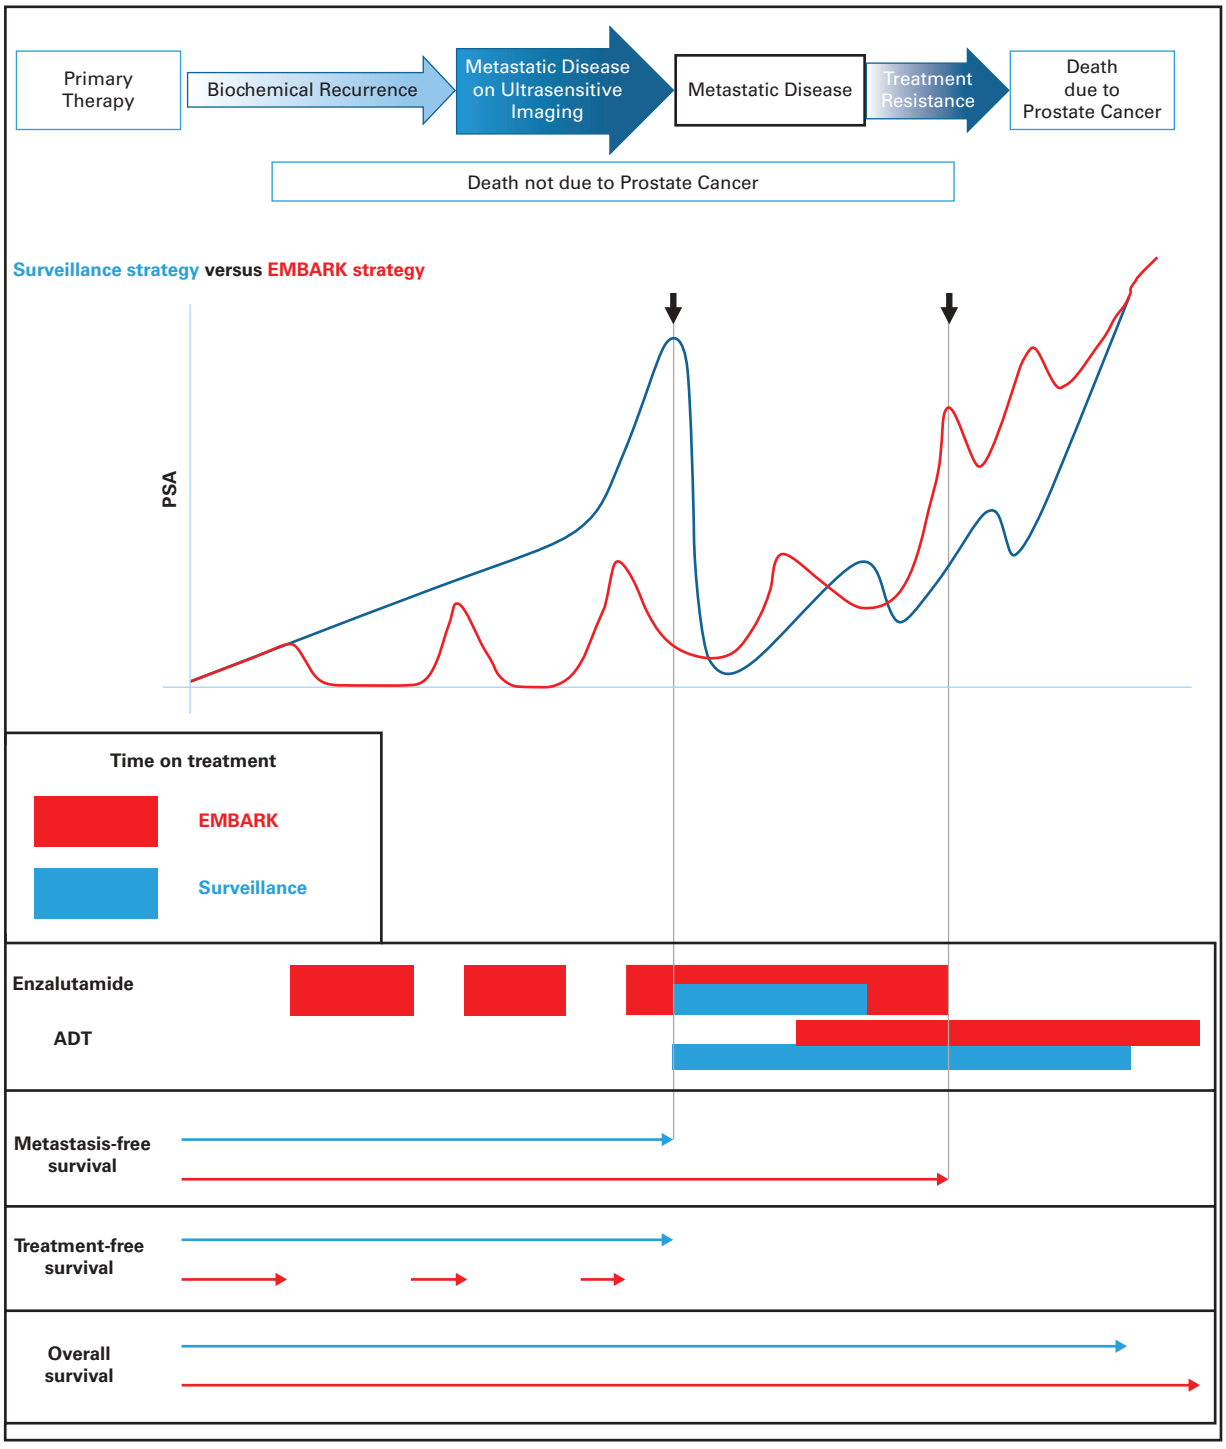
C



Panel (A) illustrates options following radical prostatectomy. Panel (B) illustrates options following radiation therapy. Panel (C) illustrates the hypothetical comparison of a surveillance strategy for biochemically recurrent prostate cancer to the EMBARK strategy with enzalutamide monotherapy. For options regarding recurrence after maximal local therapy, see Figure 14-7.

Abbreviations: ADT, androgen deprivation therapy; ARPI, androgen receptor pathway inhibitor; mCSPC; metastatic castration-sensitive prostate cancer; nmCRPC, non-metastatic castration-resistant prostate cancer; PSA, prostate-specific antigen; PSADT, prostate-specific antigen doubling time; PSMA, prostate-specific membrane antigen; RP, radical prostatectomy; RT, radiation therapy.

[a]High risk defined as pT3b or R1 (positive margin).

[b]Use and duration of ADT are variable; 6 months is common, but patients with low PSA may not benefit.

[c]Enzalutamide ± ADT. Previously, ADT, continuous or intermittent.

[d]Consider using ultrasensitive diagnostic imaging if available (eg, PET using PSMA tracers; eg, ^{68}Ga PSMA or ^{18}F[^{18}F] piflufolastat, ^{18}F fluciclovine, or ^{11}C choline); if not available, use conventional imaging modalities.

[e]Salvage local therapies may include brachytherapy, cryotherapy, radiofrequency ablation, high-intensity focused ultrasound, or salvage prostatectomy.

Role of Next-Generation Imaging in Evaluation of Patients With Biochemical Recurrence

In men with BCR considered for local salvage therapies, the most common treatment failure occurs with undetected metastatic disease. Therefore, detection of occult metastatic disease is critical and affects disease management in these patients. Historically, ^{99}T radionucleotide bone scan and CT scans have been considered conventional imaging studies to diagnose bone and pelvic metastases, respectively, despite their limited sensitivity at low levels of PSA <10 ng/mL.[66,67]

However, in recent years, newer imaging studies (eg, ^{68}Ga PSMA PET/CT, ^{18}F fluciclovine, or ^{11}C choline PET/CT) have significantly improved the sensitivity to detect recurrent disease at lower PSA levels. The rate of detection using these novel tracers depends on the PSA level and the type of tracer. A review of the literature showed the average rates of detection with ^{68}Ga PSMA PET/CT were 51.5%, 74%, and 90.5% of patients with PSA levels of <1.0, 1.0 to 2.0, and >2.0 ng/mL, respectively. The average rates of detection with fluciclovine PET/CT were 38%, 74%, and 78% of patients with PSA levels of <1.0, 1.0 to 2.0, and >2.0 ng/mL, respectively. The rates of detection with ^{11}C choline were somewhat lower: 19.5%, 44.5%, and 76% of patients with PSA levels of <1.0, 1.0 to 2.0, and >2.0 ng/mL, respectively.[68]

As noted, PSMA PET/CT may increasingly be used as part of the staging of high-risk localized prostate cancer and perhaps for unfavorable intermediate risk. For patients who have early BCR post-prostatectomy, who are increasingly offered early salvage radiation at PSAs around 0.2 ng/mL, the yield of PSMA PET/CT imaging is typically low. However, for a patient with PSA

persistence post-prostatectomy who did not undergo initial staging PSMA PET/CT or for a patient presenting for salvage radiation evaluation at higher PSAs, PSMA PET/CT may help guide the radiation treatment field and intensification of both radiation doses and potentially systemic therapy.

PSMA PET/CT restaging should generally not be performed in patients with rising PSA after primary radiation until PSA reaches 2.0 ng/mL above nadir, the Phoenix criterion. However, patients who have high initial risk and rapidly rising PSAs may be considered for PSMA PET/CT if there is a consistent, rapid rise across multiple checks.

PSMA PET/CT may have false positives, especially noted with benign rib lesions and some other malignancies, such as renal cell carcinoma and salivary gland tumors. Whether to confirm findings with biopsy depends on the overall level of suspicion and how closely any findings mirror the typical pattern of prostate cancer spread.[69]

PROSTATE CANCER: LOCAL FAILURE

ADJUVANT AND SALVAGE RADIATION THERAPY

- Adjuvant RT to the prostatic bed is considered for patients with certain high-risk features at the time of radical prostatectomy, especially pathologically positive lymph nodes.
- Salvage RT is similar but refers to RT at the time of PSA recurrence (BCR) after prostatectomy, thus limiting RT to only those patients with definitive evidence of recurrence.

Three randomized trials comparing immediate (adjuvant) versus early salvage RT indicated that early salvage is likely equally effective in the represented patient populations (ie, excluding node-positive patients). In practice, some physicians might choose to use adjuvant RT (while PSA undetectable) for very high-risk pathology (eg, seminal vesicle involvement or positive lymph nodes) and use early salvage RT (when PSA becomes detectable and rising or PSA >0.1 ng/mL in more ambiguous cases (eg, high Gleason score, EPE, or positive margins) to avoid the risk of overtreatment. Early salvage RT at low PSA levels seems to be superior to later RT at higher PSA levels. Importantly, salvage RT should not be delayed until there are positive findings on PSMA PET/CT, as this is not fully sensitive for lymph node involvement. Salvage RT may increase prostate cancer–specific survival, but one study suggested the benefit was limited to men with a PSA doubling time of <6 months.

The role of hormone therapy with RT in the salvage or adjuvant setting has also been studied by several multicenter international cooperative group randomized phase 3 studies:

- RTOG 9601: 24 months of high-dose bicalutamide (150 mg orally daily) provided an OS benefit relative to placebo but with increased cardiac toxicity and gynecomastia.[63]
  - No benefit was seen in patients who had a PSA <0.6 ng/mL, as is common in modern practice with early salvage RT.
  - An ancillary study suggested that a high score on the Decipher test, a 22-gene expression assay developed to estimate the risk of distant metastasis and prostate cancer–specific mortality post-radical prostatectomy, was associated with the benefit of ADT even in the low-PSA subgroup. This association is being prospectively validated with more modern systemic therapies.
- GETUG-AFU16, an open-label study, showed 6 months of ADT with GnRH agonist added to salvage RT improved 10-year PFS rate from 49% to 64% (hazard ratio [HR], 0.54; 95% CI, 0.43-0.68, $P < .0001$), but because this endpoint included PSA progression as "progression," this may have been artificially prolonged by the comparison of PSA-lowering ADT versus no ADT. There was no effect on the 12-year OS rate.[63]
- SPPORT is another multicenter trial that showed PFS benefit with 4 to 6 months of ADT and extending the RT field to pelvic lymph node RT compared with salvage RT only to the prostate bed.[70] It did not specifically parse out whether nodal RT without ADT would have been equally effective.
- RADICALS-HD evaluated the optimal duration of the ADT for postoperative RT, either immediate or salvage.[69] Patients were offered randomization to either (1) 6 versus 0 months of ADT or (2) 24 versus 6 months of ADT. Patients randomized within the first comparison had more favorable characteristics, and there was no difference found between short-course versus no ADT. Within the second comparison, long-course ADT had prolonged MFS versus short-course ADT. Thus, patients with higher risk factors (eg, pT3b/4) could be considered for longer-course ADT, but this study raises further questions about which patients even benefit from any ADT.

There are also questions about whether to intensify hormone therapy. An abstract from the FORMULA-509 phase 2 study suggested an MFS benefit with the addition of ARPIs in patients with higher PSAs, although not in the entire study population or in patients with other high-risk features. The STAMPEDE M0 cohort study testing the addition of abiraterone to ADT, in theory, included salvage RT patients, but few such patients were actually enrolled.

In summary, a course of ADT (4-6 months) should be considered in most patients receiving salvage RT. The RADICALS-HD study suggests that certain patients may not benefit from ADT and could be omitted in some patients (eg, older age with higher

toxicity risk, Gleason score 7 or lower, no T3/T4 disease, low PSA with long PSADT). This and other studies also suggest that intensification of ADT by prolonging the duration or adding an AR pathway inhibitor could be beneficial for patients with the highest risk features.

SALVAGE PROSTATECTOMY

Patients treated initially with RT may be considered for salvage prostatectomy if they were surgical candidates at the time of diagnosis, have a life expectancy of more than 10 years, and have no metastatic disease. Biopsy-specimen confirmation of persistent disease in the gland and no evidence of spread are essential before surgery is considered. Despite refinements in case selection, incontinence rates remain high, and virtually all patients are impotent after the procedure. Salvage treatments, including cryotherapy and brachytherapy for post-RT recurrent prostate cancer, may be considered for select patients. MRI is most useful for detecting recurrence in the prostate after RT, and a confirmatory diagnosis is then made via prostate biopsy specimen. Of note, biopsies should not be done for several months after RT because the effect of radiation is prolonged, and residual cancer cells may persist at these earlier time points.

SYSTEMIC THERAPY FOR BIOCHEMICALLY RECURRENT PROSTATE CANCER

Once local therapies have been exhausted, the two approaches to persistent BCR are surveillance or systemic (noncurative intent) therapy. Notably, BCR has a highly heterogeneous natural history. Initial Gleason score, time to recurrence, and especially PSADT are prognostic factors, but they do not necessarily predict who will most benefit from intervention versus surveillance.

Although PSA level almost always declines in response to hormone therapy, the clinical benefit in this setting is still unclear. One trial attempted to answer this question by randomly assigning patients who had BCR (as well as those ineligible for curative treatment because of age, comorbidities, or locally advanced disease) to early ADT at the time of BCR versus delayed ADT at the time of metastatic disease.[65] Although OS was improved with early ADT in the entire cohort, there was no OS benefit in the BCR-only group. In addition, the trial was under-enrolled, with too few events to allow definitive conclusions. NCCN guidelines currently recommend observation as the preferred management of non-metastatic castration-naive disease (ie, BCR), but with ADT as another option. Therefore, the decision of when to start ADT for BCR is a difficult one and must factor in patient preferences in the absence of clear evidence-based guidelines.

Historically, intermittent androgen suppression (for 8 months in each cycle, restarting ADT when PSA is >10 ng/mL) has often been used if a decision is made for systemic therapy. Randomized trials suggested this was a reasonable alternative to continuous androgen suppression, but only in the setting of non-metastatic disease. The goal is to minimize the adverse effects of chronic ADT, including hot flashes, loss of libido, bone loss, and muscle atrophy, but it is not clear to what extent this strategy, in fact, does improve patients' quality of life overall.

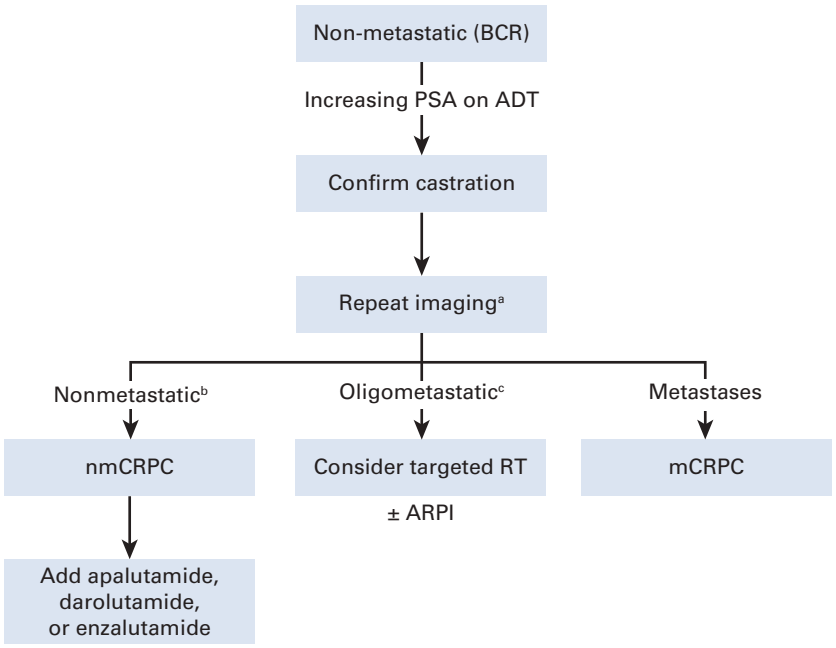
More recently, the EMBARK study randomized patients with BCR and PSADT <9 months as well as absolute PSA >1.0 ng/mL post-prostatectomy or more than 2.0 ng/mL above nadir post-primary RT to receive ADT only, enzalutamide only, or the combination.[66] A one-time treatment break was built into the protocol on all arms. Both enzalutamide alone and with ADT showed superior MFS (and a recent update showing improved OS) compared with ADT alone, resulting in FDA approval. Combination treatment had the largest MFS benefit. Nonetheless, the benefit of delaying metastases must be weighed against the alternative of starting delayed intensive hormone therapy at the first sign of radiographic recurrence (not tested in the study), and/or using oligometastasis-directed therapies; this is an individualized decision based on patient preferences. Importantly, all arms had high rates of toxicity and treatment discontinuation because of toxicity. Enzalutamide monotherapy may help avoid ADT side effects, but with increased rates of gynecomastia due to increased testosterone, which is converted to estrogen; this effect can be mitigated with prophylactic breast radiation or low-dose tamoxifen if symptoms develop. In addition, the study was conducted before the widespread availability of PSMA PET/CT, and many of the included patients would have been expected to have some degree of metastatic disease visible on ultrasensitive imaging, although the natural history of PET-detected disease may not be equivalent to that of conventional metastatic disease.

NON-METASTATIC CASTRATION-RESISTANT PROSTATE CANCER

If patients are started on ADT for BCR, some will go on to develop non-metastatic CRPC (nmCRPC), meaning increasing PSA levels despite castration-level testosterone values but without overt radiographic evidence of metastases by conventional bone scan and CT imaging (Fig. 14-8). Several randomized trials have demonstrated that the addition of second-generation AR antagonists in this setting delays the onset of radiographic metastatic disease (MFS) and OS compared with ongoing ADT alone.[71-73] The FDA approved enzalutamide, apalutamide, and darolutamide for patients who have nmCRPC with a PSA doubling time of 10 months or fewer. The novel endpoint of MFS had been established to be a strong surrogate of OS in localized prostate cancer.[74]

However, as previously discussed, it is not yet clear that starting men on early ADT and then proceeding to one of these agents before the development of metastatic disease will prolong survival relative to starting ADT (and additional therapies) only at the time of metastatic disease. The potential benefit needs to be weighed against toxicity for these non-metastatic patients who have

Figure 14-8 Treatment Options for nmCRPC



Abbreviations: ADT; androgen deprivation therapy; ARPI, androgen receptor pathway inhibitor; BCR, biochemical recurrence; mCRPC, metastatic castration-resistant prostate cancer; NGI, next-generation imaging; nmCRPC, non-metastatic castration-resistant prostate cancer; PSA, prostate-specific antigen; RT, radiation therapy.
[a]Consensus from the ASCO Expert Panel is that NGI may be considered only if a change in clinical care is contemplated. Assuming patients have received or are ineligible for local salvage treatment options, NGI may clarify the presence or absence of metastatic disease, but the data on the detection capabilities of NGI in this setting and its impact on management are limited.
[b]In nmCRPC studies, patients were included who had pelvic lymph nodes up to 2 cm in diameter.
[c]Oligometastatic disease is variably defined as one to five metastases.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

no disease-related symptoms. Apalutamide was associated with an increased risk of rash, hypothyroidism, and fracture; enzalutamide was associated with an increased risk of hypertension, myocardial infarction, fatigue, falls, and fractures; darolutamide was associated with an increased risk of fatigue.

However, patient-reported outcomes were mostly similar in these trials between the active treatment and placebo arms. In addition, these drugs carry high financial costs (to patients, insurers, and society). In addition, the proper interpretation of these studies is complicated by the inclusion of node-positive (<20 mm by short axis) patients in the ARAMIS (darolutamide, 17% vs placebo, 29%) and SPARTAN (apalutamide, 16.5% vs placebo, 16.2%) studies, whereas the PROSPER study allowed node positivity only if the lymph node was <15 mm by short axis and below aortic bifurcation, and as in the discussion of EMBARK, many included patients would have been expected to have more widespread disease visible by ultrasensitive imaging. Indeed, one study demonstrated that, in 200 patients with nmCRPC who would have been eligible for ARAMIS, PROSPER, and SPARTAN, 96% had detectable disease on PSMA PET.[75]

ROLE OF LOCAL THERAPY OUTSIDE THE PROSTATE FOR BIOCHEMICAL RECURRENCE

Patients with BCR at some point may develop oligometastatic recurrence, in which case local therapies such as targeted RT, cryoablation, or radiofrequency ablation may be used to delay the need for systemic therapy (Fig. 14-8). This strategy was demonstrated to delay the need for ADT in a randomized trial[76] although more objective measures and survival data are needed. In conjunction with this approach, more sensitive imaging modalities have been developed to detect oligometastatic disease earlier in the disease course. PSMA PET/CT may be particularly helpful for detecting early oligometastatic recurrences.

KEY POINTS

- Detectable PSA (>0.2 ng/mL) after radical prostatectomy or an increase in PSA concentration by 2 ng/mL or more above PSA nadir after RT is an indicator of recurrent prostate cancer. In the absence of evidence of metastatic disease on standard bone scan and CT imaging, this is termed BCR.

- Salvage RT may be used for patients who experience BCR after radical prostatectomy, typically combined with 6 months of ADT. Conversely, salvage prostatectomy is less commonly performed after primary RT because of high rates of urinary incontinence and impotence. Other local salvage therapies may be possible.
- The optimal timing of systemic therapy for BCR is unclear. ADT will lower PSA level in this setting and delay time to metastatic disease, but its effect on OS relative to ADT at the time of metastatic disease is unknown.
- Patients with BCR who are treated with ADT and whose PSA levels increase without evidence of metastases on standard bone scan and CT imaging have disease that has progressed to nmCRPC. The addition of the second-generation AR antagonist apalutamide, darolutamide, or enzalutamide prolongs MFS and OS in this setting.

PRESENTING CASE STUDY 1

A 70-year-old man is referred to your clinic for management of a rising PSA level following primary therapy. Five years ago, he underwent a radical prostatectomy, with pathology showing Gleason 4+3 disease confined to the prostate, with negative margins. Three years later, his PSA level rose again, prompting salvage radiation to the prostate fossa and pelvic lymph nodes along with 6 months of androgen deprivation therapy (ADT). Now, 2 years later, his PSA level has risen from undetectable while on ADT to 0.1 ng/mL after testosterone recovery, with the most recent values increasing from 0.2 ng/mL to 0.4 ng/mL to 0.8 ng/mL over the course of 16 months.

How would you assess this patient's risk of recurrent prostate cancer?

This patient is experiencing biochemical recurrence (BCR), given that his PSA level is detectable after prostatectomy (regardless of salvage radiation) and is rising with a doubling time (PSADT) of 7 months. However, the natural history of BCR is heterogeneous, and before recommending any diagnostic or therapeutic steps, it is important to first factor in patient life expectancy and comorbidities, as well as BCR prognostic details: time to recurrence, original Gleason score, and PSADT. Nomograms can be helpful for comparing the estimated time to metastases given these BCR prognostic details versus patient life expectancy.

This patient has intermediate prognostic factors for BCR. His time to initial recurrence and original Gleason score are favorable, and his current PSADT is intermediate. The MSKCC nomogram[77] would estimate an approximate 10-year risk of death from prostate cancer of 33%. Patients with a very long time to recurrence, slow PSADT (approximately >1 year), or limited life expectancy may not benefit from early use of ultrasensitive restaging imaging and most likely do not benefit from systemic therapy.

For patients in whom initial restaging seems reasonable, a prostate-specific membrane antigen (PSMA) PET scan is an option to identify oligometastatic and/or pelvic recurrence. MRI of the prostate can also be useful for local restaging in patients who did not undergo prostatectomy, especially if there are suspicious findings revealed by PET scan.

PSMA PET shows a rib lesion, SUVmax 2, without a CT correlate, and no other findings.

How do you interpret this finding?

False-positive rib findings are common with PSMA PET, especially if they are isolated, low avidity, and have no sclerotic correlate on CT. Typically, these can simply be followed.

One should initiate a nuanced discussion on surveillance versus systemic therapy. Overall, this patient's long-term prognosis is likely to be very good regardless of intervention. Systemic therapy could include enzalutamide with or without ADT as per the EMBARK trial.[78] However, the benefit in delay of metastases (and possibly a small increase in overall survival) needs to be weighed against the increased time on treatment and associated toxicity.

The patient opts for surveillance. After a subsequent PSA level rise to 2.0 ng/mL, a PSMA PET shows two aorto-caval PSMA-avid lymph nodes (SUVmax 20), both measuring <1 cm.

How do you approach this scenario?

An important consideration is to recalculate PSADT. PET findings do not always require action, especially if other prognostic factors (especially PSADT) are favorable. For a patient who wishes to defer systemic therapy until metastases, serial imaging with conventional imaging can help determine the optimal timing of treatment initiation.

The two very suspicious lesions support a diagnosis of oligometastatic recurrence. Per the STOMP and ORIOLE phase 2 trials,[79] metastasis-directed therapy (MDT) can also be considered in the hopes of delaying the need for systemic therapy. Risks of MDT can include damage to adjacent structures, such as the bowel.

The patient opts for stereotactic body radiation (SBRT) as MDT to these two areas. Do you recommend hormonal therapy along with MDT?

This is unclear. The RADIOSA phase 2 trial suggested a progression-free survival benefit with the addition of 6 months of ADT to MDT, but post hoc analysis showed that this was primarily attributable to the known suppressive effects of ADT, without any clear synergistic increase in the effect of radiation.[80]

The patient receives SBRT alone with good effect, but PSA subsequently rises about a year later. After a period of surveillance, PSMA PET at PSA 5 ng/mL (PSADT 1 year) shows widespread PSMA-avid lymph nodes, all measuring <1 cm. What do you recommend?

While it can be tempting to start intensive lifelong hormonal therapy when PSMA PET reports describe multiple sites of "metastatic" disease, one must remember that such disease is not necessarily equivalent to metastatic disease defined by conventional imaging; it can be labeled "PSMA+ BCR".[81] Those with favorable BCR prognostic factors can sometimes be monitored with conventional imaging until the latter shows evidence of metastases.

METASTATIC CASTRATION-SENSITIVE PROSTATE CANCER

ADT FOR METASTATIC PROSTATE CANCER

ADT (ie, castration therapy) is the backbone of systemic therapy for metastatic prostate cancer. It is now the standard of care to incorporate an AR pathway inhibitor (eg, abiraterone, apalutamide, enzalutamide, darolutamide) together with ADT for the treatment of metastatic prostate cancer, as they have clearly demonstrated significant benefits in PFS, time to castration resistance, time to skeletal events, and OS. The use of an AR pathway inhibitor in this setting remains inconsistent across the United States, so the benefits of these inhibitors should be emphasized.

The critical role of androgens in prostate cancer growth was established by Huggins and Hodges in the 1940s. Their findings led to the development of ADT as the treatment of advanced prostate cancer. ADT is palliative and results in PSA decline or objective tumor responses in more than 90% of patients with advanced prostate cancer. Thus, this disease status is termed metastatic "hormone-sensitive" or "castration-sensitive" prostate cancer.

Despite this almost universal initial response, the duration of response to ADT is highly variable and depends on various clinical and biological factors. Generally speaking, the median time to castration resistance or PSA progression on ADT monotherapy is about 7 to 12 months.[82-84] Almost all patients with metastatic castration-sensitive prostate cancer (mCSPC) experience treatment resistance as evidenced by rising PSAs or radiographic progression despite a castrated level of testosterone (lower than 50 ng/dL), that is, mCRPC. Despite resistance to castration therapy, treatments that target androgen biosynthesis or AR confer additional clinical benefit, indicating an androgen-dependent biology of CRPC. This benefit is a part of the reason ADT remains the backbone of systemic therapy and should be kept continuously, even if patients develop castration resistance.

There are two forms of ADT: surgical and medical castration. The goal is to keep the testosterone level below 50 ng/dL. Surgical castration can be achieved by bilateral orchiectomy. Medical castration can be achieved by either luteinizing hormone-releasing hormone (LHRH) agonist (eg, leuprolide and goserelin) or LHRH antagonist (eg, degarelix and relugolix).

Medical or surgical castration is associated with significant side effects: impotence, loss of libido, weakness, fatigue, hot flashes, loss of muscle mass, anemia, depression, cardiovascular toxicity, and loss of bone over time. Resistance and aerobic exercises can improve muscle mass, strength, and physical function. There have been conflicting data regarding the risk of dementia in patients with prostate cancer who are receiving ADT. Prolonged castration can result in osteoporosis or osteopenia; thus, monitoring with dual-energy X-ray absorptiometry (DEXA) scans can be used to screen for osteopenia or osteoporosis (see "Supportive Care for Metastatic Castration-Sensitive Prostate Cancer" section below). Response to ADT can be measured by a decline in PSA values, a decrease in the size of nodal or visceral metastases, and improvement in cancer-related symptoms. Overall, 60% to 70% of patients with abnormal PSA levels will have normalization of the value to <4 ng/mL after castration, 30% to 50% of measurable tumor masses will regress by 50% or more, and approximately 60% of patients will have palliation of symptoms. Serial bone scans will show improvement in only 30% to 40% of patients, and a scintigraphic flare on serial bone scans can occur after ADT between 3 and 6 months after initiation of therapy; this flare should not be confused with progression of skeletal metastases. The PSA value measured at 7 months after initiating therapy is prognostic, with dramatically shorter median survival for patients with a PSA concentration >4 ng/mL and dramatically longer median survival for those with a PSA concentration <0.2 ng/mL at this point.[85]

Treatment with an LHRH agonist initially increases serum testosterone level for up to a few weeks after treatment initiation, although the clinical relevance of this is debatable. Because of this, an AR antagonist (eg, bicalutamide 50 mg daily) is sometimes used concurrently to block potential effects of the testosterone surge, especially if a patient has high-risk metastatic lesions (eg, imminent spinal cord compression or urinary obstruction). Alternatively, an LHRH antagonist or surgical castration could be used to avoid testosterone flare.

An AR antagonist as monotherapy is not a standard-of-care choice for systemic treatment of metastatic prostate cancer, but they can be used in patients who decline or do not tolerate castration therapy or in patients who are significantly debilitated and have other life-limiting comorbidities.

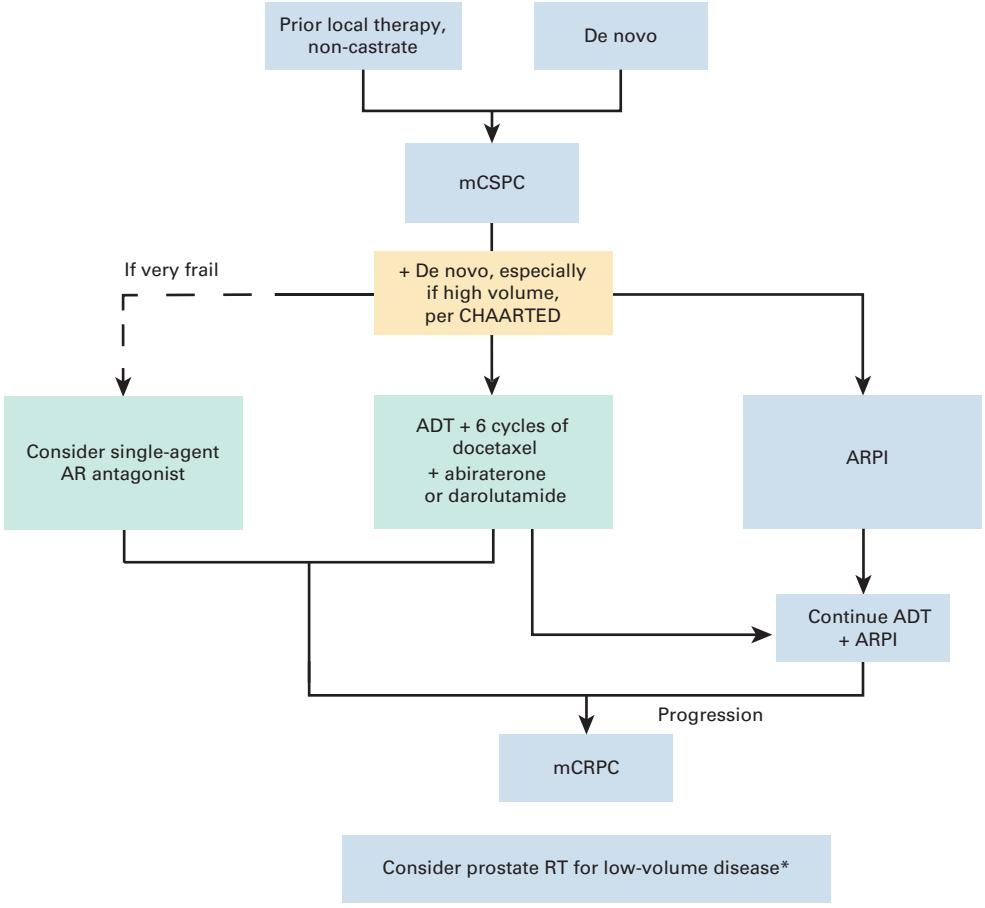
SECONDARY THERAPIES FOR mCSPC

Building on the backbone of ADT as a systemic therapy for advanced prostate cancer, several clinical trials examined intensification of systemic therapy for mCSPC by adding a secondary therapy to improve the clinical outcomes and OS. Examples include docetaxel chemotherapy and AR synthesis/pathway inhibitors such as abiraterone, apalutamide, enzalutamide, and darolutamide. There are other new agents under clinical development.

DOCETAXEL FOR mCSPC

Two randomized controlled trials, CHAARTED and STAMPEDE, showed improvement in OS with the addition of docetaxel to ADT backbone. With these data, docetaxel/ADT became one of the standards of care for mCSPC.

Figure 14-9 Standards of Care for mCSPC by Disease Volume



High volume is defined as the presence of ≥4 bone metastases with one or more lesions in the extra-axial skeleton or the presence of visceral metastasis. Abiraterone is always administered with prednisone.

Abbreviations: ADT, androgen deprivation therapy; AR, androgen receptor; ARPI, androgen receptor pathway inhibitor; mCRPC, metastatic castration-resistant prostate cancer; mCSPC; metastatic castration-sensitive prostate cancer; RT, radiation therapy.

*Supported by a prespecified subgroup analysis from STAMPEDE, but the comparison arm was ADT alone. Efficacy in the setting of intensified therapy (ADT and docetaxel or ARPI) is unknown.

- The subgroup analyses of the CHAARTED study by extent or "volume" of metastatic disease (high vs low) as determined by CT and bone scans showed that the benefit of docetaxel is most clear in patients with high-volume metastatic disease, which was defined as the presence of four or more bone metastases with at least one outside the axial skeleton (ie, skull, ribs, or extremities) or presence of visceral metastases.
- Similar benefits were not seen in the CHAARTED trial in patients with low-volume metastatic disease, even with longer follow-up or in the prior GETUG study.
- By contrast, the stratified subgroup analysis of the primary results from STAMPEDE by tumor volume did not show a difference in benefit between high and low metastatic burden subgroups for OS or failure-free survival,[72] using the CHAARTED definition.

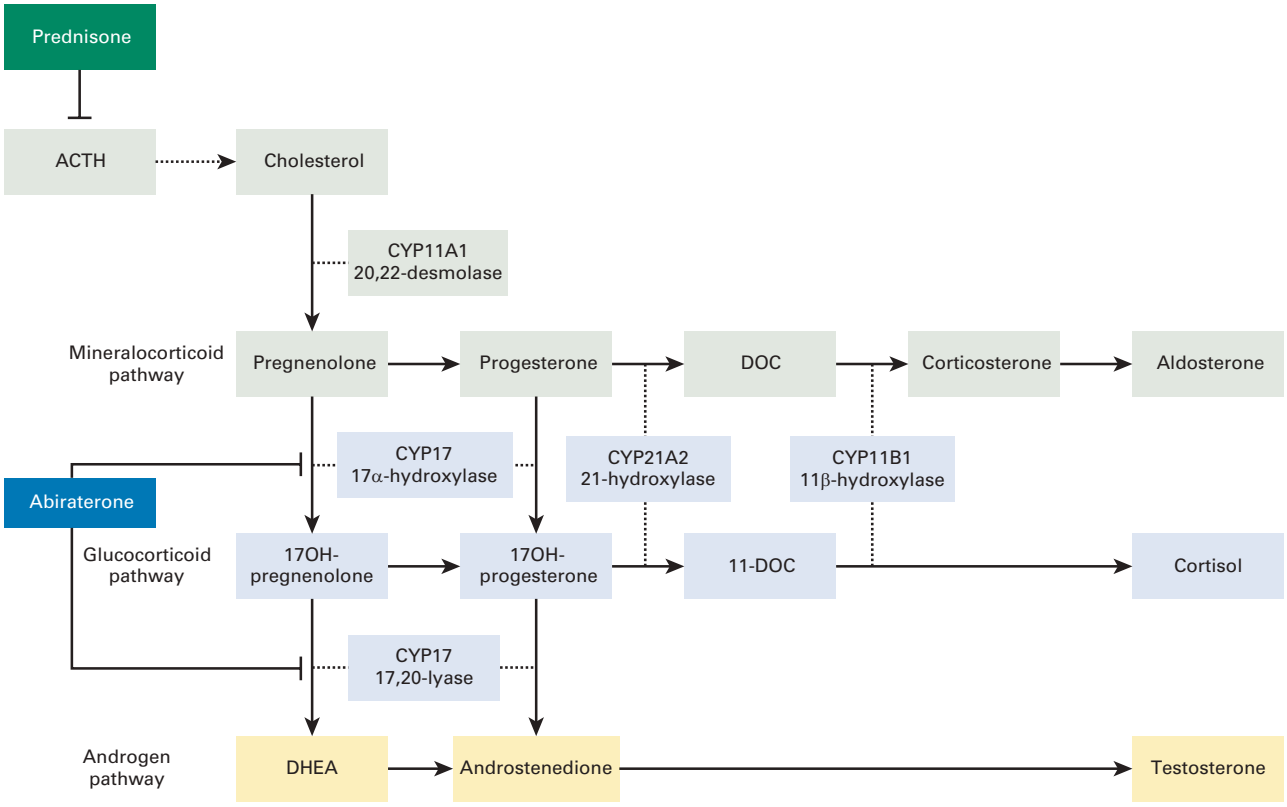
How can these differing results be reconciled? One major difference between the two trials was the relative percentage of patients with recurrent versus de novo metastatic disease. Recurrent metastatic disease may carry a better prognosis. A substantial proportion (approximately 16%) of patients with low-volume metastases in the CHAARTED trial had recurrent disease, versus a few (approximately 5%) patients in the STAMPEDE trial. Therefore, the potential benefit of docetaxel in low-volume disease may be limited to those with de novo low-volume disease, not recurrent low-volume disease (Figs. 14-9 and 14-10).

Febrile neutropenia can occur with docetaxel, although routine primary prophylaxis with granulocyte colony-stimulating factor (G-CSF) was left to the investigator discretion in clinical trials. Docetaxel is considered an intermediate-risk regimen, so by NCCN guidelines, patients with additional risk factors (eg, prior chemotherapy, persistent neutropenia, bone marrow involvement by tumor, liver or renal dysfunction, and older age) could be considered for primary prophylaxis. Docetaxel can also cause edema that is refractory to diuresis; this effect is prevented with steroid prophylaxis. In the CHAARTED trial, quality of life decreased during docetaxel treatment but was similar or better in patients treated with ADT alone at later points.

TRIPLET THERAPY FOR mCSPC

Building on this new backbone of ADT/docetaxel, two studies addressed the question of whether the addition of ARPI would result in further improvements. Notably, no trial has addressed the question of whether docetaxel is beneficial when added to

Figure 14-11 Biochemical Pathways Resulting From Abiraterone Administration and Prednisone



Administration of prednisone prevents a compensatory ACTH surge and thus decreases downstream symptoms of excess mineralocorticoid production (eg, hypertension, hypokalemia, and edema).
Abbreviations: ACTH, adrenocorticotropic hormone; DHEA, dehydroepiandrosterone; DOC, 11-deoxycorticosterone.

an ADT/ARPI backbone, as is modern practice. Thus, in the absence of randomized data addressing this issue, the question of whether to use triplet therapy (including taxane) or ADT and ARPI is guided by older data reviewed earlier. The PEACE-1 study, a multicenter European study, examined the benefit of adding abiraterone and/or local RT to the prostate with a 2 × 2 study design (Fig. 14-11).[86] The mechanism of action for abiraterone is discussed under the "Abiraterone for mCSPC" section. The study showed that abiraterone added to ADT/docetaxel significantly improves median radiographic PFS in men with mCSPC by 2.5 years.[86] The PFS benefit of abiraterone added to ADT with docetaxel was seen in both high- and low-burden metastatic disease. The results from OS analyses also showed that the addition of abiraterone resulted in an 18% reduction in the risk of death and an improvement in median OS by 1 year in the overall population, as well as in the ADT with docetaxel cohort. The OS benefit was clearly seen in the subgroup with the high metastatic disease burden. However, the OS data were immature for the low-burden subgroup. The role of triple therapy in mCSPC is being established.

Darolutamide is a potent AR antagonist that first showed efficacy in patients with nmCRPC. The ARASENS study evaluated the efficacy of adding darolutamide in an international placebo-controlled randomized phase 3 trial with OS as a primary endpoint. In this trial involving 1,306 men, darolutamide lowered the risk of death by 32.5% compared with placebo in patients receiving ADT and docetaxel, with a similar incidence of serious adverse events in the two treatment groups. The patients had to be appropriate candidates for docetaxel and ADT based on the judgment of the investigators. The baseline characteristics indicated 3% of patients had M1a disease (distant lymph node only), 79.4% had M1b (bone metastases with or without lymph node metastases), and 17.5% had M1c (visceral metastases with or without lymph node or bone metastases) at screening. Importantly, a significant majority of patients in this study were diagnosed with high-risk (LATITUDE criteria) or high-volume (CHAARTED criteria) and de novo metastatic disease. Within this trial, there was a suggestion of benefit with the addition of darolutamide regardless of volume or risk status at diagnosis, but as discussed, the benefit of docetaxel in low-volume or low-risk disease is less clear.[87] Darolutamide was approved by the FDA in combination with docetaxel for patients with mCSPC in August 2022 and is an option for patients with mCSPC and deemed appropriate candidates for docetaxel.[1] The ARANOTE trial, discussed further below, led to an approval for darolutamide in mCSPC with ADT but without docetaxel.[1]

ABIRATERONE FOR mCSPC

Abiraterone acetate is an oral CYP17 (17α hydroxylase and 17,20 lyase) inhibitor that inhibits androgen and glucocorticoid biosynthesis. Feedback loops during treatment result in adrenocorticotropic hormone-mediated excess mineralocorticoid activity, including hypertension, fluid retention, and hypokalemia. Low-dose prednisone (starting at 5 mg daily) is administered concurrently to prevent this. Potassium level, blood pressure, and liver function should be monitored during treatment. Hepatotoxicity is managed with dose holds and resumption at lower dose levels. Hypertension may be treated with standard antihypertensive mineralocorticoid receptor antagonists such as eplerenone if standard agents are ineffective. Cardiac symptoms should be monitored in patients with preexisting cardiovascular disease.

After the publication of trials demonstrating the efficacy of adding docetaxel to ADT for first-line treatment of mCSPC, two other studies, LATITUDE and STAMPEDE-G, demonstrated an improvement in OS with the addition of abiraterone and prednisone to ADT for mCSPC. The LATITUDE study included only patients with de novo mCSPC with high-risk features as defined by having two or three of the following: visceral disease, at least three bone metastases, and a Gleason score of 8 or

Table 14-1 Randomized Trials of ADT Plus Abiraterone and Prednisone for mCSPC

Trial	No. of Participants	Study Population	Design	Outcome	Notes
LATITUDE	1,199	De novo high-risk mCSPC	ADT plus placebo vs ADT plus abiraterone and prednisone	Improved OS with the addition of abiraterone and prednisone (53.3 vs 36.5 months)[89]	High risk based on 2 of 3: Gleason 8+, 3 + bone lesions, visceral metastases
STAMPEDE	1,917	High-risk localized or high-risk BCR or mCSPC (recurrent or de novo)	ADT plus placebo vs ADT plus abiraterone and prednisone (plus RT for localized or N + disease)	Improved 3-year OS with the addition of abiraterone and prednisone (83% vs 76%)	Benefit was seen across subsets, including M0 tumors, although there were few events in this group

Abbreviations: ADT, androgen deprivation therapy; BCR, biochemical recurrence; mCSPC, metastatic castration-sensitive prostate cancer; OS, overall survival; RT, radiation therapy.

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

higher (Table 14-1). After a median follow-up of 51.8 months, the LATITUDE study showed an improvement of median OS by 16.8 months (53.3 vs 36.5 months) with an HR of 0.65. The STAMPEDE-G study similarly showed an improvement of 5-year survival rate from 41% to 60% with an HR of 0.60.[88]

At the time of PSA progression on abiraterone, one study suggested that switching from prednisone to dexamethasone could produce durable PSA responses.[88]

ARPIs FOR mCSPC

Multiple trials have demonstrated benefits with the addition of the ARPIs enzalutamide, apalutamide, and darolutamide to ADT for treatment of mCSPC (Table 14-2). On the basis of these studies, apalutamide, enzalutamide, and darolutamide all have received FDA approval for use in mCSPC treatment. In addition, some of these trials were the first to evaluate intensification of AR-directed therapy together with docetaxel, although none were specifically designed to answer the question of whether docetaxel and ARPI are more effective than either alone or in combination with ADT.

Table 14-2 Randomized Trials of ADT Plus Androgen Receptor Pathway Inhibitors for mCSPC

Trial	No. of Participants	Study Population	Design	Outcome	Notes
ARANOTE[1]	669	mCSPC (recurrent or de novo)	ADT + placebo vs ADT + darolutamide	Improved radiographic PFS with the addition of darolutamide (not reached vs 25 months)	rPFS benefit seen regardless of disease volume. OS data immature
ARCHES	1,150	mCSPC (recurrent or de novo)	ADT versus ADT plus enzalutamide. Docetaxel is allowed at the investigator's discretion in either trial arm	Improved radiographic PFS with addition of enzalutamide (not reached vs 19 months)	rPFS benefit seen regardless of docetaxel use and/or disease volume. OS data immature
ENZAMET	1,125	mCSPC (recurrent or de novo)	ADT versus ADT plus enzalutamide. Docetaxel is allowed at the investigator's discretion in either trial arm	Improved OS with the addition of enzalutamide (median OS not yet estimable; 80% versus 72% OS at 3 years)	Possibly limited benefit of enzalutamide in docetaxel-treated patients. Possible increased docetaxel toxicity with the addition of enzalutamide
TITAN	1,052	mCSPC (recurrent or de novo)	ADT versus ADT plus apalutamide. Docetaxel is allowed at the investigator's discretion in either trial arm	Improved OS and radiographic PFS with apalutamide (82% vs 74% OS; 68% vs 48% rPFS)	rPFS benefit seen regardless of docetaxel use and/or disease volume. Possibly limited OS benefit of apalutamide in docetaxel-treated patients

Abbreviations: ADT, androgen deprivation therapy; mCSPC, metastatic castration-sensitive prostate cancer; OS, overall survival; PFS, progression-free survival; rPFS, radiography progression-free survival; RT, radiation therapy.

SELECTING AN AR SIGNALING PATHWAY INHIBITOR FOR mCSPC

There are no high-quality randomized studies comparing the efficacy of these ARPIs in the first-line mCSPC setting. When selecting an ARPI in combination with ADT for treatment of mCSPC, the first decision point should be if the patient would benefit from the addition of docetaxel for upfront "triplet therapy" treatment, as described in the sections above and below. If so, then darolutamide (see ARASENS study) or abiraterone (see STAMPEDE and PEACE-1 studies) should be considered. If the patient is

not a candidate for or would decline docetaxel chemotherapy, then all ARPIs would be potential options as a pair with ADT, and selection can be made based on administration, monitoring, side effect profile, drug interaction risk, and patient preferences.

Enzalutamide, apalutamide, and abiraterone are all once-daily medications. Darolutamide is taken twice daily. Apalutamide offers a "single pill once daily" option that can be dispersed in water for patients unable to swallow tablets whole. Enzalutamide and apalutamide are very similar in chemical structure and carry similar risks of fatigue, hypertension, falls, and rarely, seizures. Both have the potential to cause rash, but apalutamide has a greater risk for rash as well as thyroid disease. Non-randomized post-marketing studies have suggested slightly different rates of these side effects. Importantly, enzalutamide and apalutamide are significant CYP3A4 inducers and can result in significant drug-drug interactions with medications metabolized via this pathway (eg, direct oral anticoagulants, statins, fentanyl).

Darolutamide, in comparison, has been associated with lower rates of fatigue and seizures as its chemical structure leads to less penetration into the central nervous system (CNS). Darolutamide is a much weaker CYP3A4 inducer compared to enzalutamide and apalutamide, and thus may be a preferred option for patients with significant drug-drug interaction risk. Data on OS in the ARANOTE study, which led to its FDA approval in this setting, remain immature.

Abiraterone is associated with generally lower rates of fatigue, drug-drug interaction, and seizures compared to the alternative ARPIs above. It does carry the risks of liver function test elevation and mineralocorticoid excess (eg, hypertension, hypokalemia, edema) requiring concomitant low-dose prednisone use, with frequent lab and blood pressure monitoring as previously described. These cardiac side effects make abiraterone a less preferred option for those with significant cardiovascular disease. In addition, preliminary data from a recent meta-analysis suggested no OS benefit with abiraterone added to ADT in patients aged 75 and older, so it may be a less preferred option in this patient population.[90]

EMERGING CLINICAL QUESTIONS

Although it is encouraging to see further improvement of OS with intensification of the systemic therapy for mCSPC, the role of docetaxel in this triple regimen remains unknown. We know that ADT + docetaxel is superior to ADT alone, especially for high-volume mCSPC. We also know ADT + ARPI is superior to ADT alone. However, we do not know if docetaxel or an ARPI is superior as a secondary therapy. Only limited data are available comparing docetaxel with ARPI from the multi-arm STAMPEDE study. Because the study was neither designed nor powered to make a comparison between these two arms, there was no discernible difference in OS between the docetaxel cohort (n = 5,189) and abiraterone cohort (n = 5,377) of the multi-arm STAMPEDE trial.[91] Although we know the "triplet" of ADT + docetaxel + abiraterone or darolutamide is superior to ADT + docetaxel, we do not know whether the "triplet" regimen is indeed superior to ADT + ARPI or whether ADT + ARPI is just as good or not inferior to the triplet regimen. The role of docetaxel in this triple regimen is yet to be examined. Numerous translational biomarker studies are ongoing in efforts to improve patient selection for the "triplet" therapy regimen.

A key takeaway, as emphasized throughout the chapter, is that all patients with mCSPC should be treated with ADT and an ARPI. That is, a standard of care for a high-volume mCSPC patient includes ADT + abiraterone or darolutamide or apalutamide or enzalutamide with or without the addition of docetaxel. The standard of care for low-volume mCSPC is ADT + abiraterone or darolutamide or apalutamide or enzalutamide, with consideration of radiation therapy to the prostate. For older, frail patients at high risk for toxicity, ARPI monotherapy can be considered, but ADT + ARPI (with consideration of an initial dose reduction of the ARPI) should be considered for all.

PROSTATE-DIRECTED THERAPY FOR METASTATIC PROSTATE CANCER

Historically, the presence of metastatic disease excluded consideration for radical prostatectomy or definitive prostate RT. However, interest in prostate-directed therapy is growing even in the setting of metastatic disease. Some reports have described long-term remissions using prostate-directed therapy with targeted RT and ADT for oligometastatic prostate cancer. The definition of oligometastatic disease is likely to evolve as increasingly sensitive imaging techniques are used in this setting, and this disease state is defined by a different number of metastatic sites in different studies (see "Biochemical Recurrence" section). The HORRAD and STAMPEDE trials assessed the efficacy of prostate RT in more diffuse metastatic disease treated with ADT alone.[82,92] Neither trial demonstrated an increase in OS in the population overall, but there was an increase in OS in patients with low-volume disease (per the CHAARTED criteria) in STAMPEDE in a preplanned subgroup analysis. Therefore, there may be a role for definitive prostate RT in the setting of low-volume mCSPC. Additional data from the PEACE-1 study demonstrated an increase in OS for certain patients with high-volume disease as well, perhaps relating to patients with highly symptomatic bulky primary tumors.[93] Ongoing studies are evaluating whether patients with mCSPC should undergo treatment of the primary tumor with surgery or RT and whether treatment with docetaxel, abiraterone, or other systemic therapies or metastasis-directed RT will improve survival.

SUPPORTIVE CARE FOR mCSPC

Cardiovascular Health

As described in localized prostate cancer, long-course (or lifelong, in the case of most metastatic disease) ADT has been associated with cardiovascular (CV) risks and metabolic syndrome in patients for whom cardiovascular disease and metabolic syndrome

are already prevalent. The addition of any ARPI raises the risk of CV disease compared to ADT alone. The oral GnRH antagonist relugolix may decrease major adverse cardiovascular events compared with GnRH agonists (small event rate in a secondary endpoint of the HERO trial), though a similar agent (degarelix) was not clearly superior to GnRH agonists in another trial designed to look primarily at cardiovascular health (although this finding may also have been a result of under-enrollment and decreased power) in the context of aggressive management of baseline cardiovascular risk factors. Thus, relugolix is a consideration, particularly in patients with prior major cardiovascular events, but, as described, aggressive management of baseline risk factors is probably most critical. Surgical castration may also be considered, and it is quite cost-effective and entails fewer injections and less financial toxicity for patients; although surgical castration is often not preferred by patients, testicular implants can decrease the cosmetic effects.

It is most important that oncologists work closely with primary care physicians to ensure that baseline risk factors are well managed and that regular surveillance for the emergence of new cardiovascular conditions and metabolic syndrome is performed. A cancer diagnosis may provide a psychological cue to patients to begin regular health management if this had not previously occurred; importantly, oncologists can tell patients that this is "worth it," because even patients with metastatic disease may have a life expectancy of many years, during which cardiovascular health can certainly become a source of morbidity and mortality. For such patients, the increased frequency of oncology visits can also provide opportunities for blood pressure checks, hemoglobin A1c measurements, assessment of medication adherence, even with nononcological medications, etc.

Bone Health

Many years of ADT with possible intensification and concomitant prednisone may pose a threat to bone health, particularly in patients with baseline osteopenia/osteoporosis or risk factors for these (eg, excessive alcohol use, smoking, prior prednisone use). DEXA scans can be used at baseline and over time to screen for the development of osteopenia and osteoporosis, although there are no high-quality data to guide who should be screened or how frequently. NCCN guidelines recommend using the National Osteoporosis Foundation guidelines for screening and treatment in the general population but also mention a recommendation from the International Society for Clinical Densitometry to obtain DEXA scans at baseline and after 1 year of ADT.[94] Again, there are no high-level data to guide treatment recommendations in this population, but the Fracture Risk Assessment Tool (FRAX) score can be used with ADT, which would be considered secondary osteoporosis in this algorithm.

In practice, some clinicians might obtain a baseline bone mineral density scan at the start of long-term ADT (typically in conjunction with primary RT for high-risk localized or regional disease), especially for patients aged 70 years or older and those with additional risk factors for osteoporosis, and repeat this scan after 1 year of ADT. Any patient who had a FRAX score justifying treatment would then be treated unless testosterone recovery was imminent. FRAX score is calculated with several clinical factors and estimates the 10-year probability of fracture.[95]

Interestingly, two randomized trials of early use of zoledronic acid in the setting of mCSPC failed to show an improvement in skeletal-related events or OS, raising the hypothesis that hormone therapy was so effective for cancer control that antiresorptive therapy could not improve on this. However, there may be a role for antiresorptive therapy for the prevention of fragility fractures, especially in those with baseline or treatment-induced osteopenia/osteoporosis, and this is the subject of active research. There are no data to support using denosumab for mCSPC unless there is concomitant osteopenia/osteoporosis warranting antiresorptive therapy with the Prolia formulation (as opposed to the Xgeva formulation used for mCRPC). Denosumab has only been compared with zoledronic acid in the mCRPC setting. In addition, denosumab carries higher financial toxicity and may have a risk of increased bone turnover if discontinued, an important consideration for patients with mCSPC who may be receiving long-term therapy and may choose to hold therapy intermittently.

Sexual Health

Unfortunately, most men with metastatic disease will require lifelong ADT or, at a minimum, long periods on ADT. ADT almost always removes any libido (the "spark") present at baseline, and therefore, interventions for erectile dysfunction (the "machinery") are typically ineffective (PDE5 inhibitors) or unhelpful (intracorporeal injections, penile prostheses). Moreover, there may be lingering effects of prior local therapies on erectile function. Single-agent AR antagonist therapy preserves testosterone and libido but is not the standard of care for metastatic disease. When treating with standard ADT-based therapy, counseling is needed regarding the expectation for minimal libido. Thus, patients should be encouraged to be open about their concerns with their sexual partners and may explore alternative forms of intimacy that do not require sexual intercourse. Sexual health counselors and support groups can be very helpful in helping discuss these issues and reducing stigma.

Mental Health

A diagnosis of cancer is always life-changing. Use of ADT may further contribute to depression and other mood disturbances. Although patients with mCSPC should be reassured that their disease can be controlled for many years, most will have their lives shortened considerably by this illness. Oncology social workers, psychiatrists, and support groups can be very helpful in

managing the emotional difficulties that come along with this journey. Early involvement of palliative care—concurrently with cancer-directed care—is also recommended, although it is unclear whether this is best done at diagnosis or at the time of more resistant disease and is likely dependent on individual patients' needs. The effects of sexual health discussed earlier can be quite impactful on mental health and relationships. Financial toxicity and concerns about the ability to perform work functions can also play into mental health and should be addressed. In sum, it is important for oncologists counseling patients with mCSPC to simultaneously emphasize that this diagnosis is a serious and likely life-limiting one, but also one that can be managed as a chronic illness for many years.

METASTATIC CASTRATION-RESISTANT PROSTATE CANCER

The treatment of patients with a disease that progresses during ADT requires documentation that the patient is medically castrated (defined as a serum testosterone level <50 ng/dL). Despite castration resistance, castration is continued during all subsequent therapies because this decreases the availability of AR ligand and possibly direct antagonism of tumor LHRH receptors. Despite the development of mCRPC, AR signaling continues to play a major role in many prostate cancers. Mechanisms leading to persistent AR activation despite castrate testosterone levels include AR overexpression, ligand-independent activation, de novo synthesis of intratumoral androgens, and alterations in the AR, including splice variants and circulating subcastrate levels of androgens.

Multiple classes of therapy that improve OS are available in mCRPC, including immunotherapy (sipuleucel-T), taxane chemotherapy (docetaxel, cabazitaxel), radiopharmaceuticals (radium-223, lutetium-617), and AR signaling inhibitors. All of the ARPIs described in the mCSPC sections above first demonstrated their efficacy through improvements in survival in the castration-resistant setting. This second generation of ARPIs, as described in the mCSPC section above, includes abiraterone acetate, enzalutamide, apalutamide, and darolutamide. These agents have replaced the use of first-generation antiandrogens such as flutamide, nilutamide, bicalutamide, and ketoconazole.

For patients who have previously received primary localized therapy and present with overt symptomatic metastatic disease (after PSA and radiological progression) at the time of initiating ADT, characterization of the anatomic location and symptoms is important. The presence of new-onset back pain should raise concern for possible spinal cord or cauda equina disease, and if clinically indicated, an MRI of the spine should be performed. In approximately 10% to 15% of patients, the disease will relapse with aggressive local or distant metastases. In circumstances in which the PSA level seems to be disproportionately low for the tumor burden present or the presence of visceral metastases, a repeated biopsy of a metastatic site may indicate a neuroendocrine or small-cell phenotype. PSMA PET imaging remains a mainstay imaging modality in this setting.

ARPIs FOR mCRPC

The ARPIs abiraterone, enzalutamide, apalutamide, and darolutamide remain effective even after the onset of castration resistance. Abiraterone and enzalutamide are the two ARPIs that carry an FDA approval for use in mCRPC, as mentioned below. Enzalutamide, apalutamide, and darolutamide are also approved for use in nmCRPC, as described in the sections above.

Abiraterone acetate was FDA approved in 2011 for men with mCRPC after docetaxel treatment based on OS benefit relative to placebo. It was subsequently FDA approved in 2012 as a treatment before docetaxel therapy based on improved OS.

As discussed under abiraterone mCSPC, abiraterone acetate shuts down androgen and glucocorticoid biosynthesis by inhibiting CYP17 (17α hydroxylase and 17,20 lyase) (Fig. 14-16). Feedback loops during treatment result in adrenocorticotropic hormone-mediated excess mineralocorticoid activity, including hypertension, fluid retention, and hypokalemia, and low-dose prednisone is administered concurrently to prevent this. The FDA label includes directions to administer concurrent prednisone at 5 mg twice daily in the setting of castration-resistant disease but only 5 mg daily in the setting of castration-sensitive disease, which was studied later than mCRPC. However, given the potential adverse effects of higher-dose steroids, another off-label option is to start treatment in mCRPC at 5 mg daily (as in mCSPC) and then increase to twice daily if adrenocorticotropic hormone-mediated adverse effects develop.

Abiraterone is taken on an empty stomach because fatty food may increase absorption. Food effects on abiraterone were investigated in a randomized phase 2 noninferiority study comparing 1,000 mg of abiraterone per day after an overnight fast versus 250 mg per day after a low-fat meal in 75 patients with mCRPC.[83] The primary endpoint was a log change in PSA as a pharmacodynamic biomarker for efficacy, with second endpoints of PSA response (≥50%) and PFS. The study investigators found that there was a greater effect on PSA in the low-fat meal arm with a mean log change of −1.59 compared with the overnight fast arm with a mean log change of −1.19. The PSA response rate was 58% in the low-fat meal arm and 50% in the overnight fast arm, and the median PFS was 9 months in both arms. No difference was seen in PSA response or PFS despite higher abiraterone concentrations noted in the overnight fast arm. Taken together, the noninferiority of low-dose abiraterone (250 mg per day with a low-fat meal) to standard dosing was established with respect to PSA metrics. From a financial toxicity perspective, this alternative dosing may be considered for those who cannot afford the cost of the standard dose, though studies confirming this approach using validated endpoints such as MFS or OS are currently lacking.

Enzalutamide was FDA approved in 2012 for the treatment of mCRPC after docetaxel treatment and in 2014 for use in patients with mCRPC before docetaxel treatment. As ARPIs are increasingly used in the castrate-sensitive setting, the role of ARPIs in the castrate-resistant setting is becoming less clear. Although abiraterone and enzalutamide have changed the landscape for the management of CRPC, approximately 15% to 25% of patients have primary resistance and a high degree of cross-resistance. Starting with abiraterone and then administering enzalutamide is associated with a better time to PSA progression with second-line therapy than enzalutamide followed by abiraterone, but OS is similar between the two sequences.[84]

It must be noted that there is limited efficacy of a switch to an alternative ARPI after progression on a prior ARPI. Given an increasing number of superior alternative agents, the strategy of an "ARPI switch" in mCRPC should generally be discouraged except in certain clinical scenarios (eg, patients who have had long prior responses, have clinically indolent disease, or are ineligible for alternative therapies). Commercially available assays can be used to look for the presence of an AR splice variant (AR-v7) and inform a choice between ARPI switch (which is particularly unlikely to help in patients with detectable AR-v7) versus taxane chemotherapy, but these assays are seldom used in current practice.

As a primarily historical note, treatment-induced AR mutations could result in first-generation AR antagonists acting instead as partial agonists; thus, in the setting of PSA progression on bicalutamide, withdrawal of bicalutamide could result in a PSA decrease in a subset of patients, typically temporary. This is very infrequent with second-generation AR antagonists.

CHEMOTHERAPY FOR mCRPC

In 2004, two randomized trials were reported that compared docetaxel-based therapy with mitoxantrone and prednisone in patients with mCRPC. A significant improvement in OS was demonstrated for patients who received docetaxel, with a median survival of >18 months. Docetaxel was also superior to mitoxantrone with respect to pain response rate, PSA response rate, and quality of life indices. Based on these study results, the FDA approved the use of docetaxel (75 mg/m^2 every 21 days) together with prednisone as frontline therapy for men with mCRPC.

Cabazitaxel is a microtubule-stabilizing taxane that was FDA approved after prior docetaxel therapy based on the results of a phase 3 trial in patients who had received treatment with docetaxel and demonstrated improved OS with cabazitaxel (25 mg/m^2) versus mitoxantrone. Grade 3 to 4 neutropenic fever was the major serious toxicity in patients who received cabazitaxel, and primary prophylaxis with G-CSF should be administered routinely for patients using standard dosing. A subsequent study demonstrated that cabazitaxel at 20 mg/m^2 is noninferior in terms of survival and is less toxic.[95] In the third-line setting, the CARD trial demonstrated that cabazitaxel resulted in improved OS versus a second ARPI for patients who had mCRPC previously treated with docetaxel and a first ARPI.[85] It is important to note that progression within 12 months of first ARPI therapy was required for eligibility, so this trial may have selected for the so-called worst actors, and results may not be generalizable to patients with longer responses to hormone therapy.

Mitoxantrone and other regimens that have demonstrated activity in mCRPC may be beneficial as possible additional therapies for patients with good performance status if they have used all other available treatment options and cannot enroll in a clinical trial.

In patients with small-cell histologies, platinum-containing chemotherapy combination regimens such as cisplatin or carboplatin with etoposide or carboplatin with taxane (cabazitaxel or docetaxel) are recommended. ADT should be continued during the treatment of small-cell carcinoma because of intratumoral and intertumoral heterogeneity.

PARP INHIBITORS FOR mCRPC

The DNA-repair pathway has emerged as a validated target for cancer therapy. Although a critical defect in this DNA-repair pathway allows mutagenesis and eventually cancer development, some of these defects present themselves as targets for cancer therapy. For example, tumors with defective HRR caused by deleterious mutations in the *BRCA2* gene can be exquisitely sensitive to inhibition of PARP, a critical enzyme in initiating repair machineries for single-strand DNA breaks. PARP inhibition leads to the accumulation of single-strand DNA breaks, stalling and disrupting the replication fork, and leading to double-strand DNA breaks. Cancer cells with deleterious *BRCA2* mutations cannot repair double-strand DNA breaks via the HRR pathway.

PARP inhibitors have demonstrated their efficacy in tumors harboring somatic or germline deleterious mutations in *BRCA1* or *BRCA2* or other HRR-related genes. For patients with mCRPC, both olaparib and rucaparib received FDA approval in May 2020. The approval of olaparib was based on the results from the PROfound study, a phase 3 trial comparing olaparib versus second-line ARPI (switching to abiraterone or enzalutamide after progression on the other ARPI) in patients with mCRPC harboring deleterious mutations in any of 15 prespecified HRR-related genes. The study showed that olaparib resulted in radiographic PFS and OS in the primary analysis cohort consisting of *BRCA1*, *BRCA2*, and *ATM* alterations and in the secondary analysis cohort, which combined the primary cohort mutations with 12 other HRR gene alterations.[96] This resulted in FDA approval for olaparib in this setting (except those with *PPP2R2A* alteration). However, there are some caveats:

- Although benefits were demonstrated in the combined analysis of patients with the 14 prespecified HRR alterations, the benefit of olaparib over a second-line ARPI was most clear in patients with a *BRCA2* alteration. Exploratory analyses by individual HRR gene subgroup were limited by small sample size (eg, fewer than five cases of *BARD1*, *BRIP1*, *CHEK1*, and

RAD51D mutations). Even for groups with a sizable number of mutation cases (eg, *ATM*, *CDK12*, and *CHEK2*), the benefit seemed underwhelming. It is unclear whether patients with these mutations would still benefit from olaparib over taxane-based chemotherapy, which is an option for those who experience progression after the first-line ARPI.

Similarly, the FDA granted accelerated approval to rucaparib in patients with mCRPC after prior ARPI and taxane-based therapy on the overall response rate (ORR) of 44% seen in the TRITON2 single-arm study of patients with *BRCA*-altered mCRPC.[97] TRITON3 is currently evaluating the efficacy of rucaparib in men with mCRPC with *BRCA1*, *BRCA2*, or *ATM* alteration against chemotherapy.

The addition of platinum chemotherapy to docetaxel may also be effective in patients with alterations in DNA-repair genes because their tumors are less able to repair the platinum-induced double-strand breaks. It is hoped that ongoing research will clarify biomarkers of response to either PARP inhibition or platinum therapy (Fig. 14-13).

PARP INHIBITOR–BASED COMBINATION

Given the encouraging results from PARP inhibitor trials in prostate cancer, several combination approaches have been examined. The PROPEL study, a double-blinded phase 3 study of abiraterone and olaparib versus abiraterone and placebo in patients with mCRPC in the first-line setting, showed abiraterone combined with olaparib improved imaging-based PFS by 8.2 months over the control arm irrespective of HRR gene mutation status (HR, 0.66; 95% CI, 0.54-0.81; $P < .001$).[1] A planned radiographic PFS analysis by blinded independent central review confirmed showing improvement of median radiographic PFS by 11.2 months. Based on exploratory subgroup analysis suggesting that the radiography PFS (rPFS) benefit from the combination was driven by patients with BRCA1/2-altered tumors, the FDA approved the combination of abiraterone and olaparib only for patients with BRCA1/2-altered CRPC. Indeed, the OS analysis across the entire study population showed no difference between abiraterone alone or in combination with olaparib.[51]

The MAGNITUDE study was another study that evaluated a PARP inhibitor combined with abiraterone.[98] This was a double-blinded, phase 3 study of abiraterone and niraparib versus abiraterone and placebo in two cohorts of patients with mCRPC: (1) with specified HRR biomarker (deleterious mutations in *ATM*, *BRCA1*, *BRCA2*, *BRIP1*, *CDK12*, *CHEK2*, *FANCA*, *HDAC2*, *PALB2*) and (2) without the biomarker (BM-), in the first-line setting. Unlike the PROPEL study, the MAGNITUDE study took an a priori approach to examine the outcomes in HRR BM1 and HRR BM cohorts separately with preplanned futility analysis. The study showed abiraterone combined with niraparib improved radiographic PFS compared with abiraterone and placebo in patients with the HRR biomarker but not in patients without the HRR biomarker.[99] The final analysis did not show a statistically significant OS improvement but did show trends favoring longer OS with the niraparib + AAP combination. This data led to the approval of the niraparib + AAP combo.[100]

Talazoparib is approved in combination with enzalutamide for CRPC with alterations in one of 12 homologous recombination genes (ATM, ATR, BRCA1/2, CDK12, CHEK2, FANCA, MLH1, MRE11A, NBN, PALB2, RAD51C).[101] The TALAPRO-2 study compared enzalutamide monotherapy with talazoparib and enzalutamide in first-line mCRPC. Patients were stratified into two cohorts: (1) HRR gene alteration and (2) HRR gene status unknown or not altered. This study demonstrated improved rPFS overall as well as within each cohort. The FDA approved talazoparib and enzalutamide for first-line mCRPC treatment in patients with alterations in the tested HR genes.

Many questions remain regarding the combination of PARP inhibition and ARPI. Perhaps most critical, given the varied and limited numbers of patients in the control arms who received subsequent PARP inhibitor (PARPi) therapy, it is unclear whether men with HRR gene mutation benefit from a combination of PARPi and abiraterone as opposed to sequential therapy. Most of the study populations included in the trials above were ARPI-naive, which is an increasingly rare circumstance in CRPC, so relevance in the modern era is less clear. Given discordant results in the non–HRR altered populations from MAGNITUDE and TALAPRO-2, the role of PARP inhibitor combinations in this population remains unknown. Emerging data highlight that improved biomarkers may refine patient selection for PARP inhibitor mono- and combination therapy.

At ASCO Annual 2025, data from the AMPLITUDE study[102] were presented, investigating the efficacy of the niraparib + AAP + ADT combination compared to AAP + ADT in the metastatic castrate-SENSITIVE setting. Patients with germline or somatic HRR gene alterations (*BRCA1*, *BRCA2*, *BRIP1*, *CDK12*, *CHEK2*, *FANCA*, *PALB2*, *RAD51B*, *RAD54L*) were included. This study showed a significant radiographic PFS benefit favoring the PARP inhibitor combination (HR 0.63), even more so for the BRCA1/2 subgroup (HR 0.52). The majority of patients had high-volume de novo metastatic disease. There was a non-significant OS trend favoring the PARP inhibitor combination. As of this writing, this PARP + ARPI combination is not yet FDA approved in the mCSPC setting. This highlights the importance of germline and somatic testing for all patients with metastatic disease at initial diagnosis.

PSMA-TARGETED THERAPY

PSMA is another exciting target for both imaging and therapeutics. ^{177}Lu PSMA-617 (also ^{177}Lu vipivotide tetraxetan, or LuPSMA) is a radioligand therapy that delivers β-particle radiation to PSMA-expressing cells and the surrounding microenvironment.

The TheraP trial,[103] a randomized phase 2 study, evaluated the clinical activity of LuPSMA compared with cabazitaxel in men with PSMA-positive mCRPC by PET imaging. LuPSMA resulted in a superior PSA50 response rate and fewer grade 3 or 4 adverse events. A pivotal phase 3 trial, the VISION study,[104] evaluated the efficacy of LuPSMA and standard care versus standard care alone in men with mCRPC. Eligibility criteria included progression after an AR pathway inhibitor and at least one taxane chemotherapy with the presence of at least one PSMA-positive lesion and no PSMA-negative lesions as assessed by ^{68}Ga-PSMA-11 PET–CT. The treatment was administered intravenously once every 6 weeks for a total of four to six infusions. LuPSMA and standard care resulted in superior OS and radiographic PFS in men with previously treated PSMA-positive mCRPC. ^{177}Lu vipivotide tetraxetan was approved by the FDA in March 2022 for mCRPC with PSMA-positive lesions by a PET scan using Ga-68 gozetotide or another approved PSMA-11 imaging agent.[2]

Several phase 3 trials are underway to test the efficacy of LuPSMA in earlier disease settings. PSMAfore is examining the efficacy in patients with progressive mCRPC after one ARPI versus switching to a different ARPI. The study met its primary endpoint and demonstrated improvement in radiographic PFS in PSMA-positive mCRPC.[2] This led to FDA approval in 2025 of LuPSMA for patients with mCRPC who have progressed after at least one ARPI and have not yet received docetaxel, and would be considered appropriate to delay taxane-based chemotherapy. LuPSMA carries the risk of myelosuppression, especially in patients with high-volume bone involvement and xerostomia, given that the salivary glands also express PSMA. Due to renal excretion of the beta-emitting payload, patients with incontinence are given special instructions about frequent diaper changes after LuPSMA infusion, and all patients are cautioned about close exposure to household members, especially children.

IMMUNOTHERAPY

Sipuleucel-T is the first FDA-approved immunotherapy for the treatment of mCRPC. It is a therapeutic cancer vaccine composed of activated autologous dendritic cells loaded with an engineered fusion protein of prostatic acid phosphatase and the granulocyte-macrophage CSF, PAP-GMCSF, also called PA2024. This cellular product is prepared in three steps:

1. Leukapheresis to isolate CD541 dendritic cells.
2. Cell harvest and culture with PA2024 ex vivo.
3. Reinfusion of the activated dendritic cells into the original patient.

The preparation and administration of this autologous cellular product are performed every 2 weeks for a total of three infusions and are designed to elicit an immune response to prostatic acid phosphatase. Two small, randomized, placebo-controlled phase 3 trials, D9901 (N = 5,127) and D9902A (N = 598),[86,105] showed that sipuleucel-T resulted in a difference in median OS in asymptomatic patients with mCRPC without any effect on time to progression, which was the primary endpoint. Therefore, a third phase 3 study, IMPACT, was designed with OS as the primary endpoint. The study showed sipuleucel-T resulted in a 22% relative reduction in the risk of death compared with the placebo group. This translated into a 4.1-month improvement in median survival without any effect on time to progression. These data eventually led to FDA approval in 2010.

Other immune-based therapies have been assessed in mCRPC and have not been effective. Checkpoint inhibitors, such as inhibitors of CTLA-4 and PD-1/PD-L1, have had limited efficacy in advanced CRPC after failure of standard therapies. However, a small percentage of patients with metastatic prostate cancer have MSI-high/MMR-deficient status. The FDA approved the PD-1 inhibitor pembrolizumab for such patients regardless of primary tumor type in 2017, and some patients have had dramatic responses to pembrolizumab when no other treatment options were available.[106] In addition, the FDA approved pembrolizumab for second-line treatment of any unresectable or metastatic tumor with high tumor mutational burden (TMB), defined as 10 or more mutations per megabase. Of the small number of patients with mCRPC and high TMB, most have MSI/MMRd (microsatellite instability/mismatch repair deficiency); rarer still are TMB-high microsatellite-stable tumors (potentially as a result of DNA polymerase epsilon, or POLE, mutations), which are now also eligible for PD-1 therapy under this new approval. Responses to PD-1/PD-L1 inhibition have also been seen in a small number of patients with prostate cancer without MSI-high/MMR-deficient status, sometimes in combination with other agents, and this is an active area of research.

BONE-TARGETED THERAPY

Involvement of bone occurs at some point in the disease course in a vast majority of patients with metastatic prostate cancer. In some patients, metastatic disease is confined to or predominantly involves bone. Bone metastases may be asymptomatic or painful, and they can eventually lead to pathological fracture, spinal cord compression, need for RT, or need for surgery to the bone, all of which are collectively termed skeletal-related events (SREs).

The α-emitter radium-223 (^{223}Ra) is a bone-seeking radionuclide that has been approved by the FDA for treatment of patients with mCRPC and symptomatic bone metastases with no known visceral metastatic disease based on results of the ALSYMPCA trial.[107] Patients included in the study had received treatment with docetaxel, were unfit for docetaxel, or refused docetaxel, and toxicity included myelosuppression and gastrointestinal symptoms. This study led to the FDA approval in 2013 of ^{223}Ra

dichloride. Notably, the ERA 223 trial randomly assigned men with mCRPC with no prior treatment of mCRPC to treatment with abiraterone with or without radium-223.[108] The study was unblinded early because of an increased fracture risk and poorer OS in the combination arm. An updated analysis demonstrated that the treatment arms had similar survival, but there was an increased risk of fragility fractures in the combination arm and a low rate of treatment in the study overall, with bone-targeting agents to prevent SREs. The FDA subsequently recommended avoiding concurrent treatment with ^{223}Ra and abiraterone plus prednisone. Most recently, PEACE-3 tested enzalutamide with or without radium-223 in patients with ARPI-naive mCRPC, an increasingly rare situation in modern practice, but demonstrated prolongation in rPFS and OS, suggesting that radium-223 may have a role beyond palliation of multifocal bone pain.[109] In contrast with ^{177}Lu-PSMA-617 as described above, radium-223 targets lesions located in bone only and is not effective for the treatment of extraosseous disease.[109] The optimal sequence of these novel radioligand therapies currently remains unclear and is under investigation.

Bisphosphonates or denosumab, a fully humanized anti-RANKL monoclonal antibody, were approved by the FDA in two situations:

- Men receiving long-course ADT in combination with RT for localized prostate cancer who are found to have baseline or treatment-induced osteopenia or osteoporosis: In this case, the goal is to increase bone mineral density and prevent osteoporosis-related fractures (see note about denosumab dosing).
- Men with mCRPC and bone metastases: in this case, the goal is to prevent SREs. Notably, use of bisphosphonates in mCSPC did not improve SREs or OS in the STAMPEDE trial or CALGB 90202.[53]

Renal insufficiency, osteonecrosis of the jaw, and hypocalcemia are potential adverse effects of bisphosphonates. Patients with significant dental disease or who require dental procedures should not be treated with bisphosphonates until after dental clearance. Monthly dosing or dosing every 3 months with zoledronic acid is indicated for bone metastases, whereas yearly infusions can be used for the treatment of osteoporosis.

In a phase 3 trial, denosumab, a RANKL inhibitor, was superior to zoledronic acid for the prevention of SREs. Hypocalcemia was more common in patients treated with denosumab, and osteonecrosis of the jaw occurred infrequently in both arms. Denosumab can be used in patients with renal impairment. Of note, the approved dose and schedule of denosumab for prevention of SREs in patients with mCRPC (120 mg every month) differ from those approved for fragility fracture prevention (60 mg every 6 months). Extrapolating from data showing equivalence of zoledronic acid administered every 3 months versus monthly in preventing SREs in patients with bone metastases from any cancers,[110] some clinicians may use denosumab every 3 months off-label instead of monthly for mCRPC with bone metastases. Bisphosphonates may be stopped or administered less frequently after 2 years of therapy because of an increased risk of atypical femoral fractures and osteonecrosis of the jaw. Denosumab may be continued indefinitely, given the increase in bone turnover markers after stopping therapy, especially in the metastatic setting, although the clinical significance of this is unclear.

Both denosumab and zoledronic acid are administered with calcium to mitigate the risk of hypocalcemia, and typically, this is also administered in combination with vitamin D (especially in patients being treated for osteoporosis).

PALLIATION

An important aspect of patient care is the palliation of pain. Durable relief in selected sites can be achieved with EBRT delivered via a focal or hemibody technique. Systemic therapies can also provide palliation, especially nonsteroidal anti-inflammatory medications or steroids. Bone-seeking radiopharmaceutical agents, such as ^{223}Ra or ^{177}Lu-PSMA-617, reduce the pain of skeletal metastases, as discussed previously.

KEY POINTS

- Although not curative, ADT is palliative and results in clinical response in most patients with mCSPC.
- The addition of docetaxel, abiraterone with prednisone, or an AR pathway inhibitor (eg, apalutamide, enzalutamide, darolutamide) to ADT improves OS for patients with mCSPC.
- Recent studies indicate that the OS efficacy of triple therapy (ADT/docetaxel/NHT [eg, abiraterone or darolutamide]) was superior to ADT/docetaxel. The benefit was clear, especially for high-volume mCSPC with the addition of abiraterone to ADT/docetaxel. High-volume metastasis is defined by the presence of four or more bone metastases with one or more outside the spine and pelvis or the presence of visceral metastasis using CT and bone imaging.
- It is unknown whether the triple therapy is superior to ADT/NHT or whether they are equivalent, or whether the ADT/NHT doublet is not inferior to the triplet.
- In the setting of mCRPC, abiraterone, enzalutamide, sipuleucel-T, docetaxel, ^{223}Ra, ^{177}Lu-PSMA-617, and cabazitaxel all prolong OS. Unfortunately, cross-resistance to AR-directed therapies occurs after exposure to abiraterone or enzalutamide for a prolonged period, and the efficacy of enzalutamide after abiraterone or abiraterone after enzalutamide is limited.

- The role of PARP inhibitors is actively evolving. Two PARP inhibitors, olaparib and rucaparib, are FDA approved as monotherapy in mCRPC. Niraparib is approved in combination with abiraterone for mCRPC and BRCA1/2 alterations. Talazoparib is approved in combination with enzalutamide as first-line treatment in mCRPC for patients with selected HRR gene alterations. Although the benefit of PARP inhibitors in diseases with *BRCA2* mutations is most clear, their benefit in the setting of some other HRR gene alterations is debatable. Clinical context and alternative treatment options should be considered.

PROSTATE CANCER SURVIVORSHIP AND CONSIDERATIONS IN ELDERLY PATIENTS

With early detection and treatment, many men will be cured of prostate cancer by RT or surgery. A variety of adverse effects may develop in these patients who are related to therapy, including urinary incontinence, erectile dysfunction, and post-treatment psychosocial issues. Prostate cancer is predominantly a disease of older men with coexisting medical issues, and ADT is associated with numerous adverse effects that may be particularly pronounced in older men, including decreased libido, impotence, decreased lean body mass and muscle strength, increased fat mass, decreased quality of life, and osteoporosis. It has also been recognized that metabolic complications, such as insulin resistance, hyperglycemia, and metabolic syndrome, can occur in patients receiving long-term ADT (more than 12 months), potentially contributing to an increased risk of cardiovascular events. Men receiving long-term ADT may be monitored for the development of diabetes, and those in whom an adverse lipid profile develops should be treated according to the established guidelines for hyperlipidemia. It has been suggested that men (especially those with preexisting cardiovascular diseases) who receive as little as 6 months of ADT with RT may have an increased risk of cardiovascular-related mortality, but this observation was not confirmed in other retrospective analyses or in a meta-analysis. Other studies have suggested that men with previous cardiovascular disease may be at increased risk of cardiovascular morbidity while receiving ADT. One report suggested that cardiovascular disease risk may be highest in the first 6 months of ADT in men who experienced two or more cardiovascular events before therapy. Data are conflicting regarding the association of ADT and dementia, including Alzheimer's disease, in men with prostate cancer, and there is evidence to suggest an association between ADT and the development of depression.[108] None of these studies has established a causal link, and no randomized trials have demonstrated a significantly increased risk of cardiovascular mortality, dementia, or depression, although they have not been powered for these outcomes. In practice, the potential risks of ADT are likely justified for patients with intermediate- to high-risk localized or metastatic disease in which clear survival advantages have been established, and clinicians should be judicious about the use of ADT in lower-risk prostate cancer and low-risk BCR prostate cancer.

PRESENTING CASE STUDY 2

A 70-year-old man is admitted to the hospital with urinary retention and a several-month history of weight loss and vague back pains. He has no significant medical history in his normal state of health 1 year ago. He does report a family history of prostate cancer in his father, who died as a result, and a paternal aunt who had breast cancer in her 40s. He has never undergone screening for prostate cancer. Chest, abdominal, and pelvic CT reveals a prostate tumor causing bilateral hydronephrosis and suspicious pelvic and retroperitoneal lymphadenopathy. His PSA level is 500 ng/mL.

Should you pursue tissue diagnosis or treat it as metastatic prostate cancer based on clinical suspicion?

Tissue diagnosis is always preferred and will provide samples for genomic sequencing to inform future targeted therapies. In this case, a biopsy of the prostate or an accessible lymph node would be appropriate. It is important to note that for a patient with significant frailty with a high risk of procedural complications, or a patient who prefers to defer biopsy, the classic pattern of spread and highly suggestive tumor marker could reasonably lead to a clinical diagnosis and hormone therapy initiation.

What is your first-line therapeutic approach?

The standard of care includes androgen deprivation therapy (ADT) and, especially once out of the hospital, intensification with an androgen receptor pathway inhibitor (eg, abiraterone) or a second-generation AR antagonist. Some clinicians prefer to give luteinizing hormone-releasing hormone (LHRH) antagonists at least upfront. Alternatively, an AR antagonist (eg, bicalutamide) and LHRH agonist can be combined in patients with relatively high-volume disease owing to concerns for initial testosterone flare with an LHRH agonist. This approach is controversial, and there is some debate about the clinical consequences of testosterone flare in this setting. It is important to note that symptomatic/radiographic response will take weeks to months, so temporizing measures should be used in the meantime (eg, Foley catheter placement). In very frail patients or those who prefer a supportive approach, bicalutamide monotherapy can

be offered as it is likely to aid symptom management and is minimally toxic. For this patient, who was otherwise healthy before this illness, ADT initiation would be appropriate. After biopsy, bicalutamide could be started in the hospital or upon discharge, concurrent with LHRH agonist (eg, Leuprolide). Alternatively, an LHRH antagonist (eg, relugolix, degarelix) could be used if available.

Does the patient's family history affect treatment decision-making at this point? Is there any other lab or imaging testing that should be pursued right now?

Although it will not affect immediate treatment decisions (pending mature data from recent genomically selected trials in mHSPC), germline and somatic testing should be conducted to inform future treatment decisions and determine family members' cancer risk. Although most cases of prostate cancer are sporadic, this patient has a family history of breast and prostate cancer, which was demonstrated by BRCA2 syndrome, the most common inherited prostate cancer syndrome. Consider assessing baseline bone mineral density to inform decisions regarding antiresorptive therapy and ensure adequate calcium and vitamin D intake through diet or supplementation. Patients should be counseled on the need for aerobic/cardio exercise to address fatigue and metabolic syndrome, and weight/resistance training to address sarcopenia and osteopenia.

Are there any other systemic therapies or other treatments you would consider adding to his first-line hormone therapy?

Some patients with metastatic prostate cancer are eligible to receive docetaxel chemotherapy in addition to first-line hormone therapy. Currently, the best available evidence gathered from studies such as CHAARTED, ARASENS, and PEACE-1 suggests that patients who benefit most from adding docetaxel chemotherapy are those with de novo and/or high-volume bone disease (four or more bone lesions with one bone lesion outside of the axial skeleton) and/or visceral involvement. Since this patient has lymph node disease only, docetaxel would not routinely be used in this circumstance.

Prostate radiation may be offered to this patient. Patients in Arm H of the STAMPEDE study were found to have an overall survival benefit with radiation to the prostate, but only if they had low-volume disease by CHAARTED criteria, like this patient. There is an evolving role of using radiation to the prostate for certain patients with high-volume disease as well. If used, prostate radiation should be delayed until after resolution of urinary obstruction through alpha blockers, hormonal therapy, and/or surgical intervention, as radiation may worsen obstructive symptoms in the short term.

BLADDER CANCER

EPIDEMIOLOGY

In 2024, it is estimated that there will be 83,190 new cases of bladder cancer (n = 63,070 in men and n = 20,120 in women) and 16,840 deaths from bladder cancer (about 12,290 in men and 4,550 in women).[108] The incidence of bladder cancer is three to four times higher in men than in women, and the median age at diagnosis is 73 years. The approximate five-to-one ratio of incidence to mortality reflects the high frequency of noninvasive tumors compared with muscle-invasive tumors and metastatic disease. Although White Americans have a two-fold higher incidence of bladder cancer, Black Americans have a higher mortality rate with a higher incidence of high-grade and muscle-invasive tumors.

Risk factors for bladder cancer include the following:

- Tobacco use
- Occupational exposures
- Urinary tract diseases
- Pharmaceutical drug use

Cigarette smoking is strongly associated with an increased risk of bladder cancer among men and women. In the United States, the risk of bladder cancer in former and current smokers compared with the risk in never-smokers has increased over time. Although smoking cessation is associated with a reduced risk of bladder cancer, the risk in comparison with that in never-smokers remains elevated for those who have quit, even after 10 or more years of not smoking. This risk increases in proportion to the amount and duration of cigarette exposure with heavy smokers (>20 cigarettes smoked per day and/or greater than 40 years of smoking), resulting in up to a five-fold higher relative risk compared with nonsmokers.

Occupational exposure to aromatic amines (particularly 2-naphthylamine, benzidine, and polycyclic aromatic hydrocarbons) is associated with an increased incidence of bladder cancer (eg, workers in dyestuff manufacturing and rubber and aluminum industries).

Infection with the trematode *Schistosoma haematobium* leads to chronic irritation of the urothelium and to an increased risk of both squamous and urothelial carcinomas. Other chronic urinary tract infections, including stones and cystitis, may lead to chronic inflammation and to an increased risk of bladder cancer.

Heavy use of phenacetin-containing analgesics is associated with tumors of the renal pelvis and ureter, and cyclophosphamide also has been associated with an increased risk of urothelial carcinoma.

These myriad risk factors lead to field changes within the urothelium that predispose individuals to the development of recurrent tumors as well as to the involvement of new locations in the urothelial tract (polychronotropism). Hereditary nonpolyposis colon cancer syndrome, also known as Lynch syndrome, is associated with an increased risk for the development of bladder and other urothelial cancers, most notably upper-tract tumors. Cowden disease, characterized by *PTEN* mutations (breast and thyroid cancers), is associated with a higher incidence of urothelial carcinoma.

The three general categories of disease (ie, non-muscle-invasive, muscle invasive, and metastatic) differ in tumor biology, clinical phenotype, management, and prognosis, as follows:

- For non-muscle-invasive tumors, the goal is to prevent recurrence and progression to muscle-invasive disease or metastases.
- For muscle-invasive disease, the goal is to maximize the chance for cure using a multimodality approach incorporating systemic therapy with surgery or RT.
- For metastatic disease, the goal is palliation to improve overall quality of life and prolong survival with systemic therapies.

KEY POINTS

- Urothelial carcinoma is predominantly a disease of older men and is most associated with smoking. Additional risk factors include certain occupational exposures, chronic catheters, and chronic bladder infections, including schistosomiasis in endemic areas. Upper-tract (ureteral and renal pelvis) urothelial carcinoma may be associated with Lynch syndrome.
- The entire urothelial tract is at risk from these carcinogenic exposures (field cancerization), so patients with urothelial carcinoma in one area are at risk for separate primaries in other areas and at other times.

PATHOLOGY

Urothelial carcinoma may occur throughout the urinary tract (ie, any structure lined by the urothelium), with more than 90% of tumors originating in the bladder. Upper urinary tract tumors, including the renal pelvis and ureter, account for 5% to 7% of urothelial carcinomas, with renal pelvis tumors constituting the majority. Urothelial carcinomas usually stain positive for uroplakin III, GATA-3, p63, and cytokeratin 7.

Lesions of mixed histology generally are variants of urothelial carcinoma. Such variants include micropapillary, sarcomatoid, rhabdoid, and plasmacytoid differentiation of urothelial cancer and exhibit more aggressive behavior. Tumors with plasmacytoid differentiation may often have lepidic growth (ie, proliferation along tissue planes without invasion), appearing as infiltrative processes on imaging rather than discrete metastatic deposits.

In the United States, 92% of lower urinary tract tumors are urothelial carcinomas, 5% are squamous cell cancers, 2% are adenocarcinomas, and 1% are small-cell carcinomas. High-grade urothelial carcinomas can also be associated with other histological features, such as squamous, glandular, and small-cell or neuroendocrine differentiation. Pure adenocarcinomas may be of urachal origin, occurring at the junction of the urachal ligament and bladder dome. In Northern Africa and the Middle East, where there is a high prevalence of infection with *S. haematobium*, up to 75% of tumors are pure squamous cell carcinomas, although urothelial carcinomas are becoming more prevalent in those regions as well.

KEY POINTS

- Most bladder and ureter cancers are of urothelial (transitional cell) histology. There are several variants of urothelial carcinoma, most of which are treated similarly to pure urothelial carcinoma but may exhibit more aggressive behavior.
- Rare bladder cancers can have pure adenocarcinoma, squamous cell, or small-cell histology. These are generally more aggressive and usually present with advanced disease.

BIOLOGY

Molecular profiling has demonstrated that urothelial tumors evolve through divergent pathways, corresponding to the clinical phenotypes of recurrent non-muscle-invasive lesions, muscle-invasive lesions, and metastatic disease. Although approximately

70% of these low-grade lesions will recur, only 10% to 15% will progress to invasive lesions. The progression of low-grade lesions to invasive disease is characterized by structural and functional alterations in the tumor suppressors *TP53* and *Rb* in addition to chromosome aberrations. Alterations in *TP53* and *Rb* are also frequently seen in high-grade muscle-invasive tumors. Despite radical cystectomy and the use of perioperative chemotherapy, up to 50% of muscle-invasive tumors will progress to local and distant metastases. This ability to invade and metastasize is not only a function of alterations in the tumor cells but also involves the interactions of the tumor cells with the local microenvironment.

However, the role of *TP53* status as a prognostic or predictive biomarker remains limited. A phase 3 study of adjuvant chemotherapy after cystectomy guided by *TP53* status failed to confirm either the prognostic value of *TP53* or the benefit of chemotherapy in *p53*-positive tumors, but it was limited by methodological issues.[111]

Data suggest mutations in DNA damage-repair genes in urothelial cancers may predict response to platinum-based chemotherapy as well as to immune checkpoint inhibitors but generally do not predict benefit from poly-ADP ribose inhibitors.[112] TMB also seems to enrich for responses to immune checkpoint inhibitors.[113,114] Bladder cancer has one of the highest mutational burdens among cancers. Approximately 8% to 20% of patients who have locally advanced or metastatic bladder cancer can have alterations of the fibroblast growth factor receptor (*FGFR*) gene, with their disease associated with the luminal subtype. *FGFR* alterations are more common in non-muscle-invasive disease and upper-tract urothelial cancer. Erdafitinib, an oral FGFR inhibitor, is FDA approved for locally advanced or metastatic urothelial carcinoma with susceptible FGFR3 genetic alterations after at least one line of prior systemic therapy.

DIAGNOSIS AND STAGING

The most common presenting symptom is hematuria. Irritative voiding symptoms, including dysuria in a patient with risk factors such as tobacco use, may be related to carcinoma in situ (CIS) or a bladder tumor. Less frequently, patients present with symptoms related to distant metastases. Urine cytology can help evaluating patients with irritative symptoms (especially heavy smokers).

The diagnosis is established by cystoscopy and biopsy. As of 2011, the US Preventive Services Task Force concluded there was insufficient evidence to make a recommendation on screening for bladder cancer in asymptomatic adults.

The T staging for bladder cancer is as follows:

- Papillary urothelial neoplasms of low malignant potential.
- Ta tumors are noninvasive papillary lesions that tend to recur but not invade.
- Tis, or CIS, is the precursor of a more aggressive and potentially lethal invasive variant.
- T1 tumors invade the subepithelial connective tissue, including lamina propria or muscularis mucosa.
- T2 tumors invade the muscle.
- pT2a tumors invade superficial muscle.
- pT2b tumors invade deep muscle.
- T3 tumors invade the perivesical tissue.
- pT3a are evident microscopically.
- pT3b are evident macroscopically (extravesical mass).
- T4 tumors invade the prostate, seminal vesicles, uterus, vagina, pelvis, and/or abdominal wall.

The major problem with staging is that the correlation of depth of invasion determined by cystoscopy and transurethral resection of bladder tumor (TURBT) with the results of cystectomy is only about 60%. A TURBT specimen is mainly useful for determining the presence or absence of muscle-invasive (T2) disease but cannot give information about more advanced invasion because the urologist must avoid bladder perforation during the procedure. Muscularis propria must be present in the TURBT specimen; if it is not, then a repeated TURBT is recommended, balancing the risk of understaging with the risk of bladder perforation in aggressive TURBT. Noninvasive imaging with CT or MRI can identify extravesical or nodal disease and is more reliable if done before the transurethral resection with a distended bladder; immediately after TURBT, local adenopathy may be inflammatory. Fluorodeoxyglucose (FDG) PET/CT imaging may have a role in the staging of muscle-invasive disease and in the detection of metastatic bladder cancer,[113] but the urinary excretion of FDG limits its usefulness in local staging, and it may actually be inferior to CT for the detection of pathological presacral nodes.[115] The histological grading system of low grade and high grade is more relevant for non-muscle-invasive tumors; all muscle-invasive neoplasms are high grade.

UROTHELIAL CANCERS IN BLADDER DIVERTICULA

Urothelial cancers arising in bladder diverticula, although uncommon, pose diagnostic and therapeutic challenges. Because of the limited presence of a muscularis propria layer, bladder perforation is a potential complication if a transurethral resection is contemplated. The traditional pathological stage T2 is often eliminated, and the cancer is staged clinically as Ta, Tis, T1, or

T3, indicating extradiverticular extension. A conservative approach for disease without extradiverticular extension has been recommended and includes diverticulectomy or, in lesions that are anatomically amenable, partial cystectomy. Partial or radical cystectomy is often recommended for extradiverticular extension.

KEY POINTS

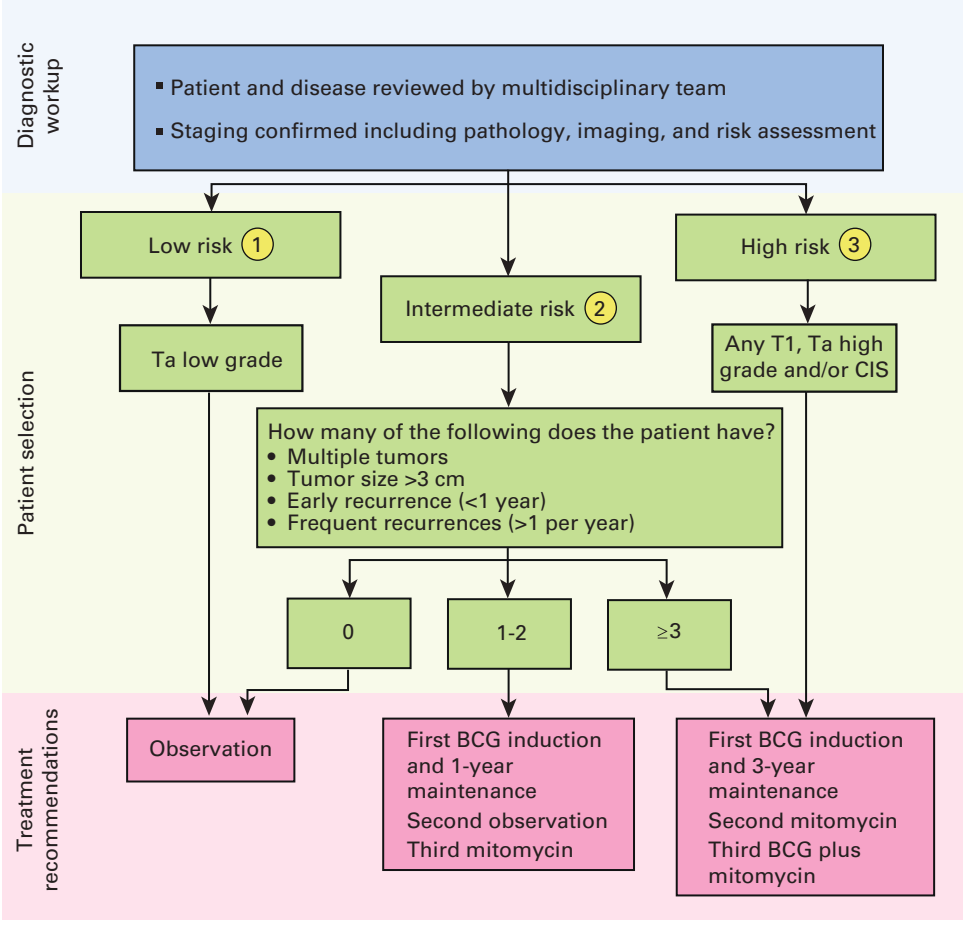
- Bladder cancer may present as painless hematuria or irritative urinary symptoms, and it is typically diagnosed via TURBT.
- Based on TURBT pathology, bladder cancer is broadly divided into non-muscle-invasive tumors and muscle-invasive tumors. Muscularis propria must be present in the TURBT specimen to enable this assessment; otherwise, a repeat TURBT is recommended.

THERAPY FOR NMIBC

The following section is specifically provided to the medical oncologist to enhance the understanding of the management issues that patients face with the diagnosis of NMIBC because most medical oncologists may not actively treat these patients until muscle-invasive disease is detected.

Up to 80% of patients with newly diagnosed bladder cancer present with non-muscle-invasive disease (which includes papillary urothelial neoplasm of low malignant potential, CIS, and low- and high-grade urothelial cancers) with 70% confined to the

Figure 14-12 Treatment Algorithm for Non-Muscle-Invasive Bladder Cancer



All of the treatment options shown may be appropriate. The selection of therapy should be individualized based on patient eligibility and the availability of the therapy at the discretion of the treating physician. These algorithms are meant to provide advice as the consensus recommendations of the Task Force. (1) The Task Force defines low risk as a solitary, primary low-grade Ta tumor. (2) Intermediate risk is defined as histologically confirmed multiple and/or recurrent low-grade Ta tumors. (3) High risk is defined as any T1, high grade, and/or carcinoma in situ.
Abbreviations: BCG, Bacillus Calmette-Guerin; CIS, carcinoma in situ.

mucosa (Ta or Tis) and 30% involving the submucosa (T1). Patients initially will be diagnosed by positive urinary cytology or after an evaluation for hematuria or dysuria. The initial evaluation is via flexible cystoscopy performed during an office visit to allow the urologist to systematically evaluate the entire urothelial surface and identify abnormal and erythematous areas. This procedure is then followed by a formal TURBT as well as random bladder biopsies in areas that do not look abnormal to the urologist on visual inspection. The urologist may use imaging techniques such as blue light fluorescent cystoscopy or narrow band imaging to enhance the identification of bladder lesions. This imaging is performed under general or spinal anesthesia and enables bladder resection, including muscle specimens to be obtained, random biopsies of both normal and erythematous-appearing areas, prostatic urethral evaluation, and assessment for determination of the need for upper-tract evaluations. Patients receive constant bladder irrigation after this procedure and are discharged home with a catheter for approximately 1 week. The determination of the presence or absence of muscle-invasive disease is made by pathologists and requires the presence of muscle in the biopsy specimen to enable accurate assessment. For non-muscle-invasive disease, an assessment of risk is performed on the basis of clinical and pathological features. American Urological Association guidelines suggest a treatment algorithm according to this risk assessment (Fig. 14-12).

A single dose of intravesical chemotherapy (mitomycin C or epirubicin) within 24 hours of TURBT may decrease tumor recurrence, and this is recommended for patients with suspected or known low- or intermediate-risk bladder cancer (unless there was extensive resection or suspected perforation). The greatest effect seems to be in patients with single small low-grade tumors, and the risk of recurrence may be decreased even when additional adjuvant intravesical therapy is administered.

Low-risk disease includes small (≤3 cm) solitary low-grade Ta lesions without CIS. Treatment typically involves a single dose of intravesical therapy just after the resection.

High-risk lesions include CIS, high-grade lesions, T1 lesions, or large (larger than 3 cm) or multiple lesions. Intermediate risk is any lesion not meeting low- or high-risk criteria. Very high-risk disease is defined as large or multiple T1 high-grade lesions, co-occurring T1 high-grade lesions with CIS or involving the prostatic urethra, or micropapillary histology. This may require early consideration of cystectomy rather than intravesical therapy.

The diagnosis of intermediate- or high-risk disease at the time of TURBT is then followed (usually within 4 weeks) with the so-called induction course of intravesical *Bacillus* Calmette-Guerin (BCG). This consists of 6 weekly instillations of BCG vaccine (alone or with the addition of intravesical interferon [IFN]). A repeated TURBT, again obtaining specimens involving muscularis propria, is then performed approximately 4 weeks after, during which biopsy specimens are collected again from the previously identified lesions along with repeated urinary cytology.

Patients in whom a complete remission is achieved (ie, negative cytological results and no evidence of residual cancer in the biopsy specimens of previous disease) may begin a 3-year program of maintenance BCG therapy. The first such treatment starts approximately 3 months after the second TURBT and then every 6 months thereafter. In contrast to the induction program, maintenance treatments are administered weekly for 3 weeks. Approximately 1 month after each maintenance program, repeated cytology and office cystoscopies are performed for continued surveillance. The maintenance program continues for 3 years if possible. Unfortunately, both the local and systemic adverse effects of intravesical BCG (with or without IFN) are significant, such that nearly 75% of patients are unable to tolerate or complete the entire program.

Regarding the management of noninvasive bladder cancer with intravesical BCG, it is not uncommon for relapse to occur at the ureteral orifices, ureter, or urethral areas that are less accessible for intravesical treatment. As such, monitoring must include periodic evaluations of the remaining urothelium with cytology and imaging to ensure relapses or new primary tumors are identified and treated when diagnosed.

Potential adverse effects of intravesical BCG include the following:

- Cystitis, including urinary frequency, dysuria, hematuria, and/or fever
- Systemic complications, including arthralgia, osteomyelitis, sepsis, and multiorgan dysfunction resulting from granulomatous involvement.

Patients who do not achieve a complete response (CR) after induction BCG and second TURBT may be considered BCG unresponsive. If muscle-invasive disease is detected, definitive bladder-directed therapy is considered. In those with persistent but non-muscle-invasive disease, cystectomy is standard treatment for patients with high-grade disease, but a second induction course of BCG or other bladder-sparing therapies can also be considered. Second-line intravesical therapies include gemcitabine, docetaxel, valrubicin, or other investigational agents. The combination of intravesical gemcitabine and docetaxel resulted in 46% recurrence-free survival in a retrospective study.[110]

There have been several approvals for novel intravesical therapies in recent years, broadening treatment options for patients with BCG-refractory NMIBC, described below.

- In December 2022, intravesical nadofaragene firadenovec-vncg, a nonreplicating adenoviral vector with a gene copy of IFN alfa-2b, was approved by the FDA to treat patients with BCG unresponsive NMIBC with CIS. This was based on the results of

a large phase 3 clinical study with 157 subjects. Nearly 53.4% of patients had a CR with a median duration of response of 9.7 months with treatment once every 3 months for 12 months or until treatment intolerance. Bladder spasms, discharge, fatigue, and fever with chills were the most common side effects.[116]

- In April 2024, Nogapendekin alfa inbakicept-pmln, an IL-15 superagonist, with BCG in combination, was FDA approved for patients with BCG-unresponsive NMIBC with CIS with or without papillary tumors. This was based on a single-arm, multicenter trial of 82 patients receiving the intravesical combination once weekly for 6 weeks as induction, followed by a shorter course every 3 months. The CR rate was 62% and 58% of patients with a CR had a duration of response over 12 months and 40% over 24 months.[117]

In September 2025, the TAR-200 device, an intravesical system for slow gemcitabine delivery, was FDA approved for patients with BCG-unresponsive NMIBC with CIS with or without papillary tumors. This was based on a single-arm multicenter trial of 83 patients receiving the intravesical system every 3 weeks for 6 months, followed by a maintenance insertion every 12 weeks up to 18 months.[5] The CR rate was 82%, and 51% of patients with a CR had a duration of response over 12 months.

Systemic therapy with intravenous pembrolizumab is also a treatment option for patients with BCG-unresponsive NMIBC. In cohort A of the single-arm phase 2 trial KEYNOTE-057, patients receiving pembrolizumab 200 mg IV every 3 weeks demonstrated a 41% CR rate at 3 months with a median duration of response of 16.2 months.[118] The risk of immune-related adverse effects with pembrolizumab (including those that are life-threatening) should be considered when discussing this option with the patient, given that only <10% of patients in this study maintained a complete response for more than 24 months.[119]

KEY POINTS

- NMIBC is stratified according to risk of recurrence.
- For low-risk tumors, surveillance (cystoscopy and urine cytology) is most appropriate.
- For intermediate- and high-risk tumors, intravesical BCG decreases the risk of recurrence, and surveillance is also crucial. Definitive bladder therapy (cystectomy) is considered in situations of very high-risk non-muscle-invasive tumors or BCG-refractory tumors.
- Intravenous pembrolizumab is currently an FDA-approved treatment option for patients with BCG-unresponsive NMIBC, in addition to several novel intravesical immune-based therapies.

UROTHELIAL CARCINOMA IN PROSTATE URETHRA AND PROSTATE GLAND

The diagnosis of carcinoma or CIS of the prostatic urethra poses diagnostic and therapeutic challenges. Increased morbidity follows resection of the prostatic urethra; however, it is important for appropriate staging. In addition, it is more challenging to treat the prostatic urethra with intravesical therapies because these are administered via Foley catheter, essentially bypassing exposure of the drug to the prostatic urethra. Patients may undergo a transurethral resection of the prostate with the expectation that more accurate staging may result, and the prostate will be exposed to optimal concentrations of BCG. If prostatic stromal invasion is found, surgical management would include cystoprostatectomy.

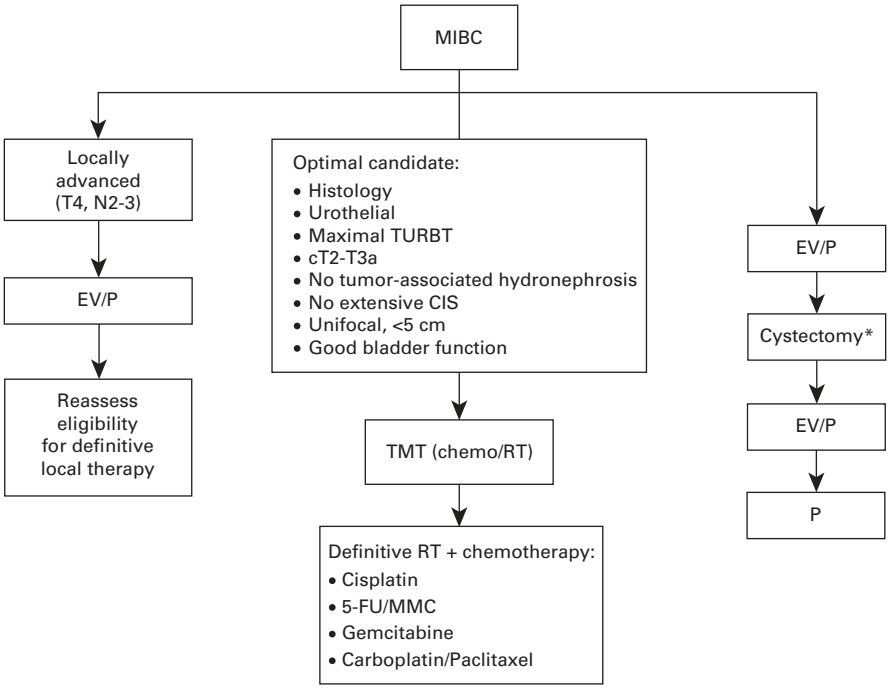
TREATMENT OF MUSCLE-INVASIVE BLADDER CANCER

Although most patients present with non-muscle-invasive disease, approximately 20% to 40% of patients either present with more advanced disease or experience disease progression after therapy for non-muscle-invasive disease (Fig. 14-13).[107] Staging for patients with muscle-invasive disease includes a CT scan of the abdomen and pelvis, chest imaging (CT preferred), and, if clinically indicated, a bone scan. FDG PET can be used to evaluate distant metastases, but because FDG is excreted through the urinary tract, FDG PET is less helpful for evaluating bladder masses, local extension, and local nodal involvement.[120,121]

Cystectomy

The standard treatment of a muscle-invasive bladder cancer (MIBC) is a radical cystectomy with bilateral pelvic lymphadenectomy that includes removal of the bladder, prostate, seminal vesicles, and proximal urethra for men and removal of the bladder, urethra, and uterus (including bilateral salpingo-oophorectomy) as well as possible excision of a portion of the anterior vaginal wall for women. Pelvic lymph node dissection is a necessary part of the radical cystectomy surgery, with a more extended lymph node dissection associated with an improvement in outcome. The three main types of urinary diversions include an ileal conduit that drains to an appliance on the anterior abdominal wall, a continent cutaneous reservoir constructed from detubularized bowel segments, and an orthotopic neobladder. More men are candidates for continent urethral reservoirs than women because of anatomic considerations. It is not clear that continent reconstruction after radical cystectomy is associated with an improvement in quality of life as compared with conduit diversion. In fact, most patients report a favorable quality of life regardless of the type of diversion used. Of note, urinary diversion may result in hypokalemic hyperchloremic metabolic acidosis due to

Figure 14-13 Treatment Options for Muscle-Invasive Bladder Cancer



Abbreviations: 5-FU, 5-fluorouracil; CIS, carcinoma in situ; ddMVAC, dose-dense methotrexate/vinblastine/doxorubicin/cisplatin; EV/P, enfortumab vedotin and pembrolizumab; GC, gemcitabine/cisplatin; MMC, mitomycin C; P, pembrolizumab; RT, radiation therapy; TMT, trimodality therapy; TURBT, transurethral resection of bladder tumor.
*If N + disease is established or suspected before scheduled radical cystectomy, and the patient has not received neoadjuvant therapy, radical cystectomy plus pelvic lymphadenectomy is still a treatment option. There is no level I evidence for adjuvant chemotherapy in the post-cystectomy node-positive setting, but many clinicians would consider its use based on results of the Advanced Bladder Cancer Collaborative meta-analysis.

reabsorption of urinary solutes by the intestinal segment, and use of ileum for a conduit may result in malabsorption of vitamin B_{12}, requiring parenteral supplementation.

Prognosis varies inversely with higher T stage, lymphatic or vascular invasion in the primary tumor, and lymph node involvement. Approximately two-thirds of patients remain recurrence-free after cystectomy with long-term follow-up, but prognosis worsens with non–organ-confined disease and/or nodal involvement. Multivariate nomograms have been developed to predict outcome after radical cystectomy. A partial cystectomy can provide adequate local control of invasive bladder cancer in highly selected patients (eg, solitary tumor with no evidence of CIS on random biopsies). Less invasive surgical techniques, including laparoscopic and robotic radical cystectomy, have been evaluated, and robot-assisted techniques may be similar to standard open surgery in terms of operative, pathologic, oncologic, complication, and most functional outcomes. The use of bladder-sparing protocols as alternatives to surgery in the management of MIBC is reviewed in the "Bladder Preservation" section.

Perioperative Chemotherapy

The use of perioperative chemotherapy in the management of invasive and locally advanced bladder cancer has been studied in the neoadjuvant and adjuvant settings. Neoadjuvant cisplatin-based chemotherapy is the standard of care for cisplatin-eligible patients. The potential advantages of neoadjuvant chemotherapy include evaluation of response to therapy in vivo with assessment of the pathological response in the cystectomy specimen, tumor downstaging to allow for a less complicated surgery, and delivery of full-dose chemotherapy without the potential problems associated with postoperative recovery. The major advantages of the use of adjuvant chemotherapy include treatment based on an exact pathological staging with the ability to select those patients at higher risk who are most likely to benefit from chemotherapy and to avoid the unnecessary treatment of patients with lower-risk disease.

Platinum Eligibility

Cisplatin is the backbone of perioperative and palliative chemotherapy regimens. However, medical comorbidities, especially renal dysfunction, may pose a challenge to treating with cisplatin-based therapy. Cisplatin ineligibility has been defined by expert consensus[122] as patients with any of the following:

- World Health Organization (WHO) or Eastern Cooperative Oncology Group performance status 2 or higher
- Estimated creatinine clearance <60 mL per minute
- Audiometric hearing loss—grade 2 or higher by the Common Terminology Criteria for Adverse Events version 4 (CTCAE v4.0)
- Peripheral neuropathy—grade 2 or higher by CTCAE v4.0
- New York Heart Association class III heart failure

However, these criteria are not based on prospective data. Renal impairment poses a particular problem because 30% to 50% of patients undergoing radical cystectomy have an estimated creatinine clearance below the threshold of 60 mL per minute,[123] meaning that the standard of care would not be offered to almost half of all patients. In addition, different equations for estimating creatinine clearance or glomerular filtration rate may result in different estimates, and the commonly used Cockroft-Gault equation, in particular, may result in lower estimates of renal function than alternative equations. A 24-hour creatinine clearance may provide a more accurate estimate of renal function in patients with borderline renal function. Second, cisplatin-based therapy may be feasible in patients with borderline renal function, as shown in observational studies, and some clinicians will use split-dose cisplatin regimens. In addition, the risk of cisplatin nephrotoxicity may be related to factors other than calculated creatinine clearance, including albumin and performance status, so these should be taken into account.[4]

Indeed, reflecting current practices, modern clinical trials are now beginning to tolerate lower creatinine clearance boundaries for cisplatin[4] eligibility—in the NIAGARA study, a study of perioperative durvalumab and neoadjuvant chemotherapy (as further discussed below), nearly 20% of patients enrolled had creatinine clearance in the range of 40 to 60 mL/min/1.73 m^2, allowing cisplatin to be given in a split-dosing strategy. This strategy was found to be safe with no perceived compromise on treatment efficacy.

Regarding the use of carboplatin, retrospective and prospective studies have evaluated carboplatin-based regimens in the neoadjuvant setting for cisplatin-ineligible patients with inferior complete response rates and OS.[124] Because of this, patients considered "cisplatin-ineligible and cystectomy eligible" should be referred for upfront cystectomy followed by adjuvant immunotherapy or consider trimodality therapy, as described below. The greater uptake of the split-dosing cisplatin strategy for patients with CrCl 40-60 will, in turn, lead to fewer patients considered "cis-ineligible."

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy is the standard of care for patients with MIBC who are eligible for both cystectomy and cisplatin-based therapy (Table 14-3). A US phase 3 Intergroup trial randomly assigned patients with T2-4aN0M0 bladder cancer to neoadjuvant methotrexate/vinblastine/doxorubicin/cisplatin (MVAC) and cystectomy (n = 5,153 patients) or to cystectomy alone (n = 5,154 patients).[125] Median survival of patients assigned to surgery alone was 46 months compared with 77 months among patients assigned to MVAC and cystectomy. The survival benefit of neoadjuvant MVAC was associated with tumor downstaging to pT0 (38% in those patients who received MVAC compared with 15% of those who received cystectomy), with an 85% 5-year survival for patients who experienced a pathological CR to neoadjuvant chemotherapy. A meta-analysis of neoadjuvant chemotherapy showed a significant OS benefit for platinum-based combination chemotherapy with a 14% reduction in the risk of death and 5% absolute survival benefit at 5 years (OS increasing from 45% to 50%). This effect did not vary between subgroups of patients or the type of local treatment.

Table 14-3 Standard Neoadjuvant Chemotherapy Regimens

Classic MVAC (28-Day Cycle)	Dose-Dense MVAC (14-Day Cycle)	Gemcitabine and Cisplatin
Methotrexate on days 1, 15, and 22	Methotrexate on day 1	21-day regimen
Vinblastine on days 2, 15, and 22	Vinblastine on day 2	Cisplatin on day 1 or 2
Doxorubicin on day 2	Doxorubicin on day 2	Gemcitabine on days 1 and 8
Cisplatin on day 2	Cisplatin on day 2	28-day regimen:
	G-CSF on days 4-10 or pegylated	Cisplatin on day 1 or 2
	G-CSF after chemotherapy	Gemcitabine on days 1, 8, and 15

Abbreviations: G-CSF, granulocyte colony-stimulating factor; MVAC, methotrexate/vinblastine/doxorubicin/cisplatin.
For classic MVAC and dose-dense MVAC, all four chemotherapy agents (methotrexate, vinblastine, doxorubicin, and cisplatin) may be given together on day 1.

Two single-arm, phase 2 studies using dose-dense MVAC (ddMVAC) with pegfilgrastim support demonstrated promising pathological response rates in patients with cT2-cT4a N0-1 M0 MIBC,[126,127] with much less myelotoxicity than seen with the classic MVAC regimen. In addition, the dose-dense regimens reduced the time needed to deliver neoadjuvant chemotherapy before definitive surgery.

The combination of GC is frequently used instead of MVAC; an extrapolation of evidence in the metastatic setting shows that GC offers equivalent response rates and less toxicity compared with classic MVAC.[126] In the randomized phase 2 clinical trial SWOG 1314, CR rates were seen in 30% patients receiving GC and 28% patients receiving dose-dense MVAC, and downstaging was achieved in 47% and 40%, respectively.[128]

The phase III VESPER clinical study compared the perioperative use of six cycles of ddMVAC every 2 weeks to four cycles of gemcitabine with cisplatin (GC) every 3 weeks.[129] Patients received neoadjuvant or adjuvant chemotherapy. Fewer patients completed all six cycles of ddMVAC compared with all four cycles of GC (60% vs 84%). The 3-year PFS in the intention-to-treat (ITT) population was 64% in the ddMVAC arm compared with 56% for GC but did not meet statistical significance. The 5-year follow-up reported no significant difference in OS in the ITT population.[130] However, OS was improved in the neoadjuvant ddMVAC group versus neoadjuvant GC group (66% vs 57%; HR, 0.71 [95% CI, 0.52-0.97]), and time to death because of bladder cancer was also improved in the ddMVAC group (27% vs 40%; HR, 0.61 [95% CI, 0.45-0.84]). More patients in the ddMVAC group achieved an equivalence of four cycles of cisplatin in comparison with patients in the GC group, suggesting the importance of optimal cisplatin dosing.[4] Thus, in patients eligible for anthracyclines, ddMVAC may be preferable to GC, although it may be reasonable to aim for four cycles rather than six.

The NIAGARA trial recently tested neoadjuvant GC with or without the addition of durvalumab as perioperative (neoadjuvant and adjuvant) therapy, showing an improvement in event-free survival and OS. This treatment led to the FDA approval for durvalumab in this setting, but unfortunately, many questions remain. Given that this trial was primarily conducted before the availability of adjuvant PD-1 inhibitors as standard of care (see below), it is unclear whether the strategy of adding durvalumab before and after cystectomy in all MIBC patients is superior to using adjuvant PD-1 inhibitors in a risk-adapted manner in the adjuvant setting for those patients with suboptimal pathological response to chemotherapy alone. The forthcoming results of EV-302 and EV-303 may make these questions less relevant if the combination of enfortumab vedotin and pembrolizumab ends up supplanting cisplatin-based chemotherapy (see further discussion of enfortumab vedotin and pembrolizumab in the advanced systemic therapy section below).[4]

When selecting a strategy of perioperative systemic therapy, the provider must now determine whether a "sandwich" approach with immunotherapy will be used (ie, using perioperative durvalumab with cisplatin-based chemotherapy in the neoadjuvant setting followed by adjuvant durvalumab) or if a traditional risk-adapted approach will be used (ie, forgoing the addition of neoadjuvant immunotherapy and considering the addition in the adjuvant setting, as further discussed below). NCCN guidelines currently endorse either approach as a category 1 recommendation.

In late 2025, the combination of enfortumab vedotin and pembrolizumab (EVP), the current preferred first-line treatment of advanced urothelial cancer, was FDA approved for perioperative therapy in patients who are deemed ineligible for cisplatin but eligible for cystectomy. This approval was on the basis of the phase 3 KEYNOTE-905/EV-303 study,[6] presented at ESMO 2025, which demonstrated that perioperative EVP significantly improved event-free survival (HR 0.40; 95% CI 0.28-0.57; $P < .001$), OS (not reached vs. 41.7 months, HR 0.50; 95% CI 0.33-0.74; $P < .001$), pathological complete response (pCR) rate (57.1% vs 8.6%). This pCR is significantly higher than previous studies, even with platinum-based chemotherapy.

The phase 3 KEYNOTE-B15/EV-304 study is currently ongoing and is investigating the efficacy of EVP in comparison to standard cisplatin-based chemotherapy in the perioperative setting for cisplatin-eligible patients. These are landmark studies that are expected to change the standard of care for patients with MIBC.

Some neoadjuvant trials described above included patients with cN1 disease, but optimal management of these patients and those with more extensive nodal involvement is not well defined. Based on the results of EV-304 described below, it is reasonable to apply the best available systemic therapy with a combination of enfortumab vedotin and pembrolizumab in this setting, especially for those with disease deemed unresectable, and then consider consolidative local therapy in those with good radiographic response.

Adjuvant Systemic Therapy

For patients who have not received neoadjuvant chemotherapy and have nodal involvement or extravesical tumor extension on surgical pathology, many physicians favor the use of adjuvant chemotherapy. However, definitive trials are lacking, with most of the completed adjuvant studies harboring major limitations, including suboptimal statistical methodology as a result of underpowered trials and early termination, as well as the use of older chemotherapy programs that did not include cisplatin. In addition, cystectomy is a major surgery entailing substantial postoperative recovery for many patients. These circumstances may limit or delay the ability to deliver adjuvant chemotherapy in a timely manner.

The largest adjuvant chemotherapy phase 3 study published to date, EORTC 30994, randomly assigned patients with pT3-pT4 or N1 M0 bladder cancer after radical cystectomy to immediate chemotherapy (four cycles of GC, dose-dense MVAC, or classic MVAC) compared with six cycles of chemotherapy at relapse.[131] The trial was closed after recruitment of only 284 of 660 planned patients. Although no significant improvement in OS with immediate treatment compared with deferred treatment was observed, median PFS was prolonged from 0.99 to 3.11 years with the addition of adjuvant chemotherapy. Several meta-analyses

have concluded there is an OS benefit with adjuvant chemotherapy, but the validity of the meta-analyses is clearly limited by the flawed trials from which the analyses are derived. In sum, adjuvant chemotherapy may be offered to high-risk patients who have not received neoadjuvant chemotherapy with the caveat that prospective evidence is lacking.

As in the neoadjuvant setting, patients who are not eligible for cisplatin are generally not treated with adjuvant chemotherapy. Randomized trials of adjuvant immune checkpoint inhibitors have reported some evidence of efficacy. In the large phase 3 clinical study CheckMate-274, patients with T3-T4a or N1 bladder cancer without cisplatin-based neoadjuvant chemotherapy or residual T2-T4a or N1 bladder cancer after cisplatin-based neoadjuvant chemotherapy were randomly assigned to adjuvant nivolumab versus placebo for 1 year.[132] At median follow-up of 3 years, median DFS was significantly longer in the nivolumab-treated group versus the placebo group (22.0 vs 10.9 months, HR, 0.71 [95% CI, 0.58-0.86]), At this interim analysis, median OS was longer in the nivolumab group compared with placebo (69.5 vs 50.1 months; HR, 0.76 [95% CI, 0.61-0.96]). Although OS benefit was observed for both the ITT and PD-L1 over 1% group (about 40% of the total population), at the time of this interim analysis, median OS had yet to be reached in the PD-L1 over 1% group.[132]

Based on these results, adjuvant nivolumab is FDA approved to treat high-risk MIBC post-cystectomy.[107] Similarly, the AMBASSADOR trial of adjuvant pembrolizumab reported DFS benefit in a high-risk MIBC population post-cystectomy, whereas OS was not different at interim analysis.[133] Finally, the IMvigor010 trial did not show a DFS benefit with adjuvant atezolizumab versus observation,[134] although patients with post-cystectomy detectable circulating tumor DNA did seem to benefit.[134,135] Given the trial findings described above, the role of PD-L1 testing to assist with decision-making for adjuvant immunotherapy is not routinely performed.

In sum, patients who are eligible for neoadjuvant cisplatin-based therapy should still receive this. In patients who did not receive neoadjuvant chemotherapy but are eligible and who have adverse pathological characteristics, adjuvant cisplatin-based treatment is reasonable. If patients received neoadjuvant chemotherapy and still have adverse pathological characteristics or if they did not receive perioperative chemotherapy, then adjuvant nivolumab should be considered.

Bladder Preservation

Although neoadjuvant chemotherapy leads to CRs in a subset of patients (30%-40%), radical cystectomy is currently recommended for all patients with muscle-invasive disease to evaluate and confirm pathological responses and remove any residual disease. The role of chemotherapy alone in bladder preservation is problematic because of the inability to definitively determine which bladders are truly without residual tumors. Chemotherapy alone cannot replace definitive treatment of the bladder by surgery or RT.

Radical cystectomy following neoadjuvant chemotherapy remains a standard of care for MIBC. Many patients are either ineligible for cystectomy, based on medical comorbidities, or prefer a bladder-sparing approach. For select patients with small solitary tumors, partial cystectomy may be considered.

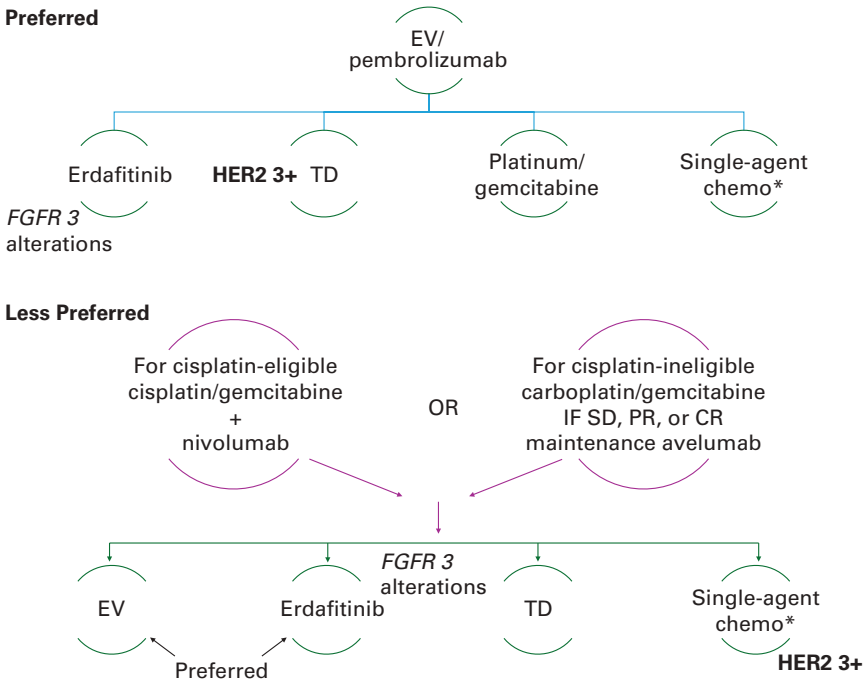
For appropriately selected patients, a trimodality treatment consisting of maximal transurethral resection (as complete as safely possible) followed by definitive RT and radiosensitizing chemotherapy has resulted in long-term DFS and OS rates approaching those seen in radical cystectomy series (Fig. 14-14). Trimodality treatment is now included as a category 1 recommendation in the NCCN guidelines alongside cystectomy.[136] Optimal patients for trimodality therapy include the following:

- Unifocal urothelial carcinoma <5 cm
- Visibly complete TURBT
- No extensive CIS
- No T4 disease or tumor-associated hydronephrosis
- Good bladder function and capacity.

An analysis of long-term outcomes of selective bladder preservation in 348 patients at the Massachusetts General Hospital from 1986 to 2013 demonstrated 5-year disease-specific survival and OS rates of 64% and 52%, respectively, with preservation of the bladder in more than 70% of patients.[137] In the years 2005 to 2013, 5-year DFS and OS improved to 88% and 84%, respectively.

The optimal radiosensitizing regimen is unclear. Current NCCN guidelines endorse cisplatin alone, low-dose gemcitabine, or 5-FU with mitomycin as preferred options. A majority of trimodality protocols have used cisplatin-based chemotherapy (typically weekly cisplatin monotherapy); however, other agents, such as paclitaxel and gemcitabine, have been used as well. In the largest randomized study to compare chemoradiation therapy using fluorouracil and mitomycin with RT alone in MIBC, the chemoradiation therapy arm was associated with an improvement in 2-year locoregional DFS from 54% to 67%.[138] It is unknown which radiosensitizing chemotherapy is optimal and whether induction therapy with standard systemic doses of chemotherapy (eg, GC) before chemoradiation therapy is beneficial. Many bladder-sparing protocols include an early evaluation of response to treatment with cystoscopy after RT; patients who show less than a CR may go on to consider salvage cystectomy.

Figure 14-14 Systemic Therapy for Advanced Urothelial Cancer



*In cases of progression after prior treatments.
Abbreviations: CR, complete response; EV, enfortumab vedotin; *FGFR*, fibroblast growth factor receptor; PR, partial response; SD, stable disease; TD, trastuzumab deruxtecan.

Quality of life is another important consideration. Radiation therapy can induce disturbances in the function of the bladder, anal sphincter, and large bowel. The morbidity of RT has decreased with imaging and radiation advances, allowing for a boost to the primary tumor and a reduction in fraction size. An evaluation of late pelvic toxicity after bladder-sparing therapy in patients with invasive bladder cancer who received treatment in four prospective Radiation Therapy Oncology Group protocols showed low rates of substantial late pelvic toxicity (7% of patients with late grade 3 or higher pelvic toxicity: genitourinary, 5.7%; gastrointestinal, 1.9%) at a median follow-up of 5.4 years. The disadvantages of bladder preservation are the requirement for lifelong cystoscopy surveillance as a result of the risk of intrabladder recurrence and the surgical and post-surgical challenges of post-radiation salvage cystectomy if needed. Nonetheless, many of these new or recurrent tumors are noninvasive and can be treated endoscopically with or without intravesical therapies.

KEY POINTS

- The most established standard of care for MIBC is neoadjuvant cisplatin-based chemotherapy followed by radical cystectomy and lymph node dissection. The optimal neoadjuvant chemotherapy regimens are GC and dose-dense MVAC. The addition of durvalumab in the perioperative setting to chemotherapy is now an approved option.
- For cisplatin-ineligible patients undergoing cystectomy, perioperative EVP is now an FDA-approved option. For those ineligible for EVP, no other perioperative chemotherapy is currently recommended, and carboplatin should not be substituted for cisplatin. Recent data suggest good safety and efficacy of a cisplatin split-dosing strategy for those with CrCl 40 to 60 mL/min; thus, cisplatin should be considered for this population.
- Adjuvant nivolumab or pembrolizumab immunotherapy for 1 year significantly improves DFS in patients with high-risk MIBC and is FDA approved for this indication.
- Maximal transurethral resection of the bladder tumor followed by concurrent definitive RT with radiosensitizing chemotherapy, also known as bladder-sparing or trimodality therapy, may offer similar long-term disease control for appropriately selected patients. Historically, this has been considered only for patients ineligible for or declining cystectomy, but based on nonrandomized data, it is now considered a reasonable alternative to cystectomy in all eligible patients.

THERAPY FOR METASTATIC BLADDER CANCER

FIRST-LINE THERAPY

Patients may develop either de novo metastatic bladder cancer or metastatic recurrence after prior therapy for localized disease. Gemcitabine and cisplatin have been the most commonly used first-line therapies for metastatic bladder cancer for many years, with de novo metastatic disease or recurrence more than 1 year following prior neoadjuvant therapy, but recent randomized clinical trials are changing the treatment paradigm. Gemcitabine and cisplatin have been the preferred therapies for cisplatin-eligible patients based on a phase 3 study of GC versus MVAC demonstrating similar response rates (approximately 50%) and median OS of approximately 14 to 15 months but less toxicity with GC.[126]

More recently, enfortumab vedotin (Nectin-4 targeting antibody-drug conjugate with a monomethyl auristatin E payload) with pembrolizumab showed significantly improved OS (HR, 0.47; median OS 31.5 vs 16.1 months), PFS (HR, 0.45; median PFS 12.5 vs 6.3 months), and objective response rates (67.7% vs 44.4%) as compared with gemcitabine and cisplatin or carboplatin in the randomized phase 3 EV-302 trial.[139] All patient subgroups analyzed appeared to benefit regardless of PD-L1 expression, cisplatin-eligibility, or primary site of disease (upper tract or lower tract). The marked efficacy benefits in EV-302 led to regulatory approval of enfortumab vedotin and pembrolizumab as first-line therapy for patients with locally advanced or metastatic urothelial cancer in late 2023. Common treatment-related adverse events in patients receiving enfortumab vedotin and pembrolizumab include peripheral sensory neuropathy, pruritus, alopecia, rash, fatigue, diarrhea, decreased appetite, nausea, cytopenias, dry eye, and hyperglycemia.

Around the same time, the randomized phase 3 CheckMate 901 trial showed the addition of nivolumab to gemcitabine and cisplatin significantly improved OS (HR, 0.78; median 21.7 vs 18.9 months), PFS (HR, 0.72; median 7.9 vs 7.6 months), and ORR (57.6% vs 43.1%).[140] This led to FDA approval of nivolumab in combination with cisplatin and gemcitabine for first-line treatment of unresectable or metastatic urothelial carcinoma. Based on the totality of the data and magnitude of benefit seen in EV-302, enfortumab vedotin and pembrolizumab are the preferred first-line therapies for most patients with locally advanced or metastatic urothelial bladder cancer, although no direct comparisons are available with the combination of nivolumab, gemcitabine, and cisplatin.

For patients who are not candidates for immunotherapy, gemcitabine and platinum remain standard-of-care first-line systemic therapies. Cisplatin is preferred for cisplatin-eligible patients because multiple phase 2 trials have suggested an improvement in outcome with cisplatin-based compared with carboplatin-based chemotherapy. However, in contrast to neoadjuvant therapy, it is acceptable in the metastatic setting to substitute carboplatin for patients with renal impairment that precludes cisplatin treatment. For patients who had stable disease or response following four to six cycles of gemcitabine and platinum, maintenance avelumab should be considered based on data from the phase 3 JAVELIN Bladder 100 study.[141] At a planned interim analysis, there was a significant OS benefit with maintenance avelumab regardless of PD-L1 status. This led to FDA approval for avelumab as maintenance therapy following gemcitabine and cisplatin. However, with the recent positive data with both enfortumab vedotin with pembrolizumab and nivolumab, gemcitabine, and cisplatin combinations, patients who are eligible for immunotherapy should start it in the upfront first-line setting.

SECOND- AND SUBSEQUENT-LINE THERAPIES

With the recent improvements in first-line treatment options, there is a lack of data to guide the optimal second- and subsequent-line therapies. Decisions on subsequent treatments will depend on the first-line therapy administered (Fig. 14-14). Options include platinum with gemcitabine (for patients who received first-line enfortumab vedotin and pembrolizumab), enfortumab vedotin monotherapy (for patients who received first-line platinum and gemcitabine with nivolumab or maintenance avelumab), erdafitinib (for tumors with susceptible FGFR3 alterations), trastuzumab deruxtecan (for HER2 IHC3-positive tumors), and single-agent chemotherapies (eg, pemetrexed, paclitaxel). Sacituzumab govitecan, an antibody-drug conjugate directed against Trop-2, had previously been granted accelerated approval in this space, but this indication was withdrawn after the confirmatory phase 3 trial failed to demonstrate an OS benefit relative to the physician's choice of single-agent chemotherapy, as well as increased toxicity, primarily neutropenic infections.

Erdafitinib is a tyrosine kinase inhibitor (TKI) of FGFR. FGFR genetic alterations are seen in approximately 20% of patients with advanced or metastatic urothelial carcinoma, with many acting as oncogenic driver mutations or fusions.[138] Erdafitinib initially showed promising activity in a single-arm phase 2 trial in patients with advanced urothelial carcinoma and prior chemotherapy (with or without prior PD-1/PD-L1 treatment) and *FGFR3 or FGFR2* alterations, demonstrating a confirmed response rate of 40% (CR, 3%).[142] The efficacy of erdafitinib was confirmed in the randomized phase 3 THOR trial in which patients with advanced or metastatic urothelial carcinoma with susceptible FGFR3 or FGFR2 alterations and progression after prior therapy were randomized to erdafitinib or investigator's choice of chemotherapy (docetaxel or vinflunine).[143] Erdafitinib significantly improved OS (HR, 0.64; median 12.1 vs 7.8 months), PFS (HR, 0.58; median 5.6 vs 2.7 months), and objective response rate (45.6% with 6.6% CR vs 11.5%). Common adverse events with erdafitinib include hyperphosphatemia, skin and nail changes, stomatitis, dry mouth, dry eye, palmar-plantar erythrodysesthesia, asthenia, and fatigue. Regular ophthalmological examination

is recommended. Initially, erdafitinib was granted accelerated approval by the FDA for patients with susceptible *FGFR2* or *FGFR3* mutations, but because the THOR study showed little activity of erdafitinib in *FGFR2* mutations, the FDA approval was amended in 2024. Erdafitinib is currently FDA approved for patients with metastatic urothelial carcinoma with susceptible *FGFR3* genetic alteration who have previously progressed on at least one prior line of systemic therapy.

Finally, trastuzumab deruxtecan is another antibody-drug conjugate that gained FDA accelerated approval in April 2024 for patients with unresectable or metastatic HER2-positive (IHC3 positive) solid tumors who have received prior systemic treatment and have no satisfactory alternative treatment options. A total of 41 patients with advanced urothelial carcinoma were treated in the phase 2 trial DESTINY-PanTumor02.[144] ORR was 56.6% in the 16 response-evaluable patients with HER2 IHC3 positive (ORR 35.0% in HER2 IHC2 positive). Median duration of response in urothelial patients with cancer (IHC3 positive or 2 positive) was 8.7 months. No confirmatory randomized study data are available. Common drug-related adverse events include nausea, diarrhea, anemia, fatigue, vomiting, neutropenia, decreased appetite, asthenia, alopecia, and thrombocytopenia. Drug-related pneumonitis occurred in 10.5% of patients, with the majority being grade 1 to 2, but there was one grade 3 and three fatal adjudicated drug-related cases of pneumonitis. HER2 positivity occurs in a minority of urothelial cancers, with a systematic literature review reporting HER2-positive prevalence of 13.0% in locally advanced or metastatic urothelial cancers.[145]

SUBSEQUENT THERAPY

Small studies of single-agent chemotherapy, such as ifosfamide, docetaxel, gemcitabine, paclitaxel, nab-paclitaxel, and pemetrexed, have demonstrated response rates between 9% and 27% with a PFS in the range of 2 to 3 months and no documented improvement in OS. Although multidrug regimens have been associated with higher response rates, this does not seem to translate into an improvement in survival. Clinical trial participation should be considered in this treatment-refractory setting for eligible patients.

KEY POINTS

- The preferred first-line therapy for patients with metastatic bladder cancer is combination EVP. Alternatively, less preferred regimens are cisplatin-based chemotherapy with or without nivolumab, followed by PD-1/PD-L1 checkpoint inhibitor maintenance. For patients who are not eligible for immunotherapy, gemcitabine and cisplatin remains a standard treatment option. In contrast with perioperative chemotherapy, carboplatin may be substituted for cisplatin-ineligible patients.
- Optimal second- and subsequent-line therapies are not well defined in the setting of the recent changes in first-line therapy. HER2 IHC and genomic testing for the *FGFR3* mutation should be requested. Options include platinum with gemcitabine, enfortumab vedotin monotherapy, erdafitinib, trastuzumab deruxtecan, and single-agent chemotherapies, depending on the prior systemic therapies used.

OTHER UROTHELIAL TRACT CANCERS

UPPER-TRACT AND URETHRAL UROTHELIAL CARCINOMA

Cancers of the renal pelvis, ureter, and proximal urethra are also typically of urothelial origin and should be treated based on primary histology. Upper urinary tract tumors may have a worse outcome in comparison with urothelial carcinomas that arise in the bladder. They can also arise in the setting of Lynch syndrome. Comprehensive genomic profiling of upper-tract tumors has revealed novel mutations, differing mutational frequencies, and expression subtypes with unique molecular profiles in comparison with bladder cancer, including a higher incidence of FGFR genetic alterations.

Upper-tract urothelial carcinomas may first be detected by imaging or retrograde pyelogram. Selective ureter cytology and/or brushing of lesions may be performed during the pyelogram. Unfortunately, unlike bladder cancer, great difficulty exists in the clinical staging of upper-tract urothelial carcinomas, and management decisions generally rely on tumor grade. Ultimately, the definitive diagnosis is made after nephroureterectomy. Lymph node dissection is not performed routinely for clinically node-negative patients, but it may be performed in the presence of radiographically suspicious lymphadenopathy. Node-positive disease is considered stage IV, but resection is still performed if possible because long-term remission is still possible.

No definitive data were available on the role of perioperative chemotherapy until the randomized POUT study evaluated the same.[146] Patients who had undergone nephroureterectomy for high-risk upper-tract urothelial carcinoma (pT2-4 and/or node positive) were randomly assigned to adjuvant GC or carboplatin and gemcitabine versus surveillance. Disease-free survival was significantly prolonged with adjuvant chemotherapy compared with no adjuvant chemotherapy. The 3-year event-free estimate was 71% for the chemotherapy arm compared with 46% for surveillance. Longer-term follow-up reported that the 3-year OS data trended toward improvement but was nonstatistically significant (79% with adjuvant chemotherapy vs 67% with surveillance).[147] The benefit was less clear in those with T2 disease, with caveats of underpowered subgroup analyses. Adjuvant nivolumab may also be considered for patients who decline or are unfit for adjuvant chemotherapy. CheckMate-274 included

21% of patients with upper-tract disease, although (underpowered) subgroup analyses suggested a lack of benefit with adjuvant nivolumab in such patients.

Neoadjuvant chemotherapy may also be reasonable, extrapolating from bladder cancer, but there are no randomized data in this setting. In addition, upper-tract disease may be diagnosed simply based on the suspicious imaging and/or cytology, so pathological information on risk may not be available until resection is performed.

Because approximately 20% to 50% of patients with resected upper-tract urothelial carcinoma will eventually develop bladder cancer, surveillance cystoscopy is necessary. The two theories for the multifocal nature of urothelial carcinoma include the field cancerization effect and monoclonality (ie, tumor cells spreading from their origin to multiple sites). Therefore, simultaneous or metachronous primary tumors of the urothelium at multiple sites may occur, and monitoring is required, including follow-up cystoscopies and imaging of the upper tracts.

NONUROTHELIAL BLADDER CANCER

It is not uncommon for urothelial carcinomas to be associated with minor components of nonurothelial histologies, and management is typically the same as for pure urothelial carcinoma. Fewer than 5% of bladder cancers in the United States have pure nonurothelial histology, including squamous cell carcinoma, adenocarcinoma, and small-cell or neuroendocrine carcinoma. Squamous cell carcinoma of the bladder is typically related to chronic urinary tract infections, RT, prior cyclophosphamide therapy, and, possibly, chronic indwelling catheters. In endemic areas, schistosomiasis can cause urothelial carcinoma as well as squamous and adenocarcinoma bladder cancers. Pure adenocarcinomas may originate from remnant urachal tissue, especially if they are located in the bladder dome. Small-cell or neuroendocrine carcinomas often behave aggressively with a propensity for distant metastases and a higher potential for brain metastasis. Plasmacytoid variant is an aggressive form of urothelial carcinoma associated with a somatic *CDH1* gene mutation with an aggressive course.[148]

The primary treatment modality for all localized nonurothelial bladder cancers is cystectomy, and the role of chemotherapy and/or RT as neoadjuvant or adjuvant therapy is not well defined. Chemotherapy regimens used for urothelial carcinoma have been considered to be less effective in non-urothelial histology tumors. Tumors with <90% variant histology are typically treated as standard urothelial carcinoma, although the optimal regimens for pure variant histologies are not well defined either. Neoadjuvant RT may have a role for squamous cell carcinomas, which have a greater tendency for local recurrence than metastatic spread.

Various strategies for the treatment of pure small-cell carcinoma of the bladder have arisen, primarily extrapolated from the treatment paradigms in small-cell lung cancer, including chemoradiation with or without induction chemotherapy with cisplatin and etoposide. Perioperative cisplatin/etoposide and surgery have been considered as well. This is a rare diagnosis with an associated poor prognosis, similar to other pure variant histology bladder tumors.

KEY POINTS

- Upper-tract (ureteral and renal pelvis) urothelial carcinoma may be diagnosed initially by imaging, urine cytology, and/or biopsy via retrograde ureteroscopy, but often a nephroureterectomy is required for pathological diagnosis as well as treatment.
- Perioperative chemotherapy should be considered for high-risk tumors based on extrapolation from bladder cancer or from one randomized trial of adjuvant platinum-based chemotherapy. For patients with high-risk disease who are unfit for or decline chemotherapy, adjuvant nivolumab may be considered as an alternative, although the supporting data are not as robust.
- Pure nonurothelial bladder cancers are typically treated with cystectomy; the role of perioperative chemotherapy and/or RT is not well defined.

BLADDER CANCER SURVIVORSHIP AND CONSIDERATIONS IN ELDERLY PATIENTS

Bladder cancer is predominantly a disease of older individuals (median age, 73 years) with coexisting medical issues, strongly affecting management decisions. Although most patients are diagnosed with non-muscle-invasive disease, lifelong surveillance, including urine cytology, cystoscopy, and periodic imaging, is required. Among those with muscle-invasive disease, the requirement for a radical cystectomy for most patients necessitates a urinary diversion procedure, and in patients receiving neoadjuvant cisplatin-based chemotherapy, the potential for short- and long-term chemotherapy-related adverse effects, including peripheral neuropathy, hearing loss, and renal dysfunction as well as others, exists. Although life expectancy is limited in patients with metastatic disease, chemotherapy-related adverse effects can have a substantial effect on quality of life. Many older patients are not candidates for perioperative chemotherapy secondary to the normal physiological decline in renal function with aging, baseline hearing loss, and other comorbidities such as cardiac disease. Additional advancements in immune-oncology, and antibody-drug conjugates may enable treatment of older patients who otherwise would be unable to receive conventional chemotherapy.

PRESENTING CASE STUDY 3

A 70-year-old man presents with hematuria. In-office cystoscopy reveals a large bladder mass, measuring approximately 6 × 4 cm. Abdominal CT shows no disease outside the bladder. His calculated creatinine clearance is 80 mL/min, and he has no major comorbidities. Transurethral resection of bladder tumor (TURBT) is performed with maximal resection. Pathology indicates muscle-invasive high-grade urothelial carcinoma.

How do the TURBT findings guide the definitive therapies you offer, and what systemic treatment would complement each approach?

Standard definitive therapies for muscle-invasive bladder cancer include radical cystectomy (with urinary diversion or neobladder creation) or definitive bladder radiation. For a cisplatin-eligible patient, as in this scenario, neoadjuvant cisplatin-based chemotherapy should be offered (gemcitabine and cisplatin for four cycles or dose-dense methotrexate, vinblastine, doxorubicin, and cisplatin [ddMVAC] for four to six cycles). One could also consider adding durvalumab to gemcitabine and cisplatin as neoadjuvant and adjuvant therapy, or alternatively, use a risk-adapted approach to PD-1 inhibition in the adjuvant setting.

If the patient opts for radiation therapy, it is important to first perform maximal TURBT. Radiosensitizing chemotherapy regimens vary and could include weekly cisplatin, once or twice weekly gemcitabine, 5-fluorouracil, and mitomycin C, or carboplatin and paclitaxel. It is unclear whether a systemic dose "induction" phase should be included.

It is important to note that treatment paradigms for patients considered "cisplatin-ineligible" are evolving. There is no role for carboplatin-based neoadjuvant therapy, and it should not be substituted for cisplatin in this setting. Of note, the NIAGARA trial demonstrated that cisplatin in a split-dosing strategy (ie, 35 mg/m^2 day 1 and day 8) can be used safely and successfully in patients with borderline renal function, CrCl 40 to 60 mL/min. Patients otherwise eligible for cisplatin with CrCl 40 to 60 mL/min should be considered for cisplatin if possible.

The patient opts for cystectomy and completes four cycles of cisplatin, gemcitabine, and durvalumab, followed by a radical cystoprostatectomy with an ileal conduit creation. Pathology revealed residual T3 disease and no lymph node involvement. How do you approach postoperative treatment?

This patient received the newest standard-of-care neoadjuvant therapy with chemo-immunotherapy as established by the NIAGARA study. He should receive adjuvant immunotherapy with durvalumab for 8 months, a strategy known as "sandwich immunotherapy." The pathological features would not change the plan for adjuvant durvalumab in this circumstance.

It is important to mention that if this patient elected to receive chemotherapy alone without immunotherapy before surgery (such as 4 cycles of ddMVAC or gemcitabine and cisplatin alone), then the patient would now be eligible instead to receive immunotherapy with either nivolumab or pembrolizumab for 1 year owing to adverse pathological findings.

If the patient had imaging evidence of metastatic disease, how would that affect the choice of systemic therapy?

The combination of enfortumab vedotin and pembrolizumab (EVP), established by the EV-302 study, is now the preferred first-line treatment of metastatic urothelial carcinoma. This regimen has been associated with the highest response rates and the most promising duration of response. Alternative options include nivolumab with gemcitabine and cisplatin, followed by nivolumab maintenance (Checkmate 901 study) and ddMVAC or gemcitabine and cisplatin, followed by avelumab maintenance therapy (JAVELIN Bladder 100 study).

Following disease progression on EVP, how do you think about next-line options?

Tumor genomic sequencing should be requested to identify a targetable *FGFR3* mutation, which would make the patient eligible for oral erdafitinib. HER2 immunohistochemistry (IHC) testing should be performed to determine trastuzumab deruxtecan eligibility, which currently has a pan-tumor approval for all HER2-overexpressing solid tumors. Platinum-based chemotherapy doublet may be offered after EVP, but data are lacking in this setting. Single-agent chemotherapies can be used as later lines of therapy (eg, pemetrexed, paclitaxel).

KEY POINTS

- Bladder cancer is predominantly a disease of older patients and frequently occurs in patients with other comorbidities. Therefore, a significant portion of patients are not candidates for many standard therapies such as cisplatin and cystectomy.
- Bladder-sparing or trimodality therapy is now considered an equal alternative to cystectomy and is increasingly offered to appropriately selected patients who wish to preserve their bladders and avoid urinary diversion; previously, it was reserved primarily for patients ineligible for cystectomy because of comorbidities.
- Cisplatin should be offered to any eligible patient regardless of age, but this requires careful assessment of baseline neuropathy, hearing, and kidney function, and serial assessment during and after treatment. Split-dosing of cisplatin should be considered for patients with CrCl 40 to 60 mL/min. Newer systemic treatment modalities (eg, immune checkpoint inhibitors, antibody-drug conjugates, and targeted therapies) are rapidly improving treatment options for patients with locally advanced or metastatic disease and those not eligible for conventional chemotherapy.

RENAL CANCER

EPIDEMIOLOGY

Renal cell carcinomas account for 90% of all malignant neoplasms of the kidney. An estimated 81,610 new cases of kidney cancer (n = 52,380 in men and n = 29,230 in women) will be diagnosed, and approximately 14,390 people (n = 9,450 men and n = 4,940 women) will die of this disease.[149,150] Renal cancers were historically called the internist's tumors based on their protean clinical presentations, including fatigue, weight loss, and anemia. Today, <10% of patients present with the classic triad of hematuria, abdominal pain, and a palpable mass. Between 1993 and 2004, the proportion of patients diagnosed with stage I renal cell carcinoma increased from 43.0% to 57.1%, whereas the proportion of patients diagnosed with stage IV disease decreased from 27.4% to 18.7%, indicating an increase in incidental diagnoses as a result of the increased use of imaging for other diagnostic purposes. Risk factors for renal cell carcinoma include smoking, obesity, hypertension, and acquired cystic kidney disease, which is associated with end-stage renal disease. Tobacco use (longer duration and exposure) is associated with an increased risk of advanced renal cell carcinoma. Environmental toxins, such as cadmium and asbestos, have also been associated with increased risk of renal cell carcinoma. Approximately 2% of cases are associated with inherited syndromes.

KEY POINTS

- Renal cell carcinoma is the most common type of kidney tumor. The classic triad of hematuria, abdominal pain, and a palpable mass is rarely seen in modern practice. Incidental diagnoses are increasing.
- Risk factors include smoking, obesity, hypertension, environmental exposures, hereditary kidney cancer syndromes, and acquired cystic kidney disease leading to end-stage renal disease.

PATHOLOGY AND MOLECULAR PATHOGENESIS

The most recent WHO classification in 2022 incorporates histological and molecular subtypes of kidney cancers.[151] The classification of adult epithelial kidney tumors has expanded to include numerous histologies and molecularly defined tumors that are associated with distinct clinical outcomes. The most common types of renal cancer in adults are clear cell (75%-80% of cases) and papillary (15% of cases) renal cell carcinomas. More rare types include chromophobe (~5% of cases), collecting-duct and renal medullary (each in ~1% of cases), and translocation (<1% of cases) carcinomas. Oncocytomas consist of neoplastic cells and can grow similarly to renal cell carcinomas, but they have benign behavior and are not considered truly malignant. However, the presence of oncocytoma should prompt thorough evaluation for coexisting renal cell carcinoma, and patients should have ongoing surveillance despite a relatively low risk of subsequent renal cell carcinoma development. Sarcomatoid or rhabdoid differentiation, which is associated with a worse prognosis, can occur with any major histological subtype.

Renal cell carcinomas can have a variable natural history that reflects the biology of the histological tumor type. The clinical course of clear–cell carcinomas, which make up most renal tumors, is typically aggressive, although some patients can have an indolent course with stable metastases for years or metastases occurring decades after complete resection of a primary tumor. Molecular studies are attempting to identify markers that may predict prognosis. Papillary tumors were previously divided into type I and type II lesions according to architectural, cytologic, and genetic features, but the latest update to the WHO classification has removed the subclassification of papillary renal cell carcinomas. Chromophobe carcinomas are also typically indolent and uncommonly result in metastases and cancer-related death, although tumor necrosis and sarcomatoid differentiation predict a more aggressive phenotype versus chromophobes lacking these characteristics. Collecting-duct carcinomas have an aggressive clinical course, with more than half of patients presenting with metastases and a median survival of only a few months for patients with metastatic disease.

Von Hippel-Lindau (VHL) disease is an autosomal dominant familial cancer syndrome that predisposes individuals to clear–cell renal cancers, retinal angiomas, pancreatic cysts and neuroendocrine tumors, hemangioblastomas of the spinal cord and cerebellum, and pheochromocytomas, as well as to other rare neoplasms. Frequent loss of at least one allele on chromosome 3p in renal tumors from patients with VHL disease led to the identification of the *VHL* tumor-suppressor gene. This gene encodes a protein that promotes the ubiquitination and degradation of hypoxia-inducible factor-a (HIF-α; Fig. 14-15). Several proteins encoded by HIF-α are involved in angiogenesis, such as VEGF and platelet-derived growth factor B chain. When the VHL protein is lost in renal cancers, VEGF, platelet-derived growth factor B chain, and other proteins are overexpressed, promoting angiogenesis and tumor cell growth. Defects in the *VHL* gene, including mutation or gene silencing through methylation, also occur in a majority of tumors from patients with sporadic clear–cell renal cell carcinomas. Tumor angiogenesis is also stimulated by other growth factors that activate AKT and mTOR signaling, which also increases HIF-α expression. Therapies that target VHL-regulated and AKT-signaling pathways have demonstrated substantial antitumor activity. A novel inhibitor of HIF-2α, belzutifan, has gained FDA approval for treatment of VHL syndrome-associated cancers as well as in treatment-refractory advanced clear–cell renal cell carcinomas.

Several other genetic syndromes may be associated with renal cell carcinoma (Table 14-4). Genetic counseling is recommended for patients with renal cancer who are aged 46 years or younger and may be considered in patients with multifocal or bilateral renal masses and/or if personal or family history is potentially consistent with an inherited renal cancer (Table 14-5).

- The most common type of renal cell carcinoma is clear cell, accounting for approximately 80% of all renal cell cancers. Papillary renal cell carcinoma is the most common non–clear-cell type.
- Clear–cell renal cell carcinoma is driven by loss of VHL tumor-suppressor activity and increased angiogenesis mediated in part by VEGF, which provides the rationale for inhibition of VEGF as a key treatment modality in renal cell carcinoma.

Table 14-4 **Genomic Alterations in Inherited and Sporadic Renal Tumors**		
Genomic Alteration	**Type of Renal Tumor**	**Syndrome**
VHL	ccRCC	Von Hippel-Lindau (autosomal dominant): • Hemangioblastomas of CNS • Retinal angiomas • Pheochromocytomas • Pancreatic serous cystadenomas and neuroendocrine tumors
Chromosome 3 translocations or *BRCA1*-associated protein 1 (*BAP1* gene)	ccRCC	Familial ccRCC
MET (germline and somatic)	Hereditary or sporadic type I papillary RCC	Hereditary papillary renal carcinoma (autosomal dominant): • Bilateral multifocal papillary renal tumors
Fumarate hydratase (germline)	Type II papillary RCC	Hereditary leiomyomatosis and RCC: • Autosomal dominant • Uterine fibroids
Succinate dehydrogenase (germline)	ccRCC or chromophobe RCC	Hereditary paraganglioma and pheochromocytoma (autosomal dominant): • Paragangliomas • Pheochromocytomas • Bilateral and/or multifocal kidney tumors
Xp11.2 (*TFE* gene)	ccRCC or papillary RCC	Early-onset RCC
Folliculin (*FLCN* gene)	Chromophobe RCC or mixed chromophobe-oncocytoma renal tumors	Birt-Hogg-Dube syndrome: hair-follicle hamartomas of the face and neck: • Renal and pulmonary cysts • Slow-growing bilateral kidney tumors
Hamartin (*TSC1*) or tuberin (*TSC2*)	Angiomyolipomas, rare ccRCC	Tuberous sclerosis complex: • Bilateral multifocal kidney tumors
SMARCB1 (germline)	Medullary carcinoma

SCREENING

Certain populations may be eligible for kidney cancer screening. Patients with end-stage renal disease who have been on dialysis for three or more years may be screened for acquired cystic disease, which can be a premalignant condition. Screening is

indicated for some inherited renal carcinoma syndromes. Patients with known hereditary kidney cancer syndromes may be screened, but the screening protocol depends on the syndrome and the nature of the anticipated kidney tumors.

STAGING

A CT scan with contrast medium is a reliable method for detecting and staging renal cancers. MRI is useful when renal function is poor, as well as when evaluating for local invasion or assessing the renal vein and inferior vena cava for thrombus. MRI can also help distinguish a benign tumor known as an angiomyolipoma, which contains fat. Staging is performed using the AJCC staging classification.

MANAGEMENT OF LOCALIZED RENAL CANCER

Surgical excision by open or laparoscopic nephrectomy is the primary treatment of patients with localized disease by either radical nephrectomy or nephron-sparing partial nephrectomy for small tumors (Fig. 14-16). The role of lymphadenectomy remains controversial and does not clearly improve OS. Tumor extension into the renal vein or inferior vena cava, indicating stage III disease, does not preclude resection, and cardiopulmonary bypass may be required for some cases; approximately 50% of such patients have prolonged survival with a successful resection. There is no benefit to postoperative RT for patients with locally advanced disease. Signs and symptoms of hepatic dysfunction may occur in patients with localized renal cancer (ie, without evidence of metastatic disease). This is a paraneoplastic phenomenon referred to as Stauffer syndrome. Although it is rare, patients with this syndrome should undergo resection, which leads to reversal of the hepatic dysfunction.

Figure 14-16 Diagnostic and Treatment Approaches to the Patient With a Kidney Mass

Small renal masses are defined as incidentally image-detected contrast-enhancing renal tumors 4 cm or less in diameter that are generally consistent with stage T1a renal cell carcinoma. Historically, small renal masses did not require biopsy, but biopsy should be considered with suspicion of hematologic, metastatic, inflammatory, or infectious etiology.[152] Active surveillance is used for patients with significant comorbidities and limited life expectancy, especially for those with lesions smaller than 2 cm. No validated protocols for active surveillance exist, but serial imaging is generally performed every 3 to 6 months for the first 2 years to establish growth rate and then every 6 to 12 months afterward. Triggers for intervention are unclear but may include a size larger than 3 cm, median growth rate greater than 5 mm per year, or increased stage.[152]

Focal therapy (eg, partial nephrectomy or cryotherapy) is preferred for patients in whom a nonsurgical intervention is indicated and with a tumor amenable to this approach. Focal therapy is associated with less risk of renal dysfunction than radical nephrectomy in patients with baseline normal renal function. Percutaneous thermal ablation or radiofrequency ablation may be considered as an alternative to partial nephrectomy in patients with cT1a masses smaller than 3 cm, although these techniques may have an increased likelihood of tumor persistence or local recurrence compared with surgery.[153]

By contrast, radical nephrectomy should be considered for complex masses that would make partial nephrectomy technically challenging in a patient with no baseline renal dysfunction or proteinuria and a normal contralateral kidney.

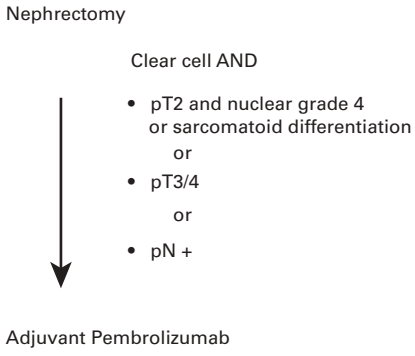
KEY POINTS

- After radiographic evaluation of a localized kidney mass, the decision whether to biopsy or to perform partial or radical nephrectomy depends on the level of suspicion of malignancy, the size of the lesion, and the age and comorbidities of the patient.
- Small renal masses are often incidentally detected as contrast-enhancing tumors <4 cm. Options for management include active surveillance, partial nephrectomy, and percutaneous ablation.
- Complex masses may require radical nephrectomy with some increased subsequent risk of renal impairment.

Adjuvant Therapy

In the phase 3 *S*-TRAC study, 615 patients with high-risk clear cell–type renal cell carcinoma after nephrectomy received 1 year of adjuvant sunitinib or placebo (Fig. 14-17).[154] The median DFS was significantly longer in patients receiving sunitinib versus placebo at 6.8 versus 5.6 years, respectively. *S*-TRAC resulted in FDA approval of sunitinib as adjuvant therapy. However, sunitinib also increases toxicity, and no data demonstrating OS benefit are available. Furthermore, four additional phase 3 studies of adjuvant TKIs have all failed to meet their primary DFS endpoints, including studies with axitinib, pazopanib, and sorafenib, as well as the ASSURE trial that included sunitinib.

Figure 14-17 Adjuvant Pembrolizumab for High-Risk Localized RCC



Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

A large phase 3 randomized clinical study, KEYNOTE-564, evaluated the role of adjuvant pembrolizumab 200 mg intravenously every 3 weeks for 1 year versus placebo in patients with clear–cell kidney cancer with intermediate high or high risk of recurrence after prior nephrectomy with or without metastasectomy. At prespecified interim analysis, the use of pembrolizumab had resulted in significant improvement in DFS (HR, 0.68; 24-month DFS 77.3% vs 68.1%).[155] Further follow-up showed an OS benefit with adjuvant pembrolizumab (HR, 0.62), which was maintained with further follow-up.[156] Common adverse effects with pembrolizumab were fatigue, diarrhea, rash, itching, hypothyroidism, and muscle aches. Based on these results, pembrolizumab is FDA approved as adjuvant therapy for renal cell carcinoma at intermediate high or high risk of recurrence following nephrectomy or following nephrectomy and resection of metastatic lesions.

METASTATIC RENAL CELL CARCINOMA

Patients with metastatic renal cell carcinoma may have a varied, unpredictable, and in some cases protracted clinical course. One prospective phase 2 study of patients with treatment-naive asymptomatic metastatic renal cell carcinoma with a primary endpoint of time to initiation of systemic therapy made at the discretion of the treating physician and patient-reported a median time of surveillance of 14.9 months.[157] Having variant features, more adverse risk factors, and more metastatic sites was associated with a shorter surveillance time. Therefore, a select subset of patients with metastatic renal cell carcinoma may be managed on a

surveillance program before systemic therapy. One nomogram used to predict survival based on patients treated in the cytokine era (Memorial Sloan-Kettering Cancer Center prognostic model) includes the following as poor prognostic variables: time from diagnosis to systemic treatment <1 year, low Karnofsky performance status (<80%), low hemoglobin level, high corrected serum calcium level, and high serum lactate dehydrogenase (LDH) level. Newer prognostic models for patients with metastatic renal cell carcinoma treated with contemporary targeted therapies have generally included these prognostic factors in addition to others, such as platelet count, alkaline phosphatase, and number and sites of metastases, although the International Metastatic Renal-Cell Carcinoma Database Consortium (IMDC) model (risk factors: anemia, thrombocytosis, neutrophilia, hypercalcemia, Karnofsky performance status <80%, and <1 year from diagnosis to treatment) has been externally and prospectively validated in patients treated with first-line VEGF-targeted treatment and also validated with first-line combination immunotherapy treatment (Fig. 14-18). This risk-stratification scheme has been used to define eligibility and stratify patients for multiple studies evaluating immunotherapy or immunotherapy/TKI combinations in frontline treatment.

Role of Surgery In Metastatic Disease

Cytoreductive nephrectomy may be considered as an initial treatment of patients with metastatic disease to relieve local symptoms or control bleeding. In the era of cytokine therapies, two prospective randomized studies demonstrated improved survival for patients subsequently treated with IFNα-2b. With improved systemic therapies in the era of VEGF TKIs as standard first-line treatment, the role of cytoreductive nephrectomy was addressed in the CARMENA trial, which randomly assigned patients with confirmed de novo metastatic clear–cell renal cell carcinoma and intermediate or poor risk by the Memorial Sloan-Kettering Cancer Center prognostic model to standard care (nephrectomy followed by sunitinib) versus sunitinib without nephrectomy.[158] OS in the sunitinib-only group was statistically noninferior (although numerically superior) to that in the standard care group at the planned interim analysis. This trial was limited by unequal allocation of T3/4 tumors to the surgery arm, failure of some

patients in both arms to undergo assigned interventions, and selection bias with particularly poor-risk patients enrolled in the study. There was also concern that patients who have symptomatic primary tumors might have been preferentially selected to undergo nephrectomy rather than be enrolled in the study, thus limiting generalizability to these patients. In the era of combination checkpoint inhibitor-based frontline therapy, the role of cytoreductive nephrectomy is not well defined. Patient selection is key, and nephrectomy may still be appropriate for some patients, especially those without poor-risk disease or patients experiencing symptoms (eg, hematuria and pain) from the renal mass, or in patients who achieve excellent response to initial systemic therapy and have minimal metastatic disease burden. In general, immediate systemic therapy is preferred over upfront nephrectomy based on the results from CARMENA, unless immediate local palliation is needed. Delayed cytoreductive nephrectomy may be considered in select cases exhibiting a favorable response to systemic therapy.

The use of neoadjuvant systemic therapies in patients with locally advanced renal cell carcinoma has demonstrated tumor downsizing as well as treatment with partial nephrectomy in a subset of patients who would otherwise have required a radical nephrectomy, but this is not standard. Use of embolization may be recommended preoperatively for large primary tumors and for the resection of metastatic lesions because of the highly vascular nature of renal cell carcinoma. Surgical excision of oligometastatic disease at presentation or after prolonged disease-free intervals may be appropriate in select patients, especially those with non–clear cell histologies.

Systemic Therapies

Available systemic therapies for renal cell carcinoma include the following:

- Agents targeting VEGF receptor (VEGFR), including monoclonal antibodies and TKIs
- Agents targeting mTOR
- Immune-based therapies, including cytokines and checkpoint inhibitors
- Inhibitor of HIF-2α

FRONTLINE THERAPY FOR METASTATIC RENAL CELL CARCINOMA (CLEAR CELL)

Immune Checkpoint Inhibitor Combination

The combination of PD1-inhibitor nivolumab with the CTLA-4 inhibitor ipilimumab demonstrated improved OS in comparison with sunitinib in treatment-naive patients with intermediate- or poor-risk advanced renal cell carcinoma (per IMDC criteria described previously) in the phase 3 Checkmate 214 trial.[159] Nivolumab was administered 3 mg/kg IV and ipilimumab 1 mg/kg IV once every 3 weeks for four doses, followed by nivolumab monotherapy every 2 weeks. Primary endpoints were OS, PFS, and ORR in IMDC intermediate- or poor-risk patients. Nivolumab and ipilimumab significantly improved OS and ORR compared with sunitinib in the primary study analyses. The safety profiles of nivolumab and ipilimumab were manageable, with fewer grade 3 to 5 adverse events seen with the combination (46%) in comparison with sunitinib (63%). However, systemic corticosteroids were required in 40% of patients treated with nivolumab and ipilimumab. This is higher than the approximately 15% to 20% of patients receiving VEGF TKI and immunotherapy combinations requiring glucocorticoids. Long-term follow-up shows that the combination of ipilimumab and nivolumab was associated with durable responses in IMDC intermediate- and poor-risk patients with a median duration of response of 75 months and a median OS of 47 months. Because combined CTLA-4 and PD-1/PD-L1 blockade is associated with significant immune-related adverse events, other trials (HCRN GU16-260 and OMNIVORE)[160] have tested a strategy of first-line PD-1/PD-L1 inhibitor monotherapy followed by the addition of CTLA-4 blockade as salvage only for those patients who have a suboptimal response to PD-1/PD-L1 monotherapy. Response rates to salvage combination therapy were modest, and some patients experienced progression too rapidly to receive it, so this strategy is currently recommended only for patients with borderline performance status that may preclude upfront CTLA-4 with PD-1 or VEGF with PD-1/PD-L1 inhibitor combinations or select patients with favorable-risk disease interested in minimizing treatment toxicity.

VEGF TKI and Immunotherapy Combinations

Several recent trials have also tested the combination of VEGF-targeted agents with PD-1/PD-L1 inhibitors because VEGF-targeted agents are active in kidney cancer and may also have immunomodulatory effects. There are no head-to-head data to inform which combination of VEGF/IO to use, so most clinicians choose the regimen with which they are most familiar.

The phase 3 KEYNOTE-426 trial demonstrated improved OS and PFS with the combination of pembrolizumab and axitinib versus sunitinib in previously untreated advanced or metastatic kidney cancer.[161] Improvement in PFS and OS was observed in the ITT patients who included all IMDC risk groups, and was irrespective of PD-L1 expression. The most common adverse effects were hypertension, diarrhea, fatigue, and transaminase elevations in the axitinib pembrolizumab arm.[161] Similarly, the phase 3 CheckMate-9ER trial demonstrated improvement in PFS and OS as well as quality of life with the combination of nivolumab and cabozantinib versus sunitinib in the frontline setting for the ITT population encompassing all IMDC risk groups.[162] Common treatment-related serious adverse effects included hand-foot syndrome, hypertension, hypothyroidism, and fatigue. The CLEAR

trial compared lenvatinib (20 mg daily) with pembrolizumab versus lenvatinib (18 mg daily) and everolimus (5 mg daily) versus sunitinib and demonstrated a prolonged PFS with both lenvatinib-containing arms; in addition, OS was improved with lenvatinib and pembrolizumab versus sunitinib in the ITT patients. Complete responses were seen in 16.1% patients on lenvatinib with pembrolizumab compared with 4% with sunitinib alone.[163] Serious side effects were more common with the lenvatinib with pembrolizumab combination compared with sunitinib. Most common side effects were diarrhea, hypertension, hypothyroidism, and fatigue.

The phase 3 JAVELIN Renal 101 trial demonstrated improved PFS with the combination of axitinib and avelumab relative to sunitinib regardless of PD-L1 status.[162] However, in contrast to the prior 3 anti–PD-1/TKI regimens, no OS benefit has been reported to date for avelumab and axitinib, and consequently, other immunotherapy combinations are preferred. The FDA approved avelumab with axitinib, pembrolizumab with axitinib, cabozantinib with nivolumab, and lenvatinib with pembrolizumab for first-line therapy of kidney cancer based on these trials. Therefore, the standard frontline treatment of locally advanced or metastatic renal cell carcinoma now includes either combined CTLA-4/PD-1 blockade or combination anti-VEGFR and anti–PD-1 therapy. Of note, FDA approval for the anti–PD-1/TKI combinations includes all treatment-naive advanced renal cell carcinoma patients regardless of IMDC risk group, whereas nivolumab and ipilimumab are approved for IMDC intermediate- and poor-risk patients, adhering to the primary endpoint population of the respective studies. However, the IMDC favorable-risk subgroup has consistently demonstrated favorable and relatively little difference in efficacy outcomes in all of these studies comparing sunitinib and immunotherapy combinations; moreover, this approach may be best for patients who value the possibility of treatment-free survival.

The role of triplet combination therapy with anti–CTLA-4/PD-1 blockade and VEGFR TKI was evaluated in the phase 3 COSMIC-313 study, in which advanced clear–cell renal cell carcinoma with IMDC intermediate- or poor-risk disease were randomized to receive first-line therapy with ipilimumab and nivolumab with either cabozantinib or placebo.[164] The addition of cabozantinib was associated with an improvement in the primary endpoint with a significantly prolonged PFS (HR, 0.73) as well as a higher ORR of 43% versus 36%. However, the toxicity of the triplet regimen also appeared to be substantially higher, and data regarding OS benefit were immature. The triplet regimen of ipilimumab, nivolumab, and cabozantinib is not currently approved by any regulatory authority, but OS follow-up is ongoing.

Single-Agent Tyrosine Kinase Inhibitors

The data from multiple phase 3 trials demonstrate that immunotherapy-based combinations involving ipilimumab with nivolumab or anti–PD-1/TKI combinations should be the preferred first-line therapy for most patients. However, some patients may be poor candidates for immune checkpoint inhibitors because of comorbidities (eg, history of orthotopic transplant or significant autoimmune disease). TKI monotherapy is a preferred option for patients who are not eligible to receive immunotherapy.

Multiple TKIs have been developed to target the kinase domain of VEGFR and were the standard of care first-line treatment for many years until the recent advancement of immune checkpoint inhibitor combinations described. The multikinase TKIs sorafenib, sunitinib, pazopanib, axitinib, cabozantinib, lenvatinib, and tivozanib have been approved by the FDA as either monotherapy or in combination with other treatments for advanced renal cell carcinoma (Table 14-6). Sunitinib, pazopanib, and cabozantinib are preferred first-line options based on clinical data and prior FDA approvals as first-line therapy. However, sunitinib monotherapy has been a standard comparator arm in several recent first-line trials, and TKI monotherapy is now considered an inferior therapy compared with any of the modern immune checkpoint inhibitor combination options.

The major toxicities of sunitinib are fatigue, oral lesions, hand-foot syndrome (also known as palmar-plantar erythrodysesthesia), hypertension, and diarrhea. Alternative dosing schedules, including 2 weeks on and 1 week off, may be associated with improved tolerability and similar efficacy as standard dosing. A randomized phase 3 noninferiority trial compared the efficacy and safety of pazopanib and sunitinib as first-line therapy. The PFS for patients treated with pazopanib was noninferior to that for those treated with sunitinib, and the OS was similar.[165] The safety profile favored pazopanib with less fatigue (55% vs 63%), hand-foot syndrome (29% vs 50%), and thrombocytopenia (41% vs 78%). A higher incidence of increased alanine aminotransferase level was seen with pazopanib (60% vs 43%). Health-related quality of life measures favored pazopanib with less fatigue and soreness of the mouth, hands, and feet. However, this trial did not allow dose reductions or alternative dosing schedules frequently used to ensure tolerability of sunitinib, as discussed previously. Other toxicities from this class of drugs include rash, myelosuppression (including thrombocytopenia), hypothyroidism, and congestive heart failure. Pazopanib therapy may also be associated with serious hepatotoxicity. Sunitinib-associated hypertension, defined as a maximum or mean systolic blood pressure greater than 140 mm Hg, was associated with an improvement in clinical outcome, suggesting that the development of hypertension during therapy may be a biomarker of response to sunitinib.

The randomized phase 2 CABOSUN trial showed that cabozantinib improved PFS relative to sunitinib in treatment-naive patients, although the difference in OS was not statistically significant.[166] Based on these trials, cabozantinib is FDA approved as first-line therapy for metastatic renal cell carcinoma or after failure of prior antiangiogenic therapy. Cabozantinib may have particular efficacy in patients with bone metastases.

Table 14-6 **Combination Therapies for Frontline Treatment of Metastatic Renal Cell Carcinoma**

	Ipilimumab + Nivolumab	Axitinib + Pembrolizumab	Axitinib + Avelumab	Cabozantinib + Nivolumab	Lenvatinib + Pembrolizumab
Randomization (control arm)	1:1 (sunitinib)	1:1 (sunitinib)	1:1 (sunitinib)	1:1 (sunitinib)	1:1:1 (lenvatinib with everolimus, sunitinib)
No. of subjects	1,096	861	886	651	1,069

First-line VEGF TKI therapy is reasonable to consider in patients who have metastatic renal cell carcinoma who have a contraindication to receiving immune checkpoint inhibitors or in selected patients with favorable risk and low burden of disease.

Cytokines

Until 2006, immunotherapy had represented the primary treatment of patients with advanced renal cancer, as conventional chemotherapy had little clinical activity. The most extensively studied agents were IFN-α and aldesleukin (human recombinant interleukin-2 [IL-2]). IFN-α demonstrated low but reproducible response rates of 10% to 20% with occasional durable responses. Increased expression of VEGF in clear–cell renal carcinomas led to investigations of bevacizumab, a humanized VEGF-neutralizing antibody, in metastatic renal cell carcinoma before and after cytokine therapy. The addition of bevacizumab to IFN for first-line therapy significantly improved ORR and PFS in two phase 3 randomized trials.[167,168] Hypertension and asymptomatic proteinuria were the most common adverse events.

Therapy with IL-2 results in responses in approximately 20% of patients of patients who have clear–cell histology, with durable responses in 4% to 5% of cases.[169] Prolonged and durable responses occur more commonly in patients with good performance status and younger age. Toxicity associated with high-dose bolus IL-2 is related to increased vascular permeability and often necessitates treating patients in an intensive-care setting. IL-2 has been associated with a 4% incidence of treatment-related death. IL-2 is associated with durable CRs and may be most appropriate for younger, good-risk patients. With advances in immune checkpoint inhibitor combinations, cytokine therapies are now used primarily in select cases, typically in treatment-refractory settings and younger patients with excellent performance status and minimal comorbidities.

mTOR Inhibitors

The mTOR pathway is frequently activated in renal cell carcinoma, which can result in increased production of HIF-1α and HIF-2α. Consequently, agents that inhibit mTOR have been studied in patients with metastatic renal cell carcinoma. The mTOR inhibitor temsirolimus improved OS compared with IFN (10.9 vs 7.3 months) in treatment-naive patients with poor-risk metastatic renal cell carcinoma. This led to FDA approval of single-agent temsirolimus in 2007. Because of the improved efficacy of immunotherapy and VEGF with immunotherapy combinations in intermediate- and poor-risk metastatic renal cell carcinoma, single-agent temsirolimus is rarely used as a frontline single agent.

SECOND AND SUBSEQUENT LINES OF THERAPY

Previous studies have shown that patients whose disease progresses while undergoing VEGF-targeted therapy can experience a response to another VEGF-targeted therapy. The phase 3 AXIS trial compared the VEGFR selective TKI axitinib with sorafenib in patients whose disease had progressed during first-line therapy.[170] The overall median PFS was 6.7 months for patients who received axitinib compared with 4.7 months for patients treated with sorafenib. Therefore, axitinib was FDA approved in 2012 for the treatment of advanced renal cell carcinoma after failure of one prior systemic therapy.

Key Phase 3 Trials of Antiangiogenic Therapy in Treatment-Refractory Metastatic Renal Cell Carcinoma

The PD-1 inhibitor nivolumab prolonged OS in comparison with everolimus in patients with metastatic renal cell carcinoma after prior angiogenic therapy (25.0 vs 19.6 months),[171] and it received FDA approval for this indication, but it is now rare for patients to be PD-1-inhibitor-naive in later-line settings (Table 14-7).

Table 14-7 Key Phase 3 Trials of Antiangiogenic Therapy in Metastatic RCC

Trial	No. of Participants	Study Population	Design	Outcome	Notes
Motzer et al[172]	750	Treatment-naive metastatic RCC	Sunitinib vs interferon-α	Improved PFS with sunitinib (11 vs 5 months)	Improved OS with sunitinib in long-term follow-up (26.4 vs 21.8 months)
Sternberg et al[173]	435	Treatment-naive and cytokine-treated metastatic RCC	Pazopanib vs placebo	Improved PFS with pazopanib (9.2 vs 4.2 months)	PFS benefit seen regardless of prior treatment
AXIS[174]	723	Previously treated metastatic RCC	Axitinib vs sorafenib	Improved PFS with axitinib (6.7 vs 4.7 months)	OS did not differ in long-term follow-up (20.1 vs 19.2 months)
METEOR[175]	658	VEGFR-treated metastatic RCC	Cabozantinib vs everolimus	Improved PFS with cabozantinib (7.4 vs 3.8 months)	More toxicity with cabozantinib. Improved OS with cabozantinib in long-term follow-up
CABOSUN[176]	157	Treatment-naive intermediate-/high-risk metastatic RCC	Cabozantinib vs sunitinib	Improved PFS with cabozantinib (8.6 vs 5.3 months)	No significant OS difference in long-term follow-up
Motzer et al[177]	153	VEGFR-treated metastatic RCC	Lenvatinib plus everolimus vs lenvatinib versus everolimus	Improved PFS with lenvatinib plus everolimus (14.6 months) or lenvatinib (7.4 months) vs everolimus (5.5 months)	Marginally improved OS with lenvatinib plus everolimus vs everolimus, but underpowered. Increased toxicity with combination therapy

Targeted therapies have also been directed against several identified mechanisms of resistance to VEGF-directed therapy. Cabozantinib is a TKI that targets MET and AXL in addition to VEGFR. The phase 3 METEOR trial demonstrated that cabozantinib was superior to everolimus in OS and PFS in previously treated patients with metastatic renal cell carcinoma.[178] Lenvatinib is a TKI that inhibits FGFR in addition to VEGF. Lenvatinib combined with everolimus improved PFS versus everolimus alone in patients previously treated with antiangiogenic therapy.[177] This combination was approved by the FDA in 2016 for the treatment of advanced renal cell carcinoma after one prior antiangiogenic therapy. In the third-line setting, another VEGF-directed TKI, tivozanib, demonstrated improved PFS and less toxicity in comparison with sorafenib after prior

VEGF-directed therapy,[179] earning FDA approval for relapsed or refractory advanced renal cell carcinoma following two or more prior systemic therapies. Based on results of a large phase 3 clinical study (Tivo-3), tivozanib, an oral VEGF inhibitor, is FDA approved for relapsed or refractory metastatic renal cell carcinoma after progression with two or more prior lines of systemic therapy, including at least one VEGF inhibitor. Common adverse effects associated with tivozanib include fatigue, hypertension, proteinuria, and diarrhea.

In practice, clinicians may switch between VEGF inhibitors if other options are exhausted and clinical trials are not available, and it may be reasonable to alternate between TKIs with broad-spectrum (cabozantinib, lenvatinib) and narrow-spectrum (axitinib, tivozanib) activity.

For patients who progress on prior immune checkpoint inhibitor therapy, there is unlikely to be a benefit from continuing or switching anti–PD-1/L1 therapy along with a TKI. The phase 3 CONTACT-03 study randomized patients with advanced renal cell carcinoma with progression on or after a prior jPD-(L)1i-based therapy to receive either cabozantinib monotherapy or cabozantinib and atezolizumab. There was no difference in any major efficacy outcome (OS, PFS, and ORR), and the addition of atezolizumab was associated with increased toxicity.[180] Similarly, the phase 3 TiNivo-2 study showed no benefit of nivolumab in addition to tivozanib in patients with progression post-PD-(L)1i.[180] These results are not applicable to patients who discontinued prior PD-(L)1i due to toxicity or reasons other than progression.

HIF Inhibitor

As described, the transcription factor HIF is a major element in clear–cell renal cell carcinoma pathogenesis. Belzutifan is an orally bioavailable inhibitor of HIF-2α. Belzutifan demonstrated clinical efficacy compared with everolimus in the phase 3 LITESPARK-005 study of advanced clear–cell renal cell carcinoma patients with progression after prior anti–PD-1/L1 and VEGFR TKI.[181] Coprimary endpoints of PFS and OS were evaluated, and belzutifan improved PFS in comparison with everolimus, but OS was not statistically different at the time of the initial data report. Belzutifan was associated with an objective response rate of 22.7% in comparison with 3.5% with everolimus. Common adverse events with belzutifan included fatigue, anemia, hypoxia, dyspnea, and nausea. Based on the PFS benefit, the FDA approved belzutifan in December 2023 for advanced renal cell carcinoma patients following prior anti–PD-1/L1 and VEGFR TKI.

Other Therapies

Everolimus is an orally administered mTOR inhibitor. In comparison with placebo, everolimus improved PFS in previously treated patients with metastatic renal cell carcinoma (4.0 vs 1.9 months). This study was the first phase 3 randomized trial to demonstrate the efficacy of second-line therapy for patients whose disease progressed during treatment with a VEGF inhibitor, and it led to FDA approval of everolimus in 2009 for the treatment of advanced renal cell carcinoma after failure of either sunitinib or sorafenib. However, everolimus monotherapy is infrequently used, given the availability of more active therapies described already, including combination therapy with lenvatinib and everolimus. Adverse reactions from mTOR inhibitors include rash, asthenia, mucositis, nausea, edema, myelosuppression, hyperlipidemia, hypercholesterolemia, hyperglycemia, and drug-induced pneumonitis.

Finally, based on the known activity of cytokine therapy and retrospective data of clinical responses in patients following anti–PD-1/PD-L1 therapy, high-dose IL-2 may be considered for select clear–cell renal cell carcinoma patients in the treatment-refractory setting.[182]

Chemotherapy

In general, renal cell carcinoma is highly resistant to conventional chemotherapy, which does not have a role in the treatment algorithm. One exception is collecting-duct carcinoma, a rare and aggressive subtype of kidney cancer that originates from medullary collecting ducts. Small studies show that gemcitabine plus platinum has activity in metastatic collecting-duct carcinoma, analogous to the treatment of upper-tract urothelial carcinoma.[183] Renal medullary carcinoma is another rare, aggressive subtype of collecting-duct carcinomas, most commonly occurring in patients with the sickle cell trait associated with SMARCB1 loss. Platinum-based chemotherapy combinations have also reported clinical activity in a small case series of patients with renal medullary carcinoma.[184]

SARCOMATOID RENAL CELL CARCINOMA

Sarcomatoid histology represents tumor dedifferentiation and can be associated with any major histological subtype of renal cell carcinoma. Sarcomatoid features are associated with aggressive tumor biology as well as relatively limited benefit from VEGFR TKIs. However, immune checkpoint inhibitors have demonstrated promising clinical activity. Nivolumab and ipilimumab demonstrated a high ORR of 61% (23% CR) in patients with sarcomatoid clear–cell renal cell carcinomas, along with significantly improved OS and PFS compared with sunitinib.[185]

Similarly, the phase 3 studies of anti–PD-1 and TKI combinations included a subset of patients with sarcomatoid histology and reported clinical benefit with these combinations over sunitinib. However, the long-term follow-up and overall data with nivolumab and ipilimumab appear more robust than the data currently available for anti–PD-1 and TKI combinations for sarcomatoid variant disease.

KEY POINTS

- Adjuvant pembrolizumab for 1 year improves DFS and OS in intermediate- and high-risk resected localized clear–cell renal cell carcinoma.
- First-line systemic therapy for metastatic clear–cell renal cell carcinoma includes combination immune checkpoint blockade with ipilimumab and nivolumab or combination of PD-1/PD-L1 inhibition and VEGFR TKIs.
- The role of cytoreductive nephrectomy in the setting of metastatic disease remains undefined in the era of immune checkpoint inhibitor combinations. For patients without symptomatic primary tumors who are eligible for first-line systemic therapy, immediate cytoreductive nephrectomy may not provide significant benefit. The role of deferred nephrectomy is being evaluated in prospective clinical trials.
- Second-line therapy for metastatic disease includes VEGFR TKIs, belzutifan, mTOR inhibitors, and cytokine therapy in select patients, with the choice of therapy dependent on prior treatment. Alternate antiangiogenesis inhibitors may still be active after prior antiangiogenic therapy.

NON–CLEAR CELL RENAL CELL CARCINOMA

Most treatment strategies in renal cell carcinoma have been tested primarily or exclusively in clear–cell renal cell carcinoma, and high-level evidence for treatment of rare non–clear cell renal cell carcinoma histologies is lacking. Importantly, non–clear cell renal cell carcinoma (RCC) is not one disease, and the biology of different histological subtypes is quite different; unfortunately, many trials have lumped these patients together, given the rarity of individual subtypes. For localized disease, the standard treatment remains nephrectomy. No adjuvant therapy has proven benefit for non–clear cell disease. For advanced disease, targeted therapies or immunotherapy may be offered (Table 14-8); chemotherapy is generally ineffective but may have

Table 14-8 Targeted Agents for Non–Clear Cell RCC

Agent	Primary Target	Histology	Outcome
Sunitinib	*VEGFR*	Papillary, chromophobe, translocation	Improved PFS with sunitinib vs everolimus (8.3 vs 5.6 months), but poor-risk patients may have better PFS with everolimus
Temsirolimus	*mTOR*	Papillary, chromophobe	Improved OS with temsirolimus vs IFN (11.6 vs 4.3 months)
Everolimus	*mTOR*	Papillary, chromophobe, translocation	See above comments on sunitinib. No clear difference between sequencing sunitinib followed by everolimus vs everolimus followed by sunitinib
Crizotinib	*MET*	Type I papillary RCC	In 4 of 23 patients with *MET* alteration, 2 had PR
Foretinib	*MET*, *VEGF*	Papillary RCC	In 10 patients with germline *MET* alteration, 5 had PR. Overall, RR was 13.5%; median PFS was 9 months
Savolitinib	*MET*	Papillary RCC	In the phase 3 SAVOIR trial, compared savolitnib vs sunitinib in *MET*-driven papillary RCC. Enrollment was closed early when new data suggested longer-than-anticipated PFS of patients with papillary RCC treated with sunitinib. PFS numerically improved, not statistically significant (with early termination). Savolitinib arm of PAPMET closed early for futility
Cabozantinib	*MET*, *VEGF*	Papillary RCC	Improved ORR and PFS were seen in comparison with sunitinib in the frontline setting in PAPMET (see above)

Abbreviations: IFN, interferon; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; PR, partial response; RCC, renal cell carcinoma; RR, response rate; VEGFR, vascular endothelial growth factor receptor.

some benefit for collecting-duct renal cell carcinoma or renal medullary carcinomas. Ipilimumab with nivolumab was recently evaluated versus the investigator's choice (primarily VEGF inhibitor monotherapy) in non–clear cell histologies in the phase two SUNNIFORECAST trial.[186] Across all histologies, OS at 12 months was improved with ipilimumab/nivolumab versus investigator's choice (86.9% vs 76.8%), with no clear differences emerging in papillary versus nonpapillary histologies in an underpowered comparison. Nonrandomized data suggest that single-agent PD-1 inhibitors may result in objective responses in patients with papillary tumors.[12,187] Combination of VEGF and PD-1 inhibition may also be a reasonable option, especially in papillary RCC, based on single-arm data.[12,187] Better therapies are needed for patients with non–clear cell renal cell carcinoma, and clinical trials are preferred when available.

Activation of the c-MET signaling pathway in papillary renal cell carcinomas has led to trials with agents that target the c-MET tyrosine kinase receptor or its ligand, hepatocyte growth factor, in patients with metastatic papillary renal cell carcinoma. MET-driven disease can be defined by chromosome 7 copy gain, focal *MET* or *HGF* gene amplification, or MET kinase domain mutations. Several MET inhibitors have been investigated in this disease. The PAPMET trial investigated the optimal therapy for patients with metastatic papillary renal cell carcinoma treated with up to one previous therapy (excluding VEGF- and/or MET-targeted agents), comparing sunitinib, cabozantinib, crizotinib, and savolitinib. Crizotinib and savolitinib arms were halted for futility; ORR and PFS were significantly improved with cabozantinib versus sunitinib.[188]

SPECIAL CONSIDERATIONS FOR PATIENTS WITH METASTATIC RENAL CELL CARCINOMA

Approximately one-third of patients with advanced renal cell carcinoma have bone metastases, and these are predominantly osteolytic. Treatment with bone-targeting agents, such as zoledronic acid (which requires dose adjustment for renal impairment) or denosumab, has been shown to decrease the risk of SREs in patients with bone metastases. As discussed in the "Prostate Cancer" section, dosing schedules may vary.

Brain metastases are a frequent complication in patients with metastatic clear–cell renal cancer. Surgical resection or stereotactic radiosurgery is a feasible alternative to whole-brain irradiation and may result in long-term survival. Patients with treated brain metastases may safely receive systemic therapy. Limited studies have also suggested that patients with severe renal impairment or end-stage renal disease who are receiving hemodialysis may safely be treated with selected targeted therapies.

TREATMENT OF CANCERS ASSOCIATED WITH VHL DISEASE

Von Hippel-Lindau disease is a rare condition characterized by a mutation of the *VHL* gene. VHL is commonly associated with the development of bilateral renal cell carcinomas, CNS, pancreatic, and retinal hemangioblastomas and other tumors. Impressive responses to oral belzutifan, an HIF-2α inhibitor, were demonstrated in renal cell carcinomas (49%), pancreatic tumors (77%), and CNS hemangioblastomas (30%) associated with VHL. Based on the results of this phase 2 single-arm study, oral belzutifan was FDA approved for the treatment of VHL-associated disease manifestations, including primitive neuroectodermal tumors, renal cell carcinomas, and hemangioblastomas.

SURVIVORSHIP AND CONSIDERATIONS IN ELDERLY PATIENTS

Radical nephrectomy is a significant risk factor for chronic kidney disease. With the normal physiological decline in renal function attributed to aging, older patients have a greater decline in kidney function compared with younger patients. Nephron-sparing approaches should be considered in appropriately selected patients in an effort to preserve renal function; however, despite having similar tumor sizes, fewer older patients are treated with a partial nephrectomy. Although checkpoint inhibitors and agents targeting the VEGF and mTOR pathways have substantially improved the outcome for patients with advanced kidney cancer, these drugs are associated with a wide spectrum of adverse effects, including immune-related adverse events, hypertension, hand-foot syndrome, thyroid dysfunction, hyperglycemia, hyperlipidemia, dysphonia, and pneumonitis, as well as others, compared with conventional cytotoxic chemotherapy. Monitoring for and management of these new toxicities are critical to ensure patients tolerate treatment and derive the greatest benefit from these effective therapies. With the substantial improvement in survival associated with targeted therapies in renal cell carcinoma, special attention to long-term adverse effects, including cardiac disease, thyroid dysfunction, renal insufficiency, and infection risk, among others, is needed. Older patients with preexisting medical issues, such as hypertension or heart disease, must be monitored closely for worsening hypertension and left ventricular function decline during treatment. For example, patients with a history of hypertension and coronary artery disease are at increased risk of cardiotoxicity related to sunitinib. An analysis of age and efficacy and toxicity from phase 3 trials of sorafenib, sunitinib, temsirolimus, and bevacizumab, and from an expanded-access experience with sunitinib and sorafenib, suggests that outcomes and major toxicities are similar for patients aged 65 years or older and younger patients. Prospective studies of immune-based and targeted agents in elderly patients with advanced renal cell carcinoma with particular attention to adverse effects are needed.

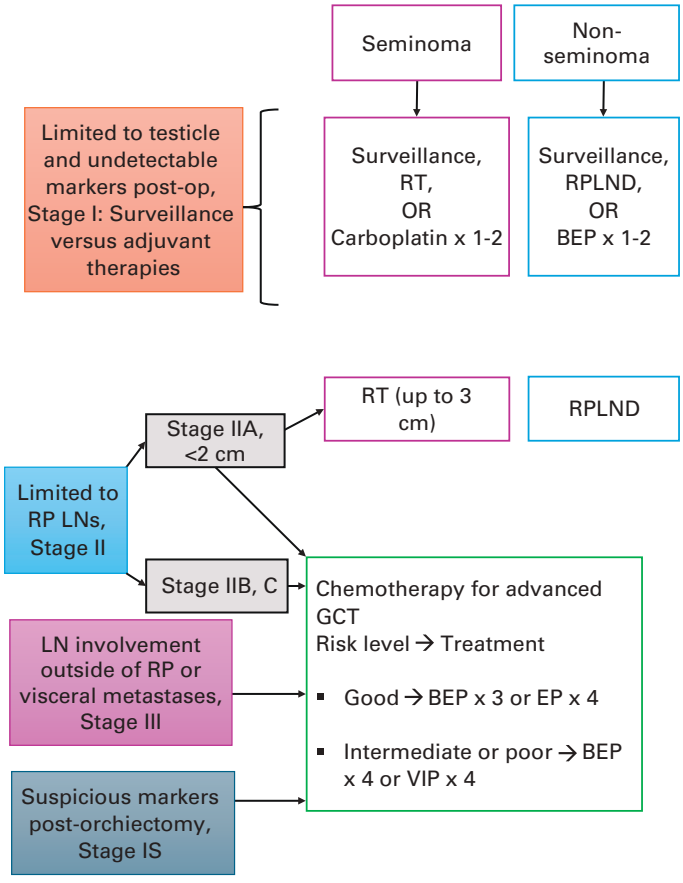
KEY POINTS

- Non–clear cell renal cell carcinomas have been underrepresented in clinical trials, and the optimal treatment strategy is not well defined. Targeted agents include standard anti-VEGF TKIs as well as an emerging role for *MET* inhibition in papillary renal cell carcinoma, especially using the dual VEGF/MET inhibitor cabozantinib.
- Bone metastases may be treated with systemic therapy and bone-protective agents such as bisphosphonates or denosumab. Brain metastases and oligometastases can be treated with local therapies (eg, surgery, RT, or ablation) followed by systemic therapy, sometimes with long-term disease control.
- Elderly patients with comorbidities may benefit from active surveillance of appropriate renal cell carcinomas or nephron-sparing approaches (eg, partial nephrectomy or stereotactic body RT) when treatment is required. For those being treated for advanced renal cell carcinoma, attention must be paid to the unique toxicities of checkpoint inhibitors and/or targeted therapies in the setting of concomitant hypertension, diabetes, chronic kidney disease, and thyroid disease, among others.

GERM CELL TUMORS

Germ cell tumors are the most common malignancies among men between ages 15 and 35 years, although there is a second peak in patients older than age 60 years (primarily seminomas).[189] Germ cell tumors most frequently originate in the gonads (testis or ovary) and less commonly in the retroperitoneum and mediastinum or CNS (primary extragonadal germ cell tumors; for a discussion of germ cell tumors in women, see Chapter 15: Gynecological Cancers). Retroperitoneal tumors in the absence of primary testicular cancer may represent pure extragonadal germ cell tumors. Occasionally, an orchiectomy in these circumstances may show no distinct cancer but rather remnants of a scar (ie, scar carcinoma or burnt-out primary), which has been attributed to rapidly proliferating testicular cancer that metastasized, leaving only a scar at its site of origin. Primary mediastinal germ cell tumors arise in the anterior mediastinum and are not associated with testicular involvement. Primary extragonadal germ cell neoplasms also

Figure 14-19 Treatment Options for Germ Cell Tumors



Abbreviations: BEP, bleomycin/etoposide/cisplatin; EP, etoposide/cisplatin; GCT, germ cell tumor; LN, lymph node; RP, retroperitoneal; RPLND, retroperitoneal lymph node dissection; RT, radiation therapy; VIP, etoposide/ifosfamide/cisplatin.

arise rarely in the sacrum, pineal gland, paranasal sinuses, and liver and may be associated with several concomitant hematological abnormalities, including idiopathic thrombocytopenia or acute megakaryocytic (M7) leukemia. Regardless of the stage or extent of disease, the therapeutic objective is cure, which requires an integrated multidisciplinary approach (Fig. 14-19).[190]

EPIDEMIOLOGY

Risk factors include both abdominal and inguinal cryptorchidism (which is associated with cancer in both the affected and, to a lesser extent, unaffected testis), spermatic or testicular dysgenesis, and family history, which confers a 4- to 10-fold increase in risk. Orchidopexy or surgical correction of abdominal cryptorchidism results in an improved ability to monitor the testis but does not affect the risk of cancer diagnosis; treatment of an undescended testis before puberty or during infancy decreases the risk of testicular cancer compared with correction after puberty. Factors associated with increased risk for testicular cancer mortality include age older than 40 years, non-White race, and lower socioeconomic status. Testicular seminoma occurs more frequently in men with HIV, and the treatment is the same as that for the HIV-negative population. Klinefelter syndrome (XXY) is a risk factor for the development of mediastinal germ cell tumors. CIS (intratubular germ cell neoplasia) is a common finding when testicular germ cell tumors are diagnosed. Men in whom in situ disease is identified during a testicular biopsy as part of an infertility evaluation have a 50% risk of an invasive tumor within 5 years. Asynchronous testicular primary germ cell tumors occur in 2% of patients with seminoma as the most common histology and should be treated as a separate entity from the first testicular primary.

BIOLOGY

Germ cell tumors are derived from the malignant transformation of premeiotic germ cells. To create a pluripotential tumor, these transformed germ cells must be able to differentiate like the totipotent zygote without the reciprocal genetic information that results from fertilization. An isochromosome of the short arm of chromosome 12 (i[12p]) is present in 80% of all histological subtypes, including CIS and primary extragonadal tumors. The remaining 20% of cases have an excess 12p genetic copy number, tandem duplication, or transposition, which indicates that one or more genes on 12p are involved in malignant transformation. Most germ cell tumors are marked by aneuploidy and reciprocal loss of heterozygosity, though whether these are passenger or driver events remains to be elucidated. I(12p) can be detected by fluorescence in situ hybridization and helps identify germ cell tumors from other malignancies.

KEY POINTS

- The most well-known risk factor for testicular cancer is the history of undescended testis (cryptorchidism). Early surgical correction can help mitigate this risk.
- Genes on chromosome arm 12p seem to be involved with germ cell tumor pathogenesis, and i(12p) is a common finding that may help differentiate germ cell tumors from other tumor types in ambiguous situations or cancers with unknown primary.

DIAGNOSIS

Most patients diagnosed with testicular cancer initially present with a painless testicular mass, though patients can also present with diffuse testicular swelling, induration, hardness, discomfort, pain, or some combination of these findings. For patients who present with scrotal or testicular pain, the initial therapy prescribed is often antibiotics for presumed infectious epididymitis or orchitis. Scrotal ultrasonography (specificity of 89%-90% and sensitivity of 98%-99% for testicular cancer) should be performed when any concern is present about the possibility of a testicular tumor. If the ultrasonogram is abnormal and a testicular tumor is suspected, levels of tumor markers (human chorionic gonadotropin [hCG], α-fetoprotein [AFP], and LDH) should be obtained. This should be followed by a radical inguinal orchiectomy with removal of the testis and ligation of the spermatic cord at the level of the internal ring. Because the testes originate in the genital ridge and migrate through the abdomen and inguinal canal into the scrotum, the vascular and lymphatic drainage of the testes is to the renal or great vessels and the retroperitoneal nodes, respectively. A testicular biopsy or transscrotal orchiectomy is contraindicated because the normal vascular and lymphatic drainage is disturbed. Levels of AFP, β-hCG, and LDH should also be determined before and after orchiectomy. Less common presentations include unilateral or bilateral gynecomastia (as a result of elevated levels of β-hCG), hyperthyroidism resulting from homology between β-hCG and thyroid-stimulating hormone, persistent back pain related to retroperitoneal nodal disease, superior vena cava syndrome from primary mediastinal tumors, supraclavicular adenopathy, and hemoptysis from extensive pulmonary metastases.

KEY POINTS

- Suspicious testicular symptoms or findings should be evaluated by ultrasonography. If the results are suggestive, diagnosis is made via inguinal orchiectomy, never via percutaneous biopsy. Tumor marker levels should be determined beforehand, and if elevated, measurement must be repeated after surgery.

- For patients who present with life-threatening symptoms (eg, bleeding brain metastases or pulmonary metastases causing respiratory failure), highly elevated AFP or β-hCG levels, and a typical pattern of spread, systemic therapy should be started immediately. Resection of a suspicious testicular lesion can be delayed until after starting or completing chemotherapy, but should still be performed to establish a pathological diagnosis and remove a potential chemotherapy sanctuary site.

PATHOLOGY

Germ cell tumors are classified histologically into seminomas and nonseminomas. Seminomas, which account for approximately half of testicular germ cell tumors, retain totipotentiality and are exquisitely sensitive to RT and chemotherapy. Nonseminomas are composed of one or more of the following cell types: embryonal carcinoma, teratoma, choriocarcinoma, and yolk sac tumors.

Classification for germ cell tumors can be found via the *AJCC Cancer Staging Manual, 8th Edition*. For more information, visit https://www.cancer.org/cancer/types/testicular-cancer/detection-diagnosis-staging/staging.html. Embryonal carcinoma is the most undifferentiated with totipotential capacity to differentiate into extraembryonic malignant cell types. Teratoma is composed of somatic cells from two or more germ cell layers (ie, ectoderm, mesoderm, or endoderm) and, thus, can differentiate into tissue types, such as cartilage, muscle, mucinous glandular epithelium, and others. Teratomas do not respond to chemotherapy or RT, and treatment primarily involves surgical resection. Yolk sac tumors are the most common testicular cancers seen in infants and children. They are associated with high AFP levels and are chemotherapy sensitive. Choriocarcinomas are frequently seen with other subtypes, are more likely to metastasize to the lungs and brain, and are sometimes associated with elevated β-hCG levels as well as a risk of hemorrhage. In patients with high-volume choriocarcinoma and marked elevation of β-hCG, a condition known as choriocarcinoma syndrome, the extent of hemorrhage can be life-threatening.

The presence of any component of nonseminoma with seminoma is treated as a nonseminomatous germ cell tumor. In addition, an abnormal serum AFP (>20-25) level is not seen in seminoma and should be treated as nonseminomatous because of either sampling error or not identifying the nonseminomatous component in the orchiectomy specimen or the nonseminomatous component being present in metastatic foci. Borderline AFP elevations can be caused by liver disease, but an occult nonseminomatous component must be considered and ruled out, especially if AFP levels climb. Most nonseminomas show mixed histologies, including embryonal carcinoma, yolk sac tumor, teratoma, and choriocarcinoma. When reporting histology, all subtypes present must be noted, starting with the most prevalent and ending with the least common component.

Seminomas are positive for placental alkaline phosphatase, CD117 (c-kit), OCT-4, and SALL-4 (Figs. 14-20 and 14-21). They are negative for cytokeratins and CD30. Embryonal carcinoma, however, almost universally expresses cytokeratins, epithelial membrane antigen, CD30, OCT-4, and SALL-4; approximately 50% express placental alkaline phosphatase. Yolk sac tumors are positive for cytokeratins, AFP, and SALL-4 but negative for CD117 and CD30. Immunohistochemical analysis and testing for i(12p) may be useful in the evaluation of patients with midline tumors of uncertain histogenesis. Serum markers consistent with germ cell tumors may also be helpful, although the elevation of β-hCG level is more specific than elevated levels of AFP or LDH.

KEY POINTS

- Germ cell tumors are divided into seminomas and nonseminomas. Seminomas must be composed entirely of seminoma; any component of other histology results in a diagnosis of nonseminoma, and an elevated AFP level (>20-25) should be treated as nonseminoma.
- Seminomas are highly sensitive to chemotherapy and RT. This has implications for therapy and evaluation of residual masses after therapy.
- Nonseminomas can be mixes of multiple histologies, including malignant germ cell tumors (embryonal carcinoma, yolk sac tumor, and choriocarcinoma) and teratomas. Malignant nonseminomatous germ cell tumors are generally chemotherapy sensitive. Teratoma is neither chemotherapy nor RT sensitive. By itself, teratoma does not usually metastasize, but it can dedifferentiate over time into malignant histologies, including (but not limited to) teratocarcinoma or certain sarcomas.

PATTERNS OF SPREAD

The primary lymphatic drainage for testicular germ cell tumors is to the retroperitoneal lymph nodes (primary landing zones). The right testicular artery originates from the aorta, and the right testicular vein drains into the inferior vena cava. The left testicular artery originates near the left renal artery, and the left testicular vein terminates in the left renal vein. Right-sided tumors spread to the interaortocaval lymph nodes immediately below the renal blood vessels, and left-sided tumors spread to the paraaortic lymph nodes immediately below the left renal artery and vein. Cross-metastases are more commonly seen from right to left but may occur in either direction if there has been a prior inguinal surgery, such as hernia repair. Invasion of the epididymis or spermatic cord may be associated with iliac nodal involvement, and inguinal metastases may be seen with scrotal invasion or disturbance of the normal lymphatic drainage related to prior surgery, such as a vasectomy or orchiopexy. A full understanding of lymphatic drainage has informed the development of retroperitoneal templates for right- and left-sided tumors that are often used when a retroperitoneal lymphadenectomy is performed, and helps minimize fertility consequences of the surgery. Additional metastatic sites include retrocrural, mediastinal, and supraclavicular lymph nodes; the lungs; and, less commonly, the liver, CNS, and bone.

KEY POINTS

- The testicles descend from the retroperitoneum embryologically; therefore, the lymphatic drainage is to the retroperitoneal lymph nodes rather than the inguinal or pelvic lymph nodes. This has implications for surveillance and treatment.
- If prior inguinal or transscrotal surgeries have been performed, the lymphatic drainage may be disrupted; therefore, the pattern of metastasis can be less predictable, and more caution is needed if considering adjuvant retroperitoneal lymph node dissection (RPLND) or radiation.
- From the retroperitoneal lymph nodes, testicular cancer may spread to mediastinal and other lymph nodes. Pulmonary metastases are much more common than other visceral metastases and do not carry as poor a prognosis as other visceral involvement.

STAGING

Pretreatment Evaluation

The extent of disease evaluation for patients with newly diagnosed germ cell tumors includes a chest radiograph, CT scan of the abdomen and pelvis, and measurement of tumor-marker levels (Table 14-9). Indications for a CT scan of the chest include an abnormal chest radiograph, known mediastinal disease, and risk for pulmonary metastases. A bone scan and MRI of the brain are indicated if related symptoms are present or patients are high risk for intracranial metastases by virtue of the presence of bone or pulmonary metastases, high β-hCG (eg, >5,000 IU/L), or choriocarcinoma-predominant histology. Measurement of tumor markers, including AFP, hCG, and LDH, is used to establish the diagnosis and may assist in determining histological subtype (Table 14-10). Sperm banking should be performed before treatment is pursued when practical, but also with an appreciation that many men with testicular cancer will have low sperm counts associated with their disease.

Table 14-9 Risk Stratification According to the International Germ Cell Consensus Classification[167]

Germ Cell Tumor	Risk Stratification
Seminoma	Good risk: • Any primary and any markers and no nonpulmonary visceral metastases
	Intermediate risk: • Any primary and any markers and nonpulmonary visceral metastases
Nonseminoma	Good risk: • Testis or retroperitoneal primary and good-risk markers, and no nonpulmonary visceral metastases
	Intermediate risk: • Testis/retroperitoneal primary and intermediate-risk markers and no nonpulmonary visceral metastases
	Poor risk: • Mediastinal primary site or testis or retroperitoneal primary with either nonpulmonary visceral metastases or poor-risk markers

Stage Groupings

A TNM staging classification system was developed by the AJCC and incorporates clinical features as well as serum tumor markers, including AFP, β-hCG, and LDH. For testicular germ cell tumors, it is useful to delineate between localized (clinical stage 1, tumor markers normal after orchiectomy) and metastatic (clinical stage 2 or 3 regardless of tumor markers, or clinical stage 1 with elevated tumor markers).[183] Adverse prognostic factors for germ cell tumors include mediastinal primary site; degree of elevation of AFP, β-hCG, and LDH; and presence of nonpulmonary visceral metastases. Regardless of the initial risk stratification, patients with advanced germ cell tumors who survive and remain without disease more than 2 years after their diagnosis have an excellent chance of remaining disease-free in subsequent years, although relapses after the 2-year mark (termed "late relapse") can occur. Late relapses after 3 or more cycles of platinum-based chemotherapy tend to be more chemorefractory, and surgery is the preferred approach for management.

Tumor Markers

Tumor-marker levels are measured before, during, and after treatment. An initial increase in tumor-marker levels may occur with chemotherapy, particularly in the setting of bulky advanced disease. The serum half-lives of AFP and β-hCG are 5 to 7 days and 24 to 48 hours, respectively, and a slow decline in marker level after orchiectomy or during chemotherapy may imply residual active disease. In the absence of radiographic metastases, markers should be checked approximately 4 to 5 weeks (five AFP half-lives) after orchiectomy to assess for residual disease (stage IS) that would require systemic treatment. Elevated or increasing AFP and/or β-hCG levels that occur without radiological or clinical findings can imply micrometastatic disease and should, at a minimum, trigger imaging and close follow-up. Other conditions associated with elevated AFP levels include hepatocellular carcinoma, liver damage, and other gastrointestinal malignancies. β-hCG elevations may occur as a result of hypogonadism or cross-reactivity with pituitary hormones, including luteinizing hormone, as well as some gastrointestinal tumors, including gastric cancer. This cross-reactivity is generally less of an issue with current assays specific for the β subunit of hCG. Hyperthyroidism may be associated with elevated levels of β-hCG related to homology between β-hCG and thyroid-stimulating hormone. A spurious elevation in hCG has also been associated with marijuana use. With these exceptions, increased levels of AFP are pathognomonic of nonseminoma and not seen in seminoma, whereas elevated levels of β-hCG may be seen in both seminoma and nonseminoma. AFP elevation in the setting of a diagnosis of seminoma should prompt re-evaluation of the pathology and often treatment of presumed nonseminoma, regardless of the official histological diagnosis; a low level of AFP elevation (<20 ng/mL) that does not change should not change management on its own. Lactate dehydrogenase levels can increase in patients with advanced seminoma or nonseminoma and are used for staging and assessment of outcome. However, LDH is a nonspecific biomarker, and as a result, a rise in LDH alone must be further evaluated before attributing this finding to germ cell tumor. Furthermore, low-level elevation (ie, three times the upper limit of normal) should not, on its own, influence treatment decisions.

KEY POINTS

- Before orchiectomy, tumor-marker levels should be measured, and patients should undergo cross-sectional imaging of the abdomen and pelvis as well as chest imaging. MRI of the head and a bone scan are indicated only for patients with suspicious symptoms or in the setting of specific risk factors.
- Advanced (metastatic) germ cell tumors are risk-stratified according to primary site, pattern of spread, and degree of serum tumor-marker elevation.

SEMINOMA

Stage I

Approximately 70% of patients with seminoma have stage I disease. After radical inguinal orchiectomy, standard treatment options include surveillance, adjuvant infradiaphragmatic RT to include the para-aortic nodes, and single-agent carboplatin, recognizing that approximately 85% of clinical stage 1 patients will never relapse and that the long-term survival is nearly 100% regardless of the initial option chosen. Observational studies of patients with clinical stage I seminoma indicate a 15% to 20% likelihood of disease relapse, mostly in the retroperitoneum, and the median time to relapse is 12 to 14 months, which is longer than that for clinical stage I nonseminomatous tumors. Given the relatively indolent course of seminoma, late relapses may occur, but as discussed, if chemotherapy-naive, then these tumors can be treated using standard approaches. A contralateral tumor in the remaining testis should be considered when relapses occur.

Based on the excellent outcomes for patients with stage I seminoma and the potential for long-term RT-related toxicity, including secondary malignancies, active surveillance represents the preferred strategy for the management of patients with clinical stage I disease.

Adjuvant RT or single-agent chemotherapy reduces recurrence risk but increases late toxicity, and patients whose disease is managed with active surveillance can almost always be cured with deferred treatment at the time of relapse. Adjuvant radiation

therapy and carboplatin are considered equally effective for risk reduction based on a randomized noninferiority study[191] but have different considerations around their use. Radiation therapy should be avoided in the setting of inflammatory bowel disease or horseshoe kidney and is associated with a small risk of secondary cancers. Inclusion of a pelvic field should be considered for men with a history of scrotal surgery (eg, vasectomy) because out-of-field recurrences can occur if the possibility of aberrant lymphatic drainage is not addressed. One to two cycles of carboplatin have clear short-term toxicity and poorly quantified long-term side effects but also reduce the risk of a second primary germ cell tumor.

In seminoma, stage IS disease is rare, and low levels of LDH or β-hCG may be attributable to other causes. In cases of ambiguously low but elevated tumor-marker levels, patients should receive ongoing surveillance to monitor for the development of radiographically apparent metastases or persistent tumor-marker rise, and alternative explanations for tumor marker elevation should be sought.

Stage IIA/B

Patients with stage IIA and nonbulky IIB disease (2-3 cm) can be treated with chemotherapy or 30 to 36 Gy of radiation to the para-aortic and ipsilateral iliac lymph nodes. There is a small risk of recurrence outside of the radiated field, although these patients can be effectively salvaged with chemotherapy. Chemotherapy is preferred for patients with clinical stage IIB seminoma with bulkier disease (>3 cm). There is emerging research as to the role of retroperitoneal lymph node dissection in stage IIA or nonbulky stage IIB disease, but given varying results in small prospective studies, this approach is generally considered investigational.

Advanced Seminoma

Patients with retroperitoneal masses >5 cm (stage IIC), supradiaphragmatic lymphadenopathy, visceral disease, bulky retroperitoneal tumors, tumor-related back pain, and mediastinal extragonadal presentations are treated with primary chemotherapy. At least 90% of patients with advanced seminoma will be classified as having a good prognosis and receive treatment with good-risk chemotherapy, which is associated with a 96% 5-year survival rate, whereas fewer than 10% of patients have intermediate-risk disease because of metastases outside lymph nodes and the lung. Pure seminomas are never classified as poor risk (see "Management of Advanced Germ Cell Tumors by Risk Classification" section and refer to NCCN guidelines for seminomas).

Post-Chemotherapy Residual Masses

Surgery after chemotherapy is technically more difficult for patients with seminoma because of a dense desmoplastic reaction after chemotherapy in seminoma that occurs less frequently in patients with nonseminoma. Post-chemotherapy residual masses usually represent fibrosis rather than persistent seminoma and may continue to shrink in the absence of any additional interventions over months to years. Residual masses smaller than 3 cm very rarely contain viable seminoma, and thus, surveillance is indicated in this context. Residual masses larger than 3 cm present more than 6 weeks after the last cycle of chemotherapy can be further evaluated by FDG PET imaging.

Though the positive predictive value of PET in seminoma for post-chemotherapy masses larger than 3 cm has been questioned,[192] guidelines recommend further intervention with serial imaging, biopsy, or surgical resection if a residual seminoma mass larger than 3 cm demonstrates FDG avidity.

KEY POINTS

- Stage I seminomas are generally managed with active surveillance. Alternatives include adjuvant chemotherapy (one to two cycles of carboplatin) or RT, which decreases the risk of recurrence but results in some degree of overtreatment and has long-term toxicities. OS is excellent regardless of immediate versus delayed intervention. Therefore, adjuvant treatment is typically offered only to patients who are eager to reduce their chance of recurrence (and the need for more intensive therapy) or who may have difficulty adhering to a surveillance schedule, with the understanding that OS will not likely be improved.
- Stage IIA and nonbulky IIB seminomas can be treated with RT to the retroperitoneal lymph nodes or chemotherapy.
- Stage IIB and advanced seminomas (stages IIC and III) are treated according to the risk stratification scheme for advanced germ cell tumors, with most falling into the good-risk category and a minority being intermediate risk because of nonpulmonary visceral metastases. Seminomas are never considered poor risk.

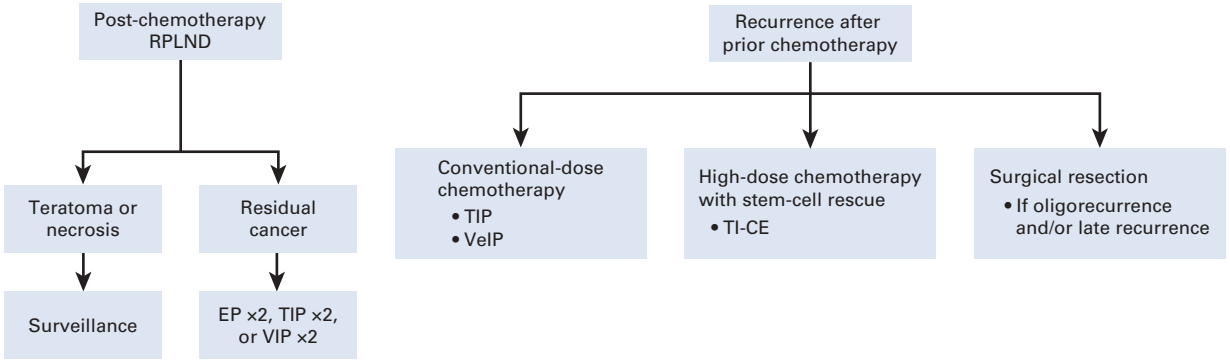
NONSEMINOMATOUS GERM CELL TUMORS

Stage I

Approximately 30% to 40% of patients with nonseminomatous germ cell tumors present with stage I disease. Management options include surveillance or adjuvant risk reduction with RPLND or chemotherapy.

Surveillance is a preferred option for patients who have stage IA disease (pT1 tumors; ie, those with no vascular or lymphatic invasion or with invasion into the tunica vaginalis, spermatic cord, or scrotum) who have a low risk of recurrence and are likely to return for follow-up (Fig. 14-22). Absence of a predominant (>50%) embryonal carcinoma component in the primary tumor is also favorable, although rarely seen without the accompanying risk factor of lymphovascular invasion (LVI). Approximately 20% to 30% of patients will experience a recurrence of the disease (most commonly in the retroperitoneum) and will need chemotherapy or primary RPLND. Most recurrences of nonseminomatous germ cell tumors will occur within 2 years of orchiectomy, and these patients must have meticulous follow-up that includes history, physical examination, and measurement of serum tumor markers every 2 to 3 months as well as a chest radiograph at months 4 and 12 and an abdominal and pelvic CT scan every 4 to 6 months during the first year (see NCCN guidelines for nonseminomas). Although the intervals for follow-up increase during subsequent years, it is important to remember that late recurrences can occur. Compliance with this surveillance schedule and with salvage therapy as indicated produces cure rates of 98% to 99%. Surveillance spares the 70% to 80% of patients without micrometastatic disease from additional therapy and associated complications. The potential long-term risk of secondary cancers associated with exposure to low-dose ionizing radiation with surveillance imaging has generated particular concern for young patients with germ cell tumors. The lifetime attributable risk of fatal secondary cancers from the current recommended surveillance schedule with modern CT techniques is challenging to estimate (one recent study suggested approximately 0.2% as a likely overestimate).[193] To minimize radiation exposure from these repeated radiographic evaluations, MRI evaluations of the abdomen and pelvis can be substituted for CT imaging.

Figure 14-22 Management After Pathology From RPLND



Abbreviations: EP, etoposide/cisplatin; RPLND, retroperitoneal lymph node dissection; TI-CE, paclitaxel/ifosfamide/carboplatin/etoposide; TIP, paclitaxel/ifosfamide/cisplatin; VeIP, vinblastine/ifosfamide/cisplatin; VIP, etoposide/ifosfamide/cisplatin.

Patients with stage I dis\ease for whom the risk of disease recurrence is high (>50%) based on pathological features, including embryonal carcinoma predominance (>50%) and/or presence of lymphatic, vascular, scrotal, or spermatic cord invasion (stage IB), may be considered for adjuvant risk reduction with nerve-sparing RPLND or one cycle of combination bleomycin/etoposide/cisplatin (BEP). RPLND should be performed by a high-volume urological oncology surgeon and may be especially considered for patients with a substantial teratoma component in the primary tumor. In a nerve-sparing RPLND, the sympathetic chains, postganglionic sympathetic nerve fibers, and hypogastric plexus are identified and spared as feasible to increase the likelihood of preserved antegrade ejaculation (non–nerve-sparing techniques may result in retrograde ejaculation and, therefore, impaired fertility). Low recurrence rates have been demonstrated in studies evaluating the use of short-course primary chemotherapy with one or two cycles of combination BEP in patients with clinical stage I nonseminomatous germ cell tumors; however, some experts have concerns regarding the many men exposed to unnecessary chemotherapy, resulting in a potential for long-term adverse effects. The decision to recommend adjuvant chemotherapy after RPLND is made based on pathological findings as described for patients who have pathological stage II disease. Surveillance in a compliant patient with stage IB is an accepted option and is preferred by some experts in the field. Patients without evidence of clinical disease and persistently elevated levels of tumor markers, including β-hCG, AFP, or both after orchiectomy (stage IS), should receive standard chemotherapy for metastatic disease rather than surgery.

Stage II

The standard treatment of a patient with stage IIA disease (retroperitoneal nodes <2 cm in diameter) is a modified bilateral RPLND. Experience with the technique is essential because, depending on the location of the tumor, an ejaculatory nerve-sparing procedure can be performed.

Approximately 20% to 25% of patients who have undergone a primary RPLND will have pathological N1 disease (metastases with node diameter ≤2 cm or five or fewer involved nodes, ie, an occult nodal metastasis that was not detected on preoperative imaging). In these patients, the risk of relapse is low; therefore, surveillance is preferred in an adherent patient. With modern CT imaging, it would be rare to have occult N2 or N3 disease discovered at the time of primary RPLND (radiographic N2 or N3 disease would be treated with chemotherapy). The likelihood of micrometastatic disease outside the templated dissection is ≤50% for patients with pathological N2 disease (an involved node diameter >2 cm, more than five involved nodes, or any extranodal extension). Assuming that serum tumor-marker levels return to normal after surgery, these patients should receive two cycles of adjuvant chemotherapy, which results in a 98% to 99% likelihood of cure. It is unusual to have patients with pathological N3 disease (node diameter >5 cm) because such evidence guiding their management is limited, but guidelines recommend three to four cycles of adjuvant chemotherapy. In circumstances in which the disease recurs or if the serum tumor-marker levels do not normalize, indicating residual active disease, three to four cycles of chemotherapy and subsequent surgical excision of residual macroscopically documented disease are recommended. Most patients with clinical stage IIB disease (nodes >2 cm but not >5 cm in diameter) are advised to receive primary chemotherapy rather than undergo RPLND.

Advanced Nonseminoma

Clinical stage IIC disease (nodes >5 cm in diameter) and stage III disease should be treated with upfront chemotherapy (see "Management of Advanced Germ Cell Tumors by Risk Classification" section). Approximately 70% to 80% of patients with metastatic disease will be cured with cisplatin-based chemotherapy combined with surgery to resect residual disease as an integral part of management. The therapeutic objective is cure with distinct approaches for disease deemed good risk (ie, high probability of cure at approximately 90%) and poor risk (ie, lower probability of cure, which is as low as 50%). For patients with good-risk disease, the goal is to minimize toxicity without compromising cure, whereas management of poor-risk disease focuses less on minimizing toxicity and more on increasing the probability of cure.

MANAGEMENT OF ADVANCED GERM CELL TUMORS BY RISK CLASSIFICATION

The treatment of germ cell tumors is based on the International Germ Cell Consensus Classification, developed in 1996 and updated in 2020, as well as 2021.[192,194]

Good Risk

Approximately 60% of patients with nonseminomatous germ cell tumors present with good-risk disease. Patients with good risk include those with stage II or III disease with testis or primary extragonadal retroperitoneal primary tumors, no nonpulmonary visceral metastases, and good-risk tumor markers. Most patients with advanced seminoma have good-risk disease. According to the results of clinical studies, more than 90% of these patients will be cured with the use of combination chemotherapy, including cisplatin and etoposide with or without bleomycin.[195-199]

Summaries of the trials are as follows:

- Four cycles of etoposide and cisplatin or three cycles of BEP lead to a durable CR in more than 90% of patients with good-risk disease.
- The elimination of bleomycin can compromise the cure if only three cycles of therapy with etoposide and cisplatin are administered or if adequate doses of etoposide are not administered. Three cycles of BEP are considered the standard therapy for good-risk germ cell tumors, but four cycles of etoposide and cisplatin without bleomycin are considered an acceptable alternative, especially for patients with risk factors for lung toxicity based on two randomized trials suggesting similar OS but higher CR rates with BEP.
- Although carboplatin has less toxicity, it cannot be substituted for cisplatin because it is less effective.

Bleomycin is associated with Raynaud phenomenon and skin and pulmonary toxicity, although clinically significant pulmonary toxicity is rare.[76] Risk factors for bleomycin-induced lung toxicity include older age, history of smoking, cumulative dose of bleomycin, subsequent exposure to high-flow oxygen, and impaired renal function. Pulmonary function tests can be obtained at baseline, and some clinicians repeat these every one to two cycles. Notably, diffusing capacity of the lungs for carbon monoxide (DLCO; adjusted for hemoglobin) is neither 100% sensitive nor specific for pulmonary toxicity. Bleomycin should be held in patients with new dry cough or dyspnea without alternative explanations. Guidance for asymptomatic drop in DLCO is variable, but some will hold bleomycin for asymptomatic drops by ≥25% from baseline, though published data suggests that DLCO will improve over time post-chemotherapy.[199]

Although bleomycin is not myelosuppressive, the combination of etoposide and cisplatin does have significant myelosuppressive effects, and the risk of febrile neutropenia with etoposide and cisplatin may exceed 20%. It is generally considered intermediate risk for febrile neutropenia, so primary prophylaxis with granulocyte growth factors could be considered based on the presence of other risk factors and/or considerations. Concerns about growth factors increasing the risk of bleomycin

pulmonary toxicity have not been validated by research to date. Though variability exists in practice about treatment modification for myelosuppression, some advocate for no delays in treatment regardless of myelosuppression because neutrophil counts will often improve through the 5 days of therapy with steroids that are administered as side-effect prophylaxis. There is also variability in practice about the use of granulocyte growth factors; some prefer to use them only if febrile neutropenia or dose delays resulting from neutropenia occur during therapy, whereas others use them as primary prophylaxis to minimize the risk of delays and dose modification.

Etoposide carries a small risk of secondary leukemia, and cisplatin carries well-known risks of renal toxicity, neuropathy, ototoxicity, metabolic syndrome, and some increase in thrombotic risk and long-term increase in cardiovascular events because of vascular irritation. Long-term survivorship care, either through specialized oncology survivorship clinics or through regular primary care, is essential for maximizing the long-term quality of life from curative chemotherapy.

Intermediate Risk

The intermediate-risk group includes patients with nonseminomatous tumors with intermediate-risk tumor markers, as well as patients with seminoma who have nonpulmonary visceral metastases. These patients comprise 20% to 30% of those with germ cell tumors and have a 5-year survival rate of approximately 89%. Intermediate risk disease is treated with four cycles of triplet cisplatin-based chemotherapy with either BEP or etoposide/ifosfamide/cisplatin (VIP) if there is a contraindication to bleomycin. Ifosfamide is commonly associated with gastrointestinal toxicity and lower blood counts and can also cause encephalopathy, cardiac arrhythmias, and hemorrhagic cystitis.

Poor Risk

Patients with poor-risk disease include those with nonseminomatous germ cell tumors with nonpulmonary visceral metastases, poor-risk tumor markers, or a primary mediastinal site. These patients comprise 10% to 20% of those with nonseminomas and have a 5-year survival of approximately 67%. For patients with poor-risk disease, the standard of care is also four cycles of cisplatin-based triplet combination chemotherapy. This may include BEP or VIP if there is a contraindication to bleomycin. In patients with primary mediastinal nonseminomatous germ cell tumors, a report from Indiana University demonstrated a high rate of postoperative pulmonary failure and mortality after BEP with a suggestion to substitute ifosfamide for bleomycin (ie, the VIP regimen) in the treatment of these patients who will undergo a major thoracic surgery,[200] but many experts still use BEP and may omit the last two doses before surgery. In this case, the anesthesiologist should be made aware of the history of bleomycin treatment and should use a low fraction of inspired oxygen (Fio_2) during the surgery because of the risk of acute respiratory distress syndrome in patients previously treated with bleomycin who have diminished pulmonary function (decrease in DLCO) and receive copious hydration in the operative period.

KEY POINTS

- Good-risk advanced germ cell tumors are treated with three cycles of BEP or four cycles of etoposide and cisplatin.
- Intermediate- and poor-risk advanced germ cell tumors are treated with four cycles of BEP or four cycles of VIP. Omission of bleomycin is not acceptable unless the patient is receiving VIP.

SECOND-LINE THERAPY FOR GERM CELL TUMORS

In 20% to 30% of patients with advanced germ cell tumors, a durable response to first-line chemotherapy regimens, including cisplatin and etoposide with or without bleomycin, will not be achieved. These patients remain curable, although, unfortunately, the chance of cure is lower. Most relapses occur within 2 years of first-line chemotherapy. Late relapses (after 2 years) may also occur. Nonseminomatous late relapses are best treated with an approach that involves maximal surgical resection of the disease.

Paclitaxel/ifosfamide/cisplatin (TIP) was evaluated as second-line therapy for patients with favorable prognostic features for response, including testis primary tumor site and a prior CR to a first-line chemotherapy program.[201] Four cycles of TIP as second-line therapy resulted in a 70% complete response rate, a 5-year PFS rate of 70%, and a 5-year OS rate of 72%. The high level of activity with TIP as salvage therapy is related, in part, to the criteria used to select patients who are more likely to benefit from conventional-dose second-line therapy (relapse >6 months after induction therapy). Ifosfamide-based therapy has been associated with significant hematologic, renal, and neurological toxicities, and the use of granulocyte growth factors is standard. An alternative second-line regimen is vinblastine, ifosfamide, and cisplatin (VeIP).

The use of high-dose chemotherapy with peripheral stem cell rescue may be considered as second-line therapy, especially for patients with incomplete response to induction chemotherapy or rapid relapse (<6 months) after first-line therapy, or as third-line therapy (Table 14-11).

Table 14-11 **Selected Treatment Regimens for Relapsed Germ Cell Tumors After First-Line Bleomycin, Etoposide, and Cisplatin Combination or Etoposide and Cisplatin**

Chemotherapy	Regimen	Agents	Results
Standard dose	TIP[91]	Paclitaxel (Taxol)	Limited to patients with favorable prognostic factors
		Ifosfamide plus mesna	ORR, 63%; 2-year PFS, 65%
		Cisplatin	
	VeIP	Vinblastine	Disease-free rate, 36% (including patients undergoing subsequent resection of masses); median survival, 12.7 months
		Ifosfamide plus mesna	
		Cisplatin	
High-dose with autologous stem cell rescue	TI-CE[103]	Two cycles of conventional-dose paclitaxel (Taxol) and ifosfamide plus mesna, followed by G-CSF, followed by stem cell collection (leukapheresis)	Limited to patients with unfavorable prognostic factors
		3 cycles of high-dose carboplatin and etoposide, followed by stem cell rescue, each cycle	5-year DFS, 47%; OS, 52%

Abbreviations: DFS, disease-free survival; G-CSF, granulocyte colony-stimulating factor; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; Tl-CE, paclitaxel/ifosfamide/carboplatin/etoposide; TIP, paclitaxel/ifosfamide/cisplatin; VelP, vinblastine/ifosfamide/cisplatin.

There are two accepted regimens for high-dose chemotherapy. One, developed by the Indiana group, involves stem cell mobilization followed by high-dose carboplatin and etoposide, and this process is repeated after recovery. The overall 2-year PFS was 60%, with improved outcomes in patients who received this regimen as second-line therapy. The second regimen, developed at Memorial Sloan-Kettering Cancer Center, involved two cycles of paclitaxel and ifosfamide followed by stem cell collection, then high-dose carboplatin and etoposide for three cycles with stem cell rescue after each cycle. Outcomes are comparable between the two regimens; thus, the choice is usually institution-dependent.

Patients with primary mediastinal (extragonadal) germ cell tumors treated with high-dose chemotherapy and stem cell rescue represent a unique clinical challenge as they tend to be more chemorefractory, perhaps in part related to *TP53* mutations. High-dose chemotherapy can be effective in up to 25% of patients with relapsed primary mediastinal disease, and these patients should be managed at specialized centers.

It is unclear whether standard-dose or high-dose chemotherapy should be used for patients whose disease recurs after prior chemotherapy. Two prospective phase 3 trials that evaluated the role of high-dose chemotherapy versus standard-dose salvage therapy demonstrated mixed results. An important phase 3 trial of initial salvage chemotherapy for patients with germ cell tumors (TIGER) has randomly assigned patients with relapsed disease to TIP for four cycles (standard-dose chemotherapy) versus a paclitaxel, ifosfamide, carboplatin, and etoposide (high-dose chemotherapy) regimen; accrual has been completed, but results are not yet available.

In patients who relapse after high-dose chemotherapy, unfortunately, there are no further curative options. Palliative chemotherapy regimens including combinations of gemcitabine, paclitaxel, and oxaliplatin can be used, but resistance is inevitable, and novel treatment approaches are desperately needed.

KEY POINTS

- Germ cell tumors refractory to first-line chemotherapy are still curable, but the prognosis is worse.
- Options for second-line chemotherapy include standard-dose regimens such as TIP and high-dose chemotherapy with autologous stem cell rescue. Which strategy is superior is unknown, but high-dose chemotherapy is generally preferred for patients with poor-prognosis features or as third-line therapy.
- Residual masses after second-line chemotherapy in nonseminomas should still undergo resection as in the first-line setting.
- Pulmonary toxicity must be managed in patients treated with bleomycin by continued monitoring of symptoms and DLCO. Bleomycin should be discontinued if there are suggestive symptoms. Small asymptomatic drops in DLCO are common, but discontinuation is generally recommended for drops of ≥25%. For bleomycin-treated patients who subsequently require surgery, low intraoperative Fio_2 and minimal hydration should be used.

ASSOCIATED MALIGNANT DISEASE

Malignant transformation of a teratoma to a somatic malignancy, including rhabdomyosarcoma, adenocarcinoma, embryonic-type neuroectodermal tumor (previously referred to as primitive neuroectodermal tumor), and leukemia, as well as others, has been well described. The presence of i(12p) or excess 12p copy number in these tumors establishes the clonal germ cell tumor origin. The finding of i(12p) or excess 12p genetic material by either molecular or cytogenetic studies correlates with response to cisplatin therapy. Mediastinal nonseminomatous germ cell tumors are also associated with the presence of myeloproliferative disorders, including acute nonlymphocytic leukemia and acute megakaryocytic leukemia, and idiopathic thrombocytopenia. A minority of patients with poorly differentiated carcinomas of unknown primary origin have a CR to cisplatin-based chemotherapy. The presence of additional clinical features, including male sex, midline tumor, relatively young age, and elevated levels of serum tumor markers, has suggested that a minority of patients with poorly differentiated carcinomas of unknown primary origin may have germ cell tumors. Clinical features, as well as molecular and cytogenetic studies, are important in the management of carcinomas of unknown primary or midline tumors of uncertain histogenesis.

SEX CORD STROMAL TESTICULAR TUMORS

Non–germ cell testicular tumors are rare and comprise sex cord stromal tumors, including Leydig cell tumors, Sertoli cell tumors, granulosa cell tumors, and other extremely rare histologies. Leydig cell tumors are the most common among sex cord and stromal tumors. Unlike the more common germ cell varieties, Leydig cell tumors arise from interstitial cells of Leydig, one of the cell types that make up the interstitium, along with cells of the seminiferous tubules. Two peaks of incidence are observed, in young childhood (age 3-9 years) and mid to later adult life (age 30-60 years). The clinical presentation is a painless testicular mass and can be accompanied by gynecomastia and other endocrine abnormalities. Ultrasonography shows a hypoechoic mass with areas of hypervascularity. Mutations in the luteinizing hormone receptor may be associated with Leydig cell hyperplasia. Levels of the common germ cell markers (serum and immunohistochemistry), AFP, LDH, and hCG are normal. Specific diagnosis is established by immunohistochemistry staining with inhibin and melan-A. Staining for calretinin and vimentin is sometimes positive. Treatment is surgical removal, and long-term survival is generally good. In the rare circumstance of metastatic disease, chemotherapy and RT are of limited utility.

SURVIVORSHIP

Cardiovascular Disease and Myocardial Infarctions

Long-term testicular cancer survivors have a moderately increased risk of myocardial infarction associated with cisplatin-containing chemotherapy and/or infradiaphragmatic radiation. Short-term risk of venous thrombotic disease may also increase as a result of increased plasma von Willebrand factor levels and endothelial damage. The Khorana score can be used to guide prophylactic anticoagulation; testicular cancer is one of several cancer types that result in a +1 point. In addition to chemotherapy-induced endothelial damage, cardiovascular toxicity is also likely related to metabolic syndrome and gonadal dysfunction.

Secondary Malignancies

Patients with testicular cancer treated with RT or chemotherapy have an increased risk of secondary malignancies for at least 35 years after treatment. Increased risks have been seen for cancers of the stomach, gallbladder, bile ducts, pancreas, bladder, kidney, and thyroid, as well as for soft-tissue sarcoma, nonmelanoma skin cancer, and myeloid leukemia.

Decreased Sperm Count and Other Late Effects

Patients with newly diagnosed testicular cancer are at risk for decreased sperm counts or impaired sperm motility even before any treatment. With treatment, infertility can result from retrograde ejaculation after RPLND or as a result of RT or chemotherapy. Some but not all patients will have long-standing chemotherapy-induced oligospermia or azoospermia. Patients who are scheduled to undergo RPLND, RT, or chemotherapy are advised to bank sperm. Other late effects of treatment include ototoxicity, chronic neurotoxicity, renal impairment, pulmonary toxicity, and anxiety disorder. Considering a young age at diagnosis and high cure rates, patients with testicular cancer require specialized follow-up care with close attention to monitoring for late effects of cancer and cancer therapy.

KEY POINTS

- Teratoma may undergo malignant transformation into teratocarcinoma, adenocarcinoma, or other histologies, generally as a late complication of unresected teratomatous components of nonseminoma.
- In a situation of diagnostic uncertainty, the presence of i(12p) points to a likely germ cell tumor origin.
- Non–germ cell testicular cancers are rare and include sex cord tumors, the most common being Leydig cell tumors. These can cause endocrinopathies and are typically cured via orchiectomy.

- Most patients with testicular cancer have long-term survival and are treated relatively early in life, so monitoring for and intervening in early and late complications of treatment are important, especially those complications related to the cardiovascular system. Cisplatin-based chemotherapy and/or RT may increase cardiovascular risk, risk of secondary malignancies, and risk of infertility, among others. Patients treated with chemotherapy and/or RT should monitor and treat other cardiovascular risk factors, including hypertension, and adhere to age-appropriate cancer screening. These risks further justify the avoidance of adjuvant therapies for most patients with stage I disease.

PRESENTING CASE STUDY 4

A 25-year-old man presents to your clinic after noticing a painless left testicular mass. Ultrasonogram reveals a solid, 4-cm mass with increased vascularity. Pathology from a transinguinal orchiectomy reveals a mixed germ cell tumor with embryonal, yolk sac, and choriocarcinoma components. Lymphovascular invasion (LVI) is present with no spermatic cord invasion. Serum alpha fetoprotein (AFP) and human chorionic gonadotropin levels were slightly elevated before surgery but decreased to within the reference range after surgery.

How would staging chest, abdominal, and pelvic CT with no evidence of metastatic disease inform your choice of next steps?

This patient has a stage I non-seminomatous germ cell tumor (NSGCT) of the testis. Options after resection of a stage I NSGCT with or without risk factors include surveillance, adjuvant chemotherapy (bleomycin, etoposide, and cisplatin [BEP] for one to two cycles), or retroperitoneal lymph node dissection (RPLND). LVI with or without an increasing percentage of embryonal carcinoma (>40%-50%) correlates with higher relapse risk, approaching 50% if both risk factors are present. Although this increased relapse risk does not mean that surveillance is not reasonable, such patients may be more likely to benefit from adjuvant therapies than those with lower risk nonseminoma. RPLND is advantageous because it can diagnose and treat any teratoma while avoiding long-term toxicities from chemotherapy.

The high-risk pathological feature of LVI characterizes this patient's case as a stage I NSGCT with risk factors. This categorization necessitates a discussion of the options for adjuvant BEP chemotherapy or RPLND. Surveillance would be the preferred initial approach for stage I NSGCT without risk factors.

What if the patient is instead found on pathology with pure seminoma, 6 cm in size, with rete testis involvement? Staging CT chest and and/pelvis again shows no evidence of metastatic disease. What is the best next step?

The approach to management of testicular pure seminoma after resection is slightly different, as pure seminoma is generally more sensitive to chemotherapy and radiation compared to NSGCT. Since these treatments are very effective for patients with recurrent disease, surveillance is the preferred approach for most patients with stage I pure seminoma. Surveillance is recommended as a preferred approach even for high-risk pathological factors such as tumor size >5 cm, LVI, and rete testis invasion, as shown in this patient. For those electing for adjuvant treatment, radiation to the retroperitoneal lymph nodes or carboplatin chemotherapy for one to two cycles is a standard-of-care option.

If this patient has a mixed (nonseminomatous) germ cell tumor but also is noted to have left retroperitoneal (RP) lymphadenopathy, how would you proceed? How would the size of the involved lymph node affect your decision-making?

Suspicious adenopathy in the "landing zone" would be diagnostic of stage II disease. Stage IIA disease (<2 cm) could be treated as advanced disease with chemotherapy, but RPLND is also an option with IIA disease, assuming serum markers are negative. Borderline radiographically suspicious lymph nodes may not actually contain cancer, so close monitoring of borderline lymph nodes is an option. Biopsies are generally not helpful owing to the potential for sampling errors and technical challenges. There is no role for FDG PET because it is neither sensitive nor specific.

Larger RP lymph nodes above the IIA cutoff would be treated as advanced disease with chemotherapy. Once the patient is determined to have advanced disease requiring chemotherapy, and *only* then, use the risk-stratification scheme to distinguish good, intermediate, or poor risk and decide on appropriate chemotherapy regimens. The risk-stratification

scheme does not apply to patients with stage I disease who are being offered adjuvant therapy. (A patient who has stage IS nonseminoma is not offered adjuvant therapy and is treated as having advanced disease.)

What do you recommend if the patient's serum markers remain outside the reference range after orchiectomy?

This scenario would be concerning for stage IS disease (treated as advanced disease), but there are a few caveats. Persistent borderline AFP elevation that does not change over many months may be caused by benign biliary processes. Borderline lactate dehydrogenase (LDH) elevation that does not significantly change over time should not be used on its own to indicate micrometastatic disease because LDH is relatively nonspecific.

If the patient has a seminoma and a 1.7 cm left retroperitoneal lymph node, what should you do next? What if the lymph node is 4 cm?

As in nonseminoma, patients who have seminoma and stage IIA disease have an option other than chemotherapy. In this case, the option is radiation rather than surgery, because seminoma is highly radiation-sensitive and does not carry a risk of teratoma. There is an evolving role of RPLND in certain patients with stage IIA seminoma. For patients with bulkier disease (>3 cm RP lymph nodes or metastases elsewhere), chemotherapy per the risk-classification schema is the only option.

What would you be looking for after chemotherapy to determine whether a patient with advanced nonseminoma is in remission and requires no further treatment? Or, in a patient with advanced seminoma?

Residual masses may simply indicate fibrosis and can often be followed for some time, especially if they are approaching the cutoffs used to determine the need for additional therapy. Following chemotherapy, there is a relatively stringent cutoff of 1 cm for any residual disease to determine the need for additional treatment. For patients with negative markers and residual disease larger than 1 cm, resection should be considered to diagnose and treat any teratoma. For patients with seminoma, the cutoff is less stringent (3 cm) because the disease is much more chemosensitive and there is no risk for teratoma. For residual masses larger than 3 cm, consider FDG PET (the *only* circumstance in which FDG PET is useful for germ cell tumors) and radiation to any residual disease that is FDG-avid.

For a patient with nonseminoma, poor initial risk, and markers that never normalize or normalize briefly before rising again, second-line chemotherapy may be considered. Conventional-dose chemotherapies, such as paclitaxel, ifosfamide, and cisplatin (TIP), or tandem high-dose chemotherapy with stem cell rescue (eg, TI-CE) are used in this setting.

PENILE CANCER

EPIDEMIOLOGY, RISK FACTORS, AND HISTOLOGY

Penile cancer is rare in industrialized nations, with fewer than one case per 100,000 men per year; in the United States, approximately 2,210 new cases and 460 deaths occurred in 2021. It is more prevalent in developing nations, and it is also more common among the elderly.

Positive associations have been described between penile cancer and human papillomavirus (HPV) infection, as have negative associations between penile cancer and circumcision that could be mediated by decreased rate of HPV infection in circumcised men. Phimosis, HIV infection, and tobacco exposure have also been described as risk factors, among others.

A vast majority of penile cancers are of squamous cell histology, although a few subtypes are identified, including verrucous carcinoma, papillary carcinoma, warty carcinoma, basaloid carcinoma, and sarcomatoid carcinoma. Warty and basaloid carcinomas may be more associated with HPV infection, especially HPV 16.

STAGING

A deep biopsy is necessary to obtain a specimen for adequate diagnosis and staging. Staging is according to AJCC criteria.[36] Invasiveness (increased T stage) or high-risk features (ie, LVI, perineural invasion, and high grade) are classified as stage II, whereas clinical node involvement is classified as at least stage III.

Although many cases present with inguinal adenopathy, only approximately half will be due to nodal metastases. Infection and/or inflammation, often with an odiferous component, can commonly cause adenopathy in conjunction with penile cancer. Clinical staging is performed based on physical examination, although imaging can be helpful in the absence of overt adenopathy on examination, and PET imaging can be used in node-positive patients to evaluate for distant spread. Pathological staging should be performed for men with high-risk features in the primary tumor. The standard method is with inguinal lymph node

dissection, but this carries significant potential for morbidity, including lymphedema. Alternatives include fine-needle aspiration of any palpable lymphadenopathy or dynamic sentinel node biopsy (with lymphoscintigraphy or fluorescent dye labeling) at experienced centers.

For men with a negative clinical examination, the NCCN recommends lymph node staging based on pathologic features in the primary tumor as follows:

- Low risk (pTis, Ta, or T1a; grade 1): surveillance
- Intermediate risk (pT1a; grade 2): sentinel node biopsy or inguinal lymph node dissection with close surveillance is also reasonable
- High risk (pT1b): sentinel node biopsy or inguinal lymph node dissection. For men with palpable lymphadenopathy, strategies include the following:
  - Empirical antibiotics followed by re-evaluation
  - Fine-needle aspiration; if negative, an excisional biopsy or inguinal node dissection can be used in patients with sufficiently high risk

Because distant metastases occur rarely and typically late in the disease course, if at all, imaging for the detection of distant metastases may only be needed in patients with bulky regional nodal metastases or concerning symptoms.

TREATMENT BY STAGE

Stage 0: Tis or Ta, N0, M0

Also known as erythroplasia of Queyrat on the glans or Bowen disease on the shaft, penile CIS is a precursor lesion to invasive disease. There are no high-level data to guide decision-making, but treatment options include Mohs surgery, laser surgery, cryosurgery, and topical fluorouracil cream or imiquimod cream.

Stages I and II: T1a, N0, M0 or T1b-T3, N0, M0

Treatment options include circumcision for tumors limited to the foreskin or, for more infiltrating tumors, surgical resection or RT.

Stage III: T1-3, N1-2, M0

As noted, inguinal adenopathy may be due to infection or inflammation rather than cancer involvement. In the event of confirmed inguinal lymph node metastases without distant metastases, bilateral ilioinguinal dissection is appropriate. If two or more nodes are involved, additional pelvic lymph node dissection may be considered.

Stage IV: T4 or N3 or M1

Distant metastases are rare and occur late in the disease course. There is no standard treatment for advanced penile cancer. Surgery and/or RT may be used for local palliation, especially for bulky or symptomatic nodal disease; some consider the addition of radiosensitizing cisplatin. Neoadjuvant chemotherapy has also been used for patients with advanced tumors and/or adenopathy. A regimen of neoadjuvant TIP was tested in a phase 2 study of patients with node-positive penile cancer and demonstrated a 50% response rate.

ADJUVANT THERAPY

There are no high-level studies to guide treatment in the setting of high-risk resected penile cancer. Adjuvant chemotherapy may be considered for patients who did not receive neoadjuvant chemotherapy and have high-risk features, including pelvic lymph node involvement, extranodal extension, bilateral inguinal node involvement, or four or more nodes involved. TIP or other cisplatin-based therapy may be used. For patients who have received neoadjuvant TIP and have residual disease with extranodal extension or bilateral lymph node involvement, adjuvant RT to the inguinal/pelvic area may be considered.

RECURRENT DISEASE

Local recurrence may be treated with penectomy if not already performed or, in some circumstances, with a second penis-preserving treatment. Inguinal recurrence may be treated with neoadjuvant chemotherapy followed by node dissection or chemoradiation therapy, but the prognosis is poor. For distant metastatic disease, cisplatin-based treatment may be used; the described neoadjuvant TIP regimen is considered the standard first-line therapy for patients with adequate performance status and renal function, despite a lack of high-level data in the metastatic setting.

The addition of pembrolizumab to 5-FU and cisplatin/carboplatin was investigated in a phase 2 single-arm multicenter trial in Brazil.[202] Of the 37 patients enrolled in this study, the ORR was 39.4% with a median PFS of 5.4 months and a median OS of 9.6 months. Four patients (10%) had a duration of response >12 months. ORR and PFS were improved for those with HPV-positive

disease and high TMB. There was no association between PD-L1 expression and response. Based on this data, 5-FU + cisplatin/carboplatin + pembrolizumab followed by pembrolizumab maintenance therapy is an alternative option endorsed by NCCN guidelines.

Clinical activity of pembrolizumab monotherapy was reported in patients with high TMB and MSI-high metastatic penile cancer. Pembrolizumab should be considered in those with metastatic penile cancer with MSI-high status, MMR deficiency, or high TMB.

HER2 testing can be performed to determine the eligibility for trastuzumab deruxtecan, given pan-tumor approval, but HER2 overexpression in penile cancer is exceedingly rare (<1%).

KEY POINTS

- Penile cancer is a rare disease associated with age, lack of circumcision, HPV and/or HIV infection, and tobacco use.
- Penile cancer is typically of squamous histology.
- The primary pattern of spread is local invasion followed by inguinal lymph node metastasis. However, inguinal nodes may frequently be enlarged as a result of concomitant inflammation and infection. Evaluation of the inguinal nodes depends on the invasiveness of the primary tumor and whether the nodes are palpable.
- Penile cancer is managed according to the degree of tumor invasion and lymph node involvement. The primary treatment modality is surgery.
- Patients with intermediate- or high-risk penile cancers should undergo assessment for lymph node involvement.
- Perioperative chemotherapy (eg, TIP regimen) and/or RT with or without radiosensitizing chemotherapy may be used for advanced tumors, but high-level evidence is lacking.

MALIGNANT ADRENAL TUMORS

Malignant adrenal tumors are extremely rare cancers with only limited information to guide specific treatment recommendations. Malignant adrenal cortical carcinoma is derived from the adrenal cortex, with approximately 60% of cases associated with hormone secretion leading to symptoms and signs of hypercortisolism, virilization, and mineralocorticoid excess. Localized disease is managed with surgery. The overall prognosis is poor, particularly in patients with larger tumors (>5 cm) and/or evidence of local invasion. The adrenocortical agent mitotane is commonly used for patients with metastatic disease; however, response rates are low, with no clear survival benefit. Although several studies have suggested higher response rates with chemotherapy and mitotane, it is not at all clear that this translates into an improvement in outcome. There may be a benefit for mitotane in the adjuvant setting, and it is commonly used in patients at high risk of recurrence after surgery. In the advanced setting, the FIRM-ACT study compared mitotane with a combination of etoposide, doxorubicin, and cisplatin every 4 weeks or streptozocin every 3 weeks and demonstrated significant improvements in response and PFS with etoposide, doxorubicin, and cisplatin plus mitotane but no difference in OS (although with a built-in crossover design). A phase 1b study of the PD-L1 inhibitor avelumab in previously treated adrenal cortical carcinoma demonstrated limited ORR but a disease control rate of approximately 50%.[108]

Malignant pheochromocytomas arise from chromaffin tissue of the adrenal medulla and are extremely rare, accounting for approximately 10% of all pheochromocytomas. Functional pheochromocytomas secrete catecholamines and lead to an array of clinical symptoms, including the classic triad of headache, diaphoresis, and tachycardia (and episodic hypertension). The typical initial diagnostic test is either a 24-hour urine collection for fractionated metanephrines and catecholamines or plasma-fractionated metanephrines (collected through an intravenous catheter placed 20 to 30 minutes before and with the patient supine), being sure to stop all antiadrenergic medications beforehand. If abnormal, localization is performed with dedicated adrenal imaging. No curative therapy exists for malignant pheochromocytoma, and the mainstay of management includes surgical resection of the tumor with preoperative α- and β-adrenergic blockade. Close collaboration with endocrinologists is essential. Data are limited, and no definitive recommendations regarding systemic therapy can be made; however, the association of pheochromocytomas with VHL has led to the use of VEGFR-targeted agents in this disease.

KEY POINTS

- Malignant adrenal tumors are extremely rare.
- After resection of localized adrenal cortical carcinoma, patients at high risk of recurrence may be considered for adjuvant mitotane.
- Adding mitotane to chemotherapy in the advanced setting increases response rates but not survival.
- Malignant pheochromocytoma is treated surgically, similarly to nonmalignant pheochromocytoma.

HIGH-YIELD TAKEAWAYS

Prostate Cancer

- Consider a diagnosis of metastatic prostate cancer in an older male presenting with lower urinary obstruction, diffuse bone pain, progressive anemia, and/or weight loss/failure to thrive.
- Immediately life-threatening complications include urinary obstruction leading to kidney injury and electrolyte abnormalities, pathological fracture, spinal cord compression, and hypercalcemia. Any high-risk bone lesions—those larger than or equal to 2 cm; involving hip, shoulder, or sacroiliac joints; in long bones with one-third to two-thirds of cortical thickness; or in junctional spine (C7-T1, T12-L1, L5-S1) and/or with posterior involvement—should be evaluated for possible prophylactic radiation.
- ADT is the cornerstone of systemic therapy, although it will not result in immediate clinical benefit. Intensification within the first several months of therapy with an androgen signaling inhibitor is standard. Taxane therapy can also be considered, especially in those with de novo high-volume (per CHAARTED) disease, and radiation to the prostate can be offered to most low-volume de novo patients and possibly in high-volume de novo patients, especially those with bulky primary lesions.

Bladder Cancer

- In patients with muscle-invasive but localized disease, systemic therapy is used as neoadjuvant treatment before radical cystectomy or concurrently with radiation as a radiosensitizer. Cisplatin-based regimens are standard for those who are eligible, although eligibility is not strictly defined.
- In patients with metastatic disease, platinum-based therapy was the standard first-line treatment of those eligible but has now been supplanted by enfortumab vedotin/pembrolizumab. This approach can also be considered in patients with node-positive disease with subsequent definitive therapy pending response, although treatment here is less well defined.
- Later-line therapies include trastuzumab deruxtecan, single-agent chemotherapies, and, for those with targetable FGFR alterations, erdafitinib.

Kidney Cancer

- Small renal masses are common incidental diagnoses and may not require intervention if they have low-risk features and slow growth rates; active surveillance is often a safe approach.
- Higher-risk lesions are typically resected, and adjuvant pembrolizumab can be considered for those with T2 grade 4, T3/T4, N positive, or fully resected M1 disease.
- First-line systemic therapy involves PD-1 blockade with either CTLA-4 blockade or VEGF blockade; there are pros and cons to each strategy that should be discussed with the patient.
- Later-line therapy can include VEGF TKIs with different spectrums of activity and, newly, the HIF-2α inhibitor belzutifan.

Testicular Cancer

- Seminomas are highly chemo- and radiation-sensitive. Nonseminomas can be chemosensitive but can be associated with teratoma. Teratoma on its own is not malignant and also neither chemo- nor radiation-sensitive, and if left in place over the long term, it can transform into aggressive malignant histologies. Thus, seminoma treatment typically incorporates chemotherapy and/or radiation, whereas nonseminomas are typically treated with chemotherapy and/or surgery.
- Stage I disease (except stage IS, defined by residual suspicious serum markers) is limited to the testicles. Active surveillance is the preferred initial approach for most patients, but adjuvant treatment can be considered for those with high-risk nonseminoma. Options for adjuvant treatment include radiation or chemotherapy for seminoma and surgery or chemotherapy for nonseminoma.
- Stage II disease involves retroperitoneal lymph nodes, which are the local draining lymph nodes of the testicles. Stage IIA disease (smaller than 2 cm) may be treated with radiation for seminoma or surgery for nonseminoma or chemotherapy for either.
- Stage IIB-C disease, stage III disease (defined by metastases outside the RP lymph nodes), and stage IS disease are all treated as advanced germ cell tumors with chemotherapy per the risk-stratification approach. ONLY use the risk-stratification algorithm for these patients and NOT for patients receiving adjuvant therapy.
- Following chemotherapy, the threshold for additional action is higher in seminoma (3 cm), given that these are typically quite chemosensitive and do not harbor teratoma compared with nonseminoma (1 cm). For seminoma, residual large masses that are FDG-avid may be radiated. For nonseminoma, residual masses larger than 1 cm should be resected to diagnose and treat any residual teratoma.

GENITOURINARY CANCERS 14

CHAPTER SUMMARY GUIDE

KEY POINTS

- Prostate cancer is a common diagnosis, and although metastatic disease develops in only a small percentage of affected patients, this translates into a large absolute number of deaths resulting from prostate cancer.
- Prostate cancer is one of the most hereditary cancers. Clinicians should take a full history of malignancies in the family and be familiar with the link between prostate cancer and germline alterations in *BRCA2* and MMR genes, which are enriched among men with metastatic prostate cancer.
- Clinicians should offer genetic counseling for all patients with high-risk or very high-risk localized, regional node-positive, or metastatic prostate cancer, regardless of family history; those with localized prostate cancer and strong family history as outlined in the preceding paragraphs; and those with alterations in DNA damage repair or MMR genes identified from tumor sequencing.
- Prostate cancer is typically diagnosed via TRUS or transperineal biopsy using a standard 12-core template to sample the posterior peripheral zone. MRI-guided biopsy combined with a standard TRUS biopsy has been shown to lessen the likelihood of missing clinically significant cancers and should be used when available.
- Among men undergoing evaluation for elevated PSA, a prebiopsy multiparametric or biparametric MRI may help triage those who require biopsy, limiting biopsies to those with a greater likelihood of clinically significant cancer. Anatomic location can help predict the pattern of spread and treatment-related risks. Disease near the base of the gland may extend into the seminal vesicles. Disease in the apex may increase the risk of positive surgical margins and urinary incontinence.
- Prostate cancer can be characterized by its typical immunohistochemistry profile: cytokeratin 7/20 negative, PSA positive, AR positive, and NKX 3.1 positive.
- As treatment resistance occurs, different phenotypes may emerge. Most CRPCs are still driven by AR signaling even after developing resistance to subsequent AR-directed therapies.
- Some advanced CRPCs may become androgen-independent, often harboring alterations in *RB1*, *PTEN*, and *p53.* These may be admixed with AR-driven tumors. A subset of these cases may have neuroendocrine features, with the most extreme exhibiting small-cell morphology.
- There are two kinds of small-cell/neuroendocrine prostate cancer: (1) de novo small-cell prostate cancer, which is a very rare disease subset and presents admixed with adenocarcinoma (more common) or pure, (2) treatment-associated small-cell/neuroendocrine prostate cancer, which occurs in about 15% to 20% of patients who have mCRPC. Small-cell/neuroendocrine prostate cancer should be suspected in patients with a rapid radiographic progression or new hepatic metastases without PSA increase. It is characterized primarily by morphology, but it can also be positive for synaptophysin and/or chromogranin A staining.
- There are no universally accepted protocols for prostate cancer prevention or screening.
- Two 5-α reductase inhibitors (eg, finasteride and dutasteride) were evaluated in large phase 3 chemoprevention trials. Although these agents decreased the overall incidence of prostate cancer by approximately 25%, this decrease was limited to low-grade tumors. The use of these agents was associated with a significantly increased incidence of high-grade prostate cancer.
- PSA-based prostate cancer screening has shown, at most, a small reduction in prostate cancer–specific mortality rate and no convincing effect on overall mortality. Screening could be more effective if targeted to men with a higher risk and to the age groups most likely to benefit (ie, younger men rather than older men), but additional studies evaluating this possibility are underway. DRE for screening does not significantly add to PSA.
- Patients with localized prostate cancer can be risk-stratified based on three clinical factors: T stage, Gleason score, and PSA level. Genomic testing of the cancer specimen may provide additional information about risk and progression, but this has not yet been prospectively validated for decision-making.
- Patients with low-risk disease may be offered active surveillance, which uses serial PSA measurements, DREs, and biopsy specimens to detect any presence of higher-risk disease, at which point definitive therapy can be offered. Sequential MRI may also be helpful. This strategy results in less treatment-associated morbidity and similar long-term cancer survival compared with immediate therapy.

- Patients with intermediate- or high-risk disease typically should receive definitive therapy, assuming a life expectancy of at least 5 (high risk) to 10 (intermediate risk) years (or if symptomatic). Definitive therapies include radical prostatectomy and RT. Long-term cancer survival is similar with either strategy, but adverse effect profiles differ.
- For patients who have intermediate- or high-risk disease undergoing RT, the addition of ADT improves biochemical disease-free survival (DFS) (intermediate risk) and OS (high risk). Duration is typically 4 to 6 months for unfavorable intermediate-risk disease and 18 to 24 months for high-risk disease.
- Patients with clinical evidence of pelvic lymph node involvement (cN1) are typically treated with definitive RT to the prostate and pelvis with long-course ADT. Although no randomized data exist, prostatectomy followed by adjuvant RT and ADT may also be an option.
- For patients who are very high-risk or regional risk (cN1) undergoing definitive EBRT and ADT, the addition of 2 years of abiraterone has been shown to improve MFS and OS.
- Prostatectomy, RT, and ADT have unique adverse effect profiles. Prostatectomy can lead to urinary incontinence and erectile dysfunction, but it can help improve significant obstructive symptoms.
- Short-term side effects of RT include irritative urine and bowel symptoms. Radiation cystitis or proctitis may occur months to years after the completion of prostate RT. Endoscopic evaluation is warranted if the symptoms persist to rule out a second malignancy (eg, urothelial carcinoma) or telangiectasias.
- Patients with preexisting urinary symptoms should avoid brachytherapy and may experience symptomatic benefit from radical prostatectomy.
- There is little to no advantage to treatment with robotic prostatectomy versus other surgical approaches or to treatment with proton therapy versus conventional RT for clinically localized prostate cancer.
- Detectable PSA (>0.2 ng/mL) after radical prostatectomy or an increase in PSA concentration by 2 ng/mL or more above PSA nadir after RT is an indicator of recurrent prostate cancer. In the absence of evidence of metastatic disease on standard bone scan and CT imaging, this is termed BCR.
- Salvage RT may be used for patients who experience BCR after radical prostatectomy, typically combined with 6 months of ADT. Conversely, salvage prostatectomy is less commonly performed after primary RT because of high rates of urinary incontinence and impotence. Other local salvage therapies may be possible.
- The optimal timing of systemic therapy for BCR is unclear. ADT will lower PSA level in this setting and delay time to metastatic disease, but its effect on OS relative to ADT at the time of metastatic disease is unknown.
- Patients with BCR who are treated with ADT and whose PSA levels increase without evidence of metastases on standard bone scan and CT imaging have disease that has progressed to nmCRPC. The addition of the second-generation AR antagonist apalutamide, darolutamide, or enzalutamide prolongs MFS and OS in this setting.
- Although not curative, ADT is palliative and results in clinical response in most patients with mCSPC.
- The addition of docetaxel, abiraterone with prednisone, or an AR pathway inhibitor (eg, apalutamide, enzalutamide, darolutamide) to ADT improves OS for patients with mCSPC.
- Recent studies indicate that the OS efficacy of triple therapy (ADT/docetaxel/NHT [eg, abiraterone or darolutamide]) was superior to ADT/docetaxel. The benefit was clear, especially for high-volume mCSPC with the addition of abiraterone to ADT/docetaxel. High-volume metastasis is defined by the presence of four or more bone metastases with one or more outside the spine and pelvis or the presence of visceral metastasis using CT and bone imaging.
- It is unknown whether the triple therapy is superior to ADT/NHT or whether they are equivalent, or whether the ADT/NHT doublet is not inferior to the triplet.
- In the setting of mCRPC, abiraterone, enzalutamide, sipuleucel-T, docetaxel, ^{223}Ra, ^{177}Lu-PSMA-617, and cabazitaxel all prolong OS. Unfortunately, cross-resistance to AR-directed therapies occurs after exposure to abiraterone or enzalutamide for a prolonged period, and the efficacy of enzalutamide after abiraterone or abiraterone after enzalutamide is limited.
- The role of PARP inhibitors is actively evolving. Two PARP inhibitors, olaparib and rucaparib, are FDA approved as monotherapy in mCRPC. Niraparib is approved in combination with abiraterone for mCRPC and BRCA1/2 alterations. Talazoparib is approved in combination with enzalutamide as first-line treatment in mCRPC for patients with selected HRR gene alterations. Although the benefit of PARP inhibitors in diseases with *BRCA2* mutations is most clear, their benefit in the setting of some other HRR gene alterations is debatable. Clinical context and alternative treatment options should be considered.
- Urothelial carcinoma is predominantly a disease of older men and is most associated with smoking. Additional risk factors include certain occupational exposures, chronic catheters, and chronic bladder infections, including schistosomiasis in endemic areas. Upper-tract (ureteral and renal pelvis) urothelial carcinoma may be associated with Lynch syndrome.
- The entire urothelial tract is at risk from these carcinogenic exposures (field cancerization), so patients with urothelial carcinoma in one area are at risk for separate primaries in other areas and at other times.

- Most bladder and ureter cancers are of urothelial (transitional cell) histology. There are several variants of urothelial carcinoma, most of which are treated similarly to pure urothelial carcinoma but may exhibit more aggressive behavior.
- Rare bladder cancers can have pure adenocarcinoma, squamous cell, or small-cell histology. These are generally more aggressive and usually present with advanced disease.
- Bladder cancer may present as painless hematuria or irritative urinary symptoms, and it is typically diagnosed via TURBT.
- Based on TURBT pathology, bladder cancer is broadly divided into non-muscle-invasive tumors and muscle-invasive tumors. Muscularis propria must be present in the TURBT specimen to enable this assessment; otherwise, a repeat TURBT is recommended.
- NMIBC is stratified according to risk of recurrence.
- For low-risk tumors, surveillance (cystoscopy and urine cytology) is most appropriate.
- For intermediate- and high-risk tumors, intravesical BCG decreases the risk of recurrence, and surveillance is also crucial. Definitive bladder therapy (cystectomy) is considered in situations of very high-risk non-muscle-invasive tumors or BCG-refractory tumors.
- Intravenous pembrolizumab is currently an FDA-approved treatment option for patients with BCG-unresponsive NMIBC, in addition to several novel intravesical immune-based therapies.
- The most established standard of care for MIBC is neoadjuvant cisplatin-based chemotherapy followed by radical cystectomy and lymph node dissection. The optimal neoadjuvant chemotherapy regimens are GC and dose-dense MVAC. The addition of durvalumab in the perioperative setting to chemotherapy is now an approved option.
- For cisplatin-ineligible patients undergoing cystectomy, perioperative EVP is now an FDA-approved option. For those ineligible for EVP, no other perioperative chemotherapy is currently recommended, and carboplatin should not be substituted for cisplatin. Recent data suggest good safety and efficacy of a cisplatin split-dosing strategy for those with CrCl 40 to 60 mL/min; thus, cisplatin should be considered for this population.
- Adjuvant nivolumab or pembrolizumab immunotherapy for 1 year significantly improves DFS in patients with high-risk MIBC and is FDA approved for this indication.
- Maximal transurethral resection of the bladder tumor followed by concurrent definitive RT with radiosensitizing chemotherapy, also known as bladder-sparing or trimodality therapy, may offer similar long-term disease control for appropriately selected patients. Historically, this has been considered only for patients ineligible for or declining cystectomy, but based on nonrandomized data, it is now considered a reasonable alternative to cystectomy in all eligible patients.
- The preferred first-line therapy for patients with metastatic bladder cancer is combination EVP. Alternatively, less preferred regimens are cisplatin-based chemotherapy with or without nivolumab, followed by PD-1/PD-L1 checkpoint inhibitor maintenance. For patients who are not eligible for immunotherapy, gemcitabine and cisplatin remains a standard treatment option. In contrast with perioperative chemotherapy, carboplatin may be substituted for cisplatin-ineligible patients.
- Optimal second- and subsequent-line therapies are not well defined in the setting of the recent changes in first-line therapy. HER2 IHC and genomic testing for the *FGFR3* mutation should be requested. Options include platinum with gemcitabine, enfortumab vedotin monotherapy, erdafitinib, trastuzumab deruxtecan, and single-agent chemotherapies, depending on the prior systemic therapies used.
- Upper-tract (ureteral and renal pelvis) urothelial carcinoma may be diagnosed initially by imaging, urine cytology, and/or biopsy via retrograde ureteroscopy, but often a nephroureterectomy is required for pathological diagnosis as well as treatment.
- Perioperative chemotherapy should be considered for high-risk tumors based on extrapolation from bladder cancer or from one randomized trial of adjuvant platinum-based chemotherapy. For patients with high-risk disease who are unfit for or decline chemotherapy, adjuvant nivolumab may be considered as an alternative, although the supporting data are not as robust.
- Pure nonurothelial bladder cancers are typically treated with cystectomy; the role of perioperative chemotherapy and/or RT is not well defined.
- Bladder cancer is predominantly a disease of older patients and frequently occurs in patients with other comorbidities. Therefore, a significant portion of patients are not candidates for many standard therapies such as cisplatin and cystectomy.
- Bladder-sparing or trimodality therapy is now considered an equal alternative to cystectomy and is increasingly offered to appropriately selected patients who wish to preserve their bladders and avoid urinary diversion; previously, it was reserved primarily for patients ineligible for cystectomy because of comorbidities.
- Cisplatin should be offered to any eligible patient regardless of age, but this requires careful assessment of baseline neuropathy, hearing, and kidney function, and serial assessment during and after treatment. Split-dosing of cisplatin should be considered for patients with CrCl 40 to 60 mL/min. Newer systemic treatment modalities (eg, immune

checkpoint inhibitors, antibody-drug conjugates, and targeted therapies) are rapidly improving treatment options for patients with locally advanced or metastatic disease and those not eligible for conventional chemotherapy.

- Renal cell carcinoma is the most common type of kidney tumor. The classic triad of hematuria, abdominal pain, and a palpable mass is rarely seen in modern practice. Incidental diagnoses are increasing.
- Risk factors include smoking, obesity, hypertension, environmental exposures, hereditary kidney cancer syndromes, and acquired cystic kidney disease leading to end-stage renal disease.
- After radiographic evaluation of a localized kidney mass, the decision whether to biopsy or to perform partial or radical nephrectomy depends on the level of suspicion of malignancy, the size of the lesion, and the age and comorbidities of the patient.
- Small renal masses are often incidentally detected as contrast-enhancing tumors <4 cm. Options for management include active surveillance, partial nephrectomy, and percutaneous ablation.
- Complex masses may require radical nephrectomy with some increased subsequent risk of renal impairment.
- Adjuvant pembrolizumab for 1 year improves DFS and OS in intermediate- and high-risk resected localized clear–cell renal cell carcinoma.
- First-line systemic therapy for metastatic clear–cell renal cell carcinoma includes combination immune checkpoint blockade with ipilimumab and nivolumab or combination of PD-1/PD-L1 inhibition and VEGFR TKIs.
- The role of cytoreductive nephrectomy in the setting of metastatic disease remains undefined in the era of immune checkpoint inhibitor combinations. For patients without symptomatic primary tumors who are eligible for first-line systemic therapy, immediate cytoreductive nephrectomy may not provide significant benefit. The role of deferred nephrectomy is being evaluated in prospective clinical trials.
- Second-line therapy for metastatic disease includes VEGFR TKIs, belzutifan, mTOR inhibitors, and cytokine therapy in select patients, with the choice of therapy dependent on prior treatment. Alternate antiangiogenesis inhibitors may still be active after prior antiangiogenic therapy.
- Non–clear cell renal cell carcinomas have been underrepresented in clinical trials, and the optimal treatment strategy is not well defined. Targeted agents include standard anti-VEGF TKIs as well as an emerging role for *MET* inhibition in papillary renal cell carcinoma, especially using the dual VEGF/MET inhibitor cabozantinib.
- Bone metastases may be treated with systemic therapy and bone-protective agents such as bisphosphonates or denosumab. Brain metastases and oligometastases can be treated with local therapies (eg, surgery, RT, or ablation) followed by systemic therapy, sometimes with long-term disease control.
- Elderly patients with comorbidities may benefit from active surveillance of appropriate renal cell carcinomas or nephron-sparing approaches (eg, partial nephrectomy or stereotactic body RT) when treatment is required. For those being treated for advanced renal cell carcinoma, attention must be paid to the unique toxicities of checkpoint inhibitors and/or targeted therapies in the setting of concomitant hypertension, diabetes, chronic kidney disease, and thyroid disease, among others.
- The most well-known risk factor for testicular cancer is the history of undescended testis (cryptorchidism). Early surgical correction can help mitigate this risk.
- Genes on chromosome arm 12p seem to be involved with germ cell tumor pathogenesis, and i(12p) is a common finding that may help differentiate germ cell tumors from other tumor types in ambiguous situations or cancers with unknown primary.
- Suspicious testicular symptoms or findings should be evaluated by ultrasonography. If the results are suggestive, diagnosis is made via inguinal orchiectomy, never via percutaneous biopsy. Tumor marker levels should be determined beforehand, and if elevated, measurement must be repeated after surgery.
- For patients who present with life-threatening symptoms (eg, bleeding brain metastases or pulmonary metastases causing respiratory failure), highly elevated AFP or β-hCG levels, and a typical pattern of spread, systemic therapy should be started immediately. Resection of a suspicious testicular lesion can be delayed until after starting or completing chemotherapy, but should still be performed to establish a pathological diagnosis and remove a potential chemotherapy sanctuary site.
- Germ cell tumors are divided into seminomas and nonseminomas. Seminomas must be composed entirely of seminoma; any component of other histology results in a diagnosis of nonseminoma, and an elevated AFP level (>20-25) should be treated as nonseminoma.
- Seminomas are highly sensitive to chemotherapy and RT. This has implications for therapy and evaluation of residual masses after therapy.
- Nonseminomas can be mixes of multiple histologies, including malignant germ cell tumors (embryonal carcinoma, yolk sac tumor, and choriocarcinoma) and teratomas. Malignant nonseminomatous germ cell tumors are generally chemotherapy sensitive. Teratoma is neither chemotherapy nor RT sensitive. By itself, teratoma does not usually metastasize,

but it can dedifferentiate over time into malignant histologies, including (but not limited to) teratocarcinoma or certain sarcomas.

- The testicles descend from the retroperitoneum embryologically; therefore, the lymphatic drainage is to the retroperitoneal lymph nodes rather than the inguinal or pelvic lymph nodes. This has implications for surveillance and treatment.
- If prior inguinal or transscrotal surgeries have been performed, the lymphatic drainage may be disrupted; therefore, the pattern of metastasis can be less predictable, and more caution is needed if considering adjuvant retroperitoneal lymph node dissection (RPLND) or radiation.
- From the retroperitoneal lymph nodes, testicular cancer may spread to mediastinal and other lymph nodes. Pulmonary metastases are much more common than other visceral metastases and do not carry as poor a prognosis as other visceral involvement.
- Before orchiectomy, tumor-marker levels should be measured, and patients should undergo cross-sectional imaging of the abdomen and pelvis as well as chest imaging. MRI of the head and a bone scan are indicated only for patients with suspicious symptoms or in the setting of specific risk factors.
- Advanced (metastatic) germ cell tumors are risk-stratified according to primary site, pattern of spread, and degree of serum tumor-marker elevation.
- Stage I seminomas are generally managed with active surveillance. Alternatives include adjuvant chemotherapy (one to two cycles of carboplatin) or RT, which decreases the risk of recurrence but results in some degree of overtreatment and has long-term toxicities. OS is excellent regardless of immediate versus delayed intervention. Therefore, adjuvant treatment is typically offered only to patients who are eager to reduce their chance of recurrence (and the need for more intensive therapy) or who may have difficulty adhering to a surveillance schedule, with the understanding that OS will not likely be improved.
- Stage IIA and nonbulky IIB seminomas can be treated with RT to the retroperitoneal lymph nodes or chemotherapy.
- Stage IIB and advanced seminomas (stages IIC and III) are treated according to the risk stratification scheme for advanced germ cell tumors, with most falling into the good-risk category and a minority being intermediate risk because of nonpulmonary visceral metastases. Seminomas are never considered poor risk.
- Good-risk advanced germ cell tumors are treated with three cycles of BEP or four cycles of etoposide and cisplatin.
- Intermediate- and poor-risk advanced germ cell tumors are treated with four cycles of BEP or four cycles of VIP. Omission of bleomycin is not acceptable unless the patient is receiving VIP.
- Germ cell tumors refractory to first-line chemotherapy are still curable, but the prognosis is worse.
- Options for second-line chemotherapy include standard-dose regimens such as TIP and high-dose chemotherapy with autologous stem cell rescue. Which strategy is superior is unknown, but high-dose chemotherapy is generally preferred for patients with poor-prognosis features or as third-line therapy.
- Residual masses after second-line chemotherapy in nonseminomas should still undergo resection as in the first-line setting.
- Pulmonary toxicity must be managed in patients treated with bleomycin by continued monitoring of symptoms and DLCO. Bleomycin should be discontinued if there are suggestive symptoms. Small asymptomatic drops in DLCO are common, but discontinuation is generally recommended for drops of ≥25%. For bleomycin-treated patients who subsequently require surgery, low intraoperative Fio_2 and minimal hydration should be used.
- Teratoma may undergo malignant transformation into teratocarcinoma, adenocarcinoma, or other histologies, generally as a late complication of unresected teratomatous components of nonseminoma.
- In a situation of diagnostic uncertainty, the presence of i(12p) points to a likely germ cell tumor origin.
- Non–germ cell testicular cancers are rare and include sex cord tumors, the most common being Leydig cell tumors. These can cause endocrinopathies and are typically cured via orchiectomy.
- Most patients with testicular cancer have long-term survival and are treated relatively early in life, so monitoring for and intervening in early and late complications of treatment are important, especially those complications related to the cardiovascular system. Cisplatin-based chemotherapy and/or RT may increase cardiovascular risk, risk of secondary malignancies, and risk of infertility, among others. Patients treated with chemotherapy and/or RT should monitor and treat other cardiovascular risk factors, including hypertension, and adhere to age-appropriate cancer screening. These risks further justify the avoidance of adjuvant therapies for most patients with stage I disease.
- Penile cancer is a rare disease associated with age, lack of circumcision, HPV and/or HIV infection, and tobacco use.
- Penile cancer is typically of squamous histology.
- The primary pattern of spread is local invasion followed by inguinal lymph node metastasis. However, inguinal nodes may frequently be enlarged as a result of concomitant inflammation and infection. Evaluation of the inguinal nodes depends on the invasiveness of the primary tumor and whether the nodes are palpable.
- Penile cancer is managed according to the degree of tumor invasion and lymph node involvement. The primary treatment modality is surgery.

- Patients with intermediate- or high-risk penile cancers should undergo assessment for lymph node involvement.
- Perioperative chemotherapy (eg, TIP regimen) and/or RT with or without radiosensitizing chemotherapy may be used for advanced tumors, but high-level evidence is lacking.
- Malignant adrenal tumors are extremely rare.
- After resection of localized adrenal cortical carcinoma, patients at high risk of recurrence may be considered for adjuvant mitotane.
- Adding mitotane to chemotherapy in the advanced setting increases response rates but not survival.
- Malignant pheochromocytoma is treated surgically, similarly to nonmalignant pheochromocytoma.

CHAPTER TABLES AND IMAGES

Table 14-1 Randomized Trials of ADT Plus Abiraterone and Prednisone for mCSPC

Trial	No. of Participants	Study Population	Design	Outcome	Notes
LATITUDE	1,199	De novo high-risk mCSPC	ADT plus placebo vs ADT plus abiraterone and prednisone	Improved OS with the addition of abiraterone and prednisone (53.3 vs 36.5 months)[89]	High risk based on 2 of 3: Gleason 8+, 3 + bone lesions, visceral metastases
STAMPEDE	1,917	High-risk localized or high-risk BCR or mCSPC (recurrent or de novo)	ADT plus placebo vs ADT plus abiraterone and prednisone (plus RT for localized or N + disease)	Improved 3-year OS with the addition of abiraterone and prednisone (83% vs 76%)	Benefit was seen across subsets, including M0 tumors, although there were few events in this group

Abbreviations: ADT, androgen deprivation therapy; BCR, biochemical recurrence; mCSPC, metastatic castration-sensitive prostate cancer; OS, overall survival; RT, radiation therapy.

Table 14-2 **Randomized Trials of ADT Plus Androgen Receptor Pathway Inhibitors for mCSPC**					
Trial	**No. of Participants**	**Study Population**	**Design**	**Outcome**	**Notes**
ARANOTE[1]	669	mCSPC (recurrent or de novo)	ADT + placebo vs ADT + darolutamide	Improved radiographic PFS with the addition of darolutamide (not reached vs 25 months)	rPFS benefit seen regardless of disease volume. OS data immature
ARCHES	1,150	mCSPC (recurrent or de novo)	ADT versus ADT plus enzalutamide. Docetaxel is allowed at the investigator's discretion in either trial arm	Improved radiographic PFS with addition of enzalutamide (not reached vs 19 months)	rPFS benefit seen regardless of docetaxel use and/or disease volume. OS data immature
ENZAMET	1,125	mCSPC (recurrent or de novo)	ADT versus ADT plus enzalutamide. Docetaxel is allowed at the investigator's discretion in either trial arm	Improved OS with the addition of enzalutamide (median OS not yet estimable; 80% versus 72% OS at 3 years)	Possibly limited benefit of enzalutamide in docetaxel-treated patients. Possible increased docetaxel toxicity with the addition of enzalutamide
TITAN	1,052	mCSPC (recurrent or de novo)	ADT versus ADT plus apalutamide. Docetaxel is allowed at the investigator's discretion in either trial arm	Improved OS and radiographic PFS with apalutamide (82% vs 74% OS; 68% vs 48% rPFS)	rPFS benefit seen regardless of docetaxel use and/or disease volume. Possibly limited OS benefit of apalutamide in docetaxel-treated patients

Abbreviations: ADT, androgen deprivation therapy; mCSPC, metastatic castration-sensitive prostate cancer; OS, overall survival; PFS, progression-free survival; rPFS, radiography progression-free survival; RT, radiation therapy.

Table 14-3 **Standard Neoadjuvant Chemotherapy Regimens**

Classic MVAC (28-Day Cycle)	Dose-Dense MVAC (14-Day Cycle)	Gemcitabine and Cisplatin
Methotrexate on days 1, 15, and 22	Methotrexate on day 1	21-day regimen
Vinblastine on days 2, 15, and 22	Vinblastine on day 2	Cisplatin on day 1 or 2
Doxorubicin on day 2	Doxorubicin on day 2	Gemcitabine on days 1 and 8
Cisplatin on day 2	Cisplatin on day 2	28-day regimen:
	G-CSF on days 4-10 or pegylated	Cisplatin on day 1 or 2
	G-CSF after chemotherapy	Gemcitabine on days 1, 8, and 15

Abbreviations: G-CSF, granulocyte colony-stimulating factor; MVAC, methotrexate/vinblastine/doxorubicin/cisplatin.
For classic MVAC and dose-dense MVAC, all four chemotherapy agents (methotrexate, vinblastine, doxorubicin, and cisplatin) may be given together on day 1.

Table 14-4 **Genomic Alterations in Inherited and Sporadic Renal Tumors**

Genomic Alteration	Type of Renal Tumor	Syndrome
VHL	ccRCC	Von Hippel-Lindau (autosomal dominant): • Hemangioblastomas of CNS • Retinal angiomas • Pheochromocytomas • Pancreatic serous cystadenomas and neuroendocrine tumors
Chromosome 3 translocations or *BRCA1*-associated protein 1 (*BAP1* gene)	ccRCC	Familial ccRCC
MET (germline and somatic)	Hereditary or sporadic type I papillary RCC	Hereditary papillary renal carcinoma (autosomal dominant): • Bilateral multifocal papillary renal tumors
Fumarate hydratase (germline)	Type II papillary RCC	Hereditary leiomyomatosis and RCC: • Autosomal dominant • Uterine fibroids
Succinate dehydrogenase (germline)	ccRCC or chromophobe RCC	Hereditary paraganglioma and pheochromocytoma (autosomal dominant): • Paragangliomas • Pheochromocytomas • Bilateral and/or multifocal kidney tumors
Xp11.2 (*TFE* gene)	ccRCC or papillary RCC	Early-onset RCC
Folliculin (*FLCN* gene)	Chromophobe RCC or mixed chromophobe-oncocytoma renal tumors	Birt-Hogg-Dube syndrome: hair-follicle hamartomas of the face and neck: • Renal and pulmonary cysts • Slow-growing bilateral kidney tumors
Hamartin (*TSC1*) or tuberin (*TSC2*)	Angiomyolipomas, rare ccRCC	Tuberous sclerosis complex: • Bilateral multifocal kidney tumors
SMARCB1 (germline)	Medullary carcinoma	

Abbreviations: ccRCC, clear–cell renal cell carcinoma; CNS, central nervous system; RCC, renal cell carcinoma.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 14-5 **Factors More Common in Hereditary RCC Useful for Referral for Genetic Evaluation**
Early age at RCC diagnosis (46 years or younger)
Bilateral renal cancer
Multifocal renal cancer
Strong family history of RCC (two or more relatives in the same bloodline)
RCC with personal or family history of one or more tumor type[a]
Unusual skin conditions (eg, leiomyomas, fibrofolliculomas, angiofibromas)
Family history of kidney cancer syndrome

Abbreviation: RCC, renal cell carcinoma.
[a]Pheochromocytoma, brain/spinal hemangioblastoma, pancreatic neuroendocrine tumor, retinal tumor, papillary cystadenoma, endolymphatic sac tumor, gastrointestinal stromal tumor, uterine fibroid (age ≤35 years), uveal and cutaneous melanomas, and solid cancer occurring in childhood.

Table 14-6 **Combination Therapies for Frontline Treatment of Metastatic Renal Cell Carcinoma**

	Ipilimumab + Nivolumab	Axitinib + Pembrolizumab	Axitinib + Avelumab	Cabozantinib + Nivolumab	Lenvatinib + Pembrolizumab
Randomization (control arm)	1:1 (sunitinib)	1:1 (sunitinib)	1:1 (sunitinib)	1:1 (sunitinib)	1:1:1 (lenvatinib with everolimus, sunitinib)
No. of subjects	1,096	861	886	651	1,069
IMDC risk (%)	23	31.2	21.4	23	31
Favorable	61	56.2	61.8	58	59.2
Intermediate poor	17	12.6	16.2	19	9.3
PD-L1 >1% (%)	24	60.5	63.2	26	30.1
OS	0.68	0.53	0.78	0.60	0.66
HR 95% CI	0.49-0.95	0.38-0.74	0.55-1.08	0.40-0.89	0.49-0.88
Median PFS (months)	12.4	15.1	13.8	16.6	23.9
Combination sunitinib	12.3	11.1	8.4	8.3	9.2
Objective RR	39%	59.3%	51.4%	55.7%	71%
Complete RR	10.20%	5.8%	3.4%	8%	16.1%
Median DoR (months)	76.2	23.6	19.4	20.2	25.8

Abbreviations: DoR, duration of response; IMDC, International Metastatic Renal-Cell Carcinoma Database Consortium; OS, overall survival; PFS, progression-free survival; RR, response rate.

Table 14-7 **Key Phase 3 Trials of Antiangiogenic Therapy in Metastatic RCC**

Trial	No. of Participants	Study Population	Design	Outcome	Notes
Motzer et al[172]	750	Treatment-naive metastatic RCC	Sunitinib vs interferon-α	Improved PFS with sunitinib (11 vs 5 months)	Improved OS with sunitinib in long-term follow-up (26.4 vs 21.8 months)
Sternberg et al[173]	435	Treatment-naive and cytokine-treated metastatic RCC	Pazopanib vs placebo	Improved PFS with pazopanib (9.2 vs 4.2 months)	PFS benefit seen regardless of prior treatment
AXIS[174]	723	Previously treated metastatic RCC	Axitinib vs sorafenib	Improved PFS with axitinib (6.7 vs 4.7 months)	OS did not differ in long-term follow-up (20.1 vs 19.2 months)
METEOR[175]	658	VEGFR-treated metastatic RCC	Cabozantinib vs everolimus	Improved PFS with cabozantinib (7.4 vs 3.8 months)	More toxicity with cabozantinib. Improved OS with cabozantinib in long-term follow-up
CABOSUN[176]	157	Treatment-naive intermediate-/high-risk metastatic RCC	Cabozantinib vs sunitinib	Improved PFS with cabozantinib (8.6 vs 5.3 months)	No significant OS difference in long-term follow-up
Motzer et al[177]	153	VEGFR-treated metastatic RCC	Lenvatinib plus everolimus vs lenvatinib versus everolimus	Improved PFS with lenvatinib plus everolimus (14.6 months) or lenvatinib (7.4 months) vs everolimus (5.5 months)	Marginally improved OS with lenvatinib plus everolimus vs everolimus, but underpowered. Increased toxicity with combination therapy

Abbreviations: OS, overall survival; PFS, progression-free survival; RCC, renal cell carcinoma; VEGFR, vascular endothelial growth factor receptor.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 14-8 **Targeted Agents for Non–Clear Cell RCC**

Agent	Primary Target	Histology	Outcome
Sunitinib	*VEGFR*	Papillary, chromophobe, translocation	Improved PFS with sunitinib vs everolimus (8.3 vs 5.6 months), but poor-risk patients may have better PFS with everolimus
Temsirolimus	*mTOR*	Papillary, chromophobe	Improved OS with temsirolimus vs IFN (11.6 vs 4.3 months)
Everolimus	*mTOR*	Papillary, chromophobe, translocation	See above comments on sunitinib. No clear difference between sequencing sunitinib followed by everolimus vs everolimus followed by sunitinib
Crizotinib	*MET*	Type I papillary RCC	In 4 of 23 patients with *MET* alteration, 2 had PR
Foretinib	*MET*, *VEGF*	Papillary RCC	In 10 patients with germline *MET* alteration, 5 had PR. Overall, RR was 13.5%; median PFS was 9 months
Savolitinib	*MET*	Papillary RCC	In the phase 3 SAVOIR trial, compared savolitnib vs sunitinib in *MET*-driven papillary RCC. Enrollment was closed early when new data suggested longer-than-anticipated PFS of patients with papillary RCC treated with sunitinib. PFS numerically improved, not statistically significant (with early termination). Savolitinib arm of PAPMET closed early for futility
Cabozantinib	*MET*, *VEGF*	Papillary RCC	Improved ORR and PFS were seen in comparison with sunitinib in the frontline setting in PAPMET (see above)

Abbreviations: IFN, interferon; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; PR, partial response; RCC, renal cell carcinoma; RR, response rate; VEGFR, vascular endothelial growth factor receptor.

Table 14-9 **Risk Stratification According to the International Germ Cell Consensus Classification**[167]	
Germ Cell Tumor	**Risk Stratification**
Seminoma	Good risk: • Any primary and any markers and no nonpulmonary visceral metastases
	Intermediate risk: • Any primary and any markers and nonpulmonary visceral metastases
Nonseminoma	Good risk: • Testis or retroperitoneal primary and good-risk markers, and no nonpulmonary visceral metastases
	Intermediate risk: • Testis/retroperitoneal primary and intermediate-risk markers and no nonpulmonary visceral metastases
	Poor risk: • Mediastinal primary site or testis or retroperitoneal primary with either nonpulmonary visceral metastases or poor-risk markers

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 14-10 **Serum Markers in Germ Cell Tumors**			
	Serum Marker		
Histology	**AFP[a]**	**β-hCG[b]**	**LDH[c]**
Seminoma	Never	+/− (Typically <100)	+/−
Nonseminoma			
Choriocarcinoma	+/−	+++	+/−
Embryonal carcinoma	+/−	++	+/−
Teratoma	—	—	—
Yolk sac tumor	+++	+/−	+/−

Abbreviations: AFP, alpha fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.
[a]Half-life: 5 to 7 days.
[b]Half-life: 1 to 2 days.
[c]Half-life: varies by isoform.

Table 14-11 **Selected Treatment Regimens for Relapsed Germ Cell Tumors After First-Line Bleomycin, Etoposide, and Cisplatin Combination or Etoposide and Cisplatin**

Chemotherapy	Regimen	Agents	Results
Standard dose	TIP[91]	Paclitaxel (Taxol)	Limited to patients with favorable prognostic factors
		Ifosfamide plus mesna	ORR, 63%; 2-year PFS, 65%
		Cisplatin	
	VeIP	Vinblastine	Disease-free rate, 36% (including patients undergoing subsequent resection of masses); median survival, 12.7 months
		Ifosfamide plus mesna	
		Cisplatin	
High-dose with autologous stem cell rescue	TI-CE[103]	Two cycles of conventional-dose paclitaxel (Taxol) and ifosfamide plus mesna, followed by G-CSF, followed by stem cell collection (leukapheresis)	Limited to patients with unfavorable prognostic factors
		3 cycles of high-dose carboplatin and etoposide, followed by stem cell rescue, each cycle	5-year DFS, 47%; OS, 52%

Abbreviations: DFS, disease-free survival; G-CSF, granulocyte colony-stimulating factor; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; TI-CE, paclitaxel/ifosfamide/carboplatin/etoposide; TIP, paclitaxel/ifosfamide/cisplatin; VeIP, vinblastine/ifosfamide/cisplatin.

Figure 14-2 Gleason Scoring

A

A Gleason score is assigned by adding the two most common grades of prostate cancer cells in a tissue sample.

How is it calculated?

Formula for Gleason scoring

Primary pattern (>50%) + Secondary pattern (<50%) = GS

Example:

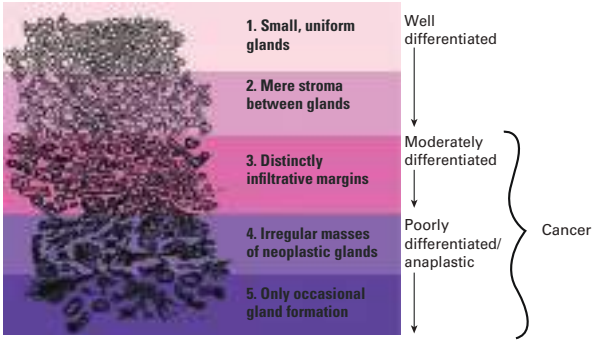
Primary pattern = 3

Secondary pattern = 4

Total GS = 7

This means that most of the tumor is grade 3 (aka dominant pattern), and a smaller portion is grade 4.

B



C

Gleason score Formula: GS = Primary pattern (>50%) + Secondary pattern (<50%)	ISUP Grade Groups derived from GS; Cancer grading
6 (</3 + 3)	Grade Group I (GS = </6)
7 (3 + 4)	Grade Group II
7 (4 + 3)	Grade Group III
8 (4 + 4)	Grade Group IV
9 (4 + 5)	Grade Group V
9 (5 + 4)	Grade Group V
10 (5 + 5)	Grade Group V

The Gleason score is a scale that helps with the staging of prostate cancer (by aggressiveness and prognosis) based on the microscopic examination of the sample tissue in the prostate biopsy. The grades in the score compare the pattern of the cancerous tissue with that of normal tissue in regard to aspects including shape, disposition, and spread. There are two grades that are awarded, each on a scale from 1 to 5. The primary grade is given to the most commonly observed type of cancerous cell; the secondary grade is given to the second most commonly observed type of cancerous cell.

(A) Calculating the Gleason score. (B) Gleason Pattern. (C) Deriving ISUP grade groups from GS.

Abbreviations: GS, Gleason score; ISUP, International Society of Urological Pathology.

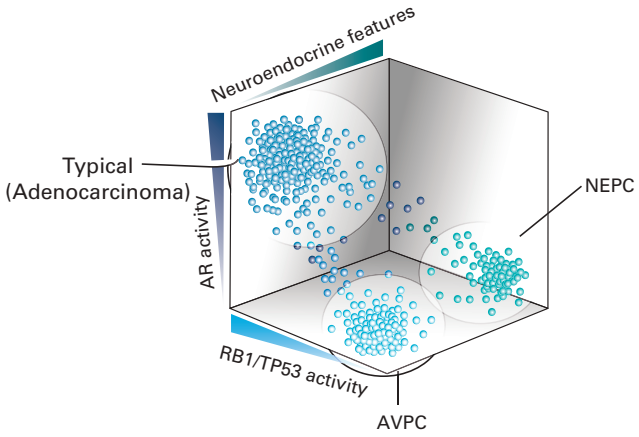
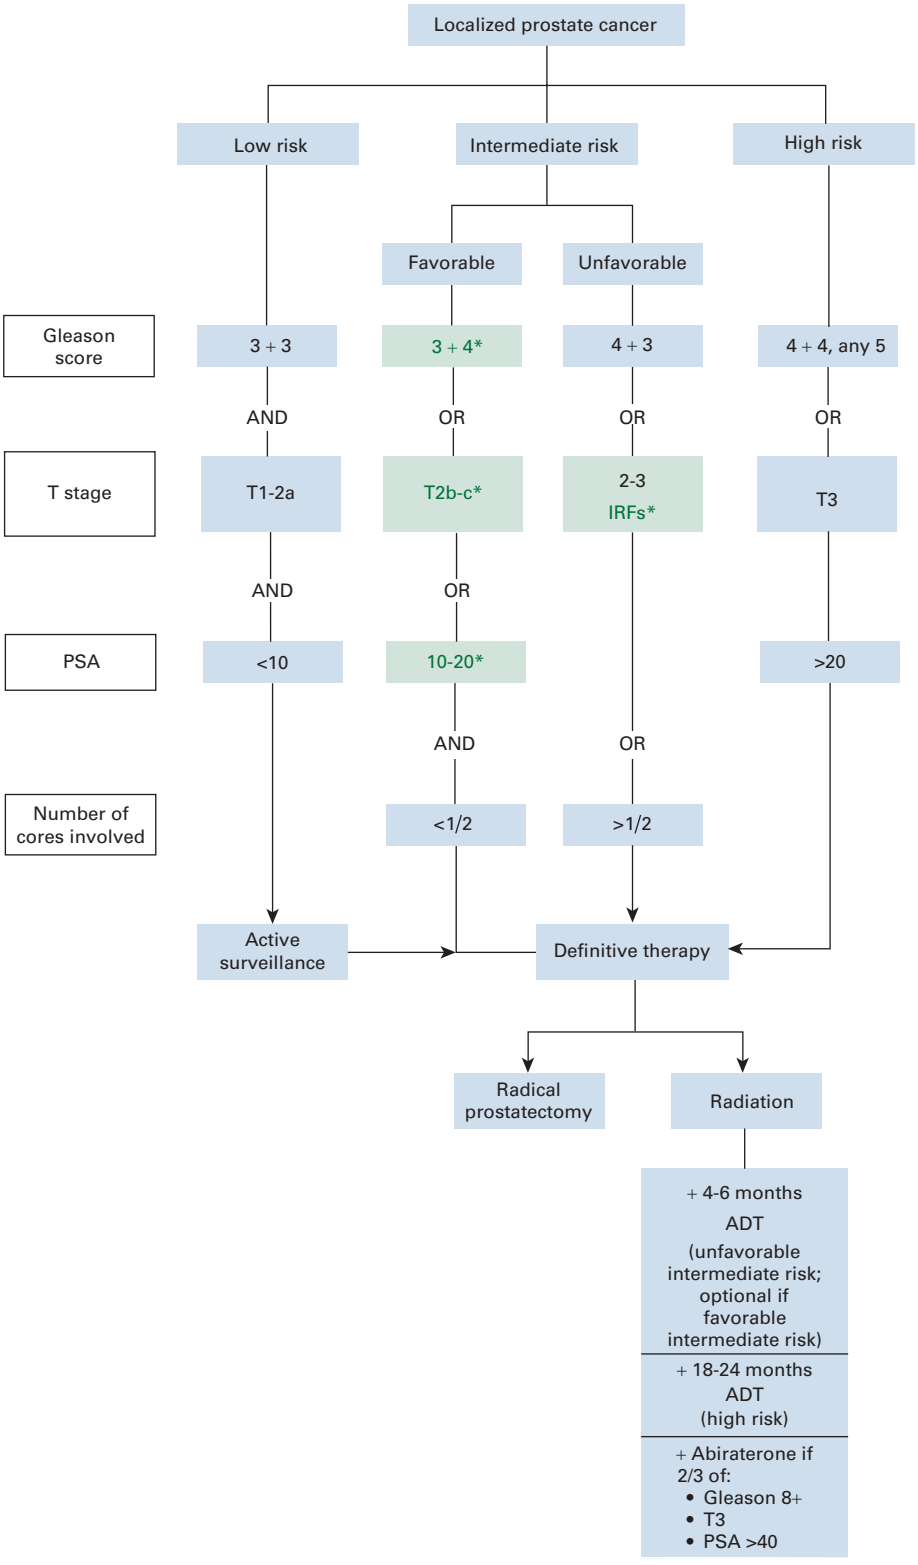
Figure 14-3 Relationship Between AR Signaling, Tumor-Suppressor Genes, and Neuroendocrine Features in Metastatic Castration-Resistant Prostate Cancer



This depicts a conceptual representation of the spectrum of profiles that include AR signaling, loss of tumor-suppressor genes, and development of neuroendocrine features during prostate cancer progression. Individual dots represent hypothetical patients, but different subclones may also be present within one individual.
Abbreviations: AR, androgen receptor; AVPC, aggressive variant prostate cancer; NEPC, neuroendocrine prostate cancer.
Reprinted with permission from Wolters Kluwer. Source: Einstein DJ, Arai S, Balk SP. Targeting the androgen receptor and overcoming resistance in prostate cancer. *Curr Opin Oncol*. 2019;31(3):175–182; figure 1. doi: 10.1097/CCO.0000000000000520

Figure 14-4 Approach to Treatment Options in Newly Diagnosed Localized Prostate Cancer According to Risk Stratification



Various forms of radiation are discussed in the text. Short course of ADT (4–6 months) is recommended for intermediate-risk category (especially if unfavorable) and long course (18–24 months) for high-risk category.
Abbreviations: ADT, androgen deprivation therapy; EBRT, external-beam radiation therapy; IRF, intermediate risk factor; PSA, prostate-specific antigen.
*IRFs.

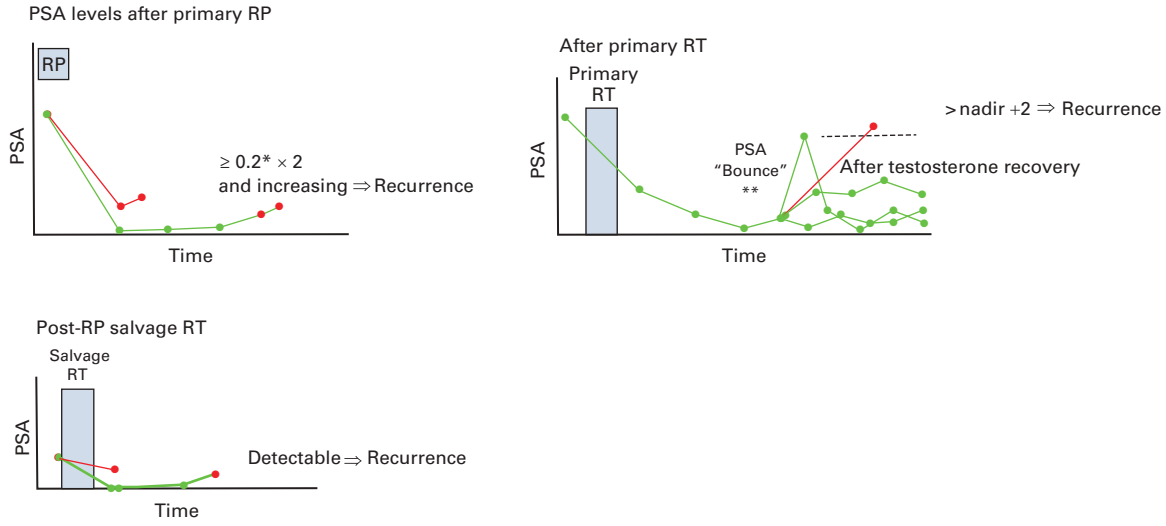
Figure 14-5 PSA Outcomes After Primary Therapies for Localized Prostate Cancer-Defining Biochemical Recurrence



Abbreviations: PSA, prostate-specific antigen; RP, radical prostatectomy; RT, radiation therapy.
*Ultrasensitive PSA assays define biochemical recurrence as any measurable PSA value after radical prostatectomy.
**PSA "bounce" observed only in the absence of ADT.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 14-6 Management Options After Primary Therapy for Prostate Cancer

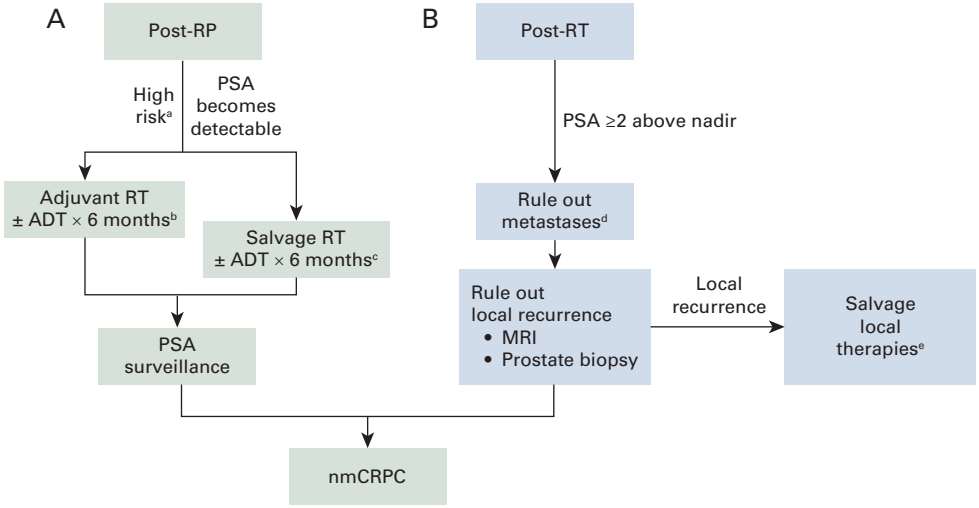


Figure 14-6 Continued

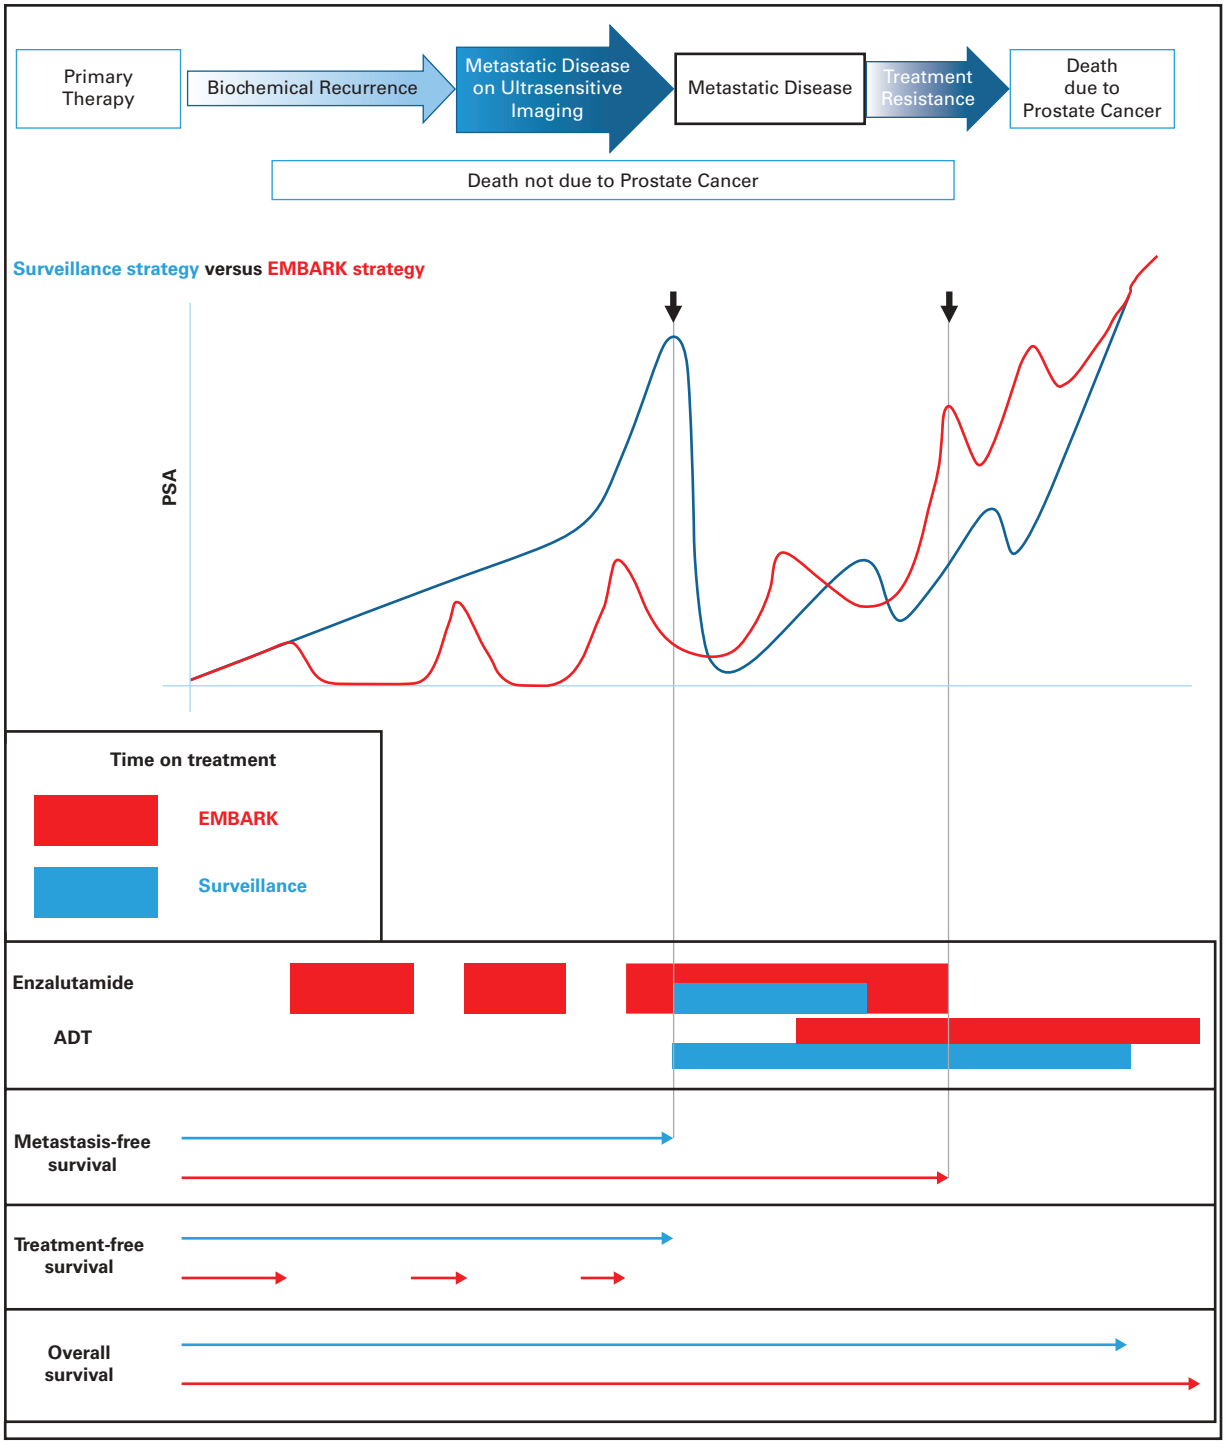
C



Panel (A) illustrates options following radical prostatectomy. Panel (B) illustrates options following radiation therapy. Panel (C) illustrates the hypothetical comparison of a surveillance strategy for biochemically recurrent prostate cancer to the EMBARK strategy with enzalutamide monotherapy.For options regarding recurrence after maximal local therapy, see Figure 14-7.

Abbreviations: ADT, androgen deprivation therapy; ARPI, androgen receptor pathway inhibitor; mCSPC; metastatic castration-sensitive prostate cancer; nmCRPC, non-metastatic castration-resistant prostate cancer; PSA, prostate-specific antigen; PSADT, prostate-specific antigen doubling time; PSMA, prostate-specific membrane antigen; RP, radical prostatectomy; RT, radiation therapy.

[a]High risk defined as pT3b or R1 (positive margin).

[b]Use and duration of ADT are variable; 6 months is common, but patients with low PSA may not benefit.

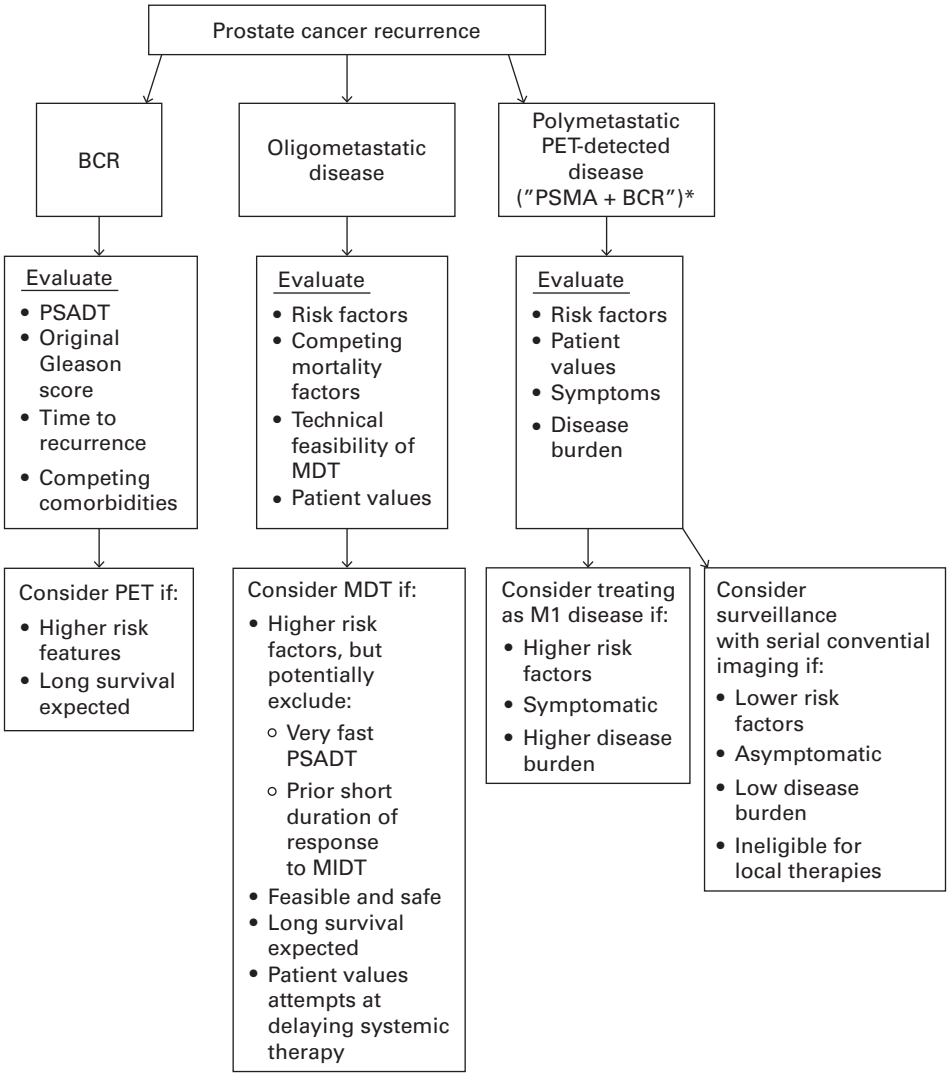
[c]Enzalutamide ± ADT. Previously, ADT, continuous or intermittent.

[d]Consider using ultrasensitive diagnostic imaging if available (eg, PET using PSMA tracers; eg, ^{68}Ga PSMA or ^{18}F[^{18}F] piflufolastat, ^{18}F fluciclovine, or ^{11}C choline); if not available, use conventional imaging modalities.

[e]Salvage local therapies may include brachytherapy, cryotherapy, radiofrequency ablation, high-intensity focused ultrasound, or salvage prostatectomy.

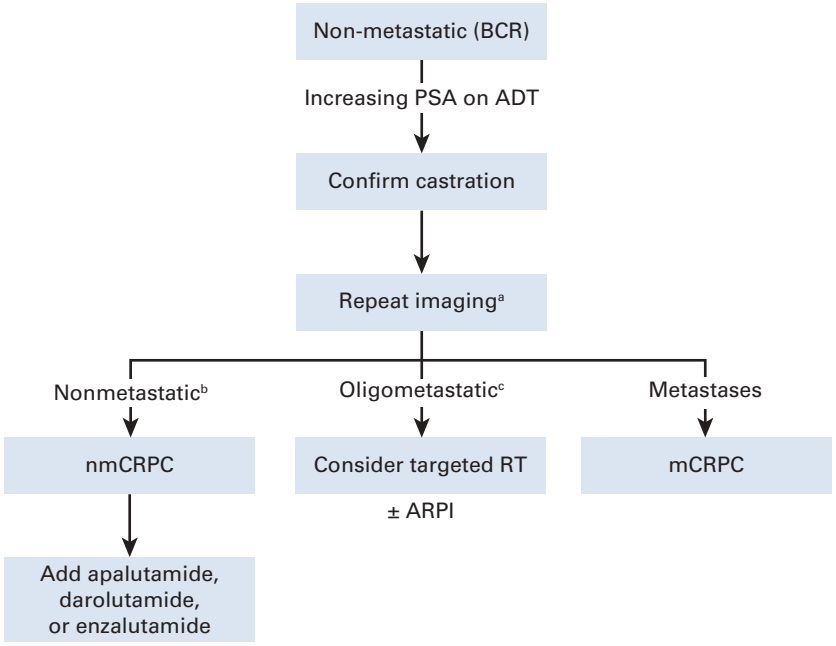
Panels (A, B) were created for ASCO. Copyright © 2026 by American Society of Clinical Oncology. Panel (C) was originally published in: David J. Einstein; Meredith M. Regan; Julia S. Stevens; David F. McDermott; Ravi A. Madan. JCO 2024 05-16. doi: 10.1200/JCO.24.00279

Figure 14-7 Recurrent Prostate Cancer After Maximal Local Therapy



Abbreviations: BCR, biochemical recurrence; MDT, metastasis-directed therapy; PET, positron emission tomography; PSADT, PSA doubling time.
*For discussion of "PSMA+BCR," see Einstein DJ, Abel ML, Aragon-Ching JB, et al. National Cancer Institute's Working Group on Biochemically Recurrent Prostate Cancer: clinical trial design considerations. *J Clin Oncol*. 2025;43(34):3672-3683. doi: 10.1200/jco-25-01693
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 14-8 Treatment Options for nmCRPC



Abbreviations: ADT; androgen deprivation therapy; ARPI, androgen receptor pathway inhibitor; BCR, biochemical recurrence; mCRPC, metastatic castration-resistant prostate cancer; NGI, next-generation imaging; nmCRPC, non-metastatic castration-resistant prostate cancer; PSA, prostate-specific antigen; RT, radiation therapy.

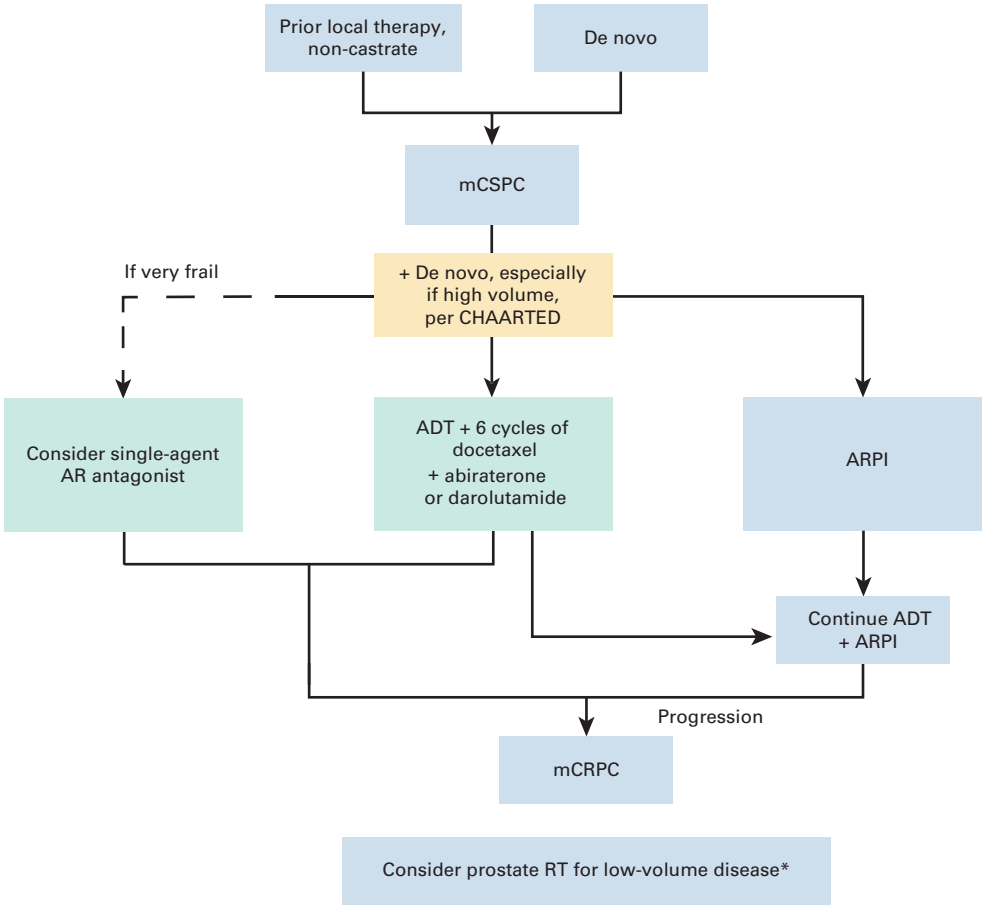
[a]Consensus from the ASCO Expert Panel is that NGI may be considered only if a change in clinical care is contemplated. Assuming patients have received or are ineligible for local salvage treatment options, NGI may clarify the presence or absence of metastatic disease, but the data on the detection capabilities of NGI in this setting and its impact on management are limited.

[b]In nmCRPC studies, patients were included who had pelvic lymph nodes up to 2 cm in diameter.

[c]Oligometastatic disease is variably defined as one to five metastases.

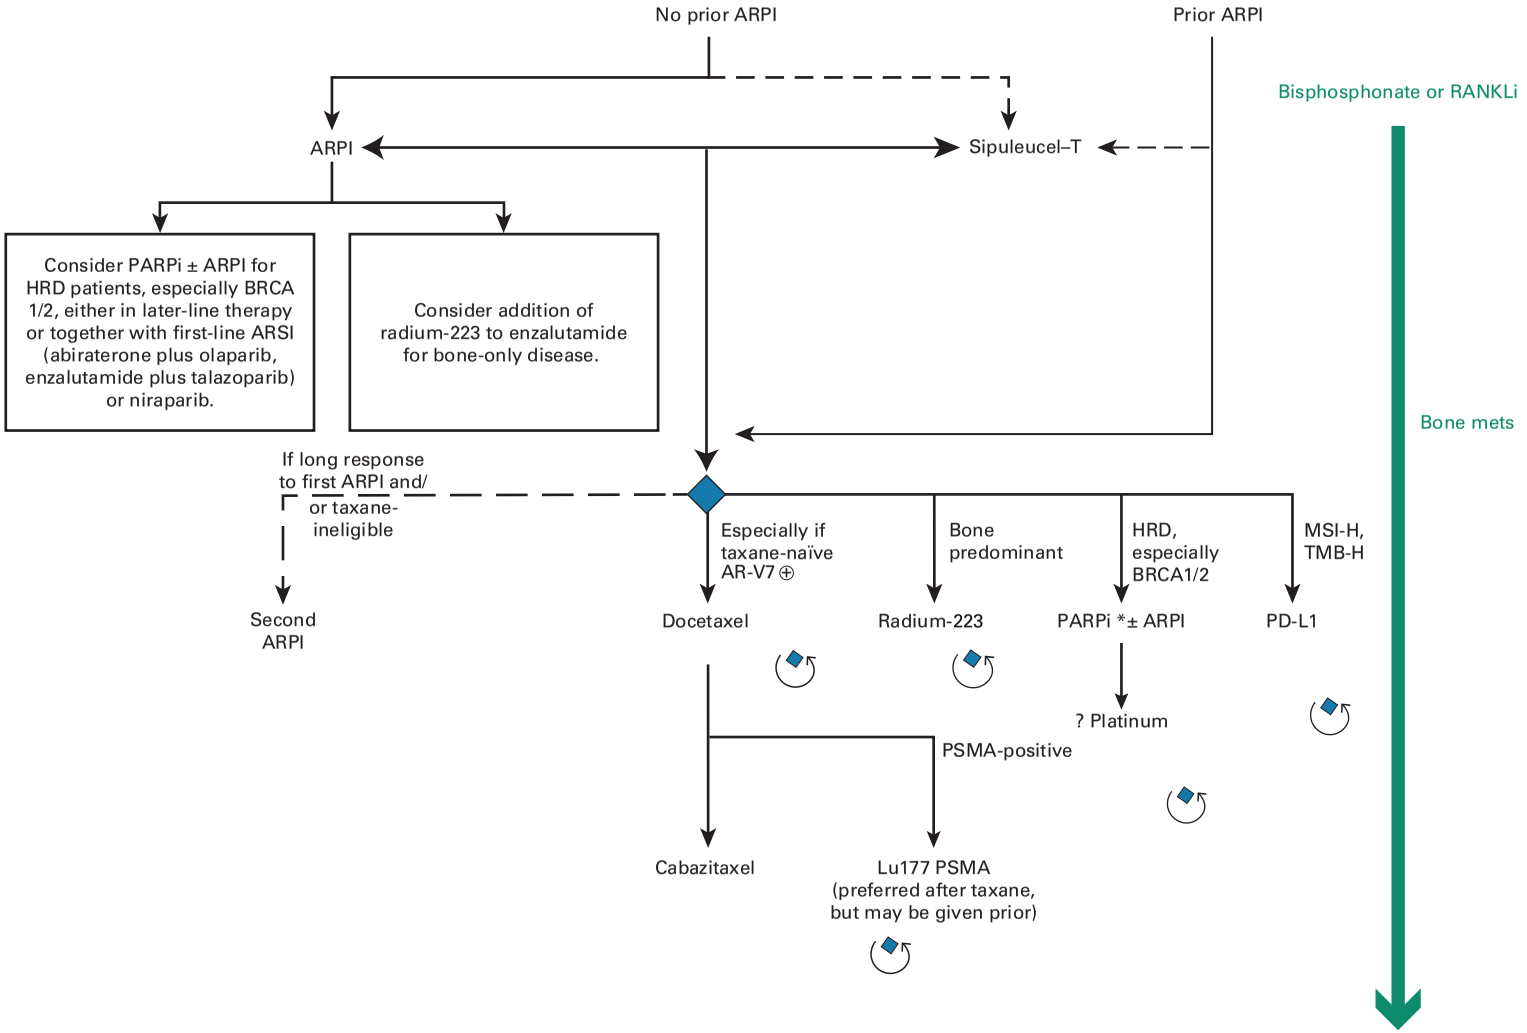
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 14-9 Standards of Care for mCSPC by Disease Volume



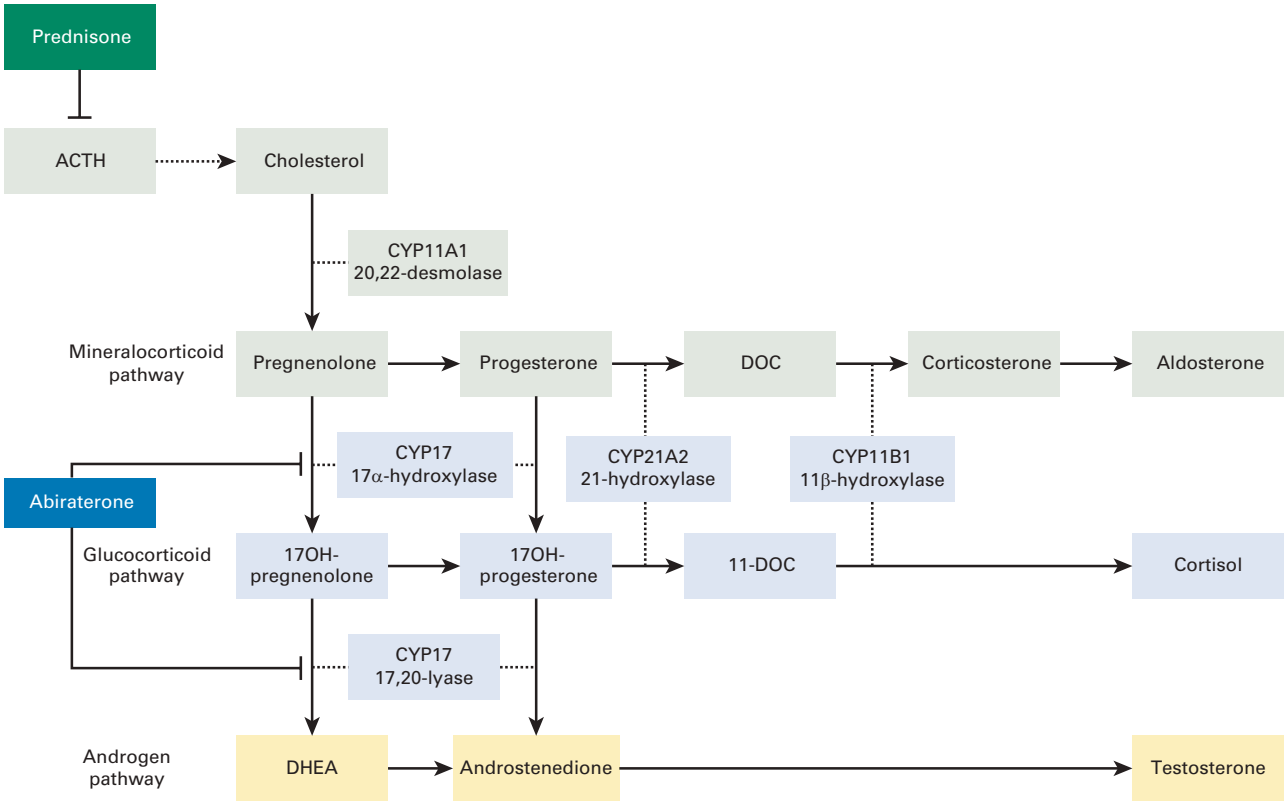
High volume is defined as the presence of ≥4 bone metastases with one or more lesions in the extra-axial skeleton or the presence of visceral metastasis.
Abiraterone is always administered with prednisone.
Abbreviations: ADT, androgen deprivation therapy; AR, androgen receptor; ARPI, androgen receptor pathway inhibitor; mCRPC, metastatic castration-resistant prostate cancer; mCSPC; metastatic castration-sensitive prostate cancer; RT, radiation therapy.
*Supported by a prespecified subgroup analysis from STAMPEDE, but the comparison arm was ADT alone. Efficacy in the setting of intensified therapy (ADT and docetaxel or ARPI) is unknown.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 14-10 Treatment Options for mCRPC



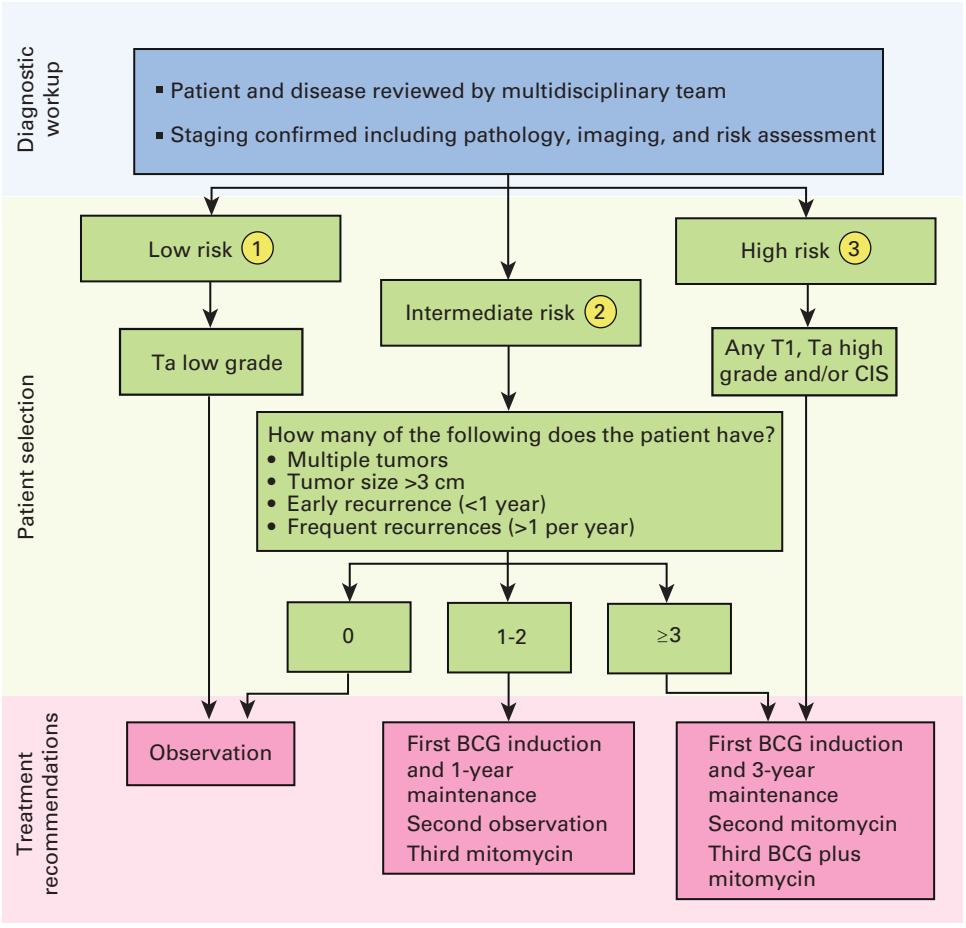
Abiraterone is always administered with prednisone.
Abbreviations: ARPI, androgen receptor pathway inhibitor; HRD, homologous recombination deficiency; mCRPC, metastatic castration-resistant prostate cancer; MSI-H, high microsatellite instability; PARPi, poly ADP-ribose polymerase inhibitor; PSMA, prostate-specific membrane antigen; TMB-H, high tumor mutational burden.
*Consider PARPi ± ARPI for HRD patients, especially BRCA1/2, either in later-line therapy or together with first-line ARSI (abiraterone plus olaparib, enzalutamide plus talazoparib) or niraparib.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology

Figure 14-11 Biochemical Pathways Resulting From Abiraterone Administration and Prednisone



Administration of prednisone prevents a compensatory ACTH surge and thus decreases downstream symptoms of excess mineralocorticoid production (eg, hypertension, hypokalemia, and edema).
Abbreviations: ACTH, adrenocorticotropic hormone; DHEA, dehydroepiandrosterone; DOC, 11-deoxycorticosterone.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

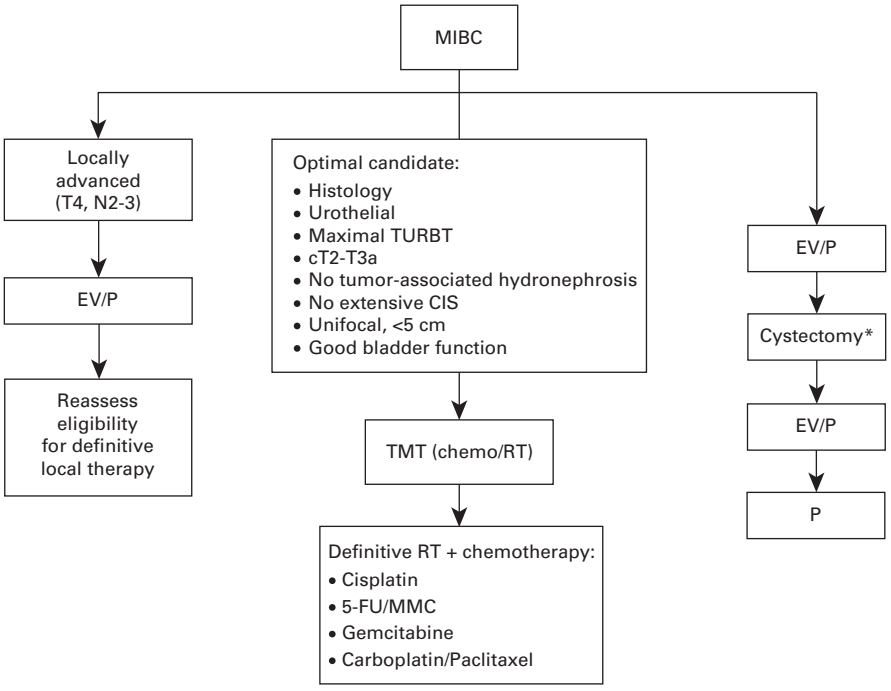
Figure 14-12 Treatment Algorithm for Non-Muscle-Invasive Bladder Cancer



All of the treatment options shown may be appropriate. The selection of therapy should be individualized based on patient eligibility and the availability of the therapy at the discretion of the treating physician. These algorithms are meant to provide advice as the consensus recommendations of the Task Force. (1) The Task Force defines low risk as a solitary, primary low-grade Ta tumor. (2) Intermediate risk is defined as histologically confirmed multiple and/or recurrent low-grade Ta tumors. (3) High risk is defined as any T1, high grade, and/or carcinoma in situ.
Abbreviations: BCG, Bacillus Calmette-Guerin; CIS, carcinoma in situ.

Reprinted under Creative Commons Attribution 4.0 International License from Kamat AM, Bellmunt J, Galsky MD, et al. Society for Immunotherapy of Cancer consensus statement on immunotherapy for the treatment of bladder carcinoma. *J Immunother Cancer*. 2017;5:68. doi:10.1186/s40425-017-0271-0

Figure 14-13 Treatment Options for Muscle-Invasive Bladder Cancer



Abbreviations: 5-FU, 5-fluorouracil; CIS, carcinoma in situ; ddMVAC, dose-dense methotrexate/vinblastine/doxorubicin/cisplatin; EV/P, enfortumab vedotin and pembrolizumab; GC, gemcitabine/cisplatin; MMC, mitomycin C; P, pembrolizumab; RT, radiation therapy; TMT, trimodality therapy; TURBT, transurethral resection of bladder tumor.

*If N + disease is established or suspected before scheduled radical cystectomy, and the patient has not received neoadjuvant therapy, radical cystectomy plus pelvic lymphadenectomy is still a treatment option. There is no level I evidence for adjuvant chemotherapy in the post-cystectomy node-positive setting, but many clinicians would consider its use based on results of the Advanced Bladder Cancer Collaborative meta-analysis.

GYNECOLOGIC CANCERS 15

Linda R. Duska, MD, MPH, and Lilie L. Lin, MD

RECENT UPDATES

Ovarian Cancer

- The combination of avutometinib and defactinib was granted accelerated approval by the FDA on May 5, 2025, for adult patients with *KRAS*-mutated recurrent low-grade serous ovarian cancer who have received prior systemic therapy. The approval was based on the RAMP 201 study, a phase 2 trial of the oral RAF/MEK clamp avutometinib, combined with defactinib, a selective inhibitor of FAK. This combination attempts to block the compensatory upstream reactivation of MEK by RAF, seen with the use of standard MEK inhibitors, as well as inhibit FAK, which is a key adaptive resistance mechanism to the RAS/MAPK pathways.[1-3] RAMP 201 evaluated avutometinib and defactinib versus avutometinib alone and demonstrated the superiority of the combination. The trial then moved into an expansion phase of the combination in both *KRAS*mut and *KRAS* wild-type low-grade ovarian cancer. In total, 115 patients were included: 58 with *KRAS*mut and 57 with *KRAS* wild type. Overall, 22% had prior MEK inhibitor treatment. The overall response rate (ORR) was 31%. Among patients with *KRAS*mut tumors, the ORR was 44%, and among *KRAS* wild-type tumors, it was 17%.[4] The confirmatory trial RAMP 301 is currently ongoing.
- Trastuzumab deruxtecan-nxki (T-DXd) was granted accelerated approval by the FDA on April 5, 2024, based on the results of the DESTINY-PanTumor02,[5] DESTINY-Lung01,[6] and DESTINY-CRC02[7] trials for any solid tumor with *HER2* immunohistochemistry (IHC) of 3+. In this basket trial, 40 patients with recurrent ovarian cancer and 2+ or 3+ IHC per *HER2* gastric scoring were enrolled. The ORR for all 40 patients was 45%. The ORR was 63.6% for centrally confirmed 3+ IHC, and it was 36.8% for centrally confirmed 2+ IHC.[8,9] The NCCN listed T-DXd for *HER2*-positive tumors (IHC 3+ or 2+) as a category A recommendation under Useful in Certain Circumstances on July 15, 2024.
- On July 14, 2025, a new drug application for relacorilant was submitted to the FDA based on results from the phase 3 ROSELLA trial (GOG-3073). ROSELLA evaluated relacorilant in combination with nab-paclitaxel versus nab-paclitaxel monotherapy in patients with advanced, platinum-resistant high-grade epithelial ovarian cancer. Relacorilant is a novel selective glucocorticoid receptor antagonist that restores the sensitivity of cancers to cytotoxic chemotherapy. Presented at ASCO in 2025, the study showed a significant improvement in progression-free survival with a hazard ratio of 0.70 in favor of the experimental arm and a trend toward improved overall survival (OS).

Endometrial Cancer

- Dostarlimab-gxly and carboplatin plus paclitaxel in recurrent/metastatic endometrial cancer: The FDA-approved dostarlimab-gxly in combination with carboplatin and paclitaxel, followed by single-agent dostarlimab-gxly for the treatment of patients with primary advanced or recurrent endometrial cancer on August 1, 2024. This approval was based on the randomized phase 3 RUBY trial,[10] which first led to the approval of this combination in mismatch repair–deficient (dMMR) tumors or tumors with microsatellite instability (MSI) in July 2023. In 2024, the indication was expanded to all tumors (dMMR and MMR proficient) on the basis of demonstrated OS benefit across the study population.[11]
- Full FDA approval for pembrolizumab and carboplatin plus paclitaxel in recurrent/metastatic endometrial cancer: The FDA-approved pembrolizumab in combination with carboplatin and paclitaxel, followed by single-agent pembrolizumab for the treatment of patients with primary advanced or recurrent endometrial cancer on June 17, 2024. This approval was based on results from the NRG-GY018/KEYNOTE-868,[12] and the indication applies to all patients, irrespective of MMR protein status.[13] A separate phase 3 double-blind, randomized, controlled trial evaluated carboplatin and paclitaxel with pembrolizumab versus placebo administered concurrently with chemotherapy and as maintenance for up to 2 years in 816 patients with measurable stage III or IVA, stage IVB, or recurrent endometrial

cancer. Previous adjuvant chemotherapy was permitted if the treatment-free interval was at least 12 months. The median progression-free survival (PFS) was 18.8 months versus 8.5 months with pembrolizumab versus placebo, respectively. In 218 patients with dMMR high MSI (MSI-H) tumors, the median PFS was not reached with pembrolizumab versus 7.6 months with placebo, and the 12-month PFS rate was 74% versus 38% (HR, 0.30).[14]

- Pembrolizumab and carboplatin plus paclitaxel as adjuvant therapy in tumors considered high risk for recurrence: The MK-3475-B21/KEYNOTE-B21/ENGOT-en11/GOG-3053 study (GOG, Gynecologic Oncology Group)[15] was presented and published in 2024. This study evaluated the addition of pembrolizumab to tumors that were International Federation of Gynecology and Obstetrics (FIGO) stage I/II of non-endometrioid histology and that also had a *TP53* alteration or stage III/IVA of any histology. All patients had surgery with curative intent followed by random assignment to paclitaxel and carboplatin with or without pembrolizumab, followed by pembrolizumab maintenance for six cycles (6-week dosing). The primary endpoints were disease-free survival (DFS) and OS in the intent-to-treat population. This study failed to show a benefit for the addition of pembrolizumab, with an HR of 1.02 (95% CI, 0.79-1.32; *P* = .570). Subgroup analysis showed that the HR for DFS was 0.31 (95% CI, 0.14-0.69) in the dMMR population and 1.20 (95% CI, 0.91-1.57) in the MMR-proficient population.[16] Regulatory decisions regarding these analyses are pending at the time of this update.
- T-DXd was granted accelerated approval by the FDA on April 5, 2024, based on the results of the DESTINY-PanTumor02, DESTINY-Lung01, and DESTINY-CRC02 trials for any solid tumor with *HER2* 3+ immunohistochemistry (IHC). In this basket trial, 40 patients with recurrent endometrial cancer and 2+ or 3+ IHC for *HER2* (gastric scoring) were enrolled. The ORR for all 40 patients was 57.5% (95% CI, 9.9-NE). The ORR for centrally confirmed 3+ IHC was 84.6% (95% CI, 9.6-NE), and the ORR for centrally confirmed 2+ IHC was 47.1% (95% CI, 3.0-NE). In addition, the ORR for 1+ IHC (only four patients) was 25%, and the ORR for centrally confirmed *HER2* 0 IHC (five patients) was 60%. The NCCN listed T-DXd for *HER2*-positive tumors (3+ or 2+ IHC) as a category A recommendation under Useful in Certain Circumstances in the July 15, 2024, update.[17]

Cervical Cancer

- The FDA granted fast-track designation to ADRX-0706 for the treatment of advanced cervical cancer in May 2025. ADRX-0706 is a Nectin-4 targeted antibody-drug conjugate that is being evaluated in a phase 1a/b clinical trial for the treatment of advanced solid tumors. Preliminary safety and antitumor activity were reported at ASCO in 2025.
- The FDA approved the Teal Wand on May 9, 2025, as the first at-home vaginal self-collection device for cervical cancer screening.
- Pembrolizumab plus cisplatin and radiation: On January 12, 2024, the FDA-approved pembrolizumab with chemoradiation therapy and as maintenance therapy for patients with FIGO 2014 stage III to IVA cervical cancer based on the results of MK-3475-A18/KEYNOTE-A18/ENGOT-cx11/GOG-3047,[18] a multicenter, randomized, double-blind, placebo-controlled phase 3 trial that evaluated pembrolizumab versus placebo with chemoradiation therapy and also as maintenance therapy in 1,060 patients with cervical cancer who had not previously undergone treatment. Pembrolizumab, 400 mg intravenously once every 6 weeks for maintenance therapy, is continued for 15 cycles after completion of cisplatin plus pembrolizumab therapy plus radiation therapy.
- Neoadjuvant chemotherapy: In 2024, the INTERLACE trial[19] was published and provided new options for planning treatment of locally advanced cervical cancer. The trial included 596 patients with stage III to IVA disease and 462 patients with stage IB2 to IIB node-positive disease.[20] A statistically significant improvement in PFS was demonstrated in the overall population. In an exploratory subgroup analysis, in patients with stage III to IVA disease, the PFS HR estimate was 0.59 (95% CI, 0.43-0.82), and 21% of patients in the pembrolizumab arm experienced PFS compared with 31% of patients in the placebo arm. By contrast, in an exploratory subgroup analysis in the 462 patients with FIGO 2014 stage IB2 to IIB disease, the PFS HR estimate was 0.91 (95% CI, 0.63-1.31). Five-year OS rates were 80% in the induction chemotherapy with chemoradiotherapy group and 72% in the chemoradiotherapy alone group, with an HR of 0·60 (95% CI, 0·40-0·91; *P* = .015).[20-24]
- T-DXd was granted accelerated approval by the FDA on April 5, 2024, based on the results of the DESTINY-PanTumor02, DESTINY-Lung01, and DESTINY-CRC02 trials for any solid tumor with *HER2* 3+ IHC. In this basket trial, 40 patients with recurrent cervical cancer and 2+ or 3+ IHC for *HER2* (gastric scoring) were enrolled. The ORR for all 40 patients was 50%. The ORR in patients with centrally confirmed 3+ IHC was 75%, and the ORR for patients with centrally confirmed 2+ IHC was 40%.[8] The NCCN listed T-DXd for *HER2*-positive tumors (3+ or 2+ IHC) as a category A recommendation under Useful in Certain Circumstances in the July 15, 2024.

▶ Tisotumab vedotin-tftv was approved by the FDA on April 29, 2024, based on the results of innovaTV 301.[25] This randomized phase 3 trial evaluated tisotumab vedotin-tftv versus investigator choice of chemotherapy in patients with cervical cancer that had recurred after 1 to 2 previous lines of systemic therapy and who had demonstrated a statistically and clinically relevant improvement in OS.[26] Tisotumab vedotin-tftv had previously received accelerated approval in September 2021 for the same population.[9,27]

OVERVIEW

Each year, more than 110,000 people are diagnosed with a gynecologic cancer, with a death rate of more than 32,000.[28,29] Although ovarian cancer continues to have a high fatality rate, endometrial cancer now has the highest mortality rate and is the most common gynecologic cancer.[28,30,31] Most gynecologic cancers are treated in the metastatic setting with carboplatin- and paclitaxel-based therapies that have high efficacy but few cures. For many years, significant advances in survival outcomes for gynecologic cancers have been elusive. This trend seems to be changing with the identification of druggable targets, the development of highly active novel therapies, and innovation in clinical trial design toward the evaluation of target-based endpoints. In this chapter, the epidemiology and clinical characteristics of the major gynecologic cancers are reviewed; established approaches to prevention are described; and updates in management, increasingly biomarker directed, are discussed. Areas of ongoing controversy in the management of these diseases are also reviewed.

CERVICAL CANCER

EPIDEMIOLOGY AND PREVENTION

Within the United States, cervical cancer is the third most common gynecologic malignancy, where approximately 13,360 new cases of cervical cancer are diagnosed, with 4,320 deaths.[28] This cancer is more common worldwide, particularly in resource-poor regions, where screening and prevention programs have not been fully established[32] and where cervical cancer is the leading cause of death resulting from cancer in women. The relatively slow growth rate of most cancers of the cervix, along with the causal association with high-risk human papillomavirus (HPV) infection, means that HPV vaccination, HPV testing, and Papanicolaou smear screening offer opportunities for cancer prevention or early detection of preinvasive changes in the cells of the surface of the cervix, and thus can prevent the development of invasive cancer.[33]

Risk factors for the development of cervical cancer include smoking (which increases the risk of persistent cervical dysplastic changes) and immunocompromised status (eg, HIV infection). Use of an intrauterine device (IUD) has been associated with a lower risk of cervical cancer, independent of HPV status.

A majority of cervical cancers are either squamous cell carcinomas or adenocarcinomas, although there are rare subtypes, including clear-cell and neuroendocrine cancers. These rare histologic types confer a worse prognosis, and treatment often requires a specialized multidisciplinary approach.

PATHOGENESIS

HPV infection is the leading cause of cervical cancer, accounting for more than 90% of all cases in the United States annually (Fig. 15-1). Approximately 70% of all cervical cancers are caused by infection with high-risk HPV strain 16 or 18. The development of cervical cancer requires four major steps. Notably, progression from persistent infection to preinvasive disease often takes up to 5 years. Cervical cancer does not affect most people with an HPV infection. Persistent infections and precancer are established in less than 10% of new infections. Invasive cancer arises over many years in a minority of people with precancer.[32]

It is widely recommended that people who are eligible for HPV vaccination receive it. The recombinant 9-valent HPV vaccine received expanded approval to include people aged 9 through 45 years (it was initially approved for those aged 26 years or younger) based on the data from a randomized trial showing efficacy against HPV vaccination in people aged 26 years or older[34] and effective prevention of other conditions, including vulvar intraepithelial neoplasia, anal disease, and oral HPV infection. Whether and to what degree the vaccine is effective in people with active HPV infection or cervical dysplasia is not clear, but vaccination is still recommended.

CLINICAL PRESENTATION AND STAGING

Most people are asymptomatic in the early stages of cervical cancer. Symptoms of vaginal bleeding (ie, intermenstrual, postcoital), pelvic pain, and vaginal discharge typically suggest the presence of more advanced disease.

Cervical cancer is staged by the FIGO system, which was updated in October 2018. This version incorporates nodal involvement as stage IIIC disease, with clarification whether the disease was detected radiologically or pathologically.[32] In clinical practice in the United States, advanced imaging with MRI or PET is often used for staging (including nodal assessment), which yields important information for treatment planning.

CURRENT TREATMENT PRACTICE

Early Invasive Cervical Cancer

A discussion of the treatment of early invasive cervical cancer must start with an understanding of current versus past staging definitions. Currently, FIGO 2018 defines stage IA tumors as microscopic invasive carcinomas with a maximum depth of invasion (DOI) of less than 5 mm. Within stage IA, tumors are subclassified as follows: stage IA1 indicates DOI less than 3 mm, while stage IA2 represents DOI of 3 mm or more but less than 5 mm. Stage IB is now divided into three categories based on tumor size: stage IB1 for DOI greater than 5 mm and less than 2 cm in greatest dimension; stage IB2 for tumors 2 cm or greater but less than 4 cm; and stage IB3 for tumors 4 cm or larger.[26]

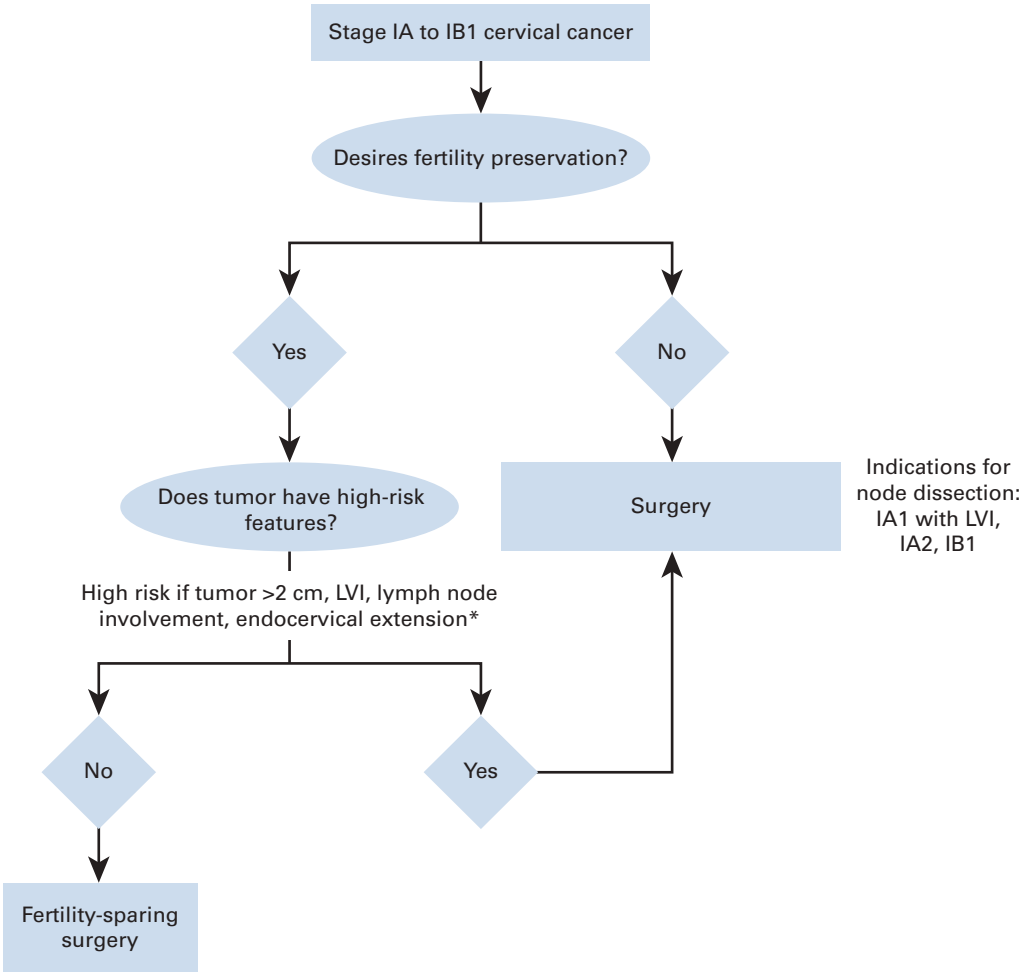
Early invasive cervical cancer is defined as stage IA or IB1 disease (Fig. 15-2). Patients diagnosed with stage IA or IB1 cervical cancer have an excellent prognosis, with 5-year relative survival rates exceeding 90%.

Early invasive cervical cancer is managed surgically. The radicality and approach for surgery are important for survival, quality of life, and preservation of fertility. The need for radical resection was challenged by the Simple Versus Radical Hysterectomy in Women with Low-risk Cervical Cancer (SHAPE) (NCT01658930) clinical trial.[35] In this trial, a subset of patients with stage I cervical cancer was deemed so low risk (based on historical data on parametrial and lymph node involvement) that de-escalation of the surgical approach was warranted. Low-risk tumors were defined as FIGO 2009 stage IA2 or IB1 with lesions less than 2 cm, DOI less than 10 mm, and MRI showing invasion of less than 50% of cervical stromal tissue (required for stage IB1 only). Preoperative imaging also had to show no evidence of lymph node metastasis. Patients were randomly assigned to a radical hysterectomy versus a simple hysterectomy; both procedures included lymph node evaluation. The primary endpoint was pelvic recurrence within 3 years after random assignment.

In all, 700 patients were randomly assigned, the majority of whom had stage IB1 tumors. With a median follow-up of 4.5 years, the incidence of pelvic recurrence was 2.17% in the radical hysterectomy arm and 2.52% in the simple hysterectomy arm, which demonstrated no loss in oncologic control with de-escalation to simple hysterectomy. Importantly, rates of urinary incontinence and urinary retention were lower in the simple hysterectomy group.[36] This study is one of the most important advances in cervical cancer because it de-escalates the radicality of surgery for a substantial number of patients with low-risk, early-stage cervical cancer and makes access to appropriate surgical care more feasible across the global landscape. It is important to emphasize that the selection criteria for this study must be followed accurately to identify patients appropriate for a simple hysterectomy.

For patients with early-stage tumors that do not meet SHAPE criteria but are still deemed appropriate for radical hysterectomy, the surgical approach may impact survival. Results of two important clinical trials indicated that people undergoing surgery for early-stage cervical cancer should undergo an open laparotomy rather than a minimally invasive approach.[37,38] In the Laparoscopic Approach to Cervical Cancer (LACC) trial, more than 600 people with FIGO 2009 stage IA1, IA2, or IB1 cervical cancer were randomly assigned to minimally invasive radical hysterectomy or an open abdominal radical hysterectomy.

Figure 15-2 Approach to Early-Stage Cervical Cancer



Abbreviation: LVI, lymphovascular invasion.
*In previous American Joint Committee on Cancer staging manuals, nodes were not considered; however, the eighth edition specifically defines nodal involvement as stage III disease.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

The 2009 FIGO stages IA1 and 1A2 were very similar to the FIGO 2018 staging, with the exception that FIGO 2009 required the horizontal dimension of the tumor to be 7 mm or less. However, FIGO 2009 stage IB1 included tumors with clinically visible lesions of 4 cm or less in greatest dimension. Therefore, stage IB1 tumors in the LACC trial may have been larger than what is currently classified as IB1 under FIGO 2018 criteria. Compared with open surgery, minimally invasive surgery was associated with lower rates of disease-free survival (DFS) (HR, 3.74; 95% CI, 1.63-8.58) and overall survival (OS; HR, 6.0; 95% CI, 1.77-20.3).[38] There has been much discussion about why a minimally invasive approach led to worse outcomes, and the leading hypothesis centers on tumor containment during the surgery. This hypothesis is being tested in the ongoing ROCC trial,[39] which enrolls patients with FIGO 2018 stage IA2 to IB2 tumors and mandates proper tumor containment and no transcervical uterine manipulators.[40] If these modifications reverse the survival detriment seen in LACC, minimally invasive approaches may become available again for those requiring radical hysterectomy. At this time, open radical hysterectomy is the standard of care. In patients who want to maintain fertility and who have an early-stage and low-risk cervical cancer, radical trachelectomy may be an option.[36,41]

The use of sentinel node dissection at the time of radical hysterectomy has been enthusiastically adopted by most providers. The SENTICOL I study was a prospective multicenter study that evaluated the diagnostic value of sentinel lymph node (SLN) biopsy in patients with early-stage cervical cancer and found no false-negative cases in patients who had bilateral SLN detection.[42] The subsequent SENTINEL II trial confirmed reduced lymphedema, reduced surgical morbidity, and better quality of life in those patients who underwent SLN mapping.[43] However, there is a paucity of data regarding survival and oncologic safety of SLN biopsy. A post hoc analysis of SENTICOL I and II showed no differences between SLN biopsy and full node dissection for

DFS and DSS.[44] In 2025, the PHENIX trial was presented at ASCO. In all, 908 patients with at least one SLN detected were randomized intraoperatively to undergo SLN biopsy alone or full lymphadenectomy, with no differences in the two groups seen with respect to 3-year DFS or 3-year cancer-specific survival rate.

Early Invasive Cervical Cancer With High-Risk Features

Adjuvant treatment may be recommended based on final pathologic findings. For patients with stage IB or IIA disease, there is a higher risk of surgicopathologic findings that may result in the need for adjuvant therapy; there is a high rate of morbidity, and careful patient selection for surgical intervention is indicated in this setting.[26,45] When adjuvant therapy is indicated after radical hysterectomy, the standard of care is pelvic radiotherapy with or without cisplatin-based chemotherapy, depending on surgicopathologic risk factors. GOG-92 randomized patients with a combination of risk factors, including tumor size, presence of lymphovascular invasion, and depth of cervical stromal invasion, to either no adjuvant therapy or adjuvant pelvic radiotherapy.[46] Results demonstrated a significant reduction in the risk of recurrence with radiotherapy (relative risk, 0.53; $P = .008$, one-tailed) with a recurrence rate of 88% versus 79% at 2 years in the radiotherapy versus no adjuvant therapy groups, respectively. With longer follow-up, there was also a significant reduction in the risk of progression or death with adjuvant radiotherapy versus no adjuvant therapy (HR, 0.58; $P = .009$), with fewer recurrences in patients with adenocarcinoma or adenosquamous histology who received radiotherapy.[47]

Patients with high-risk factors, including positive lymph nodes, positive margins, or the presence of parametrial extension, were not eligible for GOG-92. Instead, those patients were randomized to pelvic radiotherapy with or without concurrent and adjuvant bolus cisplatin 70 mg/m^2 and 96-hour infusion of 5-fluorouracil (5FU) 1,000 mg/m^2/day with two every three-week cycles delivered with radiotherapy and two cycles after radiotherapy. In this intergroup study, there was a significant improvement in PFS and OS in the group that received radiotherapy with concurrent and adjuvant chemotherapy, HR 2.01 ($P = .003$) and 1.96 (P=.007), respectively. In this study, it was not possible to determine whether the survival benefit was obtained from the addition of radiosensitizing concurrent cisplatin/5FU or adjuvant cisplatin/5FU or both. However, improved progression-free survival (PFS) and OS were noted ($P = .03$) in patients who received 3 to 4 cycles of chemotherapy. As a result, the randomized phase 3 RTOG-0724 trial was designed to test the value of four cycles of additional systemic carboplatin and paclitaxel to follow concurrent weekly cisplatin and radiotherapy compared with cisplatin and radiotherapy alone. This study enrolled patients with FIGO 2009 stage IA2, IB, or IIA with high-risk factors after surgery. Here again, it is important to convert this to the current FIGO 2018 staging. Stage II cervical cancer staging did not change dramatically between 2009 and 2018 and includes tumors that extend to the upper vagina without (IIA) and with (IIB) parametrial involvement. Stage IIIA also did not change between 2009 and 2018 and includes tumors that invade the lower third of the vagina; stage IIIB has extension of the tumor to the pelvic side wall. FIGO 2018 stage IIIC is a new stage category and includes involvement of pelvic lymph nodes (stage IIIC1) and para-aortic lymph nodes (stage IIIC2). These two categories may be annotated with r (imaging) and p (pathology) to designate how the lymph node involvement is determined.[26] If the patients in the RTOG-0724 trial were converted to FIGO 2018 staging, 50% of them would be upstaged largely on the basis of the new IIIC1 and IIIC2 stages. There was no benefit to the addition of adjuvant systemic paclitaxel and carboplatin to the treatment of patients with high-risk features after radical hysterectomy. The HR for PFS was 1.05 (90% CI, 0.65-1.68), and the HR for OS was 0.91 (90% CI, 0.49-1.69).[45]

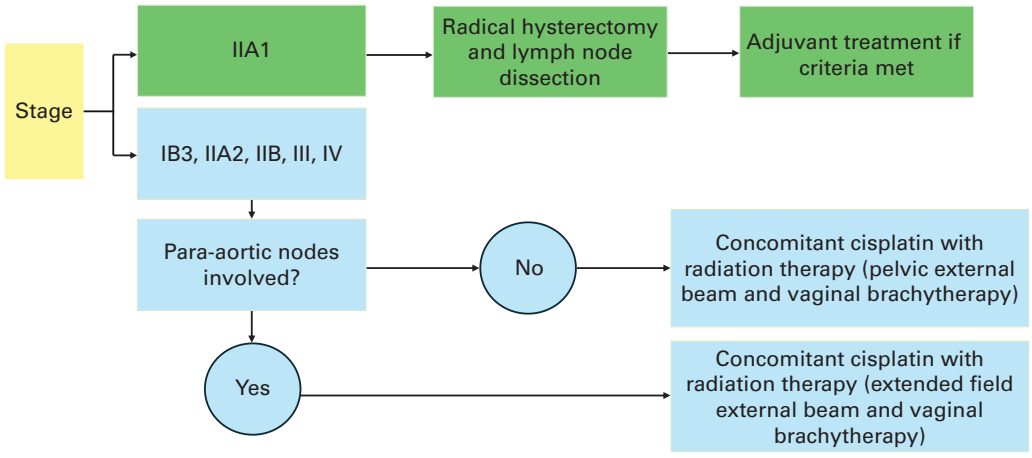
Early Invasive Cervical Cancer With Intermediate-Risk Features

The results of GOG-263 were very recently published and show the use of adjuvant therapy in intermediate-risk early-stage cervical cancer. GOG-263 was a randomized phase 3 trial of adjuvant radiation versus chemoradiation in intermediate-risk, early-stage cervical cancer following radical hysterectomy.[48] Intermediate-risk factors included combinations of lymphovascular space invasion, stromal invasion, and tumor size. Patients received conformal radiation therapy (RT) or intensity modulated radiation therapy (IMRT). In the chemoradiation (CRT) arm, six cycles of weekly cisplatin at a dose of 40 mg/m^2 were given. The primary endpoint of the trial was recurrence-free survival (RFS). The 3-year RFS was 88.5% in the CRT arm and 85.4% in the RT arm, with an HR of 0.698 (95% CI, 0.408-1.192; $P = .09$). Notably, CRT increased grade 3 and 4 adverse events with a transient decline in the quality of life.

Locally Advanced Cervical Cancer

Locally advanced cervical cancer is defined as FIGO 2018 stage IB3 or IIA2 to IVA disease (Fig. 15-3). (It should be noted that FIGO 2018 stage IIA1 may be a candidate for definitive radical surgery.) If the need for definitive chemoradiation is anticipated at diagnosis, surgery should not be performed, and chemoradiation (now with the addition of immunotherapy) should be pursued with curative intent. In locally advanced disease, concurrent chemoradiation therapy is preferred based on a series of studies that demonstrated improved outcomes with the addition of radiosensitizing chemotherapy.[49] A typical treatment protocol includes weekly administration of cisplatin 40 mg/m^2 per week during the course of external radiation therapy and continuing through brachytherapy.

Figure 15-3 Approach to Locally Advanced Cervical Cancer



People with stage IIA1 disease are candidates for primary surgery.

For women with more advanced disease, imaging (typically with PET/CT scanning) is required to evaluate nodal involvement. The presence of para-aortic nodal involvement (either suspected or pathologically confirmed) warrants the use of extended-field external beam radiation therapy (EBRT).[20,50-53] MR imaging may help determine the extent of local disease, particularly parametrial or vaginal extension, which may help determine subsequent brachytherapy.[54] Radiotherapy is the cornerstone of treatment for women with locally advanced cervical cancer. Treatment consists of a combination of EBRT and brachytherapy with concurrent cisplatin-based chemotherapy. Based on several phase III randomized studies comparing 3D conformal radiotherapy (3DCRT) versus IMRT in both the adjuvant and definitive setting, the preference is to treat with IMRT if resources are available.[55-57] Collectively, these studies have demonstrated a reduction in acute and late toxicities, particularly genitourinary and gastrointestinal toxicities. In addition, image-guided brachytherapy incorporating MR imaging for treatment planning allows for improved identification of residual disease and response after initial EBRT compared to CT imaging.[58]

After many decades of no change in the standard of care for locoregionally advanced disease, several randomized trials have resulted in a modified standard that uses cisplatin-based radiotherapy with improvements in OS.

The first hypothesis was whether systemic carboplatin and paclitaxel would improve OS in addition to standard cisplatin-based radiation in locoregionally advanced cervical cancer. The OUTBACK GOG-274[59] trial evaluated the addition of four cycles of paclitaxel and carboplatin to follow standard cisplatin-based radiation in FIGO 2009 stage IB1 disease with positive lymph nodes (FIGO 2018 stage IIIC1 or stage IB2, II, IIIB, or IVA disease). Similar to the RTOG-0724 trial, the addition of systemic chemotherapy after definitive cisplatin-based radiotherapy did not improve OS; the HR was 0.90 (95% CI, 0.70-1.17; $P = .81$). Of interest is the fact that 27% of the patients randomly assigned to the experimental arm received either no or only one cycle of planned adjuvant therapy.[50] It is noteworthy that the same trend was seen in the RTOG-0724 trial, in which 26% of patients received no adjuvant chemotherapy in the experimental arm. This suggested that new strategies were needed.

The INTERLACE trial also evaluated the addition of systemic paclitaxel and carboplatin given as neoadjuvant therapy *before* planned cisplatin-based radiation. This study enrolled patients with FIGO 2009 stage IB1 disease with nodal involvement (FIGO 2018 stage IIIC1) or stage IB2, IIA, IIB, IIIB, or IVA disease. Patients were randomly assigned to cisplatin-based radiotherapy alone versus neoadjuvant chemotherapy (NACT) followed by cisplatin-based radiotherapy. In this study, the primary endpoints were both PFS and OS. Use of NACT led to an improvement in PFS with an HR of 0.65 (95% CI, 0.46-0.91; $P = .013$) as well as an improvement in OS with an HR of 0.60 (95% CI, 0.40-0.91; $P = .015$). It is important to note that the majority of patients enrolled in this study (50%) were FIGO 2018 stage I or II, and 40% were stage IIIC (node positive).[20]

The second hypothesis tested whether the addition of an immune checkpoint inhibitor (ICI) would improve outcomes in locoregionally advanced cervical cancer. This hypothesis is derived from the HPV-driven nature of cervical cancer and clinical evidence in the advanced and metastatic setting of efficacy. The first study evaluated the addition of the PD-L1 inhibitor durvalumab to cisplatin-based radiotherapy to follow as maintenance every 4 weeks for up to 24 cycles versus standard cisplatin-based radiotherapy. The CALLA study[60] had a primary endpoint of PFS, and it enrolled patients with FIGO 2009 stage IB2 to IIB with lymph node positivity or any stage III or higher tumor. The addition of durvalumab failed to improve PFS; the HR was 0.84 (95% CI, 0.65-1.08; $P = .17$). However, the results of the ENGOT-cx11/GOG-3047/KEYNOTE-A18[18] trial confirmed the benefit of adding an ICI (pembrolizumab) to standard cisplatin-based radiotherapy and for 15 cycles of maintenance (6-week dosing intervals). Enrolled patients had FIGO 2014 stage IB2 to IIB with node-positive tumors or any stage III to IVA disease. The HR for PFS was

0.70 (95% CI, 0.55-0.89; *P* = .0020), and the HR for OS was 0.67 (95% CI, 0.50-0.90; *P* = .0040).[51,52] In this study, stage IB2 to IIB (node positive) versus stage III to IVA was a stratification factor. The margin of benefit in these subgroups led the FDA to approve the addition of pembrolizumab to cisplatin-based radiotherapy and as maintenance for 15 cycles only in FIGO 2014 stage III to IV disease. This includes patients with disease that extends to the pelvic sidewall (IIIB) and/or extends to the lower third of the vagina (IIIA), whereas stage IVA involves spread to distant organs.[53] This would not include FIGO 2018 stage IIIC1 or IIIC2 unless those tumors had extended to the side wall or involved distal vaginal tissue.[52]

Therefore, given current data and regulatory approvals, pembrolizumab should be added to cisplatin and radiation and be given as maintenance for patients with FIGO 2014 stage IIIA, IIIB, and IVA, and could be considered for patients with IIIC1 or IIIC2 disease if the primary tumor had extended to the sidewall or involved lower vaginal tissue. Otherwise, patients who have FIGO 2018 stage IB3, IIA2, IIB, IIIC1, or IIIC2 should be considered for the INTERLACE regimen.

There are currently no data to support combining the INTERLACE regimen with the A18 regimen in high-risk LACC. The NCI is prospectively studying the combination in the GY-037 trial (NCT07061977).

Metastatic or Recurrent Cervical Cancer

The prognosis is poor for patients with de novo metastatic (stage IVB) cervical cancer and for those who have disease recurrence after primary treatment (Table 15-1). For patients who have an isolated pelvic recurrence within a previously irradiated field, an en bloc resection that requires bowel and/or bladder resection (ie, pelvic exenteration) can be considered with potentially curative intent, although careful patient selection is key, and morbidity can be substantial. All other patients with advanced or recurrent cervical cancer should be treated with systemic therapy. The results of GOG-240 demonstrated that compared with chemotherapy alone, the addition of bevacizumab to chemotherapy increased OS by nearly 4 months.[61,62] For patients who have tumors that express PD-L1, pembrolizumab can be incorporated with combination platinum-based chemotherapy with or without bevacizumab based on the results of KEYNOTE-826, which showed that the addition of pembrolizumab in this population improved both PFS and OS. The assessment of PD-L1 is determined by the combined positive score, which represents the number of PD-L1-stained tumor cells, lymphocytes, or macrophages relative to all viable tumor cells. A combined positive score of 1 or higher is considered positive. In the KEYNOTE-826 trial, the PD-L1 IHC 22C3 pharmDx quantitative assay (Agilent Technologies, Santa Clara, CA, USA) was used. It is reasonable to substitute carboplatin for cisplatin because of its more tolerable toxicity profile, particularly in patients who were previously treated with cisplatin and RT.[63] A subsequent subset analysis of Keynote 826 verified the role of bevacizumab in achieving the best OS in this population. Patients who received bevacizumab and pembrolizumab experienced the best median OS (37.6 months for all comers).[64] Based on this subset analysis, all patients eligible for bevacizumab should receive this as part of this regimen.

Table 15-1 Clinical Features and Postoperative Surgical and Pathological Risk Factors to Assess the Risk of Recurrence in Cervical Cancer

Intermediate Risk (Sedlis Criteria)	High Risk (Peters Criteria)
LVSI and deep stromal invasion (outer third)	Positive surgical margins
LVSI and middle stromal invasion (one-third) and tumor size ≥2 cm	Detection of pathologically confirmed lymph node metastases
LVSI and superficial stromal invasion (inner third) and tumor size ≥5 cm	Extension into the parametrial tissue
No LVSI but deep or middle stromal invasion and tumor size ≥4 cm	

Abbreviation: LVSI, lymph-vascular space invasion.

The BEATcc study confirmed the results of Keynote 826 in a biomarker-agnostic population. In this randomized, open-label phase 3 trial, patients with advanced or recurrent cervical cancer (first-line setting) were enrolled and randomized to receive taxane, platinum, bevacizumab, and atezolizumab versus taxane, platinum, and bevacizumab alone. Patients were not required to have a PD-L1-positive tumor, and all patients were required to receive bevacizumab. The study met its primary endpoints of PFS and OS with a median OS of 32·1 months (95% CI, 25.3-36.8) versus 22·8 months (20.3-28.0), respectively (HR, 0.68; 95% CI 0.52-0.88; *P* = .0046). Data regarding PD-L1 status were not reported.[65]

After patients have progressed with combination chemotherapy, pembrolizumab is approved by the FDA for those who have not already received immune checkpoint blockade and who have PD-L1-positive disease or are found to have MSI-H/dMMR tumors.[66] The approval for treatment of PD-L1-positive cervical cancer in this setting was based on the results of the

KEYNOTE-158 phase 1 trial, in which more than 90 people were enrolled and were treated with pembrolizumab for up to 2 years.[67] The overall response rate (ORR) was 12%, and in women with PD-L1-positive tumors, it was 14.6%. The PFS rate at 6 months was 25%, and the median OS was 9.4 months. Similar to KEYNOTE-826, the KEYNOTE-158 trial used the PD-L1 IHC 22C3 pharmDx quantitative assay.

In 2021, the FDA granted accelerated approval of tisotumab vedotin-tftv, a tissue factor–directed antibody and microtubule inhibitor–drug conjugate, for patients with previously treated recurrent or metastatic cervical cancer. This approval was based on the innovaTV 204/GOG-3023/ENGOT-cx6 clinical trial, which demonstrated an ORR of 24% and a median DOR of 8.3 months (95% CI, 4.2-not reached).[68] Results of the confirmatory innovaTV 301/ENGOT-cx12/GOG-3057 trial, which randomly assigned 502 patients to receive tisotumab vedotin-tftv versus the physician's choice of chemotherapy, showed a statistically significant and clinically meaningful improvement in OS favoring tisotumab vedotin-tftv, with 48.7% of patients in the treatment arm alive at 12 months versus 35.3% in the physician's choice of chemotherapy arm (HR, 0.70; 95% CI, 0.54-0.89).[69] This study led to full approval of tisotumab vedotin-tftv on April 24, 2024. EMA approval for tisotumab vedotin-tftv is pending at the time of this review. T-DXd is also an option in this patient population.

Approach to Rare Cervical Cancers

Clear-cell and neuroendocrine tumors (including large- and small-cell carcinomas) account for 4% and up to 2% of all cervical cancers in the United States, respectively.[70] Thus, there are no large prospective trials to inform treatment. In clinical practice, treatment that consists of platinum-based therapy is extrapolated from the treatment of squamous cell cancer, adenocarcinoma, and small-cell lung cancer. These patients are typically younger, are more likely to have metastatic disease, and have poorer survival outcomes at all stages. It is noteworthy to mention the Dual Anti-CTLA-4 and Anti-PD-1 Blockade in Rare Tumors (DART) SWOG S1609 effort to study these rare tumors. Clear-cell cervical cancer was included in cohort 42, and five patients were treated with ipilimumab and nivolumab. There were zero responses, and the median PFS was dismal at one disease assessment cycle, which emphasizes the need for continued focus on these rare tumors.[71]

Reports from centers with extensive experience with neuroendocrine tumors of the cervix help guide therapies for this rare group of patients.[72]

SURVIVORSHIP

The prognosis for people treated for cervical cancer is good for those diagnosed with localized disease; 5-year survival estimates are 66% for all stages and 91% for localized disease.[73] Among those with regional nodal involvement, however, more than 40% will die within 5 years.[73] Regardless of their risk of recurrence, all patients who complete curative-intent treatment should be observed for recurrent disease with serial pelvic examinations every 3 to 6 months for 5 years and then annually.[73] Guidelines support imaging if it is clinically indicated. The general tenets of survivorship care in the Institute of Medicine report[74] are relevant for people with gynecologic cancers. Specific issues related to symptoms and follow-up recommendations depend on the primary treatment modality. Women treated with chemoradiation therapy often develop premature genitourinary symptoms of menopause. Hormone replacement therapy may be offered in an age-appropriate context.[74] The choice of agent must take into account whether the uterus is present, in which case combined hormone therapy should be prescribed. Vaginal dilators are often offered as a tool to prevent and treat vaginal tightening, adhesions, and shortening.

Patients undergoing a pelvic and/or para-aortic lymph node dissection are also at risk for lower-extremity lymphedema, even years after surgery. Education and prompt referral for decongestive therapy are important aspects of management.[74]

SPECIAL POPULATIONS

Patients With Renal Insufficiency

All patients with renal insufficiency require a workup to rule out correctable causes of renal dysfunction, including ureteral obstruction resulting from cervical cancer. This can often be improved by placing a ureteral stent; occasionally, nephrostomy may be required. It is important for obstruction to be addressed before treatment begins to allow for cisplatin therapy. For people with chronic renal insufficiency, consultation with a nephrologist is helpful to determine appropriate therapy and to follow-up with the patient. If cisplatin cannot be administered, the use of an alternative agent such as carboplatin can be considered. Other agents, such as gemcitabine or fluorouracil, could also be considered on the basis of published guidelines.

KEY POINTS

- Cervical cancer is a sexually transmitted disease associated with a chronic infection of oncogenic types of HPV. HPV strains 16 and 18 account for 70% of cervical cancers. HPV vaccination represents an opportunity to reduce the worldwide occurrence of cervical cancer. The 9-valent vaccine available in the United States can be administered to people aged 9 to 45 years.
- Although vaccination against HPV is available, cervical cancer screening remains an important part of health maintenance.

- The approach to invasive cervical cancer depends on whether a patient presents with early-stage, locally advanced, or metastatic disease. The FIGO 2018 staging of cervical cancer is defined by tumor characteristics and nodal involvement.
- For people with early-stage cervical cancer, treatment is primarily surgical. New data define tumors at such low risk that radical surgery may be de-escalated. For those who require a radical hysterectomy, the open approach is the current standard of care. Sentinel node dissection seems to be oncologically safe in this population, but more prospective data are needed.
- The indications for adjuvant treatment after radical surgery using RT with or without concomitant chemotherapy depend on final pathologic findings, including tumor grade, presence of lymphovascular invasion, and depth of stromal invasion, as well as whether there are positive surgical margins and parametrial or nodal involvement. Use of adjuvant systemic chemotherapy is not supported in this setting.
- For most people with locally advanced cervical cancer, cisplatin and RT are administered as curative treatment without surgery.
- For patients with FIGO 2018 stages sIB3 to IIB, IIIC1, or IIIC2 without side wall involvement or distal vaginal involvement, NACT should be considered with an OS advantage from the INTERLACE trial.
- For patients with FIGO 2018 stages IIIA, IIIB, IIIC1, or IIIC2 with side wall or distal vaginal involvement or IVA, the addition of pembrolizumab to chemotherapy and radiation therapy can now be considered the standard of care, with the advantage of both PFS and OS. For women with de novo metastatic (stage IVB) or recurrent cervical cancer, first-line treatment consists of platinum-based doublet chemotherapy and bevacizumab, with the addition of pembrolizumab in patients whose tumors express PD-L1.
- The first-line recurrent/metastatic regimen should include paclitaxel, platinum, pembrolizumab, and bevacizumab for patients whose tumor is PD-L1 IHC positive by CPS score or atezolizumab, regardless of PD-L1 status. Strong consideration should be given to including bevacizumab in all settings if not contraindicated for medical reasons.
- Patients whose disease progresses after first-line therapy and who have not previously received pembrolizumab may receive pembrolizumab, provided that their tumor is positive for PD-L1 expression or they are found to have an MSI-H tumor.
- Tisotumab vedotin-tftv or T-DXd (for biomarker-positive tumors) can be considered in patients who have recurrent disease after previous chemotherapy with or without immunotherapy.
- Patients with advanced or recurrent disease should have their tumors tested for *HER2* IHC via gastric scoring to assess eligibility to receive T-DXd.

ENDOMETRIAL CANCER

EPIDEMIOLOGY AND PREVENTION

Endometrial cancer is the fourth most common cancer in the United States.[75,76] At the time of this review, it is one of the only solid tumors that is increasing in incidence and mortality, mainly at the expense of Black patients. Among Black patients, the mortality rate is approximately 50% higher, and Black patients often present with advanced-stage or more aggressive histology, such as serous histology or carcinosarcoma.[75] The cause of this mortality discrepancy is largely unknown. Data from the American Cancer Society show that the incidence of endometrial cancer has increased by 1% per year in white patients and 2% to 3% per year in all other racial and ethnic groups. In addition, the death rate has increased by 1.7% per year since the mid-2000s.[75,76] In 2025, there will be 69,120 new cases of endometrial cancer and approximately 13,860 deaths.[28,76] It is notable that the number of deaths as a result of endometrial cancer now eclipses that from ovarian cancer.

Most people diagnosed with endometrial cancer (75%) are postmenopausal, the average age at diagnosis is 60 years, and approximately 70% of patients present with early-stage uterine-confined disease. There are some known genetic and environmental risk factors for endometrial cancer. Lynch syndrome results from pathogenic germline variants in *MMR* genes *MLH1, MSH2, MSH6*, and *PMS2*. Lynch syndrome can confer an increased risk of developing endometrial cancer of up to 60%.[77] Thus, all patients with newly diagnosed endometrial cancer should undergo MMR IHC testing with reflexive germline genetic testing when indicated; if there is a family history and MMR tests are normal, patients should have germline genetic testing.[75] High body mass index is a risk factor for the development of endometrial cancer. Although women receiving tamoxifen face a three- to seven-fold greater risk of endometrial cancer, its benefits for the treatment and prevention of breast cancer outweigh this risk in appropriate patients. Routine pelvic (or transvaginal) ultrasonographic surveillance in otherwise asymptomatic women who receive tamoxifen is not recommended. Prevention strategies have focused on the importance of a healthy lifestyle and a reduction in obesity as an independent risk factor. Interception strategies emphasize early recognition and appropriate workup via endometrial biopsy of abnormal uterine bleeding, especially among Black patients. Movements such as Spot Her aim to educate women as broadly as possible regarding the early symptoms of endometrial cancer, which will hopefully promote more timely diagnosis and treatment among vulnerable populations.[78]

Histologic subtypes of endometrial cancer include endometrioid adenocarcinoma, serous endometrial cancer, carcinosarcoma, clear-cell carcinoma, adenosquamous carcinomas, and other rare types such as neuroendocrine cancers and cancers with

small-cell histology. The staging and treatment of these tumors use an approach similar to that used for more typical endometrial cancers. IHC testing for MMR should be performed for all newly diagnosed patients. Patients whose tumors show loss of MMR protein expression should be referred for genetic screening for Lynch syndrome; there is also an elevated risk of germline *BRCA1* mutations in patients with serous endometrial cancers. MMR deficiency is also predictive of the potential benefit related to treatment with ICIs as monotherapy or in combination in the setting of recurrence.

There has been a transition toward the use of molecular features to classify endometrial cancer (Table 15-2). An integrated genomic analysis of endometrial cancer was conducted as part of The Cancer Genome Atlas (TCGA); based on the mutation frequencies, tumors could be stratified into the following four groups:

1. *POLE*-ultramutated
2. Tumors with MSI (hypermutated)
3. Low copy number (endometrioid)
4. High copy number (serous-like)[79]

Table 15-2 Molecular Classification for Endometrial Cancer

TransPORTEC Classification (TCGA Classification)	Prognosis	Treatment Approach	Other Molecular Features
POLE mut (ultramutated)	>90%; 5 years, OS	Candidate for de-escalation of therapy	
MMRd (hypermutated)	Very good	Checkpoint inhibitor therapy	Can occur as a germline or somatic mutation or through methylation of the *MLH1* gene promoter in the tumor
NSMP (copy number low)	Very good for most patients, but a subset with worse outcomes	May have functional hormonal receptors and can consider hormonal therapy	More likely to have ER/PR. Most common associated mutations: *PTEN*, *ARID 1A*, *PIK3CA*, *CTNNB1*, *PIK3R1*, *KRAS*
*P53*abn (copy number high)	Poor <50%; 5 years, OS	Recommend an aggressive approach with chemotherapy	Can look for *HER2* overexpression/ amplification, HRD

Abbreviations: abn, abnormal; ER, estrogen receptor; HRD, homologous recombination–deficient; MMRd, mismatch repair–deficient; mut, mutated; NSMP, no specific molecular profile; OS, overall survival; PR, progesterone receptor; TCGA, The Cancer Genome Atlas.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

The FDA approval of trastuzumab deruxtecan-wxki for *HER2* 3+ IHC and NCCN listing for 2+ and 3+ IHC has also prompted more widespread testing of *HER2* IHC either at diagnosis for advanced-stage tumors or at the time of recurrence, although these recommendations may change with emerging clinical trial data.

PATHOGENESIS

Historically, endometrial cancers are classified on the basis of features that define the underlying genetics as proposed by TCGA.

These subgroups are associated with PFS; patients with *POLE*-type tumors have the best prognosis, and those with high copy number (serous-like) tumors have the worst prognosis. Subsequent work has refined these categories into subtypes that parallel the TCGA subtypes; a combination of IHC and next-generation sequencing (NGS) clinical tests can be performed rapidly to determine these molecular subtypes according to the following categories: *POLE*-mutated, mismatch repair–deficient (dMMR), no specific molecular profile, and abnormal expression of *p53*.[80,81] Because additional IHC markers (such as *HER2*) are validated as predictive biomarkers, these subgroups may be defined further for both prognosis and treatment planning, as will be described below. The World Health Organization (WHO) and the Society of Gynecologic Oncology (SGO) have recommended incorporating molecular classification into pathology reports on endometrial cancers.[82,83]

CLINICAL PRESENTATION AND STAGING

The most common symptom associated with endometrial cancer is postmenopausal bleeding or blood-tinged discharge from the vagina. Therefore, all postmenopausal women with abnormal uterine bleeding or discharge require evaluation by their

gynecologist along with endometrial sampling. Some endometrial cancers may or may not present with bleeding; for these patients, the presence of nonspecific symptoms (eg, abdominal pain, bloating, sexual dysfunction, changes in bowel or bladder habits) often heralds more advanced disease.

The FIGO staging system for endometrial cancer was revised in 2023, and greater emphasis was placed on histology, tumor grade, and the presence of lymphovascular invasion.[84] The TCGA molecular categorization was also incorporated. Endometrial cancer is surgically staged, and all patients should be evaluated by and receive surgery from a gynecologic oncologist. The standard surgical staging procedure for endometrial cancer includes hysterectomy, bilateral salpingo-oophorectomy, pelvic washings (possibly), and examination of the entire abdominal cavity. Nodal evaluation may not be necessary for all patients, but many gynecologic oncologists recommend nodal staging for patients with newly diagnosed endometrial cancer using SLN identification and biopsy. Patients with advanced unresectable disease may be candidates for chemotherapy before surgery.

PRESENTING CASE STUDY

A 64-year-old woman presents with 6 months of vaginal bleeding and 2 months of vague abdominal discomfort. Pelvic ultrasound shows a thickened endometrial stripe and small-volume ascites. Endometrial biopsy confirms endometrial serous carcinoma. Chest CT is unremarkable, and abdominal/pelvic CT indicates small-volume ascites and pelvic adenopathy. The patient undergoes surgery and is found to have endometrial serous cancer with 40% myometrial invasion, enlarged pelvic lymph nodes with metastases to both ovaries, and two out of three positive pelvic nodes. Based on the 2023 endometrial cancer staging system, the cancer is stage IIICii. Further testing reveals mismatch-repair proficiency (MMRp), *HER2* positivity (2+ on IHC), and a *p53* mutation.

She begins adjuvant chemotherapy with carboplatin and paclitaxel. During the second cycle, NGS returns as MMRp, *TP53* mutated, *CCNE1* amplified, and *HER2* positive (2+ on IHC) with no *ERBB2* amplification. Because the patient does not qualify for the addition of trastuzumab to her chemotherapy regimen due to the lack of ERBB2 amplification, and recent data demonstrate no benefit to adding ICIs to nonmeasurable adjuvant therapy, she continues with six cycles of paclitaxel and carboplatin.

Ten months later, she presents with shortness of breath and is found to have new lung and liver metastases.

Based on the patient's clinical history, endometrial cancer histology, and known specific biomarkers, how would you proceed with further workup and treatment?

Endometrial serous carcinoma is an aggressive endometrial cancer that is typically MMRp, with a low tumor mutational burden and high copy number changes. This patient's cancer is also *HER2* positive (2+ on IHC [immunohistochemistry]) and meets gastric cancer criteria. Higher levels of *HER2* expression are associated with this histologic subtype. If the cancer was 3+ on IHC, she would be eligible to receive Trastuzumab deruxtecan-nxki (T-DXd) per the FDA label. *HER2* positivity of 2+ and 3+ is both listed on the National Comprehensive Cancer Network uterine cancer guidelines as category 2A T-DXd in the second-line metastatic or subsequent-line setting.

Another option would be a therapy that includes ICIs. KEYNOTE-775, a phase 3, randomized trial, enrolled patients with recurrent endometrial cancer of any histology to either chemotherapy (paclitaxel or doxorubicin) or pembrolizumab and lenvatinib (20 mg/day). Median PFS and OS were both significantly longer with lenvatinib and pembrolizumab compared to chemotherapy; this regimen is FDA approved for advanced MMRp endometrial cancer. Toxicities with this regimen are quite significant, with nearly 66% of patients needing to have the dose of lenvatinib reduced and approximately 33% of patients needing to discontinue treatment.

Other possible treatments include returning to carboplatin or a carboplatin doublet, such as carboplatin and paclitaxel. FDA approvals have been granted for the addition of either dostarlimab or pembrolizumab combined with carboplatin and paclitaxel, regardless of MMR status.

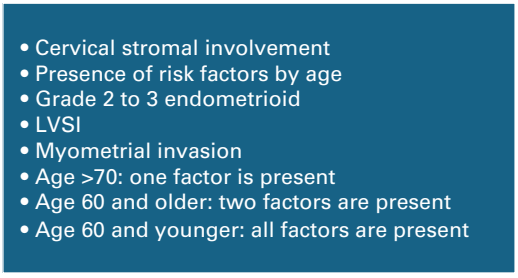
Clinical trials should be considered for novel ADCs. Endometrial serous cancers on NGS may have cyclin E1 amplification, and several trials targeting CCNE1 amplification, such as Wee1 and CDK2 inhibitors, are ongoing. Endometrial serous tumors also express *FOLR1*, and several camptothecin payload ADCs are enrolling endometrial cohorts.

CURRENT TREATMENT PRACTICE

Adjuvant Treatment

For patients who undergo surgery with curative intent, there is no single approach to adjuvant therapy, and the approach should consider the presence or absence of high-risk pathologic factors (Fig. 15-4). Patients without these features have low-risk disease that does not require additional treatment. However, the approach in patients with stage I, high-intermediate risk, or high-risk disease continues to evolve, and an individualized approach is often recommended.

Figure 15-4 High- to Intermediate-Risk Factors in Early-Stage Endometrial Cancer



Abbreviation: LVSI, lymphovascular space invasion.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

The role of radiotherapy in the adjuvant setting for stage I/II endometrial cancer was investigated in multiple randomized studies, which examined the role of radiotherapy for intermediate-risk endometrial adenocarcinoma. GOG-99 was a prospective study that randomized women with "intermediate-risk" endometrioid adenocarcinoma after surgical staging (hysterectomy, bilateral salpingo-oophorectomy, and selective bilateral pelvic and para-aortic lymph node dissection) to either pelvic radiotherapy or observation. PORTEC-1, which was a multinational study led by Dutch investigators, had similar randomization post-surgery: observation versus pelvic radiotherapy. Important differences in the studies include the absence of a requirement for nodal evaluation in PORTEC and exclusion of the highest risk stage I patients from randomization (FIGO Stage IC grade 3[1988]1988]).[85,86] The two studies reached similar conclusions: pelvic radiotherapy reduced locoregional recurrences without any differences in OS. An important finding in both studies was that approximately two-thirds of the locoregional recurrences in patients who were randomized to observation were located in the upper vagina. As a result of this finding, PORTEC-2 investigated whether vaginal cuff brachytherapy could be sufficient adjuvant therapy for women with high-intermediate risk endometrioid adenocarcinoma (which included women with stage IA grade 3 disease, stage IB grade 3 without LVSI or stage IB, grade 1 or 2 with age ≥60 years and/or lymphovascular invasion, stage IB, grade 3 without lymphovascular invasion or stage II grade 1[2009]).[87,88] Patients were randomized to pelvic radiotherapy or vaginal cuff brachytherapy. A 10-year isolated pelvic recurrence was 2.5% versus 0.5% (P = .10) for patients who received vaginal brachytherapy versus pelvic radiotherapy, respectively. Rates of grade 1 to 2 gastrointestinal toxicity were significantly lower with vaginal brachytherapy versus pelvic radiotherapy, 12.6% versus 53.8%, respectively. Thus, depending on risk factors, vaginal brachytherapy may be the preferred adjuvant therapy for women with high-intermediate risk endometrioid carcinoma.[89]

Three trials sought to clarify the appropriate adjuvant systemic therapy for endometrial cancer. GOG-249 was a prospective phase 3 study of patients with GOG-defined high-intermediate risk, stage II (any histology), or stage I to II serous or clear-cell cancer. Patients were randomly assigned to whole-pelvis irradiation with or without vaginal brachytherapy versus adjuvant paclitaxel and carboplatin chemotherapy with intravaginal brachytherapy.[90] With a median follow-up of 24 months, RFS was the same in both treatment arms (82% with pelvic irradiation vs 84% with vaginal brachytherapy and chemotherapy). GOG-258 enrolled people with stage III or IVA endometrial cancer and randomly assigned them to six cycles of paclitaxel and carboplatin chemotherapy or an investigational regimen consisting of chemoradiation therapy (cisplatin and tumor volume–directed RT) followed by paclitaxel and carboplatin for four cycles.[91] There were no differences in RFS between the two arms; with a median of 112 months of follow-up, Matei et al reported no difference in OS between the two arms.[92] Although local relapse rates were lower in the investigational arm, distant relapse rates were higher. In an ancillary study of GOG-258, Clements et al examined whether molecular classification using MMR and p53 protein expression predicts RFS and OS in this cohort. They observed worse RFS for patients with *p53*abn tumors. Furthermore, *p53*wt predicted improved RFS with chemoradiotherapy versus chemotherapy (77% vs 60%; HR, 0.54; 95% CI, 0.32-0.94), while OS was similar.[93] PORTEC-3 enrolled patients with stage I, grade 3, and clear-cell or serous histology and myometrial invasion or stage II or III cancer and randomly assigned them to a standard treatment of pelvic irradiation (and vaginal brachytherapy if there was cervical involvement) or cisplatin and RT followed by paclitaxel and carboplatin for four cycles.[94] There were no differences in RFS or OS between the two arms. However, on subset analysis[95] for stage III disease, there was a significant difference in RFS favoring the investigational arm.[95]

The results of PORTEC-3 and GOG-258 supported the role of chemotherapy generally being reserved for advanced endometrial cancer; exceptions to this would be consideration of chemotherapy for early-stage, high-risk histologies such as serous endometrial cancers or carcinosarcoma; expert opinion from pathologists and oncologists specializing in gynecologic oncology is warranted in these cases. The role of RT in endometrial cancer remains unclear, although there may be a benefit in reducing local recurrences. RT modalities include intravaginal radiation therapy (IVRT) and/or pelvic radiation therapy.

Medically Inoperable Uterine Cancer

Surgery is the cornerstone of therapy for patients with uterine cancer. For those patients with medical comorbidities, a thorough assessment should be performed by their gynecologic oncologists as well as other medical professionals to determine whether the patient is medically inoperable. For women with medically inoperable uterine cancer, definitive radiotherapy should be considered as an option. Initial staging should include a pelvic MRI to determine the extent of myometrial invasion (greater or less than ½) and the presence of cervical stromal invasion, as this may impact the risk of nodal metastases. For patients with well-differentiated grade 1 endometrioid carcinoma with limited myometrial invasion and without cervical stromal invasion or pelvic/para-aortic nodal metastases, oral progestins or levonorgestrol (LNG)-releasing IUDs can be considered. In the morbidly obese patient group, LNG-IUDs may serve as a bridge while weight loss interventions can be pursued with surgery as an ultimate goal. Brachytherapy alone may be considered for women with well to moderately differentiated carcinoma without deep myometrial invasion, cervical stromal invasion, or lymph node metastases on MR imaging. For all others, a combination of EBRT 45 to 50.4 Gy in 1.8 Gy fractions to the pelvis and brachytherapy (2-5 fractions 5-8.5 Gy) is typically recommended.[96]

Advanced-Stage, Recurrent, or Metastatic Disease

For patients with pelvic recurrence (either vaginal or nodal), GOG-238 tested whether the addition of cisplatin weekly 40 mg/m^2 to fractionated EBRT and brachytherapy as appropriate could improve PFS. Median PFS was longer in patients who received radiotherapy alone versus chemoradiotherapy (median not reached vs 73 months, respectively, HR, 1.25; 95% CI, 0.75-2.07). PFS at 3 years was 73% versus 62% for the radiotherapy alone versus the chemoradiotherapy group, respectively.

Immune Checkpoint Inhibitors GY018: In this phase 3 study, pembrolizumab was added to carboplatin and paclitaxel and then given as maintenance for 2 years versus carboplatin and paclitaxel alone; eligibility included measurable stage III to IVA or measurable/nonmeasurable stage IVB or recurrent endometrial cancer. The primary endpoint was PFS as assessed by the investigator. The addition of pembrolizumab to carboplatin and paclitaxel improved PFS in both the MMR-proficient (pMMR) and dMMR populations. In the pMMR population, median PFS was 11.7 months for the pembrolizumab arm and 8.7 months for the placebo arm (HR, 0.57; 95% CI, 0.44-0.74); $P < .0001$). In the dMMR population, median PFS was not reached for the pembrolizumab arm and was 7.6 months for the placebo arm (HR, 0.3; 95% CI, 0.19-0.48; $P < .0001$). OS was a secondary endpoint, and there were favorable trends for the addition of pembrolizumab to chemotherapy in both pMMR and dMMR populations. On June 17, 2024, the FDA-approved pembrolizumab with carboplatin and paclitaxel for primary advanced or recurrent endometrial cancer, regardless of the MMR status.

RUBY study: The RUBY study was a phase 3 study of dostarlimab-gxly added to carboplatin and paclitaxel, followed by 3 years of dostarlimab maintenance versus carboplatin and paclitaxel alone. This trial had dual primary endpoints of PFS by the investigator and OS. PFS was improved in both dMMR and pMMR populations, with a statistically significant OS benefit in the overall population. On July 31, 2023, the FDA-approved dostarlimab-gxly with carboplatin and paclitaxel with dostarlimab-gxly maintenance, and on August 1, 2024, this approval was extended to patients with primary advanced or recurrent endometrial cancer, regardless of MMR status.

DUO-E: The results of this trial led to the FDA approval of durvalumab on June 14, 2024, combined with carboplatin and paclitaxel, followed by single-agent durvalumab for patients with newly diagnosed advanced or recurrent endometrial cancer with dMMR tumors. In DUO-E, patients were randomly assigned to carboplatin and paclitaxel with durvalumab followed by durvalumab maintenance, carboplatin and paclitaxel with placebo followed by placebo maintenance, and a third arm that tested olaparib maintenance. FDA-approved durvalumab for use in patients with dMMR tumors because median PFS was not reached in the durvalumab arm and was 7 months for placebo in the placebo arm (HR, 0.42; 95% CI, 0.22-0.80).

For patients with serous endometrial carcinoma or those in whom a *p53* mutation was identified,[97,98] testing for *HER2*/neu overexpression is recommended, because a multicenter phase 2 randomized clinical trial showed that the addition of trastuzumab to chemotherapy improved PFS and OS in patients with *HER2* 3+ or 2+ IHC and amplification.[99] Phase 3 clinical trials are ongoing to substantiate the use of trastuzumab with carboplatin and paclitaxel.

For patients requiring second-line therapy after previous systemic chemotherapy with a platinum-based regimen, the results of KEYNOTE-775 support the use of pembrolizumab and lenvatinib. In this trial, more than 820 volunteers were randomly assigned to pembrolizumab and lenvatinib or to single-agent chemotherapy of the physician's choice (doxorubicin or paclitaxel).[100] Treatment with pembrolizumab and lenvatinib resulted in a significant improvement in ORR, PFS, and OS compared with single-agent chemotherapy. Benefits were seen in those with pMMR disease as well as in all comers, although single-agent approval for pembrolizumab at this time is limited to patients with dMMR disease. Treatment with pembrolizumab and

lenvatinib was associated with a higher rate of serious adverse events compared with traditional chemotherapy, including hypertension and hypothyroidism. KEYNOTE-775 enrolled patients who had not received previous checkpoint inhibition, so for those patients who received an ICI with carboplatin and paclitaxel, there are no data for the use of an ICI after an ICI.

Pembrolizumab is FDA approved for patients who have tumors with dMMR or MSI-H after first-line therapy has failed, based on the KEYNOTE-158 study. The data regarding additional benefits with the addition of lenvatinib in these patients are limited. Another FDA-approved option for patients who have tumors with dMMR or MSI-H is dostarlimab-gxly, based on the GARNET study. Multiple other agents are available and appropriate for use (see NCCN guidelines).

ADCs: As mentioned above, T-DXd was granted accelerated approval by the FDA on April 5, 2024, based on the results of the DESTINY-PanTumor02 trial for any solid tumor with *HER2* 3+ IHC. This basket study enrolled 40 patients with recurrent endometrial cancer and 2+ or 3+ IHC for *HER2* (gastric scoring). The ORR for all 40 patients was 57.5%. The ORR in patients with tumors having centrally confirmed 3+ IHC was 84.6%, and the ORR for those with tumors having centrally confirmed 2+ IHC was 47.1%.[8] The NCCN listed T-DXd for *HER2*-positive tumors (3+ or 2+ IHC) as a category A recommendation under Useful in Certain Circumstances in the 2024 update.[17]

Hormonal Therapy: Clinical features that are predictors of response to endocrine therapy, with responses of up to 38%, include grade 1 or 2 histology, a long disease-free interval from diagnosis, and the presence of estrogen or progesterone receptors on the tumor cells. Strategies include the use of megestrol acetate, tamoxifen, aromatase inhibitors, or fulvestrant. Another approach combines the mammalian target of rapamycin inhibitor everolimus with letrozole. This was evaluated in a phase 2 trial conducted by NRG Oncology.[101,102] In 38 patients, the ORR was 32%; no patients stopped treatment because of toxicity. In addition, CDK4/6 inhibitors and aromatase inhibitors, ribociclib, and abemaciclib, have been studied in phase 2 trials in recurrent endometrial cancer with promising results and incorporation into NCCN guidelines.

SURVIVORSHIP

People treated for endometrial cancer should be observed, with pelvic examination as part of routine surveillance, using a risk-based strategy. For people who experience premature menopause related to treatment, estrogen therapy can be provided with no significant risk within appropriate age ranges. This was shown in a randomized trial that included more than 1,200 people with stage I or II endometrial cancer[103]; there was no difference in recurrence rates in those who received estrogen compared with those treated with a placebo preparation. Guidance discussed previously in this chapter for people treated for cervical cancer remains relevant for this population as well.

Patients with advanced or recurrent disease who are receiving immuno-oncology (IO) maintenance should undergo serial scans to confirm no progression while on treatment. The role of routine surveillance scans in the post-treatment setting remains unclear. The most up-to-date recommendations for surveillance can be found in the SGO white paper.[104]

In addition, some patients with endometrial cancer are morbidly obese and/or too ill to proceed with surgery. Diagnosis via endometrial sampling and obtaining pathology is critical. Patients who cannot receive surgical treatment and who have cancer confined to the uterus may be managed by a gynecologic oncologist with hormone therapy or with RT and other systemic treatments. Fertility preservation may be appropriate in certain selected patients, which would be explored with a gynecological oncology team.

KEY POINTS

- Endometrial carcinoma is the most common gynecologic cancer in the United States. The major risk factors for endometrioid endometrial carcinoma are those typically associated with increased estrogen exposure. More aggressive subtypes are often estrogen independent and associated with older age and non-white race.
- For people who receive surgical treatment, adjuvant therapeutic options include RT (pelvic irradiation with or without IVRT) and/or chemotherapy, typically with paclitaxel and carboplatin, and RT should be determined using an individualized approach. Postoperative risk factors can help determine who should be offered adjuvant treatment.
- All patients with endometrial adenocarcinoma should undergo MMR and/or MSI assessments. This information will identify patients who are appropriate for treatment with pembrolizumab, dostarlimab-gxly, or durvalumab. It is also important to identify patients with Lynch syndrome. Patients whose tumors show dMMR expression should be referred for genetic screening for Lynch syndrome.
- Pembrolizumab and lenvatinib combination therapy represents an important advance for patients with MMRp recurrent disease after treatment with paclitaxel and carboplatin.
- The combination of chemotherapy and immunotherapy (pembrolizumab or dostarlimab-gxly) is considered the standard of care in the treatment of patients with advanced-stage or recurrent dMMR endometrial cancer. The addition of IO to the chemotherapy backbone may also be appropriate for patients with pMMR tumors; we await mature data from GY018 and RUBY to further determine recommendations.

UTERINE SARCOMAS

EPIDEMIOLOGY AND PREVENTION

Uterine sarcomas make up less than 10% of all uterine cancers. The most common of these are leiomyosarcoma and low-grade endometrial stromal sarcoma. Other variants include undifferentiated sarcoma and adenosarcomas. Unfortunately, there are no preventive strategies against these mesenchymal tumors. Of note, carcinosarcomas are not considered true sarcomas but rather dedifferentiated carcinomas. They are staged and treated as endometrial adenocarcinomas, and their treatment should be followed as such.

PATHOGENESIS

Little is known about the pathogenesis of uterine sarcomas.

CLINICAL PRESENTATION AND STAGING

Uterine sarcomas typically present with nonspecific symptoms, including abnormal uterine bleeding, a pelvic mass, or abdominal pain or pressure. However, these are not pathognomonic of sarcoma and are also commonly reported among people ultimately diagnosed with leiomyomas. Uterine sarcomas are staged differently from endometrial adenocarcinoma, with separate staging for adenosarcoma and all other sarcomas.

CURRENT TREATMENT PRACTICE

Leiomyosarcoma

Leiomyosarcoma is a high-risk cancer of the uterine smooth muscle with a propensity for early hematogenous dissemination. Patients with uterus-limited disease have a 50% to 70% risk of recurrence. Despite this high risk of recurrence, there are no data to suggest that adjuvant treatment affords a survival advantage. As a result, the standard of care is surgical resection. Tumor size is a prognostic indicator, and a cutoff of 5 cm is used; nodal involvement is rarely encountered if the disease is confined to the uterus. Adjuvant radiation therapy can be considered to decrease the rate of pelvic recurrence but has no effect on survival outcomes.

For patients with advanced, recurrent, or metastatic leiomyosarcoma, an anthracycline-based regimen is used, with gemcitabine and docetaxel as a typical alternative. In a randomized phase 3 trial that included 150 patients with metastatic leiomyosarcoma of both uterine and nonuterine origin, doxorubicin and trabectedin, followed by trabectedin, improved PFS and ORRs over doxorubicin alone, and these same benefits were seen when restricted to the uterine leiomyosarcoma population of 67 patients.[105] However, the combination is associated with a higher toxicity rate. If not used in the initial regimen, other active agents include doxorubicin, gemcitabine, ifosfamide, trabectedin, pazopanib, and dacarbazine.

Endometrial Stromal Sarcoma

Endometrial stromal sarcomas may be high or low grade. High-grade endometrial sarcomas are referred to as undifferentiated endometrial sarcomas. Histopathologic features and molecular alterations can help differentiate low-grade from high-grade tumors. Low-grade tumors nearly always express estrogen and progesterone receptors. Although the risk of recurrence is approximately 30% for women with disease limited to the uterus at the time of diagnosis, 10-year survival rates exceed 90% because of the indolent pace of progression. The treatment of choice is surgery, and recurrence rates seem to be lower in women who undergo bilateral oophorectomy at the time of diagnosis. For patients who require medical therapy for recurrence, endocrine therapy, such as aromatase inhibition, is typically administered. There are limited data that support a preferred chemotherapy approach for advanced metastatic high-grade endometrial stromal sarcoma, but regimens used in the treatment of leiomyosarcoma are typically considered.

Adenosarcoma

Adenosarcomas are tumors of mixed histology in which the sarcomatous portion seems similar to low-grade endometrial stromal sarcoma, and the adeno portion seems to be benign. Prognosis and management are similar to those for endometrial stromal sarcoma unless there is evidence of sarcomatous overgrowth. Adenosarcomas with sarcomatous overgrowth are high-risk cancers, the prognosis and treatment of which are driven by the high-grade portion of the tumor. Surgery is the primary treatment of choice, with systemic or RT reserved for recurrent or metastatic disease.

Undifferentiated Uterine Sarcoma

Undifferentiated uterine sarcomas are hormone receptor–negative and behave aggressively. Because of their rarity, there are no prospective studies that address active agents for these tumors. Retrospective data and sarcoma treatment guidelines support doxorubicin-based treatment or gemcitabine and docetaxel treatment. Enrollment in clinical trials for soft tissue sarcomas is encouraged.

SURVIVORSHIP

The approach to treating women who have uterine sarcoma is similar to that for women being treated for endometrial cancer. For patients with endometrial stromal sarcoma, hormone therapy should not be offered because these tumors express estrogen

and progesterone receptors. Follow-up may include routine chest radiographs and periodic imaging, as is performed for other soft tissue sarcomas.

KEY POINTS

- Sarcomas are a heterogeneous group of diseases that account for 4% of all uterine cancers.
- Surgery is the mainstay of treatment for uterine sarcoma. There is no evidence that adjuvant treatment improves survival outcomes, and adjuvant treatment is typically not recommended.

EPITHELIAL OVARIAN CANCER, FALLOPIAN TUBE CANCER, AND PRIMARY PERITONEAL CANCER

Epithelial cancers arising from the ovary, fallopian tube, or peritoneum (collectively referred to as ovarian cancer for the remainder of this section) are one of the leading causes of death resulting from gynecologic cancer in the United States. Epithelial adenocarcinomas can be histologically subclassified into several categories, the most common of which is high-grade serous ovarian cancer (HGSOC), which comprises ~80% of ovarian cancers. Other rarer subtypes include low-grade serous, endometrioid (low grade or high grade), mucinous, or clear cell. Ovarian carcinosarcomas are considered epithelial cancers and are considered high-grade epithelial ovarian cancer. A rare variant, small-cell carcinoma of the ovary (hypercalcemia type), is highly malignant and typically affects women in their second decade. In 2014, mutations in *SMARCA4*, which plays a role in chromatin modification, were identified as critical drivers of these tumors. Subsequent research also found loss of *SMARCA2*.

EPIDEMIOLOGY AND PREVENTION

In the average-risk population, ovarian cancer will develop in approximately one person in 70 in the United States (Figs. 15-5 and 15-6). The mean age at diagnosis is 63 years. Risk factors have implications for both treatment and cancer prevention. Carriers of deleterious mutations in *BRCA1* or *BRCA2* have a high lifetime risk of HGSOC, estimated at ~16% and up to 50% to 60%. Other germline mutations in genes related to homologous recombination are also associated with a moderately increased risk of ovarian cancer and include *BRIP1, RAD51C, RAD51D*, and *PALB2*. People with genetic mutations that are part of Lynch syndrome are also at increased risk of endometriosis-associated ovarian cancer, although the lifetime risk likely varies depending on the specific *MMR* gene mutation. Emerging data are elucidating whether there is a clinically relevant increased risk of epithelial ovarian cancer associated with other germline mutations. However, a person without a known germline mutation but with at least one first-degree relative with ovarian cancer has a relative risk of ~2 to 3 for the development of ovarian cancer, meaning that their lifetime risk of ovarian cancer is approximately 3% to 5%. Regardless of risk factors, all patients with a new diagnosis of ovarian, fallopian tube, or primary peritoneal cancer should be offered genetic testing.[106]

At this time, there is no effective ovarian cancer screening strategy. People with known genetic mutations that increase the risk of ovarian cancer are recommended for prophylactic bilateral salpingo-oophorectomy, with or without hysterectomy, for risk reduction. Several studies indicate that performing a bilateral risk-reducing salpingo-oophorectomy (RRSO) may substantially reduce the risk of ovarian cancer and improve mortality for women who are carriers of deleterious *BRCA1* or *BRCA2* mutations (an approximately 80% lower risk of ovarian, fallopian tube, and peritoneal cancers, with an average follow-up of 5.6 years from surgery, and 77% reduction in all-cause mortality). Opportunistic salpingectomies can also be considered in women at average risk for ovarian cancer when other procedures for benign conditions are performed. However, removal of the tubes (or even both tubes and ovaries) does not completely negate the risk of ovarian or primary peritoneal cancer. Ongoing studies are testing risk-reducing salpingectomy (rather than bilateral salpingo-oophorectomy) in those at high genetic risk for ovarian cancer.

PATHOGENESIS

Contemporary data implicate the fallopian tubes as the origin of HGSOC, b3ecause high-grade intraepithelial carcinomas have been identified in the fimbria of people with a *BRCA1* or *BRCA2* mutation who have undergone bilateral salpingo-oophorectomy.[107] These precursor lesions include *p53* signature, secretory cell outgrowths (SCOUT), serous tubular intraepithelial lesions (STIL), and serous tubular intraepithelial carcinoma (STIC) and are thought to have clonal relationships to invasive HGSOCs.

Management of STIC is challenging, as there are limited data available to guide management. Currently, risk-reducing salpingectomy is recommended for all women undergoing surgery, particularly pelvic surgery. For average-risk (most) women, opportunistic salpingectomy is recommended during routine procedures such as hysterectomy or cesarean section, with an increased push for opportunistic salpingectomy at any surgery.[108,109] This intervention has demonstrated significant potential in reducing ovarian cancer incidence while maintaining safety and feasibility.[110]

For high-risk individuals, particularly *BRCA* mutation carriers, RRSO remains the gold standard. Alternative approaches, such as salpingectomy alone, are under investigation to preserve ovarian function in younger patients (NCT04251052). To improve STIC detection, the SEE-FIM pathology protocol is recommended when patients are undergoing risk-reducing surgery to prevent ovarian cancer, but challenges such as diagnostic variability and limited data persist.

When STIC is detected incidentally, management varies based on risk factors and lesion characteristics. Genetic counseling and testing are recommended when STIC is identified, as hereditary predisposition may guide further management. Chemotherapy is not routinely recommended for the treatment of STIC. Surveillance is suggested when STIC has been diagnosed, but there are no set guidelines as to the frequency and type of monitoring.

Older case-control studies reported that endometriosis is associated with a threefold increased risk of clear-cell carcinoma of the ovaries and a twofold increase in the risk of low-grade or endometrioid carcinomas.[111]

CLINICAL PRESENTATION AND STAGING

Patients with early-stage ovarian cancer often have nonspecific symptoms, including irregular menses (if premenopausal), urinary frequency, persistent bloating, and constipation.[112] Most patients with advanced disease will present with symptoms reflecting advanced disease, including abdominal pain, bloating, dyspnea, emesis, early satiety, anorexia, and constipation.

The definitive diagnosis of ovarian, fallopian tube, or primary peritoneal cancer is made by preoperative biopsy or surgical exploration, with stage assigned based on the FIGO system. Prognosis is linked to the amount of residual tumor after surgical cytoreduction (debulking surgery). Optimal cytoreduction has been defined as no residual tumor measuring larger than 1 cm at the end of the surgical procedure, although a more contemporary definition is no gross residual disease (R0 cytoreduction). People with a tumor larger than 1 cm at the end of surgery are deemed to have had a suboptimal cytoreduction, which confers a worse prognosis.

ASCO and SGO practice guidelines recommend that all patients with suspected epithelial ovarian cancer undergo evaluation by a gynecologic oncologist to determine whether the patient is a candidate for upfront cytoreductive surgery or will require a biopsy to confirm ovarian cancer, followed by NACT.[113]

CURRENT TREATMENT PRACTICE

The approach to treating people with ovarian cancer is guided by whether patients are surgical candidates at presentation and, ultimately, by disease stage. All women with ovarian cancer, regardless of stage, age, family history, and ovarian cancer histology, should be referred for genetic counseling and testing at diagnosis to assess the risk of other cancers and familial risk, and because the information can affect treatment in the first and/or subsequent line of treatment in advanced disease or recurrence. Other recommendations include somatic (tumor) testing to look for tumor *BRCA1/2* and other mutations, and testing for homologous recombination deficiency (HRD) to confirm eligibility for PARP inhibitor (PARPi) maintenance therapies.

Early-Stage Ovarian Cancer

Patients with stage I ovarian cancer are classified as having early-stage ovarian cancer. Historically, women with stage II disease were included in this category, but contemporary data show that stage II disease is associated with a less favorable prognosis.

As a result, these patients are often considered to be in the same group as patients who have advanced ovarian cancer and are treated the same way.

Not all patients with early-stage ovarian cancer require adjuvant treatment. Patients with stage IA or IB grade 1 or 2 tumors have 5-year DFS rates greater than 90% with surgery alone, and the risks of adjuvant chemotherapy likely outweigh the benefits. For patients with stage IA or IB grade 3 tumors, stage IC disease, or clear-cell carcinoma, adjuvant chemotherapy is recommended. An analysis of data from more than 900 patients with high-risk early-stage disease showed that adjuvant platinum-based chemotherapy led to an 11% improvement in the 5-year PFS rate and an 8% improvement in the 5-year OS rate compared with a strategy of observation. Although patients are often recommended to undergo six cycles of therapy, the optimal duration of therapy is not clear. One randomized trial of patients with stage I to II ovarian cancer showed that those who received three cycles of therapy had a trend toward a higher risk of recurrence compared with those who received six cycles, particularly in HGSOC, although there was no difference seen in OS.[114]

Advanced Ovarian Cancer

For people with stage II or higher ovarian cancer who undergo primary surgical cytoreduction, a series of randomized phase 3 trials have established combination intravenous platinum (cisplatin or carboplatin) and taxane (paclitaxel or docetaxel) chemotherapy as the standard of care in first-line treatment. Results generally have shown a significant improvement in OS with a combination of platinum and taxane regimens. The angiogenesis inhibitor bevacizumab, in combination with platinum and taxane chemotherapy and then used as single-agent maintenance treatment, has been approved by the FDA on the basis of an improvement in PFS, although no OS benefit was seen.[115,116]

For patients who undergo optimal cytoreduction (ie, residual disease of less than 1 cm), intraperitoneal chemotherapy can be offered with OS improvement on the basis of the results of the GOG-172 trial. However, toxicities were higher in the intraperitoneal arm, and a careful risk:benefit assessment needs to be discussed with the patient. Lowering the cisplatin dose to 75 mg/m^2 intraperitoneally was tested in the GOG-252 trial; in this study, one arm with intraperitoneal treatment was compared with two arms of intravenous treatment (although all patients received bevacizumab), with no improvement in outcomes.

The typical schedule of administration of intravenous carboplatin and paclitaxel is every 3 weeks for six cycles. Alternative approaches use a dose-dense schedule, as compared in the ICON8 phase 3 trial,[117,118] which showed no difference in PFS among the three arms. Compared with carboplatin and paclitaxel every 3 weeks, carboplatin every 3 weeks with weekly paclitaxel and weekly carboplatin and paclitaxel both had a higher frequency of grade 3 or 4 toxicities (63% and 53% vs 42%, respectively).

The use of NACT in advanced ovarian cancer is favored in patients for whom a complete cytoreduction seems unlikely or when other circumstances are present that make patients poor candidates for surgery at the time of diagnosis; these patients should be assessed by a gynecologic oncology surgeon before initiation of NACT. ASCO and the SGO have published clinical practice guidelines on the role of NACT that support its use in appropriate candidates.[113]

There have been multiple historical randomized trials designed to determine the superior surgical approach to advanced ovarian cancer (upfront vs interval cytoreductive surgery) (the interested reader is referred to these studies).[119-122] The Trust trial is the most modern of these, presented at ASCO in 2025. Trust is an international randomized multicenter phase 3 trial in patients with stage IIIB-IVB OC and good performance status comparing primary cytoreductive surgery (PCS) followed by six cycles of IV chemotherapy to neoadjuvant IV chemotherapy (NACT) followed by interval cytoreduction and three further IV cycles. The primary endpoint was OS. The study demonstrated an improvement in PFS (a secondary endpoint) for patients who underwent upfront surgery. But there was no benefit seen in the OS. Median PFS was 22.2 months in the PCS group and 19.7 months in the interval cytoreductive surgery (ICS) group (HR, 0.80; 95% CI: 0.66-0.96; P = .02). Median OS was 54.3 months in the PCS group and 48.3 months in the ICS group (HR, 0.89l; 95% CI, 0.74-1.08; P = 0.24). Patients with complete cytoreduction after PCS had the most favorable outcome, with a median PFS and OS of 27.9 and 67.0 months, respectively.

For those who undergo surgery after neoadjuvant therapy (ie, an interval cytoreduction), the optimal treatment in the adjuvant setting is not clear. For women who have an optimal cytoreduction, limited data suggest intraperitoneal treatment; one randomized trial reported an OS advantage with heated intraperitoneal chemotherapy.[123] Otherwise, the current approach for treatment of these patients is to continue platinum and taxane therapy (with or without bevacizumab), typically for a total of six cycles. Regardless, bevacizumab should be held for the treatment before and immediately after the interval surgery to allow optimal postoperative healing.

Regarding maintenance therapy after initial chemotherapy, the optimal choice of treatment should be based on careful assessment of ovarian cancer genetic markers. Bevacizumab is approved in this setting because of a PFS benefit, but randomized trials do not show an OS benefit. PARPis are another option for maintenance treatment in advanced ovarian cancer, with the magnitude of benefit depending on *BRCA* or HRD status; PRIMA and ATHENA monotherapy have both shown neither OS benefit nor detriment in any population treated with a PARPi. In the SOLO1 and PAOLA-1 trials, there was a trend toward improved OS for the PARPi arm. For those who present with advanced ovarian cancer, PARPis have demonstrated PFS and/or OS benefit as single agents or, in one instance, in combination with bevacizumab maintenance therapy. [124-128] Knowledge of germline or somatic *BRCA* mutations or HRD status is also relevant for optimizing treatment in the setting of recurrent disease.

The effect of maintenance olaparib after completion of a platinum-based regimen was demonstrated in the SOLO1 trial, which included 391 volunteers with advanced-stage III or IV high-grade endometrioid or serous carcinoma and a known genetic or somatic *BRCA1* or *BRCA2* mutation. The volunteers were randomly assigned in a 2:1 ratio to olaparib (300 mg twice daily) or placebo to be taken for a maximum of 2 years. Compared with placebo, maintenance olaparib significantly reduced the risk of disease progression or death at 3 years (27% vs 60%, respectively; HR, 0.30; $P < .001$). Data from this study led to FDA approval of olaparib in this setting. The benefit of maintenance olaparib in this setting was confirmed in a 5-year follow-up of SOLO1 trial participants. Compared with those in the placebo arm, patients in the maintenance olaparib arm had a median PFS of 56 months versus 13.8 months.[126] OS showed a clinically meaningful trend toward improved OS with olaparib.

In the PAOLA-1 trial, 806 volunteers were randomly assigned to maintenance olaparib and bevacizumab versus bevacizumab alone. Compared with bevacizumab alone, the combination with olaparib significantly improved PFS (median, 22.1 months vs 16.6 months, respectively; HR, 0.59; 95% CI, 0.49-0.72), with benefits seen in subgroups with a known *BRCA1* or *BRCA2* mutation and those with HRD tumors. In patients with HRD-negative tumors (n = 277), the median PFS was 16.6 months in the olaparib group and 16.2 months in the bevacizumab group (HR, 1.00; 95% CI, 0.75-1.35).[127] OS showed a clinically meaningful trend toward improvement with olaparib and bevacizumab compared with bevacizumab alone in patients with *BRCA* mutations and those with HRD tumors, but not in those with homologous recombination–proficient (HRP) tumors.

In the PRIMA trial, 733 volunteers were randomly assigned to maintenance niraparib therapy or placebo.[129] Compared with placebo, niraparib treatment resulted in significant improvement in PFS in those with HRD tumors (median, 21.9 vs 10.4 months; HR, 0.43; 95% CI, 0.31-0.59), in those without HRD tumors (8.1 vs 5.4 months; HR, 0.68; 95% CI, 0.49-0.94), and in the entire population (median, 13.8 vs 8.2 months; HR, 0.62; 95% CI, 0.50-0.76). Based on the initial PRIMA PFS results, niraparib received FDA approval on April 29, 2020, for use as maintenance treatment of patients with advanced ovarian cancer who are in a complete or partial response to first-line platinum-based chemotherapy. OS results were recently reported by ESMO 2024 in the overall population; median OS for the niraparib group was 46.6 months, and median OS for the placebo group was 48.8 months (HR, 1.01; 95% CI, 0.84-1.23; $P = .8834$).[130] Because this was not a significant difference, the HRD group was not formally tested. However, median OS results were provided per group: HRD, niraparib 71.9 months and placebo 69.8 months (HR, 0.95; 95% CI, 0.71-1.29), HRP, 36.6 months (niraparib) versus 32.2 months (placebo) (HR, 0.93; 95% CI, 0.69-1.26). The specific results for patients who had HRD/*BRCA*-mutated tumors were not reported, but the OS curves were provided in the Supplementary section of the manuscript,[131] and the HR was 0.94 (95% CI, 0.63-1.41). There was 57.7% crossover PARPi use for the placebo arm. In 2025, the first-line maintenance indication for niraparib (approved in 2020) was restricted to HRD-positive tumors.

ATHENA is a phase 3 trial testing four maintenance arms after first-line treatment with platinum and taxane chemotherapy for advanced ovarian cancer; patients were randomly assigned at 4:4:1:1, and the arms consisted of rucaparib plus nivolumab, rucaparib, nivolumab, and placebo. The primary endpoint was investigator-assessed PFS in the intention-to-treat population. In the intention-to-treat population of ATHENA-MONO, median PFS was 20.2 months for the rucaparib arm versus 9.2 months for the placebo arm (HR, 0.52; 95% CI, 0.40-0.68; $P < .0001$). In the HRD group, median PFS was 28.7 months for the rucaparib arm versus 11.3 months for the placebo arm (HR, 0.47; 95% CI, 0.31-0.72; $P = .0004$); for the HRD-negative group, median PFS was 12.1 months for the rucaparib arm and 9.1 months for the placebo arm (HR, 0.65; 95% CI, 0.45-0.95). Interim OS showed for the HRD population,[132] median OS for both the rucaparib and placebo arms was not reached (HR, 0.84; 95% CI, 0.44-1.58). For the intention-to-treat population, median OS for rucaparib was not reached, and for the placebo arm, it was 46.2 months (HR, 0.83; 95% CI, 0.58-1.17). For the exploratory subgroup of non–tumor tissue *BRCA*/loss of heterozygosity-low, OS was 42.9 months for the rucaparib arm and 32.4 months for the placebo arm (HR, 0.75; 95% CI, 0.48-1.17). OS results were recently presented; for the overall intention-to-treat group, median PFS was 15.0 months for the rucaparib and nivolumab arm and 20.2 months for the rucaparib and placebo arm (HR, 1.29; 95% CI, 1.08-1.53). For the placebo-alone arm, median PFS was 9.2 months. Interim OS results at 46.5% maturity showed a median OS of 49.4 months for the rucaparib and nivolumab arm versus 58.0 months for the rucaparib alone arm (HR, 1.13; 95% CI, 0.93-1.38).[132] To date, the addition of ICIs to chemotherapy has not added any benefit and should not be used in this setting.

Recurrent Ovarian Cancer

The approach to recurrent ovarian cancer is often based on whether the recurrent disease is platinum resistant (defined as progression within less than 6 months of first-line platinum-based therapy completion) or platinum sensitive (defined as recurrence more than 6 months after completion of first-line platinum-based therapy).

For women with a platinum-sensitive disease recurrence, the typical recommendation is to offer retreatment with carboplatin in combination with paclitaxel, liposomal doxorubicin, or gemcitabine, with or without bevacizumab, which can then be continued as maintenance therapy.[133] For patients with recurrent disease who respond to second-line platinum-based therapy and have a *BRCA* mutation, there are three FDA-approved PARPis that have demonstrated consistent and statistically significant benefits in PFS when used as maintenance therapy in the PARPi-naive setting; one trial has shown PFS benefit with retreatment with a PARPi in the setting of previous use of a PARPi. The SOLO2 trial specifically evaluated the magnitude of benefit of maintenance

PARP inhibition among women with *BRCA* mutation–positive recurrent ovarian cancer. Compared with placebo, olaparib (dosed in tablet formulation) significantly improved PFS (5.5 months vs 19.1 months, respectively; HR, 0.30; $P < .0001$) and time to first subsequent treatment or death (7.1 months vs 27.9 months, respectively; HR, 0.28; $P < .0001$). Updated data from the SOLO2 trial showed that for those with a known *BRCA* mutation, maintenance olaparib conferred a statistically nonsignificant OS advantage compared with placebo (51.7 months vs 38.8 months; HR, 0.74; $P = .054$).

Long-term OS results show that the HRs of the populations with HRD and HRP tumors are not in favor of PARPi for NOVA and ARIEL3. The OS data for patients with non-germline *BRCA*-mutated tumors from NOVA and ARIEL3 and from Study 19 led to the withdrawals of niraparib (in September 2022),[131] rucaparib (in December 2022; Clovis filed for bankruptcy in 2023), and olaparib (in September 2023) as maintenance treatment for patients who had ovarian cancer with platinum-sensitive recurrent *BRCA* wild-type tumors. The FDA indication for use in maintenance for patients with *BRCA*-mutated tumors remains for all three drugs (germline or somatic for rucaparib and olaparib; germline for niraparib). The EMA has not withdrawn any of the PARPi approvals in the recurrent maintenance setting, and thus, the standard of care differs between the United States and Europe. As a result, approval for niraparib, rucaparib, and olaparib is now limited to use in patients with a germline *BRCA* mutation, and rucaparib approval is granted only for patients with either a germline or somatic *BRCA* mutation.[124] The primary adverse effects are similar to all the commercially available agents and include gastrointestinal toxicities (eg, diarrhea, nausea, anorexia) and myelosuppression (eg, neutropenia, anemia, thrombocytopenia). In addition, the risk of acute myeloid leukemia or myelodysplastic syndrome is higher with PARPi use in the recurrent platinum-sensitive setting compared with use in the newly diagnosed upfront setting. Risk factors include the number of previous lines of therapy, duration of PARPi use (set duration vs given until either disease progression or toxicities), and presence of a *BRCA* mutation, which allows for more treatment to be used.

Data from three phase 3 trials demonstrated PFS benefit in recurrent platinum-sensitive disease for secondary cytoreduction, particularly when complete gross surgical cytoreduction was achieved. An OS benefit was seen in one trial, but not in another, and OS data are immature in the third trial. In these trials, there was a trend toward worse OS if surgery was performed and optimal cytoreduction was not achieved.[134-136] Evaluation by a gynecologic oncologist for consideration of secondary cytoreduction in the setting of recurrent platinum-sensitive disease is recommended.

For women with platinum-resistant disease recurrence, use of sequential single-agent chemotherapy with or without bevacizumab, on the basis of data from the AURELIA study, is advised, and enrollment in clinical trials is strongly encouraged. Data from a randomized trial showed that compared with single-agent therapy (ie, weekly paclitaxel, liposomal doxorubicin, or topotecan), the combination of bevacizumab and chemotherapy improved PFS, which led to the approval of bevacizumab in this setting.

Antibody-drug conjugates: The antibody-drug conjugate (ADC) mirvetuximab soravtansine-gynx has been tested in a single-arm phase 2 study (SORAYA) and a randomized phase 3 study (MIRASOL). Mirvetuximab soravtansine-gynx is an ADC that targets *FOLR1* with a tubulin targeting agent as the payload (DM4). The FDA granted accelerated approval of mirvetuximab soravtansine-gynx in November 2022 based on the data from the global single-arm phase 3 study of the ADC in 106 patients who had platinum-resistant ovarian cancer with high folate receptor alpha expression, defined as 75% or more tumor cells staining with 2+ intensity. All patients had received bevacizumab and up to three previous lines of systemic therapy. The ORR was 31.7%, and the median DOR was 6.9 months.[28] A randomized phase 3 trial was subsequently conducted comparing mirvetuximab soravtansine-gynx with the physician's choice of chemotherapy in platinum-resistant ovarian cancer; it demonstrated an improvement in median PFS from 3.98 months to 5.62 months, an objective response in 42.3% versus 15.9% of patients, and an improvement in median OS from 12.75 to 16.46 months with mirvetuximab soravtansine-gynx compared with standard-of-care chemotherapy; mirvetuximab soravtansine-gynx received full FDA approval in March 2024. In addition, patients receiving mirvetuximab soravtansine-gynx experienced fewer grade 3 or higher adverse events (41.7% vs 54.1%) and a lower rate of treatment discontinuation (9.2% vs 15.9%).[137] These data led to full FDA approval of mirvetuximab soravtansine-gynx in March 2024.

Mirvetuximab soravtansine-gynx has also been studied as a single agent in patients with platinum-sensitive recurrent ovarian cancer, yielding a response rate of 51.9%, median DOR of 8.25 months, and median PFS of 6.93 months.[138]

T-DXd was granted accelerated approval by the FDA in April 2024, based on the results of the DESTINY-PanTumor02 trial for any solid tumor with *HER2* 3+ IHC. In this basket trial, 40 patients who had recurrent ovarian cancer and 2+ or 3+ IHC for *HER2* (gastric scoring) were enrolled. The ORR for all 40 patients was 45%; the ORR in centrally confirmed 3+ IHC was 63.6%, and the ORR for centrally confirmed 2+ IHC was 36.8%. The NCCN listed T-DXd as a 2A recommendation for *HER2*-positive tumors (3+ or 2+ IHC) under Useful in Certain Circumstances in the 2024 update.[9,17] Somatic testing should be performed that includes hotspot testing for dMMR, *NTRK* fusions, and other rare mutations for which there are disease-agnostic FDA-approved agents, such as pembrolizumab and Larotrectinib, for such targets.

The data from the Rosella study were presented at ASCO in 2025. These data demonstrated a PFS advantage for the combination of weekly nab-paclitaxel and relacorilant versus nab-paclitaxel alone. The OS data are not yet mature.

For women who have previously received chemotherapy and have a known genetic or somatic mutation in *BRCA* or other evidence of HRD tumors, olaparib, rucaparib, and niraparib no longer carry approvals as single-agent treatment strategies and should not be used. SOLO3 and ARIEL4 trials that compared PARPis to chemotherapy all demonstrated poorer OS outcomes with

PARPis used as treatment compared with chemotherapy. The QUADRA trial was a single-arm trial, and the FDA indications for all three agents as treatment in this setting have been withdrawn. The updated ASCO guideline on the use of PARPis in ovarian cancer reflects these updates.[124]

Low-Grade Serous Ovarian Cancer

Low-grade serous ovarian cancer (LGSOC) is a less common subtype of ovarian cancer with molecular features different from those of high-grade ovarian cancer.[139] Mutations in *p53* are much less common and are seen in less than 10% of patients. This disease more commonly harbors mutations in genes of the mitogen-activated protein kinase pathway. Abnormalities in *HER2* mutation and expression can also be seen.[140]

LGSOC is typically characterized by an indolent clinical course and a longer 5-year OS compared with HGSOC. Of concern is that this disease is relatively resistant to chemotherapy. Although chemotherapy is considered the standard of care in newly diagnosed disease, hormone therapy is used as a maintenance therapy in this setting and as an active treatment of recurrent disease.[141] A phase 3 randomized trial (NRG-GY019) is currently evaluating the use of hormone therapy alone compared with chemotherapy with carboplatin and paclitaxel followed by maintenance with hormone therapy.[142] In the setting of recurrence, hormone therapy and targeted therapy with MEK inhibitors can be used, although in some cases, chemotherapy can provide periods of disease control. It is recommended that molecular testing of tumors be performed in the setting of recurrent disease to assess the presence of molecular targets for disease-agnostic approved agents.

The combination of the RAF-MEK clamp avutometinib with the FAK inhibitor defactinib was tested in a phase 2 study of patients with recurrent LGSOC, either *KRAS*-mutated or *KRAS* wild-type tumors; mature results were presented at a meeting of the International Gynecologic Cancer Society in 2024.[4] ORR was 31% in all evaluable patients; ORR was 44% in patients with *KRAS*-mutated tumors, and the ORR was 17% in patients with *KRAS* wild-type tumors. A longer PFS of 22 months was seen in patients with *KRAS* mutations, and a PFS of 12.8 months was seen for patients with *KRAS* wild-type tumors. This drug combination received accelerated FDA approval on May 8, 2025. This is the first-ever FDA-approved treatment for LGSOC.

SURVIVORSHIP

Despite standard treatment, women with ovarian cancer are at high risk of cancer relapse. Whether a cancer antigen-125 (CA-125) value is determined as part of follow-up can be individualized, but CA-125 levels are usually followed closely. One randomized trial showed no survival or quality-of-life advantage to routine monitoring of CA-125 for relapse detection, because early treatment based on increasing CA-125 levels in the absence of measurable disease or symptomatic recurrence did not improve survival. Women treated for ovarian cancer may experience physical and emotional adverse effects, even months after treatment has ended. These include fear of recurrence, depression, paclitaxel-induced neuropathy, and fatigue. Prompt evaluation and referral are necessary to help women adjust to survivorship.

KEY POINTS

- Gynecologic oncologists play a key role in the management of patients with ovarian cancer, particularly as it relates to surgical cytoreduction.
- Risk factors for ovarian cancer include genetics, increasing age, nulliparity, family history, early menarche, and late menopause.
- Oral contraceptive use, tubal ligation, breastfeeding, and higher parity are protective.
- For women who are not candidates for surgery because of tumor burden or morbidity, NACT is a reasonable option.
- Women who undergo an optimal cytoreduction should receive six cycles of intravenous platinum and taxane adjuvant therapy. Exceptions to this include women with stage IA or IB disease, grade 1 or 2 cancer, or non-clear-cell histology. Maintenance therapy should be discussed.
- Women whose disease relapses can be stratified as having platinum-sensitive or platinum-resistant disease. This can help in devising treatment strategies, with retreatment using a platinum-based doublet regimen favored for women with platinum-sensitive disease and the use of a nonplatinum single agent, or in combination with bevacizumab, for those with platinum-resistant disease.
- All women should undergo genetic testing for hereditary risk at diagnosis. Patients with stage III or IV high-grade serous or endometrioid tumors are candidates for maintenance with a PARPi after primary therapy. Benefit is most often seen in those with *BRCA1* or *BRCA2* mutation, followed by those with HRD versus HRP tumor status. Alternatively, patients with wild-type *BRCA* status who started with bevacizumab as part of the primary regimen may continue with bevacizumab maintenance.
- PARPis are also indicated as maintenance therapy after a response to retreatment with platinum-based therapy in women with a *BRCA* mutation.

OTHER TUMORS OF THE OVARY

TUMORS OF LOW-MALIGNANT POTENTIAL

Low-malignant-potential tumors of the ovary (also referred to as borderline ovarian tumors) are noninvasive ovarian cancers. The primary approach is surgical, because most women have early-stage disease at diagnosis. Because their outcomes are excellent (ie, 5-year OS rates are more than 95%) and because chemotherapy has no role in this tumor, adjuvant chemotherapy is not recommended in these patients.

SEX CORD–STROMAL CELL TUMORS

Sex cord–stromal tumors are subclassified as granulosa cell tumors and androgen-producing tumors, such as Sertoli-Leydig cell tumors. Adult-type granulosa cell tumors are generally stage I at diagnosis and are classically diagnosed in women between the ages of 40 and 70 years. Most granulosa cell tumors have a somatic mutation in *FOXL2*, which may be useful in diagnosis. Serum inhibin B levels may be elevated in granulosa cell tumors and can be measured as part of the disease evaluation. Treatment for granulosa cell tumors is surgical resection. Adjuvant therapy is not generally recommended. For those whose disease relapses, surgical resection is strongly favored. For those who are not candidates for surgery or who have residual disease after surgery, a platinum-based combination is often administered as treatment. Bevacizumab, as well as hormonal options including leuprolide, also has activity. Sertoli-Leydig tumors commonly present before 40 years. More than 90% of patients have stage I disease at diagnosis and, as with granulosa cell tumors, surgery is the preferred treatment. Platinum-based chemotherapy may be considered for patients with poorly differentiated tumors and for patients with advanced or recurrent disease.

GERM CELL TUMORS

Germ cell tumors of the ovary account for 2% to 3% of ovarian cancers and usually affect adolescent and young women; 50% are dysgerminomas (Table 15-3). Other histologic types include yolk sac tumors (endodermal sinus tumors), teratomas (immature, mature, and monodermal types), embryonal cell tumors, polyembryoma, nongestational choriocarcinomas, and mixed germ cell tumors. These cancers typically can be followed with serum tumor markers (Table 15-4). Dysgerminomas are more likely to be confined to one ovary at diagnosis and carry a favorable prognosis. Adjuvant chemotherapy is typically not administered to patients with stage I dysgerminomas who have undergone complete staging surgery and those with stage I grade 1 immature teratomas because they can generally be cured with surgery. For all others, adjuvant treatment is indicated, which includes three to four cycles of bleomycin, etoposide, and cisplatin based on the risk.[143] For patients with germ cell tumors that relapse after initial chemotherapy, platinum-based chemotherapy can be repeated (as paclitaxel, ifosfamide, and cisplatin or cisplatin, ifosfamide, and either etoposide or vinblastine), and in patients with platinum-resistant tumors, high-dose chemotherapy with stem cell rescue may offer a cure. Given the typically young age of these patients, fertility concerns should be discussed, and appropriate referrals should be made to tertiary care centers where germ cell tumor expertise exists for these patients.

Table 15-3 **Seminal Phase 3 Trials of Maintenance PARP Inhibitors in First-Line Treatment of Advanced Ovarian Cancer**

Characteristic	PAOLA-1	PRIMA	SOLO1	ATHENA
Volunteers	All comers	All comers	*BRCA* mutation associated	All comers
Intervention	Olaparib and bevacizumab	Niraparib	Olaparib	Rucaparib
Comparator	Bevacizumab	Placebo	Placebo	Placebo
HR for PFS (vs comparator)				
All comers	0.59	0.62	NR	0.52
BRCA1/2 positive	0.31	0.4	0.31	0.40
HRD (any)	0.33	0.43	NR	
HRD positive (no *BRCA*)	0.43	0.5	NR	0.47
HRD negative/unknown	0.92	NR	NR	
HRD proficient	NR	0.68	NR	
HRD unknown	0	0.85		

Abbreviations: HR, hazard ratio; HRD, homologous recombination–deficient; NR, results not reported; PFS, progression-free survival.

KEY POINTS

- Sex cord–stromal tumors are rare gynecologic malignancies that typically affect younger women.
- The primary treatment of sex cord–stromal tumors is surgical excision. Medical therapy is often reserved for patients with tumors that are not resectable at diagnosis (either initially or at relapse).
- For women with germ cell tumors, systemic treatment with platinum-based chemotherapy is often recommended after surgery. Exceptions to this rule include stage I dysgerminomas after complete staging surgery and stage I grade 1 immature teratomas, because they rarely relapse.

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease (GTD) comprises diseases of the human placenta that occur in women of childbearing age. There is a spectrum of malignant potential, from lesions with very low-malignant potential (ie, complete and partial hydatidiform moles) to invasive tumors with metastatic potential (ie, invasive moles) to tumors with an exceedingly high risk of systemic metastases (ie, gestational choriocarcinoma, epithelioid trophoblastic tumors [ETT], and placental type trophoblastic tumors [PSTT]). Despite the risk of metastatic disease, nearly all women with GTD can be cured with the appropriate use of chemotherapy, careful monitoring for treatment response, and surveillance for relapse using sensitive beta human chorionic gonadotropin (hCG) assays. Given the rarity of this disease and the highly curative nature with appropriate treatment, all patients should be referred to a specialized center.[144]

Malignant GTD is also referred to as gestational trophoblastic neoplasia (GTN). All patients with GTN require FIGO staging and WHO risk assessment, with the exception of ETT/PSTT, which is always treated with platinum-based multi-agent chemotherapy regimens. Treatment for GTN is then based on risk classification. For patients requiring chemotherapy, response is evaluated by longitudinal assessment of the quantitative level of serum hCG. Treatment is continued for several cycles after a negative hCG level is achieved. The finding of a plateau or increase in hCG while receiving treatment indicates relapse, and if an increase is observed, all patients require restaging and additional treatment.[145]

SURVIVORSHIP

After hCG levels have been normalized, patients should have their levels rechecked at monthly intervals for 12 months, and physical examination should be performed every 6 to 12 months. Most women who require chemotherapy will resume menses during surveillance. It is strongly recommended that women use contraception to avoid pregnancy during the first year after treatment. Beyond that, patients can be counseled that pregnancy after GTN is typically uncomplicated, although there is a 1% to 2% risk of GTD developing again. Survivorship issues after treatment of GTD should follow the principles in place for patients receiving curative treatment of other solid tumors, because their prognosis is typically excellent.

KEY POINTS

- GTNs are the malignant tumors within the category of GTD. If suspected or diagnosed, all patients require FIGO staging and WHO scoring.
- Medical treatment of GTN is based on the WHO score. Patients with low-risk disease (WHO score: 0-6) have a good prognosis and can be treated with single-agent chemotherapy. Both methotrexate and actinomycin D are used in this situation.

- For patients with high-risk disease, combination chemotherapy is preferred. The most commonly used regimen is EMA/CO, a sequential treatment using etoposide, methotrexate, and actinomycin D during week 1, followed by cyclophosphamide and vincristine during week 2 of a 14-day cycle.
- ETT/PSTT are considered high risk, and treatment is surgery for early-stage disease and multi-agent platinum-containing chemotherapy for more advanced disease or disease with long latency from antecedent pregnancies.
- GTN is a highly curable group of diseases. However, given the rarity of this disease, referral to a specialty center is highly advised.

VULVAR CANCER

Most vulvar cancers are squamous cell carcinomas. There are approximately 6,000 cases annually in the United States, and these occur mostly in older postmenopausal women (median age, 68 years). Risk factors include smoking, vulvar dystrophy, HPV infection, history of cervical cancer, and previous immunodeficiency syndrome. The primary approach to vulvar cancer is surgical. Patients with lymph node involvement are at greater risk of recurrence and death (5-year survival rate, 25%-41%) and are often treated with adjuvant EBRT with or without concomitant sensitizing cisplatin. There may be other indications for adjuvant radiotherapy after surgical excision, particularly if margins are close or positive, but the close observation is also an option, as vulvar recurrences can be re-resected. For patients with locally advanced disease that cannot be completely resected, primary chemoradiation therapy with weekly cisplatin is used; patients who have an excellent clinical response to chemoradiation therapy may subsequently be considered for resection of residual disease.[146] For those who experience a local recurrence, surgical re-excision should be considered. If the disease is unresectable, RT is administered, provided that the patients were not previously treated with RT. For all other patients (including those with metastatic disease), palliative chemotherapy can be used, although there are no prospective data that evaluate the efficacy of systemic chemotherapy for metastatic vulvar cancer. Agents such as cisplatin, carboplatin, paclitaxel, vinorelbine, and erlotinib are reasonable options for patients who are fit for chemotherapy. Pembrolizumab can also be used in this setting for PD-L1-positive disease or MSI-H/dMMR disease, as can cemiplimab (although cemiplimab is not approved in the US).

SURVIVORSHIP

After patients are treated for vulvar cancer, all of them should be observed by using serial physical examinations, including pelvic examinations. The schedule is similar to that for cervical cancer.

KEY POINTS

- Most vulvar cancers are squamous cell carcinomas. The primary treatment is surgical.
- For patients with locally advanced disease that cannot be completely resected, primary chemoradiation therapy with weekly cisplatin is used.

VAGINAL CANCER

Primary cancers arising from the vagina are rare and represent 1% to 2% of vaginal malignancies. Most vaginal carcinomas are squamous cell carcinomas and affect women in the sixth or seventh decade of life. Because of the increase in the incidence of HPV infections, there has been an increase in the number of women diagnosed with vaginal cancer before 40 years. Other risk factors include smoking, early age at first intercourse, multiple lifetime sexual partners, previous sexually transmitted diseases, and a history of cervical cancer. Other vaginal cancer histologic types are extremely rare and include clear-cell carcinoma, melanoma, sarcoma, and adenocarcinoma. It is important to consider metastatic or recurrent disease from other sites (eg, cervix, vulva, ovary, breast, endometrium, or uterus) in the evaluation of a new vaginal lesion, because metastatic disease is more common than primary vaginal carcinoma. There are no prospective studies on which to base treatment recommendations for vaginal carcinomas. As with vulvar cancers, primary treatment is surgical; if surgery is not feasible, treatment using RT with or without concomitant cisplatin is used. Although there are no prospective comparison data showing chemoradiation therapy to be superior to RT alone, many physicians extrapolate the data from randomized trials in cervical cancer and interpret data from retrospective studies in vaginal cancer to support the recommendation of chemoradiation therapy. Patients with unresectable metastatic disease may be offered palliative cytotoxic chemotherapy, but there are no prospective data to establish which agents are active. Once again, incorporation of ICIs in this setting is based on disease site–agnostic approvals and extrapolation from cervical carcinoma treatment paradigms.

SURVIVORSHIP

As with vulvar cancer, after treatment for vaginal cancer, all patients should be observed by using serial physical examinations, including pelvic examinations, following a schedule similar to that for cervical cancer.

KEY POINTS

- Vaginal cancers are typically squamous cell carcinomas and should be considered for definitive surgical resection.
- For patients with a history of another primary cancer, it is important to consider that the vaginal lesion may be metastatic from another site.
- For patients who are not candidates for surgical treatment, RT affords palliation.

HIGH-YIELD TAKEAWAYS

- Surgery by a board-certified gynecologic oncologist has been shown to improve outcomes. The importance of multidisciplinary consultation at the diagnosis stage should not be understated.
- Regardless of stage, histology, age, or family history, all patients with epithelial ovarian cancer need to undergo germline genetic testing.
- For HGSOC, regardless of stage, all patients should receive platinum and taxane chemotherapy.

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

GYNECOLOGIC CANCERS 15

CHAPTER SUMMARY GUIDE

KEY POINTS

- Cervical cancer is a sexually transmitted disease associated with a chronic infection of oncogenic types of HPV. HPV strains 16 and 18 account for 70% of cervical cancers. HPV vaccination represents an opportunity to reduce the worldwide occurrence of cervical cancer. The 9-valent vaccine available in the United States can be administered to people aged 9 to 45 years.
- Although vaccination against HPV is available, cervical cancer screening remains an important part of health maintenance.
- The approach to invasive cervical cancer depends on whether a patient presents with early-stage, locally advanced, or metastatic disease. The FIGO 2018 staging of cervical cancer is defined by tumor characteristics and nodal involvement.
- For people with early-stage cervical cancer, treatment is primarily surgical. New data define tumors at such low risk that radical surgery may be de-escalated. For those who require a radical hysterectomy, the open approach is the current standard of care. Sentinel node dissection seems to be oncologically safe in this population, but more prospective data are needed.
- The indications for adjuvant treatment after radical surgery using RT with or without concomitant chemotherapy depend on final pathologic findings, including tumor grade, presence of lymphovascular invasion, and depth of stromal invasion, as well as whether there are positive surgical margins and parametrial or nodal involvement. Use of adjuvant systemic chemotherapy is not supported in this setting.
- For most people with locally advanced cervical cancer, cisplatin and RT are administered as curative treatment without surgery.
- For patients with FIGO 2018 stages sIB3 to IIB, IIIC1, or IIIC2 without side wall involvement or distal vaginal involvement, NACT should be considered with an OS advantage from the INTERLACE trial.
- For patients with FIGO 2018 stages IIIA, IIIB, IIIC1, or IIIC2 with side wall or distal vaginal involvement or IVA, the addition of pembrolizumab to chemotherapy and radiation therapy can now be considered the standard of care, with the advantage of both PFS and OS. For women with de novo metastatic (stage IVB) or recurrent cervical cancer, first-line treatment consists of platinum-based doublet chemotherapy and bevacizumab, with the addition of pembrolizumab in patients whose tumors express PD-L1.
- The first-line recurrent/metastatic regimen should include paclitaxel, platinum, pembrolizumab, and bevacizumab for patients whose tumor is PD-L1 IHC positive by CPS score or atezolizumab, regardless of PD-L1 status. Strong consideration should be given to including bevacizumab in all settings if not contraindicated for medical reasons.
- Patients whose disease progresses after first-line therapy and who have not previously received pembrolizumab may receive pembrolizumab, provided that their tumor is positive for PD-L1 expression or they are found to have an MSI-H tumor.
- Tisotumab vedotin-tftv or T-DXd (for biomarker-positive tumors) can be considered in patients who have recurrent disease after previous chemotherapy with or without immunotherapy.
- Patients with advanced or recurrent disease should have their tumors tested for HER2 IHC via gastric scoring to assess eligibility to receive T-DXd.
- Endometrial carcinoma is the most common gynecologic cancer in the United States. The major risk factors for endometrioid endometrial carcinoma are those typically associated with increased estrogen exposure. More aggressive subtypes are often estrogen independent and associated with older age and non-white race.
- For people who receive surgical treatment, adjuvant therapeutic options include RT (pelvic irradiation with or without IVRT) and/or chemotherapy, typically with paclitaxel and carboplatin, and RT should be determined using an individualized approach. Postoperative risk factors can help determine who should be offered adjuvant treatment.
- All patients with endometrial adenocarcinoma should undergo MMR and/or MSI assessments. This information will identify patients who are appropriate for treatment with pembrolizumab, dostarlimab-gxly, or durvalumab. It is also important to identify patients with Lynch syndrome. Patients whose tumors show dMMR expression should be referred for genetic screening for Lynch syndrome.
- Pembrolizumab and lenvatinib combination therapy represents an important advance for patients with MMRp recurrent disease after treatment with paclitaxel and carboplatin.

- The combination of chemotherapy and immunotherapy (pembrolizumab or dostarlimab-gxly) is considered the standard of care in the treatment of patients with advanced-stage or recurrent dMMR endometrial cancer. The addition of IO to the chemotherapy backbone may also be appropriate for patients with pMMR tumors; we await mature data from GY018 and RUBY to further determine recommendations.
- Sarcomas are a heterogeneous group of diseases that account for 4% of all uterine cancers.
- Surgery is the mainstay of treatment for uterine sarcoma. There is no evidence that adjuvant treatment improves survival outcomes, and adjuvant treatment is typically not recommended.
- Gynecologic oncologists play a key role in the management of patients with ovarian cancer, particularly as it relates to surgical cytoreduction.
- Risk factors for ovarian cancer include genetics, increasing age, nulliparity, family history, early menarche, and late menopause.
- Oral contraceptive use, tubal ligation, breastfeeding, and higher parity are protective.
- For women who are not candidates for surgery because of tumor burden or morbidity, NACT is a reasonable option.
- Women who undergo an optimal cytoreduction should receive six cycles of intravenous platinum and taxane adjuvant therapy. Exceptions to this include women with stage IA or IB disease, grade 1 or 2 cancer, or non-clear-cell histology. Maintenance therapy should be discussed.
- Women whose disease relapses can be stratified as having platinum-sensitive or platinum-resistant disease. This can help in devising treatment strategies, with retreatment using a platinum-based doublet regimen favored for women with platinum-sensitive disease and the use of a nonplatinum single agent, or in combination with bevacizumab, for those with platinum-resistant disease.
- All women should undergo genetic testing for hereditary risk at diagnosis. Patients with stage III or IV high-grade serous or endometrioid tumors are candidates for maintenance with a PARPi after primary therapy. Benefit is most often seen in those with *BRCA1* or *BRCA2* mutation, followed by those with HRD versus HRP tumor status. Alternatively, patients with wild-type *BRCA* status who started with bevacizumab as part of the primary regimen may continue with bevacizumab maintenance.
- PARPis are also indicated as maintenance therapy after a response to retreatment with platinum-based therapy in women with a *BRCA* mutation.
- Sex cord–stromal tumors are rare gynecologic malignancies that typically affect younger women.
- The primary treatment of sex cord–stromal tumors is surgical excision. Medical therapy is often reserved for patients with tumors that are not resectable at diagnosis (either initially or at relapse).
- For women with germ cell tumors, systemic treatment with platinum-based chemotherapy is often recommended after surgery. Exceptions to this rule include stage I dysgerminomas after complete staging surgery and stage I grade 1 immature teratomas, because they rarely relapse.
- GTNs are the malignant tumors within the category of GTD. If suspected or diagnosed, all patients require FIGO staging and WHO scoring.
- Medical treatment of GTN is based on the WHO score. Patients with low-risk disease (WHO score: 0-6) have a good prognosis and can be treated with single-agent chemotherapy. Both methotrexate and actinomycin D are used in this situation.
- For patients with high-risk disease, combination chemotherapy is preferred. The most commonly used regimen is EMA/CO, a sequential treatment using etoposide, methotrexate, and actinomycin D during week 1, followed by cyclophosphamide and vincristine during week 2 of a 14-day cycle.
- ETT/PSTT are considered high risk, and treatment is surgery for early-stage disease and multi-agent platinum-containing chemotherapy for more advanced disease or disease with long latency from antecedent pregnancies.
- GTN is a highly curable group of diseases. However, given the rarity of this disease, referral to a specialty center is highly advised.
- Most vulvar cancers are squamous cell carcinomas. The primary treatment is surgical.
- For patients with locally advanced disease that cannot be completely resected, primary chemoradiation therapy with weekly cisplatin is used.
- Vaginal cancers are typically squamous cell carcinomas and should be considered for definitive surgical resection.
- For patients with a history of another primary cancer, it is important to consider that the vaginal lesion may be metastatic from another site.
- For patients who are not candidates for surgical treatment, RT affords palliation.

CHAPTER TABLES AND IMAGES

Table 15-1 Clinical Features and Postoperative Surgical and Pathological Risk Factors to Assess the Risk of Recurrence in Cervical Cancer

Intermediate Risk (Sedlis Criteria)	High Risk (Peters Criteria)
LVSI and deep stromal invasion (outer third)	Positive surgical margins
LVSI and middle stromal invasion (one-third) and tumor size ≥2 cm	Detection of pathologically confirmed lymph node metastases
LVSI and superficial stromal invasion (inner third) and tumor size ≥5 cm	Extension into the parametrial tissue
No LVSI but deep or middle stromal invasion and tumor size ≥4 cm	

Abbreviation: LVSI, lymph-vascular space invasion.
Adapted from Fleischmann M, Chatzikonstantinou G, Fokas E, et al. Molecular markers to predict prognosis and treatment response in uterine cervical cancer. *Cancers*. 2021;13(22):5748. doi:10.3390/cancers13225748

Table 15-2 **Molecular Classification for Endometrial Cancer**

TransPORTEC Classification (TCGA Classification)	Prognosis	Treatment Approach	Other Molecular Features
POLE mut (ultramutated)	>90%; 5 years, OS	Candidate for de-escalation of therapy	
MMRd (hypermutated)	Very good	Checkpoint inhibitor therapy	Can occur as a germline or somatic mutation or through methylation of the *MLH1* gene promoter in the tumor
NSMP (copy number low)	Very good for most patients, but a subset with worse outcomes	May have functional hormonal receptors and can consider hormonal therapy	More likely to have ER/PR. Most common associated mutations: *PTEN*, *ARID 1A*, *PIK3CA*, *CTNNB1*, *PIK3R1*, *KRAS*
*P53*abn (copy number high)	Poor <50%; 5 years, OS	Recommend an aggressive approach with chemotherapy	Can look for HER2 overexpression/amplification, HRD

Abbreviations: abn, abnormal; ER, estrogen receptor; HRD, homologous recombination–deficient; MMRd, mismatch repair–deficient; mut, mutated; NSMP, no specific molecular profile; OS, overall survival; PR, progesterone receptor; TCGA, The Cancer Genome Atlas.

Table 15-3 **Seminal Phase 3 Trials of Maintenance PARP Inhibitors in First-Line Treatment of Advanced Ovarian Cancer**

Characteristic	PAOLA-1	PRIMA	SOLO1	ATHENA
Volunteers	All comers	All comers	*BRCA* mutation associated	All comers
Intervention	Olaparib and bevacizumab	Niraparib	Olaparib	Rucaparib
Comparator	Bevacizumab	Placebo	Placebo	Placebo
HR for PFS (vs comparator)				
All comers	0.59	0.62	NR	0.52
BRCA1/2 positive	0.31	0.4	0.31	0.40
HRD (any)	0.33	0.43	NR	
HRD positive (no *BRCA*)	0.43	0.5	NR	0.47
HRD negative/unknown	0.92	NR	NR	
HRD proficient	NR	0.68	NR	
HRD unknown	0	0.85		

Abbreviations: HR, hazard ratio; HRD, homologous recombination–deficient; NR, results not reported; PFS, progression-free survival.

Table 15-4 **Serum Tumor Markers in Ovarian Germ Cell Tumors**

Marker	Tumor Type
hCG	Embryonal cell carcinoma
	Choriocarcinoma
	Mixed germ cell tumors
	Dysgerminoma
AFP	Yolk sac tumors
	Embryonal cell carcinoma
	Polyembryoma carcinoma
	Mixed germ cell tumors
	Immature teratomas
LDH	Dysgerminoma

Abbreviations: *AFP*, alpha fetoprotein; *hCG*, human chorionic gonadotropin; *LDH*, lactate dehydrogenase.

Jacob S. Choi, MD, PhD, and Upendra P. Hegde, MD

RECENT UPDATES

- In SWOG S1801, a randomized phase 2 study of adjuvant versus neoadjuvant-adjuvant therapy with pembrolizumab for patients with resectable stage IIIB to IV melanoma, neoadjuvant pembrolizumab followed by adjuvant pembrolizumab significantly improved event-free survival compared with adjuvant pembrolizumab only.[1] Further supporting evidence for neoadjuvant immunotherapy for resectable, macroscopic stage III melanoma was observed in the phase 3 trial (NADINA study),[2] which demonstrated superior event-free survival for neoadjuvant ipilimumab and nivolumab when compared to adjuvant nivolumab therapy alone.
- In a non–randomized phase 2 trial (C-144-01), lifileucel, an autologous tumor-infiltrating lymphocyte (TIL) adoptive cell therapy, demonstrated a meaningful clinical benefit with a durable response in patients with unresectable or metastatic melanoma who were refractory to anti–PD-(L)1 therapy.[3] On the basis of this study, lifileucel was the first TIL therapy approved by the US Food and Drug Administration (FDA) in February 2024 for adult patients with advanced melanoma refractory to PD-1 blockade and BRAF/MEK inhibitor therapy if *BRAF* mutated.
- In a randomized phase 3 trial (C-POST) of adjuvant cemiplimab versus placebo for patients with resected, high-risk cutaneous squamous cell carcinoma, adjuvant cemiplimab achieved significantly longer disease-free survival.[4]

OVERVIEW

This chapter primarily focuses on cutaneous melanoma, with sections dedicated to nonmelanoma skin cancers, including basal cell carcinoma (BCC), cutaneous squamous cell carcinoma (CSCC), and Merkel cell carcinoma (MCC), as well as mucosal melanoma and uveal melanoma.

CUTANEOUS MELANOMA

EPIDEMIOLOGY

Cutaneous melanoma accounts for 232,100 of all new cancer cases worldwide (1.7%). However, the melanoma-specific mortality rate is only 0.7% of all cancer-related deaths[5] because of screening, early detection, and adequate surgical management of early-stage disease. In the United States, cutaneous melanoma is the fifth most common cancer in men and women[6] with an estimated lifetime risk of developing invasive melanoma in white, Black, and Hispanic people of about 1 in 33, 1 in 1,000, and 1 in 200, respectively. In 2025, about 104,960 new cases of invasive melanoma are expected to be diagnosed in the United States with about 8,430 subjects projected to die from it. At the time of new melanoma diagnosis, 84% of cutaneous melanomas are localized (stages I and II), 8% are regional (stage III), and only 4% are distant metastatic (stage IV). Therefore, most early-stage cutaneous melanomas are highly treatable and do not cause death.

After decades of increase, invasive melanoma incidence rates declined from 2005 to 2018 in patients younger than 50 years (by approximately 1% per year). Incidence rates seem to have stabilized for men aged 50 years or older but are continuing to increase by approximately 1% per year for women aged 50 years or older.[6] Melanoma-specific mortality has dropped steeply from 2015 to 2019 (by approximately 4% per year) because of advances in systemic treatment. Figure 16-1 shows annually projected incidence, mortality, and mortality-to-incidence ratios from American Cancer Society Annual Surveillance and Health Services Research for cutaneous melanoma.

RISK FACTORS

Geography and ethnicity play a role in the risk of cutaneous melanoma development. Australians and New Zealanders have the highest incidence of cutaneous melanoma development (42 per 100,000 person-years for males and 31 per 100,000 person-years

Figure 16-1 Melanoma Incidence, Mortality, and Mortality-to-Incidence Ratios

for females), followed by Western Europeans (19 per 100,000 person-years for males and females) and North Americans (18 per 100,000 person-years for males and 14 per 100,000 person-years for females).[7] In the United States, approximately one-half (48%) of patients with newly diagnosed cutaneous melanoma are aged 55 to 74 years. In addition, within the United States, non–Hispanic white people have a 25-fold higher risk of cutaneous melanoma development than Black people and an approximately six-fold higher risk than Hispanic white people. Melanoma outcomes are significantly worse for Black Americans. Of all cancers, melanoma exhibits the largest differential in survival rates between Black and white people, with an observed absolute difference of 24% in overall survival. While a higher incidence of acral melanoma has been observed in Black Americans, worse survival outcomes are observed in this population even after accounting for stage and histology, with differences in survival partly due to diagnosis occurring at later stages and less access to health care.[8]

The most important risk factors for cutaneous melanoma are as follows:

- UV light exposure is the most well-characterized risk factor for cutaneous melanoma. A higher number of tanning bed sessions and sunburns increase the risk of development of cutaneous melanoma.
- Various forms of immunosuppression increase the risk of cutaneous melanoma, including immune senescence of older age, malignancy-associated immunosuppression (eg, non–Hodgkin lymphoma and chronic lymphocytic leukemia), virally induced immunosuppression (eg, HIV infection), and iatrogenic immunosuppression as in recipients of a solid organ transplant.
- Skin phenotype, a polygenic trait with various polymorphisms among pigment-associated genes (eg, *MC1R, TYR, TYRP1*, and *ASIP*) regulating the amount and type of melanin present in the skin, has also been associated with cutaneous melanoma development. For example, people with light skin (Fitzpatrick skin types I and II), red hair, and light eye color have an increased risk of cutaneous melanoma.
- Precursor melanoma lesions known to harbor cancer-associated mutations, such as atypical or common nevi (odds ratios [ORs], 17.40 and 1.02, respectively), personal history of melanoma (OR, 12.78), personal history of nonmelanoma skin cancer (relative risk, 4.28), and family history of cutaneous melanoma are also associated with increased risk of cutaneous melanoma.
- Familial atypical mole melanoma syndrome
- Xeroderma pigmentosum (caused by mutations in UV damage repair genes)
- Certain genes bearing germline mutations or gene variants are associated with a higher risk of development of familial melanoma, as discussed in the Familial Melanoma section of this chapter.

KEY POINTS

- Cutaneous melanoma accounts for 1.7% of all new cancer diagnoses annually worldwide; 0.7% of all cancer-related deaths are a result of cutaneous melanoma.
- Projected melanoma-specific mortality rates have been declining since 2016; overall incidence rates seem to have stabilized for men after decades of increase while continuing to increase for women.
- In 2025, about 104,960 new cases of invasive melanoma are expected to be diagnosed in the United States with about 8,430 projected deaths.
- Both cutaneous melanoma incidence and mortality rates are higher in men than in women.
- UV light exposure is the most well-characterized risk factor for cutaneous melanoma.
- Australia and New Zealand have the highest incidence of melanoma but relatively better survival outcomes, while Black Americans experience low melanoma incidence but relatively worse survival.

BIOLOGY

Melanocytes are derived from neural crest cells, and they resemble dendritic cells and neurons. Their dendritic shape, along with the vesicles (ie, melanosomes) and molecules they secrete, implies that melanocytes have a prominent function within their microenvironment. Melanoma cells share several common antigens with melanocytes (eg, MAGE family, melan A-MART-1, and GAGE family).[9] Antigens from these shared proteins can stimulate a strong immune response.

Melanin is the principal multiprotein pigment structure within melanosomes and has complex physicochemical properties that protect against UV radiation–induced DNA damage. The primary function of the melanocyte is to respond to UV radiation–induced damage that occurs within keratinocytes by activating the production of melanin. However, the intermediate enzymatic steps leading up to melanin production are pro-oxidative and, therefore, lead to higher levels of oxidative stress and reactive oxygen species within melanocytes. Conditions such as high UV radiation exposure and p16 deficiency, which generate more reactive oxygen species within melanocytes, can lead to melanocyte transformation. High oxidative stress and defects in DNA repair may lead to genomic instability and can account for the high somatic mutation burden seen in cutaneous melanoma compared with other cancers[9,10] (Fig. 16-2).

The production of melanin, which is packaged within melanosomes (Fig. 16-2, filled black circles) and secreted to nearby keratinocytes in response to UV radiation, is highly regulated in part through the *MC1R* gene, which activates the master melanocyte transcriptional regulator MITF. In response to UV exposure or skin repair, melanocytes also respond to growth factors (eg, human growth factor, platelet-derived growth factor, and stem cell factor) through growth factor receptors (eg, epidermal growth factor receptor, platelet-derived growth factor receptor, KIT, and vascular epidermal growth factor receptor) by means of a highly regulated process. Growth factor–mediated stimuli signal through the Ras-Raf-Mek-Erk pathway and, to a lesser extent, others, including the phosphatidylinositol 3-kinase-Akt-mammalian target of rapamycin pathway.

Aggressive melanomas have several unique characteristics, including the ability to (1) increase proliferative capacity (eg, *CDKN2A* locus genetic, or epigenetic aberrations), (2) escape senescence (eg, telomerase transcriptase [*TERT*] gene promoter mutations), (3) upregulate autonomous cell growth independently of membrane receptor signaling (eg, *PTEN* loss, *NRASQ61* mutation, *BRAF* V600 mutations, and *NF1* highly functional mutations), (4) exhibit deficiencies in DNA repair and alter melanin production (mutations or polymorphisms in the *MC1R* gene [*MC1R**]), and (5) accumulate epigenetic changes with altered patterns of gene expression that affect immunogenicity (expression of major histocompatibility complex [MHC] class 1, β2-microglobulin) and interaction with cell partners from keratinocytes to melanoma cells themselves (eg, loss of E-cadherin and P-cadherin, upregulation of N-cadherin, MelCam, and αVβ integrins).

Progression from benign nevi to dysplastic nevi, to melanoma in situ, and to invasive melanoma is associated with increases in the numbers of somatic mutations and copy number alterations in melanomas arising from nevi. *BRAF* V600 is the most frequent somatically mutated gene codon identified in benign nevi. More genetic events (eg, NRAS, Q61, mutations in the promoter for *TERT*,[11] and mutations or gene copy number deletions of the *CDKN2A* locus[12]) occur even before invasive melanoma is detected (ie, melanoma in situ). Invasive melanomas are associated with a higher frequency of activating mutations in oncogenes (*BRAF* V600E, *NRAS* Q61, *CDK4* K22, *RB1* Y498, *PPP6C* R264, and *PIK3CA*), genetic aberrations in tumor suppressor genes (*CDKN2A* locus, *PTEN*, and *TP53*), genes encoding for chromatin remodeling complexes (*ARIDs*, *SMARCA4, PBRM1*, and *EZH2*), and increased expression of genes encoding for proteins involved in the mitogen-activated protein kinase (MAPK) signaling pathway.[13]

SPORADIC MELANOMA

The Cancer Genome Atlas project in cutaneous melanoma (N = 333) confirmed the mutational landscape of cutaneous melanoma that had been previously reported (ie, 52% *BRAF* V600 codon, 31% *CDKN2A* gene loss, 28% *RAS* oncogenic mutations, 15% *TP53*, 14% *NF1* mutations, and 13% *CDKN2A* gene locus mutations).[14] Genetic or epigenetic aberrations in melanoma cells have consequences regarding the host immune response. Decreased protein expression of tumor suppressor genes (eg, *PTEN, CDKN2A*, and *APC*/*CTNNB1*) or mutations in distinct oncogenes (eg, *NRAS* Q61) are associated with a decreased incidence of tumor-infiltrating lymphocytes (TILs), poor response to systemic therapies, and worse prognosis. Coexistence of these genetic aberrations, or lack thereof, along with other more frequently mutated genes,[14] may enable more personalized combination therapy strategies in the future. More recently, additional (secondary) driver genes that are somatically mutated and involve the transforming growth factor-β pathway, chromatin remodeling, and histone modification were identified. Interestingly, these new mutation driver genes are rarely shared among the different genetic subgroups (*BRAF* V600 mutated, *NRAS* Q61 mutated, *NF1* mutated, and triple wild type) and may be associated with overall prognosis and response to immune checkpoint blockade.[15]

Of therapeutic relevance, The Cancer Genome Atlas in cutaneous melanoma showed that MEK1/2 proteins are activated in both *BRAF* and *RAS* hotspot mutation subtypes.[9] The high level of activation of MEK1/2 accounts for the clinical benefit with concurrent BRAF and MEK inhibition in *BRAF* V600–mutated melanoma.

The approximate 50% incidence of cutaneous melanoma–bearing TILs (ie, inflamed) at least partially accounts for the high incidence of antitumor responses to immunotherapies.

FAMILIAL MELANOMA

Approximately 10% of patients with cutaneous melanoma have familial melanoma.[16] The *CDKN2A* gene locus is the most well-studied and strongest genetic factor for familial cutaneous melanoma. Carriers of *CDKN2A* germline mutations have a 60-fold higher risk of cutaneous melanoma development, partly because of high penetrance of gene mutations (60%-90%). Carriers of germline mutations in the *BAP1* gene are also at high risk of developing cutaneous melanoma (OR, 17.3), as well as uveal melanoma. Carriers of the *MITF* Mi-E318K variant, the master regulator of melanocyte development, have a higher risk of development of either multiple primary melanomas or renal cell carcinoma. Carriers of the *MC1R* gene variant have a moderate risk of cutaneous melanoma; variants corresponding to red hair color confer a higher risk than non–red hair variants (OR, 2.4 vs 1.2). Furthermore, the number of *MC1R* variants increases the relative risk of cutaneous melanoma in *CDKN2A* mutation carriers. Mutations in the telomere-related genes such as POT1, shelterin complex genes, and TERT have been identified in families with clusters of cutaneous melanomas.

Patients with multiple primary melanomas, a personal history of melanoma and another noncutaneous cancer, a family history of at least two relatives with cutaneous melanoma, a family history of cancers, and/or early age (35 years or younger) at onset should be offered genetic counseling, given a recent study showing that germline genetic testing in these individuals resulted in the diagnosis of clinically impactful hereditary cancer predisposition for 15% of patients who met these criteria. Emerging evidence suggests that more common cancer predisposition genes involving DNA repair genes, such as *BRCA1/2* and Lynch syndrome genes, are also involved in hereditary melanoma.[17]

KEY POINTS

- Familial cutaneous melanomas represent approximately 10% of melanomas.
- Germline mutations in the *CDKN2A* and *BAP1* gene locus are associated with an increased risk of developing cutaneous and uveal melanoma.
- All patients with melanoma and a personal history or family history of cancer should be referred to genetics.
- *BRAF* V600E is the most frequent somatic mutation in sporadic melanomas, followed by mutations in *NRAS*, *CDKN2A*, *TERT*, and *NF1*.

SCREENING AND PREVENTION

The broad availability of smartphones with high-resolution cameras is changing the early evaluation of atypical, pigmented skin lesions, with technology now supplementing, but not replacing, routine skin screening. The question of whether skin examination

for cutaneous melanoma detection increases melanoma-specific overall survival has been investigated. The SCREEN project was a massive population-based skin cancer screening program conducted in the German state of Schleswig-Holstein. More than 1,700 physicians and more than 360,000 participants older than 20 years participated for the duration of the intervention (2003-2004). In the years before the start of the project, the feasibility of physician training, screening test performance, and documentation of screening examinations was evaluated. The mortality rate before (1998-2000) and after (2007-2008) the intervention was calculated for Schleswig-Holstein, three neighboring German states (Hamburg, Mecklenburg-Vorpommern, Lower Saxony), and the neighboring country of Denmark. Schleswig-Holstein, the only state where the intervention was applied, was the only state with an almost 50% decline in melanoma-specific mortality in the period after intervention.[18] Atypical nevi, a personal history of melanoma, and multiple (≥40) nevi were associated with an increased risk of melanoma detection. A screening strategy that focused on only three risk factors (age ≥35 years, family history, and congenital nevi) reduced the number of people needed to screen to detect one melanoma from the originally screened 360,000 participants to 178 participants.[19]

Apart from early detection, sunscreens, antioxidants, anti-inflammatory drugs, vitamins, and supplements have been considered for chemoprevention in cutaneous melanoma.[20] Only regular sunscreen use has the highest level of clinical evidence for melanoma prevention. A prospective study in Queensland, Australia, of 1,621 participants who were randomly assigned to daily use of sunscreen versus any other sun protective factor at the discretion of investigators showed that sunscreen use significantly reduced the development of invasive melanomas (hazard ratio [HR], 0.27; 95% CI, 0.08-0.97).[21]

KEY POINTS

- Population-based skin cancer screening programs have identified risk factors that can render melanoma screening cost efficient to select high-risk patients.
- The use of sunscreens has the highest level of clinical evidence for melanoma prevention.

CLINICAL PRESENTATION

STAGING SYSTEM

Stage at diagnosis, as defined in the American Joint Committee on Cancer 2018 staging system, is the most significant predictor of overall survival.[22] The Surveillance, Epidemiology, and End Results (SEER) program 5-year overall survival rates for localized (stages I and II), regional (stage III), and distant metastatic melanoma (stage IV) diagnosed between 2009 and 2015 were 99%, 65%, and 25%, respectively. The current eighth edition of the American Joint Committee on Cancer staging system is distinguished from the previous seventh edition because it

- Retains the major histopathologic parameters of the primary melanoma (Breslow depth of invasion for thin [T1], intermediate [T2, T3], or thick [T4] melanoma; ulceration) and regional lymph node status (N) staging (number of metastasis-containing regional lymph nodes; the presence of satellite, microsatellite, or in-transit lesions)
- Simplifies reporting of Breslow depth of invasion value to the nearest 0.1 mm
- Reclassifies thin melanomas (T1a and T1b) by Breslow depth of invasion of either less than 0.8 mm versus 0.8 mm or greater and the presence or absence of ulceration (T1a melanomas have <0.8 mm Breslow depth of invasion and are also nonulcerated)
- Simplifies the terminology of locoregional (satellite and in-transit disease) or regional lymph node involvement (clinically occult vs clinically detected)
- Introduces the fourth substage for stage III, identified by D
- Refines distant metastatic disease (M) by introducing a D substage (central nervous system metastases) and takes into consideration biochemical changes (by elevated serum lactate dehydrogenase [LDH]) across each M1 subcategory designated as "[0]" for not elevated LDH and "[1]" for elevated LDH)

The eighth edition of the American Joint Committee on Cancer staging system provides more accurate prognostic information for patients with stage III melanoma without any significant loss of prognostic value for stages I and II.[23]

OTHER PROGNOSTIC FACTORS

Younger women, white patients, and immunocompetent patients have an overall better prognosis than older men, Black patients, and patients with immunosuppression, respectively. Several histopathologic features not included in the 2018 American Joint Committee on Cancer staging system remain important prognostic factors, such as the mitotic rate of the primary cutaneous melanoma and density of TILs, whether measured in the primary cutaneous melanoma, regional lymph nodes,[9] or distant metastatic sites.

An increasing number of molecular assays have been used to evaluate the prognosis of patients with stage I to II cutaneous melanoma. However, they still lack validation in prospective studies. DecisionDx-Melanoma (Castle Biosciences) is based on a

retrospective analysis of RNA extracted from archival formalin-fixed paraffin-embedded primary melanoma tissue and tested for a 31-gene expression profiling signature. This test categorizes patient risk as class 1 (A or B) or 2 (A or B). In a retrospective analysis of 259 patients with cutaneous melanoma who had negative sentinel lymph node (SLN) mapping, those whose disease was classified as class 2 by the DecisionDx-Melanoma test had worse relapse-free survival and overall survival than patients in any other class. In patients with stage I or IIA cutaneous melanoma, the 31-gene expression test predicted relapse-free survival independently of Breslow thickness. However, Breslow thickness and SLN status remain the stronger prognostic indicators.[24] Therefore, the clinical utility of the DecisionDx-Melanoma test is not yet clear, and its application in stage I to II melanoma is not considered routine at this time.

PATIENT EVALUATION

Clinical

The initial evaluation of a patient with a recent diagnosis of cutaneous melanoma involves obtaining a thorough history and performing a physical examination. To investigate the need for further genetic risk evaluation, the patient history should document a family history of melanoma or other noncutaneous cancers (eg, breast cancer, prostate cancer, renal cell carcinoma, and mesothelioma). A personal history of (1) multiple cutaneous melanomas (two or more); (2) regressing pigmented skin lesions, raising the possibility of melanoma of unknown primary; or (3) nonmelanoma skin cancers should also be documented. Younger patients diagnosed with cutaneous melanoma have a higher incidence of *BRAF* V600 somatic mutations.

Constitutional symptoms can be a sign of advanced melanoma, and new-onset headaches or other neurologic symptoms can be a sign of central nervous system metastases.[25] New-onset pulmonary or neurologic symptoms should elicit radiologic workup in patients with a history of early-stage melanoma.[25] The physical examination can be remarkable for the presence of chronically sun-damaged skin (eg, actinic keratosis, solar elastosis, and lentigines) or other nonmelanoma skin cancers. Alternatively, multiple atypical, pigmented lesions suggest that cutaneous melanoma may have arisen from nevi. Blood tests have little prognostic significance for patients with stage I to III melanoma. However, high white blood cell count, neutrophilia, monocytosis, low absolute lymphocyte count, and elevated serum LDH have been associated with worse prognosis in patients with stage IV melanoma.[22]

Surgical Staging

A patient with a recently diagnosed primary cutaneous melanoma should undergo wide excision and, when indicated, concurrent SLN mapping and biopsy. Wide excision with 1- to 2-cm margins decreases the incidence of a local recurrence.[26] SLN mapping is the recommended method to complete the regional surgical staging by assessing the incidence of regional lymph node metastases for patients at risk of regional nodal involvement (≥T1b). SLN biopsy should be offered to all patients with at least T2 lesions. SLN biopsy could also be considered for patients with thinner lesions, in particular, young patients whose diseases also bear aggressive histopathologic features (eg, high mitotic rate and the presence of ulceration).[27] In experienced hands, the use of standardized probes (eg, technetium-99 sulfur colloid and intraoperative vital blue dye around the primary tumor) results in an overall SLN identification rate of 95% and low morbidity. SLN status is an independent prognostic factor for overall survival. At a median follow-up of 20 months, 15% of patients with positive SLNs who did not undergo complete lymph node dissection had a nodal recurrence. MSLT-I was a prospective phase 3 study in which 2001 patients with at least T2 cutaneous melanoma, but no patients with clinically detectable nodal disease, were enrolled. Patients were randomly assigned to undergo immediate complete lymph node dissection if SLN biopsy was positive versus nodal observation at the time of study entry. MSLT-I showed no difference in the 10-year overall survival rate.[28] These data suggest that SLN mapping provides only prognostic information, and control of regional clinically undetectable disease may not have an effect on overall survival.

Radiographic Staging

Radiographic staging in cutaneous melanoma has considerably lower sensitivity and specificity compared with SLN mapping because it cannot detect microscopic (ie, ≤3 mm) lymph node involvement. Cross-sectional imaging should be considered for the initial staging of higher-risk patients (stage ≥IIB).[29]

SURVEILLANCE AFTER ORIGINAL DIAGNOSIS AND THERAPY

Any surveillance strategy should consider patterns of recurrence after resection of the primary lesion and/or nodal staging or resection. Approximately one-half of recurrences are within the regional lymph node bed, 20% are locoregional, and 30% involve distant metastases. Most recurrences occur within the first 2 years of cutaneous melanoma diagnosis, with a decreasing risk between the second and fourth years. All patients should undergo follow-up with a medical history and physical examination, including skin and lymph node examinations every 3 to 6 months for the first 3 to 5 years and then annually for their lifetime. Patients should have skin screening for additional primary melanomas and other nonmelanoma skin cancers at least annually for their lifetime.

Radiographic cross-sectional imaging with either whole-body PET/CT scans or CT scans and MRI of the brain is recommended for patients with stage III disease to screen for locoregional and distant metastases and can be considered in patients with high-risk stage II disease (stages IIB and IIC) as well.

KEY POINTS

- Clinical evaluation of a patient with newly diagnosed cutaneous melanoma should include a full medical history, including family and personal histories of melanoma and other cancers.
- Physical examination should include skin and lymph node examinations every 3 to 6 months for the first 3 to 5 years and then annually for their lifetime.
- Surgical management includes wide local excision concurrent with SLN biopsy when indicated. SLN status is an independent prognostic factor for overall survival.

SURGICAL TREATMENT OF TIS TO T4 (STAGE 0-II) MELANOMA

The standard for definitive treatment of localized melanoma is complete removal with adequate margins (Table 16-1). Several large randomized controlled trials have established optimal wide-excision margins for Tis to T4 melanoma. Surgical margins are clinically defined from the edges of the primary tumor, or primary melanoma scar, to the edges of the gross resection specimen and are not based on the histopathologic margins reported by the pathologist. Fewer standardized criteria are available regarding the optimal depth of wide excision. A phase 3 randomized trial (MelMarT-II) of 1-cm versus 2-cm margin of excision in patients with stage II (Breslow thickness >2 mm or 1-2 mm with ulceration) primary cutaneous melanoma is currently ongoing to evaluate for difference in risk of melanoma recurrence (ClinicalTrials.gov identifier NCT03860883).

Table 16-1 Recommended Wide and Deep Excision Margins for Tis to T4 Melanoma

Breslow Depth of Invasion (mm)	Wide Surgical Margin (cm)	Deep Surgical Margin
In situ	0.5-1	Excised to the depth within the adipose layer
≤1.0	1	
>1.0 and ≤2.0	1-2	Excised to the depth immediately above muscle fascia
>2.0	2	

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

KEY POINT

- Melanoma with deep Breslow thickness (ie, ≥4.0 mm) and ulceration, even without positive regional lymph nodes (stage IIC), has a high risk of recurrence.

ROLE OF SURGERY

CLINICALLY OCCULT (NON-PALPABLE) REGIONAL LYMPH NODE METASTASES

On the basis of the results of the Multicenter Selective lymphadenectomy Trial (MSLT-II) and the German Dermatologic Cooperative Oncology Group Sentinel Lymph Node Trial (DeCOG-SLT), completion lymph node dissection is no longer considered the standard recommended treatment of all patients with positive SLN biopsy specimens (ie, nonclinically detected).

MSLT-II, a phase 3 randomized study (N = 1,939 patients), aimed to address the question of whether immediate completion lymph node dissection versus surveillance ultrasonograms of the affected nodal basin after positive SLN mapping in patients without clinical evidence of regional lymphadenopathy increased the rate of regional disease control and/or prolonged overall survival. This was an important question because complete lymph node dissection could identify additional positive lymph nodes (21%) after positive SLN mapping at the cost of surgical morbidities (eg, pain, lymphedema, seroma, and infection). Although regional disease control was improved with complete lymphadenectomy in patients with SLN-positive disease, melanoma-specific overall survival was not prolonged in this group.[30]

The German DeCOG-SLT study also reported a lack of an overall survival benefit of complete lymphadenectomy in patients with occult reginal lymph node metastases in a phase 3 multicenter randomized trial that included 483 patients.[31] Lack of an overall survival benefit after control of regional disease implies that a patient's outcome is not solely influenced by eradication of the regional clones. Regional nodal disease might not be the launchpad for the development of distant metastatic disease, as was previously thought.

In cutaneous melanoma patients with clinically occult, SLN-positive stage III disease, the new-generation FDA-approved adjuvant therapy with anti–PD-1 agents (pembrolizumab and nivolumab) and BRAF-directed treatment in *BRAF* mutation–positive

melanoma has improved relapse-free survival and shown trend toward overall survival with longer follow-up. Complete lymph node dissection can be discussed and offered to select patients with positive SLNs. ASCO guidelines recommend a balanced discussion about the risks and benefits of foregoing complete lymph node dissection in favor of watchful observation with serial nodal ultrasonograms.[27] Many centers have primarily adopted the observation approach, given the lack of an overall survival benefit with complete lymph node dissection, followed by adjuvant anti–PD-1 therapy. Also important to note is that staging will be influenced by the decision to avoid complete lymph node dissection in these patients.

CLINICALLY DETECTED REGIONAL LYMPH NODE METASTASES

Therapeutic Lymph Node Dissection and Role of Adjuvant Radiation Therapy

Therapeutic lymph node dissection (TLND; level I-III dissection in the axilla, superficial groin dissection in the groin, and level II-V radical lymph node dissection in the neck) is the historical treatment standard for patients with clinically detected stage III melanoma and no radiographic evidence of distant metastases because it offers the best opportunity for locoregional control. However, patients with sizable nodal tumor burden or extracapsular nodal extension of tumor still have a high risk of regional and distant relapse after complete lymph node dissection.

The role of adjuvant radiation therapy after complete lymph node dissection for patients presenting with palpable lymph node involvement was examined in the phase 3 multicenter ANZMTG 01.02/TROG 02.01 trial, in which patients were randomly assigned to regional adjuvant radiation therapy versus observation. Compared with those receiving observation only, radiation therapy–treated patients had a significantly lower incidence of lymph node in-field relapse (HR, 0.52; 95% CI, 0.31-0.88).[32] Of note, however, this trial did not demonstrate an overall survival benefit (HR, 1.27; 95% CI, 0.89-1.79; $P = .21$) or relapse-free survival benefit (HR, 0.89; 95% CI, 0.65-1.22; $P = .51$) for the adjuvant radiation therapy group.

Recent SWOG 1801[1] and NADINA[2] trials provide emerging data for consideration of neoadjuvant treatment approaches typically with either anti–PD-1 monotherapy or a preferred neoadjuvant combination of anti–PD-1 and anti–CTLA-4 checkpoint blockade, while other combined regimens incorporating LAG-3 inhibitors or BRAF-directed treatment in *BRAF* mutation–positive melanoma have also shown benefit prior to lymph node dissection (see "Neoadjuvant Therapy" section).

Although adjuvant radiation therapy to the locoregional or regional lymph node site may no longer be standard for all patients in this era of immune checkpoint inhibitors and BRAF-directed treatment in *BRAF*-mutated melanoma patients, it can be considered in select patients at high risk of local or regional recurrence identified on index lymph node specimen or lymphadenectomy specimen following neoadjuvant treatment such as no pathologic response or minimal pathologic response. Additionally, patients with high-risk features such as metastases in multiple lymph nodes, matted lymph nodes, or the presence of extracapsular extension of the tumor should also be considered for adjuvant radiation.

Isolated Limb Infusion and Perfusion

Therapeutic isolated limb perfusion (ILP) and isolated limb infusion (ILI) are surgical techniques that achieve temporal regional vascular isolation to enable regional delivery to the tumor of chemotherapeutic agents at doses many-fold higher than those administered systemically without causing irreversible organ and bone marrow toxicity.

ILP involves hyperthermia and oxygenation of the circulation that potentiates tumoricidal effects of chemotherapeutic agents.

ILI is a low-flow ILP procedure performed via percutaneous catheters without oxygenation.

Patients with advanced locoregional cutaneous melanoma involving an extremity are eligible. The most frequently used cytotoxic agent is melphalan (10 mg/L in lower-limb tissue perfused and 13 mg/L in upper-limb tissue perfused), and the usual perfused time is 60 to 90 minutes. Local complications include myotoxicity, neuropathy, erythema, edema, blistering, and desquamation. Systemic complications depend on the level of systemic drug leakage and include nausea, vomiting, and bone marrow toxicity. Other agents used include Thiotepa, Mechlorethamine with or without tumor necrosis factor alpha, and Interferon gamma. Experienced academic institutions achieve high overall response rates (81% for heated ILP and 43% for ILI) and low mortality rates.[33] The procedure requires a hospital stay. Both these procedures may help shrink the tumor and improve patient's quality of life by controlling local pain that may not be possible with surgery. An overall survival benefit was not demonstrated in clinical trials that were largely conducted before the modern era of targeted therapies and immune checkpoint inhibitors. Although ILI use has largely fallen out of favor, it can be a useful option in select patients.[33]

KEY POINTS

- Completion lymph node dissection did not improve overall survival after a positive SLN biopsy specimen in two randomized clinical trials and is not considered standard of care for all patients with clinically occult stage III melanoma. Completion lymph node dissection decreases the incidence of regional lymph node recurrence and can be considered in select patients.
- For patients with clinical stage III melanoma (clinically palpable regional lymph nodes), neoadjuvant treatment approaches preferably containing combination immunotherapy is recommended. Total lymph node dissection with or without external

radiation therapy to the lymph node basin should be reserved for patients who are refractory to neoadjuvant treatment (ie, no pathologic response or minimal pathologic response) of the regional nodal basin.

- Although adjuvant radiation decreased the risk of in-field recurrence, there was no significant decrease in relapse-free survival or overall survival. Adjuvant radiation can be considered for select patients with a high risk for locoregional recurrence.

ROLE OF SYSTEMIC THERAPY IN THE ADJUVANT SETTING

ADJUVANT THERAPY FOR STAGE II MELANOMA

Historically, systemic adjuvant therapy for completely resected stage IIB/IIC disease consisted of high-dose interferon alpha-2b (IFN-alpha-2b). Given the frequent dosing schedule and high burden of toxicities in administering adjuvant high-dose IFN-alpha-2b, as well as the unclear overall survival benefit in stage IIB/IIC melanoma in the era of more effective and less toxic immune checkpoint inhibitors for stage III/IV melanoma, high-dose IFN-alpha-2b is no longer used in patients with high-risk stage II melanoma.

There are recently published phase 3 studies regarding the use of adjuvant immune checkpoint inhibitors (anti–PD-1 monotherapy) in patients with stage IIB/IIC melanoma that led to FDA approvals: one with pembrolizumab and the other with nivolumab (KEYNOTE-716 and CheckMate 76K, respectively).

The KEYNOTE-716 phase 3 trial randomly assigned 976 patients with completely resected stage IIB/IIC melanoma to pembrolizumab or placebo for up to 1 year. At a median follow-up of 20.9 months, patients receiving pembrolizumab had significantly prolonged relapse-free survival compared with patients receiving placebo (HR, 0.61; 95% CI, 0.45-0.82; median not reached for both).[34] This trial led to FDA approval in December 2021 of pembrolizumab as adjuvant treatment of adult and pediatric (age >12 years) patients with completely resected stage IIB/IIC melanoma. Longer-term follow-up at a median follow-up of 27.4 months showed that adjuvant pembrolizumab also significantly improved distant metastasis–free survival (HR, 0.64; 95% CI, 0.47-0.88; $P = .0029$) versus placebo.[35] Treatment-related grade 3 or worse toxicities were experienced by 17.2% of patients in the pembrolizumab arm, and immune-mediated adverse events were experienced by 37.7%.

Nivolumab also earned FDA approval for adjuvant therapy in resected, stage IIB/IIC melanoma based on the evidence of CheckMate 76K, which demonstrated superior relapse-free survival of nivolumab when compared with placebo (HR, 0.42: 95% CI, 0.30-0.59).[36] Treatment-related grade 3 or 4 adverse events occurred in 10.3% of patients who received nivolumab, including one treatment-related death (0.2%). The decision to pursue adjuvant therapy in a population with a high surgical cure rate should include a careful discussion of potential risks versus benefits, particularly when there is not yet evidence of an overall survival benefit (Fig. 16-3).

ADJUVANT THERAPY FOR STAGE III MELANOMA

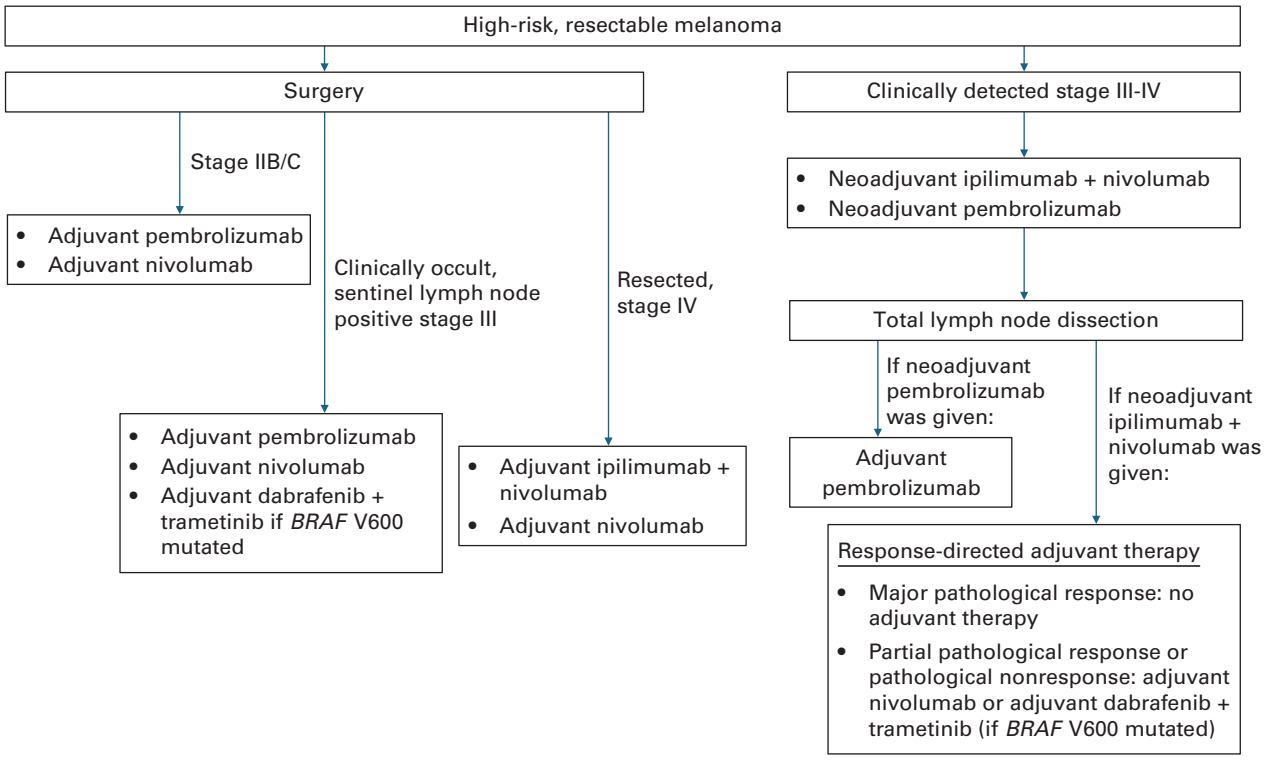
Seminal studies have also changed standard-of-care treatments for patients with stage III melanoma. All FDA-approved adjuvant therapies are administered for up to 1 year. Experimental drugs in most adjuvant clinical trials were tested in patients with stage III melanoma and compared against placebo, with the exceptions of CheckMate 238 and SWOG 1404. CheckMate 238 compared adjuvant nivolumab to adjuvant ipilimumab in patients with resected stage III and IV melanoma. SWOG 1404 compared pembrolizumab against either ipilimumab or high-dose IFN-alpha-2b in the adjuvant setting.[37,38]

Adjuvant pembrolizumab (200 mg administered intravenously every 3 weeks for 18 doses or 400 mg every 6 weeks) was approved based on KEYNOTE-054 showing relapsed-free survival benefit compared with placebo (HR, 0.56; 95% CI, 0.47-0.68). Similarly, adjuvant nivolumab (240 mg administered intravenously every 2 weeks or 480 mg every 4 weeks) gained FDA approval based on improved relapse-free survival compared with adjuvant ipilimumab (high dose; 10 mg/kg administered intravenously every 3 weeks for up to four doses and then every 12 weeks) for up to 1 year observed in CheckMate 238 (HR, 0.65; 95% CI, 0.51-0.83) (Fig. 16-3). With a minimum follow-up of 4 years (CheckMate 238), no overall survival benefit was observed in favor of nivolumab over ipilimumab.[39,40] Although a significant improvement in recurrence-free survival was observed with adjuvant pembrolizumab in SWOG 1404 (HR, 0.77; 95% CI, 0.59-0.99), there was again no significant difference in the primary endpoint of overall survival between pembrolizumab and adjuvant high-dose IFN-alpha-2b/ipilimumab at a median follow-up of 47.5 months.[39] It is unclear whether with longer follow-up in KEYNOTE-054, overall survival will be significantly improved by pembrolizumab (vs placebo).

If the longer follow-up studies in patients with anti–PD-1 adjuvant therapy show no overall survival benefit, such a finding might imply that patients could be equally effectively treated at the time disease recurs rather than with adjuvant therapy.

BRAF-directed adjuvant therapy of *BRAF*-mutated stage III cutaneous melanoma: In the COMBI-AD clinical trial, adjuvant dabrafenib (150 mg administered orally twice daily), a BRAF inhibitor, and trametinib (2 mg administered orally once daily), a MEK inhibitor, showed improved relapse-free survival compared with placebo in patients with stage III melanoma, leading to the FDA approval of this combination for patients with completely resected stage III *BRAF* V600–mutated melanoma (Fig. 16-3). The COMBI-AD trial had a minimum follow-up duration of 59 months and relapse-free survival HR, 0.51 (95% CI, 0.42-0.61).[41] As in studies of adjuvant immunotherapy, an overall survival difference was not observed to be statistically significant in the final

Figure 16-3 Perioperative Treatment Options for High-Risk, Resectable Melanoma



Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

10-year analysis of adjuvant BRAF/MEK inhibition in comparison with placebo (median follow-up 8.33 years; HR for death, 0.80; 95% CI, 0.62-1.01; $P = .06$).[42]

Adjuvant ipilimumab and nivolumab (attenuated dosing schedule) for cutaneous melanoma in stage IIIB-IIID compared with nivolumab monotherapy. In a large phase 3 randomized study (CheckMate 915) of resected stage IIIB to IIID melanoma, combination immunotherapy with attenuated dosing schedule of ipilimumab at 1 mg/kg every 6 weeks and nivolumab at 480 mg every 4 weeks versus nivolumab monotherapy at 480 mg every 4 weeks did not significantly prolong relapse-free survival.[43]

In patients with surgically resected stage IV melanoma without any evidence of disease, the role of systemic immunotherapy versus watchful observation was evaluated in IMMUNED, a phase 2, placebo-controlled trial. A total of 167 patients were randomly assigned (1:1:1) to receive ipilimumab and nivolumab at the FDA-approved dosing schedule (3 and 1 mg/kg, respectively, every 3 weeks for four doses; group A) versus nivolumab monotherapy (3 mg/kg every 2 weeks and ipilimumab-matching placebo during weeks 1-12; group B) versus double-matching placebo (group C). At a median follow-up of 28.4 months, the 1-year relapse-free survival rate was 75% for group A versus 52% for group B and 32% for group C. Both nivolumab-treated groups had significantly longer relapse-free survival compared with the placebo group (HR point estimate, 0.23 and 0.56, respectively). In the 2022 final analysis, overall survival was significantly improved in patients who received adjuvant ipilimumab/nivolumab (HR, 0.41; 95% CI, 0.71-0.99) in comparison with those who received placebo; no survival benefit over placebo was seen in the group receiving adjuvant nivolumab monotherapy (HR, 0.75; 95% CI, 0.36-1.56). Notably, the incidence of grade 3 to 4 treatment-related adverse events was 71% in the nivolumab and ipilimumab group and 29% in nivolumab alone.

IMMUNED is the only reported randomized trial in patients with stage IV melanoma with no evidence of disease to show that a nivolumab-based treatment is superior to observation for this patient population.[44]

In summary, given the higher clinical benefit and significantly lower toxicity of pembrolizumab, nivolumab, dabrafenib, and trametinib in the adjuvant setting, ipilimumab (at any dose) and high-dose IFN are no longer recommended as adjuvant therapy options. Recurrence-free survival and distant metastasis–free survival are significantly improved with pembrolizumab, nivolumab, dabrafenib, and trametinib, but overall survival benefit has not yet been observed. The role of ipilimumab and nivolumab in the adjuvant setting requires further study regarding the most appropriate dosing schedule, patient population, and toxicity profile versus clinical benefit, although a survival benefit in the resected stage IV setting has been observed. Certainly, given the increased incidence and severity of potential immune-related adverse events (irAEs) with combination ipilimumab and nivolumab compared with pembrolizumab or nivolumab monotherapy, the role of combination immunotherapy in the adjuvant setting remains to be investigated.

KEY POINTS

- Adjuvant pembrolizumab and nivolumab are FDA approved for patients with resected stage IIB/C melanoma because of improved relapse-free survival; however, the decision to pursue adjuvant therapy should include a careful discussion of risks and benefits.
- Combination dual targeted therapy with dabrafenib and trametinib (in *BRAF* V600–mutated disease), as well as nivolumab and pembrolizumab, is an adjuvant treatment option for patients with completely resected stage III melanoma based on improved relapse-free survival and reasonable tolerability.
- Active surveillance alone, without adjuvant therapy, is an equally acceptable option for patients with high-risk resected melanoma, given that there is no clear overall survival benefit with adjuvant anti–PD-1 monotherapy or adjuvant targeted therapy. The decision between treatment and observation requires shared decision-making between the patient and provider, including a detailed discussion of risk and potential benefit.
- Adjuvant ipilimumab and nivolumab at attenuated doses showed no clinical benefit in resected stage IIIB-IIID melanoma patients and is not a recommended adjuvant therapy of melanoma.
- The combination of nivolumab and ipilimumab in the adjuvant setting has shown overall survival benefit in the resected stage IV setting with a significantly higher immune-related adverse event rate than definitive treatment for stage IV melanoma.

NEOADJUVANT THERAPY

Neoadjuvant treatment approach of locally advanced cancer incorporates presurgical use of effective anti–cancer agent/agents as it is expected to shrink the tumor enabling complete surgical resection while reducing the risk of delayed tumor recurrence by eliminating systemic micrometastases. Historically, melanoma did not attract neoadjuvant treatment approaches due to the lack of effective systemic therapies to potentially transform a patient's melanoma from unresectable to resectable tumor. With the availability of effective treatment options of melanoma such as immune checkpoint inhibitors and BRAF-directed therapy for *BRAF*-mutated melanoma, trials to explore neoadjuvant treatment approaches became logical and received support. Additional advantages with neoadjuvant use of immune checkpoint inhibitor therapy of melanoma included expansion and activation of in situ tumor–exposed antigen-specific effector T cells and the opportunity to review available tumor tissue obtained at surgery offering several immune and histologic correlates as well as biomarkers of treatment response (or lack of) to help plan future treatments.

The potential risk of neoadjuvant treatment approaches includes tumor progression both locally or systemically if the tumor did not respond to the neoadjuvant treatment or if definitive surgery is delayed due to the management of toxicity from systemic therapy.

Patients with clinically detected stage III and resectable stage IV melanoma became ideal candidates to trial neoadjuvant approaches since this group of patients represent the high-risk population with poor long-term outcomes when treated with upfront surgery alone or with surgery, followed by adjuvant treatment.

Early neoadjuvant studies in melanoma enrolled modest sample sizes and were heterogeneous in design with regard to the type of neoadjuvant therapy, number of preoperative doses administered, and whether/what kind of adjuvant therapy was administered postoperatively. To show that pathologic response from neoadjuvant therapy correlated with clinical outcomes, data were pooled from six neoadjuvant clinical trials in clinical stage III melanoma for patients with nodal metastases who underwent definitive surgery as part of the International Neoadjuvant Melanoma Consortium. Of the 189 patients whose data were analyzed, 138 received immunotherapy, and 51 received targeted therapy. Despite differences between neoadjuvant immunotherapy and BRAF/MEK inhibitor therapy trials in terms of stage (IIIB vs IIIC), anatomic location of involvement (axilla vs groin), treatment duration of the neoadjuvant strategy, median time to surgery, and median follow-up after surgery, the incidence of complete pathologic response was high (37%-47%). Across all patients, 2-year relapse-free survival rates were higher for those who achieved complete pathologic response (89% vs 50%, respectively). Radiologic response had a moderate correlation with pathologic response; for example, 38% of patients who received immunotherapy and had stable disease by Response Evaluation Criteria in Solid Tumors (RECIST) preoperatively also had complete or near-complete pathologic response at the time of surgery.[45]

According to the International Melanoma Neoadjuvant Consortium recommendations, a 6- to 8-week duration of preoperative neoadjuvant therapy is recommended followed by surgery and possible use of additional adjuvant component postsurgery for a total duration of treatment of 1 year. However, assessment of pathologic response in the index lymph node (largest metastatic lymph node in the lymph node basin at the baseline) after initial preoperative treatment has been a reliable biomarker of response and determines postsurgery treatment.

Neoadjuvant immune therapy protocols include standard dose combined ipilimumab and nivolumab or altered dose ipilimumab (1 mg/kg) and nivolumab (3 mg/kg), single-agent anti–PD-1 agent either nivolumab or pembrolizumab, fixed-dose relatlimab and nivolumab or BRAF and MEK inhibitor agents in patients with *BRAF* mutation–positive melanoma where the upfront immune checkpoint inhibitor is not favored. Altered dose ipilimumab (1 mg/kg) and nivolumab (3 mg/kg) confer similar response rates, but the toxicity is lower compared to the standard dose of combined therapy and hence is the preferred treatment regimen.

Combined immune checkpoint inhibitor therapy with the standard dose confers high response rates but also high rates of immune-related adverse effects while single-agent anti–PD-1 agents confer lower response rate but lower risk of immune-related adverse events. The decision to choose upfront treatment depends upon patient conditions such as comorbidities and autoimmune disease history.

Typically, two cycles of combined immune checkpoint inhibitors or three cycles of single-agent anti–PD-1 agents were administered about 3 weeks later by surgical resection of the index lymph node or involved lymph node/nodes. Postsurgery treatment is decided by pathologic response and the status of systemic metastases as assessed by imaging studies.

Recent notable updates supportive of the clinical benefit of neoadjuvant therapy include the SWOG S1801 and NADINA trials.

SWOG S1801 was a phase 2 study that randomly assigned 313 patients with stage IIIB to resectable stage IVC melanoma to three doses of neoadjuvant pembrolizumab, followed by surgery and 15 doses of postsurgery adjuvant pembrolizumab (neoadjuvant-adjuvant group) or surgery, followed by pembrolizumab (200 mg intravenously every 3 weeks for a total of 18 doses) for approximately 1 year until disease recurred or unacceptable toxic effects developed (adjuvant-only group). The primary endpoint was event-free survival, defined as documented tumor progression rendering the patient unable to receive planned surgery, no initiation of pembrolizumab within 84 days of surgery, tumor relapse after surgery, or death resulting from any cause. With a median follow-up of 14.7 months, event-free survival was significantly higher with the neoadjuvant-adjuvant group compared with the adjuvant-only pembrolizumab group (Cox HR, 0.59; 95% CI, 0.40-0.86; one-sided log-rank P = .0015). The benefit of neoadjuvant over adjuvant therapy was consistent across age, sex, performance status, stage, LDH, ulceration, and BRAF status. Notably, the same proportion of patients made it through surgery to adjuvant pembrolizumab in both arms, and the rates of adverse events attributed to pembrolizumab or surgery were similar in both arms. The improved event-free survival in the neoadjuvant over the adjuvant arm is striking and provides strong rationale for the neoadjuvant approach.[2]

The NADINA study demonstrated further support for neoadjuvant immunotherapy. The rationale for the NADINA trial was based on analysis from the prior PRADO trial, which suggested that two doses of neoadjuvant ipilimumab 1 mg/kg and nivolumab 3 mg/kg may have significant clinical efficacy and that there may be an opportunity to personalize treatment after neoadjuvant immunotherapy based on the pathologic response.[46] In the NADINA trial, 423 patients with resectable (clinical), macroscopic stage III melanoma was randomized to either neoadjuvant ipilimumab (80 mg) and nivolumab (240 mg) every 3 weeks for two cycles or the adjuvant nivolumab group. Patients in both groups underwent TLND. Patients in the neoadjuvant group who had major pathologic response (≤10% residual viable tumor) did not receive any adjuvant therapy, and the patients who had either pathologic partial (11%-50% residual viable tumor) or nonresponse (>50% residual viable tumor) received additional 11 cycles of nivolumab or, if *BRAF* V600E or V600K mutated, received adjuvant dabrafenib and trametinib for 46 weeks. The primary endpoint was event-free survival, defined as disease progression to unresectable melanoma before surgery, melanoma recurrence, or melanoma or treatment-related death. After a median follow-up of 10.6 months in the neoadjuvant group and 9.9 months in the adjuvant group, event-free survival at 12 months was significantly longer in the neoadjuvant arm (83.7% vs 57.2%; HR, 0.32; 95% CI 0.15-0.66).[1] On pathologic review of surgically resected tissue, 59.0%, 8.0%, and 26.4% of patients treated with neoadjuvant ipilimumab and nivolumab had major, partial, and no response, respectively; 2.4% of patients had disease progression prior to surgery. The estimated recurrence-free survival at 12 months was 95.1% in patients with major pathologic response (importantly, these patients did not receive adjuvant therapy), 76.1% in patients with partial pathologic response, and 57.0% in patients with pathologic nonresponse. These results taken together with data from the SWOG S1801 trial have strengthened the rationale for a neoadjuvant approach in clinical practice for patients with clinically palpable/resectable, stage III-IV melanoma (Fig. 16-3).

Neoadjuvant-adjuvant relatlimab and nivolumab in clinical stage III and stage IV (M1a) melanoma: In a multi-institutional clinical trial, 30 patients with stages IIIB, IIIC, IIID, and IV (M1a) received neoadjuvant relatlimab 160 mg and nivolumab 480 mg for two cycles administered intravenously every 4 weeks (Q4W), followed by response assessment and surgery (at week 9) for evaluation of pathologic response. Postsurgery, patients received additional 10 adjuvant doses (total of 1 year) of relatlimab and nivolumab combination. A major pathologic response (complete pathologic response or near-complete responses) was seen in 63% patients. At a median follow-up of 24.4 months, 1- and 2-year event-free survival rates were 90% and 81%, respectively, and 1- and 2- year relapse-free survival rates were 97% and 82%, respectively. Patients with high pathologic responses showed higher rates of event-free and relapse-free survival with 1- and 2-year overall survival rates for all patients at 93% and 88%, respectively.[47]

KEY POINTS

- Neoadjuvant approach is relevant and effective in high-risk clinically palpable stage III and resectable stage IV melanoma.
- Status of pathologic response in an index lymph node helps determine the need for lymph node dissection and additional adjuvant treatment in high-risk stage III disease.
- Neoadjuvant and adjuvant pembrolizumab improved event-free survival compared with adjuvant pembrolizumab in a randomized phase 2 trial.
- In a phase 3 trial, neoadjuvant ipilimumab and nivolumab had superior event-free survival compared with adjuvant nivolumab. The patients who achieved major pathologic responses after two doses of neoadjuvant ipilimumab and

nivolumab did not receive adjuvant therapy and had an estimated 12-month recurrence-free survival of 95.1%, highlighting the potential role of pathologic response as a predictive biomarker to personalize adjuvant therapy.

- In a smaller multi-institutional study, neoadjuvant relatlimab and nivolumab regimen was found to be effective and safe option in melanoma patients with stages IIIB, IIIC, IIID, and IV (M1a) disease.

STAGE IV MELANOMA

BIOLOGY

Few studies with matched (ie, same patient) primary and metastatic melanoma tumors are available to investigate what makes advanced melanomas biologically distinct from their primary lesion. Beyond the well-described frequently mutated *BRAF, NRAS, PTEN, CDKN2A*, and *TP53* genes, infrequent mutations in a few other genes (eg, *RAC1* and *SPEN*) may have prognostic significance in metastatic melanoma.[48] Whereas important mutated oncogenes that are present early in melanoma development (eg, *BRAF* V600E and *NRASQ61*) are retained at a high frequency between primary and metastatic tumors in the same patient, other somatically mutated tumor suppressor genes (eg, *CDKN2A*) are more frequent in distant metastases. The finding that the *BRAF* V600E mutation is also present in metastases is the molecular basis for targeting a protein present in earlier stages of melanoma development, such as mutant *BRAF* V600.[13] Considerable intratumoral genetic heterogeneity of large metastatic melanoma lesions provides a molecular explanation for the lower responses seen with all systemic therapies in advanced melanomas with high tumor burden.[49]

Two reports that analyzed at least two metastatic melanoma tumors from the same patient, using gene expression profiling and targeted panel sequencing, showed that intertumoral (ie, molecular differences between different metastatic lesions) homogeneity and heterogeneity are both seen in advanced melanoma.[50] Molecular homogeneity between extracranial and intracranial metastases may account for concordance in extracranial and intracranial responses seen with combination ipilimumab and nivolumab administration in patients with active brain metastases (CheckMate 204).[51] Intratumoral heterogeneity (ie, molecular differences between different locations of the same tumor) is an adverse prognostic factor as well as a predictor of poor response to available systemic therapies. Epigenetic heterogeneity, which is not only driven by genetic aberrations but also influenced by physicochemical factors, such as pH, hypoxia, and cues derived from the metastatic organ-specific niche, is poorly understood at this time. The recent discovery of distinct bacteria in both melanoma and tumor-infiltrating immune cells and their association with response to immunotherapies adds another level of complexity to the intratumoral microbiome that may shape biologic behavior, prognosis, and response to systemic treatments.[52] Even more intriguing is the role of the gut microbiome as a predictor of response to PD-1/PD-L1 inhibitors.[53,54] Knowledge about the biology of metastatic melanoma has tremendous implications in the treatment approach to advanced melanoma, as discussed in the next sections.

SURGERY

In appropriately selected patients (eg, those with oligometastatic melanoma), curative-intent metastasectomy was a standard treatment option before 2010. Analysis of the SEER database for patients diagnosed with advanced melanoma between 1986 and 2006 (N = 4,229) showed that approximately one-third of patients underwent metastasectomy. These patients were usually younger and had more recently diagnosed advanced melanoma. Patients who underwent metastasectomy had longer overall survival compared with patients who did not undergo metastasectomy, irrespective of M1 substage (M1a vs all others). Selection bias to perform a metastasectomy was a limitation of the study. It also implied, however, that patients with oligometastatic melanoma might have an inherently better prognosis than patients with multiple distant metastases. A single-institution study conducted at the Royal Marsden Hospital NHS Foundation Trust showed that since 2011, there have been fewer excisions for in-transit melanoma and more abdominal metastasectomies.[55] Surgery continues to have a treatment role in selected patients with advanced melanoma, both for palliative intent and for disease control.

RADIATION THERAPY

Palliative management of melanoma metastases: hypofractionated radiation therapy (≥2.5 Gy per fraction) is a standard treatment option in the palliative care of patients with advanced melanoma who have symptomatic lesions (eg, pain, mass effect, hemorrhage, and bone destruction) that are not amenable or responsive to systemic treatment or surgery. Advances in imaging techniques, patient mobilization, and instrumentation have enabled radiation oncologists to provide even higher doses per fraction, sparing adjacent normal tissues from toxicity through a variety of radiation delivery methods (eg, external-beam radiation therapy, stereotactic radiosurgery, and intensity-modulated radiation therapy).

Radiation therapy in melanoma brain metastases: stereotactic radiosurgery should be considered in patients with limited parenchymal brain metastases who are candidates for systemic therapy with immune checkpoint inhibitor agents or BRAF-directed therapy in *BRAF* mutation–positive melanoma.

Adjuvant whole-brain radiation is not routinely recommended in newly diagnosed melanoma brain metastases. A phase 3 multicenter randomized trial of patients with melanoma brain metastases who had local treatment (surgery or stereotactic

radiosurgery) for one to three brain metastases showed that follow-up adjuvant whole-brain radiation therapy did not significantly improve distant intracranial failure compared with observation, and it was associated with earlier decline in performance status and higher toxicity.[56] Therefore, the use of whole-brain irradiation should be reserved for patients with refractory e central nervous system disease and for palliation in patients who fail standard treatment.

Concurrent administration of MAPK inhibitors with radiation therapy can significantly worsen radiation therapy–related toxicities; therefore, concomitant use of MAPK inhibitors and radiation therapy should be avoided.[57,58]

Radiation can induce immunogenic cell death, and the resulting release of tumor-associated antigens may expand anti–melanoma activity of immune checkpoint inhibitor-activated T cells. In small phase 2 trials, the combination of radiation and immune checkpoint inhibitors seemed to be well tolerated[59]; however, the synergism in the antitumoral effect of the two therapies is being further investigated in several clinical trials.

KEY POINTS

- Surgical resection can be considered in select patients with symptomatic melanoma brain metastases and for disease control (ie, oligometastatic disease) or with palliative intent.
- Systemic therapy with immune checkpoint inhibitor-based or BRAF-directed therapy in BRAF mutation–positive melanoma should be considered for primary treatment of melanoma brain metastases.
- Stereotactic radiosurgery is a standard palliative treatment option in advanced melanoma and can be considered for disease control in select patients with oligometastatic disease or limited central nervous system disease or when the tumor is inaccessible for surgery.
- Whole-brain irradiation did not reduce distant intracranial failure and was associated with earlier decline in performance status and hence not routinely recommended.
- Concurrent administration of MAPK inhibitors with radiation therapy worsens radiation therapy–related toxicities.
- Concurrent use of immune checkpoint inhibitor treatment and stereotactic radiosurgery of melanoma brain metastases is found to be safe in retrospective studies. However, optimal sequencing of immune checkpoint inhibitor treatment and radiation therapy is under clinical investigation in patients with melanoma brain metastases.

SYSTEMIC THERAPY FOR UNRESECTABLE/METASTATIC MELANOMA

Effective systemic treatments for advanced melanoma have prolonged overall survival and reduced melanoma-specific mortality over the last several years (Fig. 16-1). In 2010, there were only two systemic treatment options for advanced melanoma: dacarbazine and high-dose bolus interleukin-2 (IL-2). Since 2011, three treatment combinations targeting the MAPK signaling pathway (vemurafenib and cobimetinib, dabrafenib and trametinib, and encorafenib and binimetinib), five immune checkpoint inhibitors (ipilimumab, fixed combination of relatlimab and nivolumab, pembrolizumab, and atezolizumab), and one oncolytic virotherapy administered intratumorally (talimogene laherparepvec [TVEC]) have been FDA approved. In 2024, a first-in-class TIL therapy, lifileucel, was approved for patients who were refractory to anti–PD-1-based therapy, and BRAF/MEK inhibitors if *BRAF* mutated (Fig. 16-4). The increasing number of options has generated questions about their comparative safety and efficacy, optimal combinations and sequences, and rational combination with a growing number of investigational drugs currently in clinical development. The following sections elaborate on the essential data from pivotal clinical trials that led to the FDA approval of these drugs and provide recommendations regarding optimal use and sequence, as well as discussing mechanisms of resistance and the potential for rechallenge.

IMMUNOTHERAPY—T-CELL ACTIVATION

Historically, patients with metastatic melanoma exhibited spontaneous regressions of tumors, raising suspicion of anti–melanoma immune responses as an underlying mechanism of this clinical observation. Pathologic assessment of melanoma revealed tumor infiltration by numerous T lymphocytes (TIL) aiding the discovery of multiple melanoma antigenic epitopes used as vaccine candidates. In order to activate a T cell when presented with a tumor antigen, two signals are required:

- Signal 1. T-cell priming: First, the antigen is required to be presented by the antigen presenting cells (APC) in the tumor microenvironment at their MHC molecules (class 1 for CD8 and class 2 for CD4 T cells) to the T-cell receptors of T cells.
- Signal 2. T-cell activation: The binding of the costimulatory molecules between APC (CD80 and CD86) and T cell (CD28 molecule) brings the antigen on APC closest to the TCR on T cells resulting in transmission of signal to T-cell nucleus and activation of the T cell.

Successful transmission of the signal and T-cell activation results in the expansion of antigen-specific T cells, cytokine generation, and induction of T-cell memory against the presented tumor antigen.

The use of systemic therapies to augment host immune response to melanoma has been ongoing since at least the 1960s.[60] In retrospect, high-throughput and histopathologic analyses of cutaneous melanoma samples as part of The Cancer Genome

Atlas and other projects have explained the immunogenicity of this tumor in terms of the high somatic mutation burden, the aberrant expression of various melanoma-associated and other cancer/testis antigens, and the increased frequency of TILs.[16] Various cytokines, growth factors, and melanoma vaccines constituted the early immunotherapies that were tested in metastatic melanoma, with overall low success before the advent of immune checkpoint inhibitors.[60]

HIGH-DOSE IL-2

High-dose IL-2 was the second treatment to be FDA approved in advanced melanoma after dacarbazine in 1975. IL-2, previously known as T-cell growth factor, plays an essential role in T-cell survival, proliferation, and activation. High-dose IL-2 was approved in 1988 on the basis of the durability of antitumor responses (6% and 10% incidence of complete and partial responses, respectively) from several phase 2 non–randomized single-arm studies.[61,62] The median overall survival of 11.4 months was the new bar set for any new systemic treatments in advanced melanoma, and approximately two-thirds of patients who experienced complete responses following high-dose IL-2 treatment remained alive and progression free even decades after receiving therapy. Given the severe adverse effects of high-dose IL-2, its safe use is limited to select fit patients diagnosed with metastatic melanoma, and strict guidelines for its administration have been developed.[58] Use of high-dose IL-2 has largely been supplanted by use of immune checkpoint inhibitors, given their more favorable efficacy and toxicity profiles.

The identity of melanoma antigens and demonstration of antigen-specific T-cell responses following exposure of effector T cells to diverse melanoma antigens led to trial of therapeutic melanoma vaccines in humans. Although the concept was successful in mice, its results in humans were unpredictable and lacked efficacy. Also, elicitation of antigen-specific T-cell response following melanoma vaccination did not translate to clinical responses in patients.

Research showed that although effector T cells against melanoma are generated and documented, its therapeutic efficacy is compromised by T-cell expression of inhibitory molecules called checkpoints. T-cell checkpoints serve to prevent excessive inflammation and maintain immune homeostasis but remain a barrier to effective anti–cancer T-cell activity.

Cytotoxic T lymphocyte antigen 4 (CTLA-4) was the first T-cell checkpoint to be studied in mice blockade of which by a monoclonal antibody led to successful anti–melanoma T-cell effects. Ipilimumab was the first humanized monoclonal antibody against CTLA-4 that was tested successfully in melanoma patients and approved by the FDA for treatment of melanoma.

Additional T-cell checkpoint discovered on an activated effector T cell and responsible for interference with anti–tumor activity is the PD-1 molecule (programmed death-1) binding of which to the PD-L1 molecule expressed on tumor cells result in effector T-cell exhaustion. Reactivation of the effector T cell against melanoma has become successful with therapeutic use of monoclonal antibodies to PD-1 (nivolumab and pembrolizumab) or PD-L1 (atezolizumab) approved by the FDA in melanoma treatment.

IPILIMUMAB

MDX-020-010 was the first phase 3 randomized trial (N = 676) in advanced melanoma that tested the clinical benefit of ipilimumab (3 mg/kg administered intravenously every 3 weeks for up to four infusions) alone and in combination with an HLA-A*0201–restricted gp100 vaccine.[63] Both ipilimumab-treated arms had longer relapse-free survival and overall survival compared with the gp100 vaccine–treated arm. Although the median overall survival seen in the ipilimumab-treated arms from this trial was comparable with that seen with high-dose IL-2, the outpatient administration of the ipilimumab regimen every 3 weeks and its less severe acute toxicities compared with those of high-dose IL-2 broadened the use of ipilimumab to a far larger group of medical oncologists. Interestingly, a randomized trial of ipilimumab (10 mg/kg administered intravenously every 3 weeks for up to four infusions) versus lower-dose ipilimumab (3 mg/kg administered intravenously every 3 weeks for up to four infusions) for patients with advanced melanoma resulted in prolonged overall survival in favor of the high dose (median overall survival, 15.7 vs 11.5 months; HR, 0.84; 95% CI, 0.70-0.99) but at the expense of higher incidence of treatment-related toxicities (37% vs 18%).[63] Despite the higher clinical benefit of high-dose ipilimumab in stage IV melanoma and given the fact that this trial was conducted before the advent of PD-1 inhibitors, standard lower-dose ipilimumab remains the FDA-approved standard of care. Ipilimumab monotherapy is not recommended as standard first-line therapy because of the superiority of anti–PD-1 agents, as detailed in the next section.

PD-1 INHIBITORS

Pembrolizumab was the first PD-1 inhibitor to be approved by the FDA in September 2014 for ipilimumab-refractory advanced melanoma (and MAPK inhibitor–refractory advanced melanoma, if *BRAF* V600 mutated) on the basis of the results of the KEYNOTE-002 study.[64] Pembrolizumab was subsequently approved by the FDA as a first-line treatment of patients with advanced melanoma on the basis of results from the randomized KEYNOTE-006 trial (N = 834) that compared pembrolizumab (10 mg/kg administered intravenously either every 2 or every 3 weeks) versus ipilimumab (3 mg/kg administered intravenously every 3 weeks). Based on dosing data from KEYNOTE-002 and KEYNOTE-006, the FDA-approved dose of pembrolizumab was 2 mg/kg administered intravenously every 3 weeks. On the basis of pharmacokinetic analysis, dosing was subsequently updated to flat dosing of either 200 mg every 3 weeks or 400 mg every 6 weeks.

Nivolumab was FDA approved in December 2014 as a result of data from CheckMate 037, a randomized (2:1) study that compared the efficacy of single-agent nivolumab (3 mg/kg administered intravenously every 2 weeks) with investigator's choice of chemotherapy in a similar patient population to that enrolled in the KEYNOTE-002 study. The study met its primary endpoint of significantly higher durable antitumor responses with nivolumab.[65] Nivolumab was similarly approved in the first-line setting on the basis of the CheckMate 066 trial, a phase 3 randomized study of patients without *BRAF* V600 codon mutations. As part of this trial, nivolumab significantly prolonged progression-free survival and overall survival compared with dacarbazine.[65] Nivolumab also demonstrated an improved overall survival benefit over ipilimumab in the CheckMate 067 trial in the first-line setting. The dosing was subsequently updated to flat dosing of either 240 mg every 2 weeks or 480 mg every 4 weeks.

CTLA-4 AND PD-1 INHIBITOR COMBINATION

CheckMate 067 was tested in treatment-naive advanced melanoma patients, the efficacy and toxicity profile of the combination of ipilimumab (3 mg/kg) and nivolumab (1 mg/kg) every 3 weeks for four doses followed by nivolumab maintenance dosing at 3 mg every 2 weeks; nivolumab at a dose of 3 mg/kg every two weeks and placebo; or ipilimumab at 3 mg/kg dose every 3 weeks for four doses and placebo, until tumor progression, the occurrence of unacceptable toxic effects, or withdrawal of consent. Randomization was stratified by PD-L1 status, *BRAF* mutation status, and metastases stage. The two primary endpoints were progression-free survival and overall survival in the nivolumab and ipilimumab group and in the nivolumab groups versus the ipilimumab group.

At a minimum follow-up of 10 years from last patient random assignment, the median overall survival was 71.9 months with nivolumab and ipilimumab, 36.9 months with nivolumab, and 19.9 months with ipilimumab (the HR for death was 0.53 for nivolumab and ipilimumab as compared to ipilimumab and 0.63 for nivolumab as compared to ipilimumab).

Median melanoma-specific survival was more than 120 months with nivolumab and ipilimumab (not reached) compared to 49.4 months with nivolumab and 21.9 months for ipilimumab. Among patients who had been alive and progression free at 3 years, a 10-year melanoma-specific survival was 96% with nivolumab and ipilimumab, 97% with nivolumab, and 88% with ipilimumab. The 10-year melanoma-specific survival for combination ipilimumab and nivolumab, nivolumab alone, and ipilimumab alone was 52%, 44%, and 23%, respectively.[66] Of note, this study was powered to detect a difference between the ipilimumab and nivolumab arm versus the ipilimumab alone arm, not between the two nivolumab-containing arms. Post hoc analysis of the systemic treatments after exit from the trial showed that patients in the nivolumab alone arm received salvage ipilimumab-containing regimens more frequently than patients who were randomly assigned to the combination arm (28% vs 6%).[66] This implies that ipilimumab may potentially be a salvage treatment of patients who receive nivolumab alone, such that the overall survival may not be significantly different.

S1616, a phase 2 study, addressed this question by randomly assigning 92 patients at a 3:1 ratio who had primary resistance to first-line PD-1 blockade to receive either combination ipilimumab and nivolumab or ipilimumab alone. Patients in the

combination therapy arm had significantly longer progression-free survival (HR, 0.63; 90% CI, 0.41-0.97) and a greater objective response rate (28% vs 9%) compared with those receiving ipilimumab monotherapy. As expected, there was an increased incidence of grade 3 or worse toxicity (57% vs 35%) with the combination therapy. No difference in overall survival was observed; however, this study was not powered to detect a difference in overall survival.[67]

Therefore, this study supports the use of combination ipilimumab and anti–PD-1 in patients who experience progression with single-agent anti–PD-1 and suggests that primary resistance to PD-1 inhibitors can be reversed in select patients with dual CTLA-4 and PD-1 blockade. Caution must be exercised, nonetheless, because there was increased toxicity associated with the combination therapy, and its impact on overall survival remains unknown.

Flipped-dose regimen of nivolumab and ipilimumab was tested in CheckMate 511, a phase 3b/4 study comparing standard-dose ipilimumab and nivolumab (3 and 1 mg/kg, respectively) versus alternative doses of 1 mg/kg of ipilimumab and 3 mg/kg of nivolumab, often referred to as a flipped-dose regimen.[68] The study met its primary endpoint, which measured grade 3 to 5 treatment-related adverse events, and found a lower incidence of serious adverse events with the alternative doses (48% vs 34%; $P = .006$). This study was not powered to measure noninferiority for treatment efficacy outcomes.

PD-1 AND LAG-3 INHIBITOR COMBINATION

Although checkpoint inhibition with anti–CTLA-4 and anti–PD-1 agents have revolutionized treatment of patients with advanced melanoma, novel combinations are needed to optimize the risk/benefit profile of combination therapy.

LAG-3 is a negative regulator of T-cell activity and is upregulated in melanoma, among other tumor types. The RELATIVITY047 study tested a novel immune checkpoint inhibitor combination of relatlimab, a human immunoglobulin G4 LAG-3–blocking antibody, and nivolumab in a phase 2/3 randomized double-blind study. Treatment-naive patients ($N = 714$) were randomly assigned 1:1 to receive relatlimab and nivolumab in a fixed-dose combination of 160 and 480 mg every 4 weeks or nivolumab monotherapy at 480 mg every 4 weeks. At a median follow-up of 13.2 months, the median progression-free survival in the fixed relatlimab and nivolumab combination group was significantly prolonged as compared to nivolumab alone arm (10.1 vs 4.6 months; HR, 0.75; 95% CI, 0.62-0.92; $P = .006$). The toxicity profile of the combination was promising, with incidence of grade 3 to 4 treatment-related adverse events noted to be 18.9% in the combination arm and without unexpected safety signals (compared with a grade 3-4 treatment-related adverse event incidence of 59% with nivolumab and ipilimumab in CheckMate 067).[69] Updated data included a confirmed overall response rate of 43.1% (95% CI, 37.9-48.4) in the fixed-dose relatlimab and nivolumab combination arm versus 32.6% (95% CI, 27.8-37.7) in the nivolumab-only arm.[70] These results are the first from a phase 3 study showing clinical benefit of dual LAG-3 and PD-1 pathway inhibition. On the basis of these data, relatlimab and nivolumab in a fixed-dose combination were approved by the FDA in March 2022 for patients with previously untreated unresectable and metastatic melanoma.

TARGETED THERAPIES

BRAF represents a central oncogene of the MAPK signaling pathway that is critical for growth and differentiation of melanocytes and the most frequently mutated oncogene detected in about 50% of cutaneous melanoma patients. Single point mutation of the codon 600 (mostly V600 E) in exon 15 is the most frequently detected mutation accounting for about 70 to 88% of cases while V600K, V600R, and V600D make up for about 12% of cases.

Oncogenic *BRAF* mutations result in constitutive activation of the MAPK signaling pathway resulting in uncontrolled cellular proliferation and survival of melanocytes and is linked to the etiology and progression of melanoma. Although *BRAF*-mutated melanoma exhibits aggressive growth patterns and metastases, it offers opportunities for molecular therapy with agents targeting BRAF. However, resistance to BRAF inhibition eventually develops in the majority of patients.

Although not mutated, BRAF-independent hyperactivity is detected in the downstream MEK protein in patients harboring *BRAF* mutation promoting acquired resistance to BRAF inhibition treatment of melanoma. Combining BRAF with MEK inhibitors improved the progression-free and overall survival of *BRAF*-mutated cutaneous melanoma, indicating clinical relevance of enhanced inhibition of the MAPK signaling pathway.

Vemurafenib and dabrafenib were the first two BRAF inhibitors to be FDA approved for patients with *BRAF* V600–mutated advanced melanoma on the basis of results from the BRIM-3 and BREAK-3 phase 3 randomized studies, which tested each BRAF inhibitor against dacarbazine.[71,72]

Single-agent MEK inhibitors were clinically developed because direct inhibition of a downstream effector of an oncogenic protein, such as BRAF V600, adds clinical benefit to BRAF inhibitors, especially in distinct subgroups of patients with *BRAF* V600 mutation. In line with this, early clinical studies using single-agent MEK inhibitors showed that although MEK inhibition alone had activity in *BRAF* V600–mutated melanoma, all clinical endpoints (ie, antitumor responses, progression-free survival, and overall survival) seemed inferior to those obtained with single-agent BRAF inhibitors.[73] Part of the explanation for the inferior results is the inherent weakness of a drug that targets a downstream effector of an oncogenic protein, MEK, which is usually nonmutated in melanoma.[10] This, along with the essential physiologic role of MEK signaling in normal cells, makes dose escalation of even high-affinity MEK inhibitors challenging because of frequent toxicities.

COMBI-d, COMBI-v, and coBRIM were three phase 3 randomized clinical studies that tested the dabrafenib and trametinib combination (150 mg administered orally twice daily and 2 mg administered orally once daily, respectively) and the vemurafenib and cobimetinib combination (960 mg administered orally twice daily and 60 mg administered orally daily, respectively, on a 21-days-on, 7-days-off schedule) versus a single-agent BRAF inhibitor in patients with advanced *BRAF* V600–mutated melanoma. All three studies showed higher activity of the combination strategy over single-agent BRAF inhibition across all clinical endpoints (ie, relative risk, progression-free survival, and overall survival).[74-76] A landmark 4-year analysis of longer follow-up for COMBI-d and COMBI-v (N = 563) showed that approximately 34% of patients who received the dabrafenib and trametinib combination treatment were still alive at 5 years after treatment initiation, and approximately 13% remained free of progression.[77]

Combination encorafenib and binimetinib is the most recent FDA-approved BRAF/MEK inhibitor combination for *BRAF* V600–mutated melanoma. Encorafenib is a novel ATP-competitive inhibitor that binds its target at least 15 times longer than dabrafenib and vemurafenib (the dissociation half-life from the target for encorafenib was 30 hours; for dabrafenib, 120 minutes; and for vemurafenib, 30 minutes, in a biochemical assay). Binimetinib is a selective allosteric ATP-noncompetitive inhibitor of MEK1/2 with a shorter half-life than those of the other two FDA-approved MEK inhibitors. Paradoxically, concurrent administration of encorafenib and binimetinib allowed for higher dosing of encorafenib (450 mg administered orally once daily [E450]) compared with the maximum tolerated dose identified in the phase 1 study of encorafenib (ie, 300 mg administered orally once daily [E300]).

A phase 3 randomized study, COLUMBUS part 1, tested concurrent E450 and binimetinib (45 mg administered orally twice daily) against E300 and against vemurafenib alone (960 mg administered orally twice daily) in patients with *BRAF* V600–mutated BRAF inhibitor–naive advanced melanoma.[78] E450 and binimetinib showed a superior antitumor response, progression-free survival, and overall survival compared with vemurafenib alone. At 99.7-month follow-up, the median overall survival for the E450 and binimetinib combination was 33.6 months. When compared with E300, the E450 and binimetinib combination resulted in higher antitumor responses and significantly longer progression-free survival, but no significant difference in overall survival was observed.[79] A secondary analysis showed that E300 was superior to vemurafenib alone across all important clinical endpoints (ie, relative risk, progression-free survival, and overall survival).[78]

A number of phase 3 randomized studies are under way to address the question of whether PD-1/PD-L1 pathway inhibition in addition to BRAF/MEK inhibition results in superior clinical benefit compared with BRAF/MEK inhibition alone in patients with *BRAF* V600–mutated melanoma.

IMspire150 was the first of these studies to report on its progression-free survival endpoint, testing atezolizumab, an anti–PD-L1 antibody, and vemurafenib and cobimetinib combination against vemurafenib and cobimetinib combination alone as first-line therapy for patients with *BRAF* V600–mutated unresectable stage IIIC or IV melanoma[80]; this resulted in FDA approval of this triplet therapy. Patients (N = 514) were randomly assigned 1:1 to each arm. At a median follow-up of 18.9 months, the addition of atezolizumab significantly prolonged the median progression-free survival compared with vemurafenib and cobimetinib combination alone (15.1 vs 10.6 months; $P = .025$). The addition of atezolizumab did not significantly increase the incidence of grade 3 to 4 adverse events compared with vemurafenib and cobimetinib combination alone (79% vs 73%, respectively). Other triplet combination trials (COMBI-I, a phase 3 study of spartalizumab, dabrafenib, and trametinib combination compared with placebo, dabrafenib, and trametinib combination; KEYNOTE-022, a phase 2 study of pembrolizumab, dabrafenib, and trametinib combination) have shown negative results with regard to their primary endpoint of progression-free survival, emphasizing the importance of longer follow-up to assess whether the triplet combination significantly prolongs overall survival parameters.

There are no FDA-approved targeted treatments for patients with somatic mutations other than *BRAF* V600. Of note, melanomas with mutations other than non–*BRAF* V600 comprise 50% to 60% of cutaneous melanomas.[9] A high proportion of melanomas in this group have hotspot mutations in the *NRASQ61* codon (15%-20%). Constitutive activation of RAS, a signaling molecule upstream from RAF proteins, involves more than one signaling pathway, in contrast to BRAF V600, which predominantly dysregulates a single pathway (ie, MAPK).[9] Several approaches have indirectly targeted constitutively activated NRAS by blocking distinct downstream signaling pathways, such as the MAPK pathway.

NEMO was a phase 3 randomized (2:1) study that tested the efficacy of binimetinib (45 mg administered orally twice daily) compared with dacarbazine (1,000 mg/m^2 administered intravenously every 3 weeks) in patients with advanced *NRASQ61*-mutated melanoma. Although the study met its primary endpoint, showing that binimetinib significantly prolongs progression-free survival compared with dacarbazine, the difference (2.8 vs 1.5 months) was not clinically meaningful; furthermore, no overall survival difference was observed.[81] The results emphasize the challenges when the target cannot be directly pharmacologically inhibited; therefore, the alternative approach of blocking only one of the several downstream effectors of RAS signaling does not lead to a meaningful clinical benefit.

ADOPTIVE CELL THERAPY

TILs represent an adoptive cell therapy in which tumor-resident T lymphocytes are harvested from a patient's tumor for ex vivo expansion for intravenous infusion after lymphodepleting chemotherapy. After the transfer of cells to the patient, IL-2 is administered to induce the growth of TILs in vivo and promote their antitumoral activity. The clinical activity of TILs in melanoma was first reported in 1994 by Rosenberg et al.[82] More recently, lifileucel, a one-time autologous TIL therapy, was evaluated in the

C-144-01 study. In this non–comparative phase 2 trial, lifileucel achieved an objective response rate of 31.4%, with eight complete responses and 40 partial responses in patients with unresectable or metastatic melanoma who had experienced progression with anti–PD-1 therapy.[3] With a median follow-up of 27.6 months, the median progression-free and overall survival were 4.1 and 13.9 months, respectively. Based on these findings, lifileucel became the first TIL product to gain FDA approval in February 2024; this therapy is indicated for adult patients with advanced melanoma for whom PD-1 blocking antibody therapy or, if *BRAF* V600 mutation–positive, therapy with a BRAF inhibitor with and without a MEK inhibitor has failed. With a 5-year follow-up, the median duration of response was 36.5 months, and 31.8% of the responses were ongoing at the 5-year assessment demonstrating a clinically meaningful durability of lifileucel.[83] Recently, a Dutch randomized phase 3 trial compared a regionally distributed TIL product against ipilimumab at 3 mg/kg as first- or second-line treatment.[84] 168 patients (84 in each arm) with stage IIIC or IV melanoma were randomized in a 1:1 ratio to receive TIL or Ipilimumab. Infusion of at least 5×10^9 TILS was preceded by non–myeloablative lymphodepleting chemotherapy consisting of cyclophosphamide and fludarabine, followed by high-dose interleukin-2. The primary endpoint was progression-free survival. In 86% of patients who were refractory to anti–PD-1 therapy, this TIL product demonstrated significant improvement in median progression-free survival (7.2 vs 3.1 months; HR, 0.50; 95% CI, 0.35-0.72). A phase 3 trial is under way to examine the efficacy and safety of lifileucel in combination with PD-1 blockade in the first-line setting for unresectable or metastatic melanoma (ClinicalTrials.gov identifier NCT05727904).

TALIMOGENE LAHERPAREPVEC

TVEC is a type 1 herpes simplex virus that has been genetically modified to attenuate viral pathogenicity (through deletion of the neurovirulence factor ICP34.5) in favor of greater immunogenicity through insertion and expression of the gene encoding for the human granulocyte-macrophage colony-stimulating factor. In line with an immune-mediated mechanism of action, analysis of TVEC-injected and non–injected distant lesions from patients with melanoma showed that TVEC was able to break local immune tolerance in the microenvironment of injected lesions by suppressing regulatory T cells and myeloid-derived suppressor cells and activating melanoma antigen-specific effector T cells. The effect of TVEC in distant non–injected melanoma lesions was also present but was much weaker.

A phase 3 randomized (2:1) study tested the clinical benefit of intralesional TVEC injections versus systemic granulocyte-macrophage colony-stimulating factor injections for patients with lesions 1 cm or larger amenable to direct or ultrasonography-guided injection. In this heterogeneous patient group (IIIB-M1c), incidence of antitumor responses lasting at least 6 months was significantly higher in patients in the TVEC-treated arm compared with those in the systemic granulocyte-macrophage colony-stimulating factor–treated arm (19.3% vs 1.4%). At a median follow-up of 49 months, both the median time to treatment failure and overall survival were significantly longer in the TVEC-treated arm as opposed to the granulocyte-macrophage colony-stimulating factor–treated arm. From these results, the FDA-approved TVEC for patients with unresectable stage IIIB to IV melanoma.[85]

This drug has since been evaluated in combination with various immune checkpoint inhibitors. Despite promising early trial results, the phase 3 MASTERKEY-265 study that randomly assigned patients with advanced melanoma to TVEC and pembrolizumab versus pembrolizumab monotherapy did not show a progression-free survival benefit in the combination arm. Although there was a 5.8-month numeric difference in progression-free survival between arms favoring the combination arm, the results were not statistically significant (HR, 0.86; 95% CI, 0.71-1.04; $P = .013$). Furthermore, no difference in overall survival was observed.[86]

CHEMOTHERAPY

Before 2010, cytotoxic chemotherapy, along with high-dose IL-2, was a mainstay in the treatment of advanced melanoma. After the initial FDA approval of dacarbazine in 1975, subsequent trials using combination chemotherapy regimens or biochemotherapy did not show any overall survival benefit, although higher toxicity rates were reported.[87] European Organisation for Research and Treatment of Cancer (EORTC) 18,032 tested the efficacy and toxicity of escalated-dose temozolomide (150 mg/m^2 once daily for 7 days, followed by 7 days off) against those of standard-dose dacarbazine (1,000 mg/m^2 administered intravenously every 3 weeks) in patients with advanced melanoma. No significant differences in progression-free survival or overall survival were seen between the two arms. However, antitumor responses were significantly higher with temozolomide compared with dacarbazine (14.5% vs 10%).[88] Although the FDA never approved temozolomide for the treatment of advanced melanoma, the convenience of administering a pill over an infusion, the ability of temozolomide to better penetrate the blood-brain barrier, and the significantly higher antitumor responses with temozolomide favor its use in patients whose quality of life may depend on antitumor response.

At present, chemotherapies are primarily used as salvage treatment in patients whose disease has progressed with immunotherapies or targeted therapies (if *BRAF* V600 mutated) and who are not eligible for clinical trial participation, although early data suggest that the clinical benefit is small.[89]

KEY POINTS

- Dual checkpoint blockade is the preferred first-line immunotherapy treatment option in unresectable/advanced melanoma.

- Concurrent ipilimumab and nivolumab should be considered for patients with small asymptomatic central nervous system metastases; both topics are discussed later in the chapter.
- Four phase 3 randomized clinical studies in patients with *BRAF* V600–mutated metastatic melanoma have shown significant progression-free survival and overall survival benefits favoring concurrent BRAF/MEK inhibition compared with a single-agent BRAF inhibitor.
- Oncolytic viral therapy such as TVEC represents a reasonable option to control local tumor in selected patients and showed superior responses lasting at least 6 months when compared to the granulocyte-macrophage colony-stimulating factor-treated arm. However, its combination with anti–PD-1 agent did not improve progression-free or overall survival.
- Lifileucel, a one-time autologous TIL therapy, is approved by the FDA for patients with anti–PD-1 refractory melanoma and can have clinically meaningful durable effect.
- Although systemic chemotherapy is not recommended as a first-line treatment of melanoma, it may be used in selected clinical scenarios as a bridge to future treatments.

ROLE OF SYSTEMIC TREATMENT IN THE MANAGEMENT OF MELANOMA BRAIN METASTASES

Historically, the mainstay of treatment of melanoma brain metastases included consideration for upfront surgery and/or stereotactic radiation therapy. Since the approval of immune checkpoint inhibitors and molecularly targeted therapy options, results of several phase 2 trials have shown that systemic therapy can achieve meaningful intracranial (as well as extracranial) responses.

Targeted therapy has intracranial activity in patients with *BRAF* V600–mutated melanoma, demonstrating intracranial response rates of 25% to 40% with BRAF inhibitor monotherapy and up to 58% with combined BRAF and MEK inhibition.[90-95]

Immune checkpoint inhibitors have shown activity against melanoma brain metastases as well, with intracranial response rates of 24% with ipilimumab alone,[96] approximately 20% with anti–PD-1 monotherapy,[97] and greater than 55% with combination nivolumab and ipilimumab.[51]

CheckMate 204 results were practice changing in solidifying combination nivolumab and ipilimumab as standard of care for the treatment of a select group of patients with melanoma metastatic to the brain. CheckMate 204 was a phase 2 single-group study designed to investigate the efficacy and safety of treating patients with untreated melanoma brain metastases with combination nivolumab and ipilimumab at standard dosing (1 and 3 mg/kg, respectively); patients were eligible if they were neurologically asymptomatic, had an Eastern Cooperative Oncology Group performance status (ECOG PS) of 0 to 1, were not receiving steroids, and presented with intracranial metastases measuring no larger than 3 cm in diameter.[51] This study met its primary endpoint of intracranial clinical benefit rate; longer-term results for the original asymptomatic cohort (cohort A) of CheckMate 204, at a median follow-up of 34.3 months, confirmed an intracranial clinical benefit rate (percentage of patients with stable disease for at least 6 months, partial response, or complete response) in 58 (57.4%; 95% CI, 47.2-67.2) of 101 patients in cohort A.[98] Results were also reported for a smaller cohort of symptomatic patients (cohort B) with an ECOG PS of 0 to 2 who could receive low-dose dexamethasone. An intracranial clinical benefit was observed in only three (16.7%; 95% CI, 3.6-41.4) of 18 patients in cohort B. For patients in cohort A, the 36-month intracranial progression-free survival and overall survival rates were 54.1% (95% CI, 42.7-64.1) and 71.9% (95% CI, 61.8-79.8), respectively. For patients in cohort B, the 36-month intracranial progression-free survival and overall survival rates were 18.9% (95% CI, 4.6-40.5) and 36.6% (95% CI, 14.0-59.8), respectively.

In the ABC clinical trial, an open-label randomized phase 2 study, patients diagnosed with asymptomatic, treatment-naive melanoma brain metastases (ECOG PS 0-2) were randomized to receive intravenous ipilimumab 3 mg/kg and nivolumab 1 mg/kg every 3 weeks for four doses, then nivolumab 3 mg/kg every 2 weeks (cohort A), or nivolumab 3 mg/kg every 2 weeks (cohort B). A third cohort, C, included patients with previous brain-directed treatment, symptomatic brain metastases, or those with leptomeningeal disease assigned to receive nivolumab 3 mg/kg dose. The primary endpoint was best intracranial response (complete or partial response) from week 12. Secondary survival endpoints included intracranial progression-free survival and overall survival. Out of 79 eligible patients enrolled into the study, 36 patients were assigned to cohort A, 27 patients to cohort B, and 16 patients to cohort C. At a median follow-up of 7.6 years, the overall intracranial response occurred in 18 patients (51%) of cohort A, five (20%) from cohort B, and one (6%) from cohort C. The 7-year intracranial progression-free survival was 42%, 15%, and 6% in cohorts A, B, and C, respectively. The 7-year overall survival was 48%, 26%, and 13%, respectively, in cohort A, B, and C, respectively.[99]

In an Italian multicenter study of asymptomatic melanoma brain metastases patients, patients (age 18 years or above, ECOG status 0-1, asymptomatic brain metastases measuring between 5 and 20 mm, a life expectancy of more than or equal to 12 weeks) were randomized 1:1:1 to fotemustine 100 mg/m^2 (arm A) or ipilimumab 10 mg/kg and fotemustine 100 mg/m^2 (arm B), or ipilimumab 3 mg/kg and nivolumab 1 mg/kg (arm C). Treatment was continued until progressive disease, unacceptable toxicity, or patient refusal. The primary endpoint was overall survival; the secondary endpoint was progression-free survival, best overall response, and duration of response. Surveys for health-related quality of life were collected at weeks 1, 4, 7, 12, 24, and 36 and at end of treatment using the EORTC Quality of life Questionnaire (QLQ)-C30 V.3 and the QLQ-Brain neoplasm (BN20).

At a median follow-up of 67 months, the median overall survival was 8.5, 8.2, and 29.2 months for arm A, B, and C, respectively. The 7-year overall survival was 10%, 10.3%, and 42.8% in arm A, B, and C, respectively.

Quality of life was preserved in all three arms. Most functional scales evaluated from baseline to week 12 were preserved, with a lower mean score for EORTC QLQ-C30 and an increase for EORTC QLQ-Brain neoplasm (BN20) in patients receiving ipilimumab and nivolumab.

Although data directly comparing nivolumab and ipilimumab with combinations of BRAF/MEK inhibitors in patients with *BRAF* V600–mutated melanoma brain metastases are lacking, intracranial responses have been shown to be more durable in patients with asymptomatic parenchymal brain metastases who were treated with nivolumab and ipilimumab as opposed to dabrafenib and trametinib; disease in patients with *BRAF* V600–mutated melanoma who receive concurrent dabrafenib and trametinib tends to relapse earlier in the brain as opposed to at extracranial sites.[51,92]

Understanding that *BRAF*-mutated melanoma can behave more aggressively and that symptomatic patients with melanoma brain metastases specifically harbor poor prognosis, the TRICOTEL study results are particularly notable. This single-arm phase 2 study was designed to have two cohorts: a *BRAF* wild-type cohort and a *BRAF* V600–mutated cohort. Patients in the *BRAF* wild-type cohort received atezolizumab and cobimetinib. Patients in the *BRAF* V600 mutation–positive cohort received atezolizumab with oral vemurafenib and oral cobimetinib. The *BRAF* wild-type cohort was closed early; however, the intracranial objective response rate was 42% (95% CI, 29-54) by independent review committee assessment in the *BRAF* V600 mutation–positive cohort and 27% (95% CI, 8-55) by investigator assessment in the wild-type cohort.[100] Survival data with longer follow-up are required to better assess the effect of the combination of atezolizumab, vemurafenib, and cobimetinib in this population.

The question of concordance between intracranial and extracranial responses has also been explored. Overall, intracranial antitumor responses are similar to same-patient extracranial antitumor responses and are overall higher in patients who receive either combination targeted therapies or immunotherapies.[51,89-91,94] The similar response seen in extracranial and intracranial disease is supported by translational studies showing that same-patient intracranial and extracranial lesions are biologically similar.[50]

It is important to note, however, that the clinical benefit for patients with leptomeningeal disease or with symptomatic parenchymal brain metastases was disappointingly low, irrespective of whether concurrent BRAF/MEK blockade, single-agent PD-1 inhibitors, or combination PD-1 and CTLA-4 inhibitors were administered.[98]

Overall, data from these studies have provided evidence to support upfront systemic therapy in a select population of patients with metastatic melanoma to the brain. Asymptomatic patients who do not require urgent local treatment with surgery or stereotactic radiation therapy for small central nervous system metastases (<3 cm) can be treated with ipilimumab and nivolumab, with a high rate of durable intracranial response. However, close monitoring is required for early detection of progressing brain metastases, which would require surgery or stereotactic radiation therapy.

KEY POINTS

- Patients with small untreated asymptomatic parenchymal brain metastases can be safely and effectively treated with concurrent ipilimumab and nivolumab, without local surgery or radiation therapy.
- Intracranial responses are durable in patients with asymptomatic parenchymal brain metastases treated with concurrent ipilimumab and nivolumab; the combination of dabrafenib and trametinib results in less durable intracranial responses.
- The care of patients with symptomatic melanoma brain metastases remains challenging. Coordination of multidisciplinary care, including expertise in surgery and radiation therapy, is recommended for this population.

TOXICITIES FROM SYSTEMIC TREATMENTS IN ADVANCED MELANOMA

Immune checkpoint inhibitor treatment and toxicity: Immune checkpoint inhibitors can result in a novel class of toxicities called immune-related adverse effects or irAEs. These toxicities mimic autoimmune diseases in their clinical presentation; however, both diagnosis and treatment of irAEs differ from those of their naturally occurring autoimmune counterparts. ASCO, the European Society for Medical Oncology, the Society for Immunotherapy of Cancer, and the National Comprehensive Cancer Network have published clinical practice guidelines for the management of immune-mediated adverse events in patients treated with immune checkpoint inhibitors.[101] These guidelines provide recommendations for specific organ-based toxicities. Similar guidelines exist for the management of toxicities from high-dose IL-2.[62]

Overall incidence of serious treatment-related adverse events increases with combination versus single-agent immunotherapy (Table 16-2); the incidence was 55.4% versus 9.9% in a pooled analysis from all phase 3 trials that tested single-agent nivolumab versus standard-dose ipilimumab and nivolumab (3 and 1 mg/kg, respectively).

The timing and number of treatment-related adverse events have been associated with overall response rates to immunotherapy; higher response rates were associated with longer time to adverse event development (>12 vs ≤12 weeks from treatment initiation) and more adverse events (one or more vs no adverse events).[102] A lower dose of ipilimumab (1 mg/kg), compared with the FDA-approved dose of 3 mg/kg, concurrently administered with PD-1 inhibitors significantly reduced serious adverse

events in patients with advanced melanoma in two studies, KEYNOTE-029 and CheckMate 511. However, in both studies, clinical outcome was not a primary study endpoint.[103,104] The use of ipilimumab at 1 mg/kg in combination with PD-1 blockade is not a currently approved regimen.

Table 16-2 Incidence and Timing of Organ-Specific Adverse Events From Combination Therapy With Ipilimumab and Nivolumab Versus Nivolumab Alone

	Median Onset (weeks; %)	
Affected System	**Combination Therapy**	**Single-Agent Nivolumab**
Skin	2; 64	5; 33
Gastrointestinal	5; 47	7.3; 14
Hepatic	6.1; 29	7.7; 4
Endocrine	7.4; 30	10.4; 8
Pulmonary	10.6; 8	8.9; 2
Renal	10.2; 4	15.1; 2

A detailed medical history and clinical examination followed by appropriate laboratory tests and imaging studies help diagnosis of irAEs. Attention to severity of adverse events graded using Common Terminology Criteria for Adverse Events (CTCAE) on a scale from 1 to 5 (1 = mild, 2 = moderate, 3 = severe, 4 = life threatening, and 5 = death related to toxicity) (National Cancer Institute, 2009) offers effective approach to treatment. Clinical judgment of patient symptoms often complements an objective grading system in managing irAE. Steroids are the cornerstone of immune suppressive treatment of irAEs with biologic agents reserved in specific clinical circumstances.

With expanded use of immune checkpoint inhibitor therapy and growing body of clinical experience of irAEs, there was an increasing need felt to develop a common terminology to describe heterogeneity of natural history, clinical patterns, and response to treatment.

The Society for Immunotherapy of Cancer (SITC) convened expert panel offers such guidance that may be used in managing irAE in patients. This includes terminology for:

- Natural history: onset of irAE such as acute versus chronic (persisting beyond 3 months), delayed onset (occur more than 3 months after immune checkpoint inhibitor treatment), recurrent irAE—occurring in the same organ at least twice after discontinuation of immune checkpoint inhibitor treatment.
- Patterns of irAEs: such as multisystem irAEs occurring in the same or different organ system or occurring concomitantly with another irAE or during treatment for the first irAE.
- Response to steroids: such as steroid-responsive versus steroid-unresponsive irAE, steroid-resistant irAEs or steroid dependent irAEs.

irAEs are generally reversible with corticosteroids and other immunosuppressive agents, with the exception of endocrinopathies. Corticosteroid doses and tapers vary by toxicity but generally are initially dosed between 1 and 2 mg/kg and are continued until toxicities diminish to grade 1 or lower, after which a taper should occur over 4 to 6 weeks.[101] Autoimmune endocrinopathies, such as immune-mediated hypothyroidism and/or adrenal insufficiency (primary or secondary), can be managed with hormone replacement therapy. Grade 3 toxicities generally warrant suspension of immune checkpoint inhibitors. For grade 4 toxicities (with the exception of endocrine-related toxicities that are controlled with appropriate therapy), permanent discontinuation is generally recommended. Steroid-refractory gastrointestinal irAEs may require infliximab or vedolizumab treatment, whereas steroid-refractory hepatic adverse events may require mycophenolate mofetil, budesonide, azathioprine, or tacrolimus.

Discontinuation of immunotherapy because of treatment-related toxicity did not significantly diminish treatment efficacy in a pooled analysis of phase 2 and 3 trials using concurrent ipilimumab and nivolumab.[105] Resumption of anti–PD-1 alone in patients who experienced high-grade toxicity with combination PD-1 and CTLA-4 blockade was often well tolerated, although 18% had recurrent toxicities, and another 21% had onset of distinct toxicities.[106] Rechallenge with anti–PD-1 after cessation for toxicity resulted in a 30% to 50% rate of recurrent toxicities.[107-110] Patients with preexisting autoimmune disorders who were treated with PD-1 inhibitors frequently experienced a flare of their underlying autoimmune disorder; the type of flare was usually an exacerbation of their preexisting symptoms that could be managed with corticosteroids as opposed to an extension of their underlying autoimmune disorder. Although response rates were comparable to those in patients without preexisting autoimmune diseases (ie, 33%), patients receiving immunosuppressant therapy had a lower frequency of response compared with those not receiving immunosuppressants (15% vs 44%).[106]

Steroid use has improved outcomes of irAE in patients, but the decisions about its dose and duration require consideration of affected organ and grade of irAE. Inadequate dosing of steroids results in relapse of irAE while indiscriminate and excessive dose of steroid may adversely affect clinical outcome in patients.[107,108]

A small proportion of immune-related toxicities may be fatal. An international multicenter pharmacovigilance database from seven centers demonstrated a 0.6% fatality rate from immunotherapy. Colitis and myocarditis were the most common causes of death resulting from combination CTLA-4/PD-1 inhibition, and pneumonitis, hepatitis, and neurotoxicities were the most common reasons for fatality resulting from anti–PD-1 monotherapy.[107,111] Classes of irAEs with the highest rates of mortality include myocarditis, neurotoxicities (eg, Guillain-Barre syndrome, myasthenia gravis, aseptic meningitis, encephalitis, and transverse myelitis), and pneumonitis.[107,111] The overlap syndrome of myocarditis, myositis, and myasthenia gravis, sometimes called triple M or triple M overlap syndrome (TMOS), has particularly high fatality rates, with estimates of up to 60% mortality in those who develop this presentation.[54]

Targeted therapy of melanoma and toxicity: Targeted therapy has a more consistent toxicity spectrum; however, there are class-specific differences in treatment-related toxicities between combinations of BRAF and MEK inhibitors (Table 16-3). Irrespective of the choice of doublet therapy, common adverse events of any grade include nausea (30%-41%), diarrhea (24%-36%), skin rashes (23%-39%), fatigue (29%-32%), and arthralgias (24%-32%). Uncommon adverse events associated with MEK inhibitors that warrant careful and timely assessment are cardiac toxicity (decreased left ventricular ejection fraction), ocular toxicity (central serous retinopathy due to fluid accumulation in the retina and may increase risk of serous neuroretinal detachment, retinal vein thrombosis, uveitis, and conjunctivitis), pulmonary toxicity (interstitial lung disease and pneumonitis), and fever.[73] Within each drug class, there are differences in the incidence of certain adverse events. For example, vemurafenib tends to cause diarrhea, transaminitis, photosensitivity, secondary nonmelanoma skin cancers, and hypertension more frequently than the other BRAF inhibitors. Encorafenib not only tends to cause vomiting, alopecia, palmar-plantar erythrodysesthesia, and myalgias more frequently than dabrafenib or vemurafenib but also tends to cause photosensitivity, fatigue, and pyrexia less frequently. Trametinib not only tends to cause rash, dry skin, and alopecia more frequently than binimetinib but also can cause acneiform dermatitis, peripheral edema, nausea, vomiting, and serum creatinine kinase elevation less frequently. The treating physician must have a balanced discussion with the patient regarding the specific adverse events of each drug, given that certain options may be more favorable for some patients than for others. Pretreatment assessment of cardiac function, ophthalmologic exam, and assessment of lung function is recommended with close clinical monitoring of symptoms and surveillance of toxicity in patients. Concurrent treatment with BRAF and MEK inhibitors has toxicity profiles distinct from either agent as monotherapy.

Table 16-3 Differences in Treatment-Related Adverse Effects of Any Grade Between Combinations of BRAF Inhibitors and MEK Inhibitors

Adverse Effect	BRAF Inhibitors (%)	MEK Inhibitors (%)
Diarrhea	12-34	40-43
Alopecia	26-37	17 (trametinib only)
Palmar-plantar erythrodysesthesia	14-47	NR
Hyperkeratosis	29-39	NR
Skin papilloma	9-18	NR
Secondary nonmelanoma skin cancer	9-18	NR
Photosensitivity	4-30	NR
Fatigue	26-35	22-26
Headache	19-26	NR
Arthralgia	27-45	NR
Myalgia	22-27	NR
Acneiform dermatitis	3-4	19-36
Peripheral edema	5	26-36

Abbreviation: NR, not reported.

Irrespective of the treatment combination, certain adverse events warrant particular attention, such as pyrexia, decreased left ventricular ejection fraction, hypertension, and QTc prolongation. Pyrexia (≥38°C) can occur in more than 50% of patients in the early course of combined treatment with dabrafenib and trametinib (median time to onset, 19 days), can last longer than 1 week (median duration, 9 days), and can recur. Early treatment can involve non–steroidal anti-inflammatory drugs and hydration;

however, high-grade and prolonged pyrexias may require the use of dose interruption and systemic corticosteroids. Excellent reviews regarding the optimal management of other adverse events in patients who receive MAPK inhibitors are available.[112] Knowledge about class-specific, drug-specific, and regimen-specific adverse events is key to the selection of the most appropriate doublet therapy and the decision of whether to interrupt, modify, or reduce the dose or even switch to another doublet if toxicity, but not disease progression, is the issue.

KEY POINTS

- Toxicities from immune checkpoint inhibitors are generally reversible with dose suspension and use of corticosteroids and/or other immunomodulatory agents. The exception is endocrine toxicities, which may require permanent hormone replacement. For serious adverse events, suspension or discontinuation of immune checkpoint inhibitors is recommended.
- Discontinuation of immunotherapy because of severe adverse events has not been shown to affect overall clinical benefit.
- Physicians should be aware of drug- and class-specific adverse events of the three currently FDA-approved BRAF/MEK combinations (vemurafenib and cobimetinib, dabrafenib and trametinib, and encorafenib and binimetinib), as well as appropriate dose reductions, delays, or even treatment discontinuations, if necessary.

SEQUENCING OF THERAPY, INITIAL TREATMENT SELECTION, AND STOPPING OF THERAPY

After the approval of immunotherapy and BRAF/MEK inhibitors for frontline therapy in advanced, unresectable melanoma, a major question in the field was the sequencing of therapy for patients with *BRAF* V600–mutated melanoma. The DREAMseq ECOG-ACRIN EA 6134 study has provided the first prospective data regarding clinical outcomes in this patient population.[113,114] This phase 3 trial randomly assigned treatment-naive patients with *BRAF* V600–mutated metastatic melanoma to first-line therapy (step 1) with nivolumab and ipilimumab (arm A) or dabrafenib and trametinib (arm B). At disease progression, patients enrolled in step 2 and received the alternative therapy of dabrafenib and trametinib (arm C) or nivolumab and ipilimumab (arm D), respectively. At the time of the fourth interim analysis (59% of patients being 2 years from enrollment), available data led the data safety monitoring committee and National Cancer Institute Cancer Therapy Evaluation Program to recommend halting accrual and releasing data. The 2-year overall survival rate significantly improved for those starting with combination immunotherapy (arm A) was 72% (95% CI, 62%-81%) compared with 52% for those starting with targeted therapy (arm B) (95% CI, 42%-62%; log-rank $P = .0095$). Progression-free survival showed a trend in favor of arm A (log-rank $P = .054$). The objective response rates in each arm were 46% (52 of 113 patients) for arm A, 43% (49 of 114 patients) for arm B, 48% (11 of 23 patients) for arm C, and 30% (8 of 27 patients) for arm D. The final update with nearly 5 years of follow-up confirmed the superior overall survival for patients with *BRAF* V600–mutated metastatic melanoma receiving nivolumab and ipilimumab first-line compared with those receiving the treatment sequence beginning with dabrafenib and trametinib with nearly doubling of the overall survival rate (63.3% vs 33.9%, $P \leq 0.01$).[115] Thus, combination immunotherapy is preferred over targeted therapy in the first-line setting for stage IV *BRAF* mutant melanoma.

Another question is whether first-line concurrent PD-1/CTLA-4 blockade should be a universal strategy for any patient with advanced melanoma or whether PD-1/LAG-3 blockade is sufficient. The optimal upfront combination regimen should consider patient preferences and perceptions about the severity of life-threatening treatment-related toxicities, total tumor burden, requirement for a prompt response if tumor volume and location of metastatic tumors (eg, CNS) cause life-threatening symptoms, and overall performance status. Although a combination immunotherapy regimen is favored as the first-line treatment of patients with metastatic melanoma, single-agent anti–PD-1 therapy may be considered as an alternative treatment option when the risks of irAE is high, or in those who decline combination treatment, if the patient has oligometastatic disease (low burden/small volume disease and 1-2 organ involvement), normal LDH, PD-L1 expressive melanoma, and good performance status of 0-1. In these clinical scenarios, single-agent anti–PD-1 treatment has comparable outcomes as combined immune checkpoint inhibitor treatment with lower risks of irAE.

Once secondary resistance to MAPK inhibitors develops, rechallenge after several months after the end of initial MAPK inhibitor treatment can be beneficial. A multicenter retrospective analysis of patients (N = 116) who had previously received MAPK inhibitors and whose disease subsequently progressed showed that rechallenge with MAPK inhibitors was associated with a high antitumor response rate (42%). Of interest, responses on rechallenge were usually higher in patients who had longer intervals between the first treatment and rechallenge.[116]

PD-1 inhibitors may result in long-lasting durable responses after stopping treatment. An analysis of patients who received at least one dose of pembrolizumab as part of the phase 1 pembrolizumab study (KEYNOTE-001; N = 655) and stopped treatment after a complete response after 2 years (n = 67) showed that responses were durable after stopping.[117] Less is known about outcomes after rechallenging patients with metastatic disease progression whose disease had previously responded to PD-1 inhibitors, but treatment was stopped; however, patients can respond again after resuming immunotherapy.

KEY POINTS

- In treatment-naive patients with advanced *BRAF* V600–mutated melanoma, intermediate-term data show significantly improved overall survival for those who start with nivolumab and ipilimumab and then switch to dabrafenib and trametinib at the time of disease progression rather than the reverse treatment sequence.
- Although anti–PD-1 monotherapy remains a first-line option, the decision to treat with single or dual checkpoint blockade (PD-1/CTLA-4 vs PD-1/LAG-3) should be individualized on the basis of risk for immune-related toxicities, tumor burden, central nervous system disease status, performance status, tumor-associated symptoms, and patient preference.
- Immunotherapy can result in durable complete responses after stopping therapy. Treatment discontinuation of immunotherapy should be discussed with patients who have a confirmed complete response.

PRESENTING CASE STUDY

A 59-year-old woman with past medical history significant for hypertension and type 2 diabetes mellitus presents to her dermatologist for an "ugly mole" on her left forearm that has been getting larger in the past 3 months. It began to intermittently bleed 1 month ago, prompting a visit to a dermatologist. A shave biopsy demonstrated a nodular melanoma with a Breslow depth of 3.4 mm without ulceration, four mitoses per mm^2, and positive deep margins. She is referred to surgical oncology for excision, and further evaluation reveals a 3.5-cm palpable, enlarged left axillary node. A core needle biopsy of the lymph node is consistent with melanoma. She has no prior personal or family history of skin cancer or autoimmune disease. The patient's Eastern Cooperative Oncology Group performance status is 0.

Based on the information gathered from the skin and lymph node biopsies, what are your next steps to complete staging? What other information about this patient's melanoma would have potential treatment implications?

This patient's melanoma is at least stage IIIB (pT3aN1bMx) based on the Breslow depth, absence of ulceration, and clinically detected regional lymph node involvement. The first step would be to complete staging with chest, abdominal, and pelvic CT with intravenous contrast (or PET/CT) and brain MRI with and without intravenous contrast. Tumor testing for *BRAF* should be performed to assess for *BRAF* V600E/K mutation.

The result of the molecular test performed on tumor for *BRAF* V600E/K mutation status are positive for *BRAF* V600E.

Scenario 1

There is no evidence of distant spread on imaging. How does this finding affect your choice of next steps?

Neoadjuvant-adjuvant immunotherapy demonstrated improved event-free survival compared to adjuvant-only immunotherapy in clinically detected, resectable stage III melanoma; therefore, a neoadjuvant approach, followed by surgical resection should be considered for this patient. One option is neoadjuvant pembrolizumab monotherapy (200 mg) for 9 weeks (3 cycles), followed by total lymph node dissection per SWOG 1801. All patients would receive 15 cycles of postoperative adjuvant pembrolizumab. For this patient, a more preferrable approach could be combination neoadjuvant immunotherapy with ipilimumab (80 mg) and nivolumab (240 mg) for 6 weeks (2 cycles), followed by total lymph node dissection per the NADINA trial. In this option, the decision for adjuvant therapy is guided by pathologic response. Patients who achieve major pathologic or complete response (≤10% residual viable tumor) would be allowed to omit adjuvant therapy. Patients who have partial or no pathologic response (≥11% residual viable tumor) would receive either adjuvant nivolumab for 44 weeks (11 cycles) if *BRAF* wild type or adjuvant dabrafenib and trametinib daily for 46 weeks if *BRAF* V600E/K mutated.

Scenario 2

Three pulmonary nodules and two hepatic lesions, all measuring between 1 and 3 cm in size, suspicious of metastases, are discovered on preoperative staging. Biopsy of the liver lesion confirms metastatic melanoma. How would your choice of treatment differ from the first scenario?

Combination immunotherapy with standard-dose ipilimumab (3 mg/kg) and nivolumab (1 mg/kg) or nivolumab and relatlimab should be considered in the frontline setting for this patient. Of note, there may be a select group of patients

for whom anti-PD-1 monotherapy is appropriate based on their disease status, comorbidities, performance status, and preference. For patients with *BRAF* V600E/K-mutated melanoma, including the patient for this particular case study, combination immunotherapy is still the preferred upfront therapy rather than BRAF/MEK inhibitor therapy based on the results of DREAMSeq and SECOMBIT trials, which showed superior overall survival in patients who received immunotherapy before switching to BRAF/MEK inhibitor therapy at progression compared to patients who started with BRAF/MEK inhibitor therapy before switching to immunotherapy at progression.

SURVIVORSHIP

The number of melanoma survivors living in the United States has increased over the last few years (Fig. 16-1). As of 2022, cutaneous melanoma is the second and fourth most common tumor among male and female survivors, respectively.[118] Patients with previously diagnosed cutaneous melanoma have a 1% to 8% lifetime risk of developing another invasive melanoma. Melanoma survivors also tend to be diagnosed with nonmelanoma skin cancers more frequently. Patients with lymphedema had significantly lower scores on a majority of health-related quality-of-life measures. Younger patients reported financial issues, ranging from poor performance at work requiring a career change to financial difficulties associated with the cost of lymphedema therapy, whereas young men and women reported worse social functioning and poorer body image scores. Female long-term melanoma survivors had a higher frequency of fatigue, nausea, insomnia, appetite loss, and constipation. In the modern era of immunotherapy and targeted therapy, survivorship care must include management of long-term and chronic adverse effects, which are characteristic, in particular, of immunotherapy-based regimens.[119]

MELANOMA IN OLDER ADULTS

Of patients diagnosed with cutaneous melanoma, 30.7% are older than the age of 60 years.[120] In fact, the gradual increase in cutaneous melanoma incidence over the last 20 years shown in Figure 16-1 is predominantly attributable to men older than 70 years and to a lesser extent to women older than 70 years.[121] Older men have significantly higher cutaneous melanoma incidence and mortality rates than older women. Cutaneous melanoma occurring in patients older than 60 years is biologically and clinically different from the cutaneous melanoma occurring in younger patients. Melanoma in older adults usually has greater Breslow thickness of invasion, has a lower incidence of positive SLNs, and is less frequently of the superficial spreading melanoma histologic subtype. The incidence of positive SLNs is lower in older patients. Melanomas in older adults have a higher incidence of somatic mutations of the UV radiation signature type, implying chronically sun-damaged skin. In this patient population, *BRAF* V600K and *NRASQ61* mutations are more frequently seen. Despite the under-representation of older patients with melanoma in the pivotal studies that led to the FDA approval of various systemic treatments, older patients respond at least as well as younger patients and do not experience worse toxicities.[122] Nevertheless, the incidence of severe adverse events from targeted therapies tends to be higher in older than in younger patients. Data are mixed regarding whether the incidence of irAEs from checkpoint inhibition changes with age,[123,124] although generally, cancer-related outcomes are similar in older and younger patients.[125]

In the treatment of older patients with advanced melanoma, geriatric assessments may be considered to determine the level of fitness and, therefore, eligibility for the potentially higher-risk higher-benefit combined-modality treatment. In cases of oligometastatic melanoma, upfront surgery (ie, metastasectomy), if possible, is a reasonable approach as an attempt to delay initiation of systemic treatments, given the possibility of their administration for the patient's remaining lifespan and their association with adverse events. Overall, immunotherapy is relatively safe to use in this cohort; however, further research is warranted to understand optimal decision-making.[126]

NONCUTANEOUS MELANOMA

EPIDEMIOLOGY AND RISK FACTORS

Although most prevalent in the skin, melanocytes can be found in other organs of the body and can give rise to noncutaneous melanomas. Noncutaneous melanomas comprise 5% of all melanomas. Approximately 3% to 5% are uveal, and the remaining 1% to 2% are mucosal. Mucosal melanomas represent a heterogenous disease based on primary anatomic origin, which include head and neck (55%; conjunctival, sinonasal, and oropharyngeal), anorectal (24%), and vulvovaginal (18%) areas.

HISTOPATHOLOGY, BIOLOGY, AND PROGNOSIS

Mucosal Melanoma

Oncogenic *BRAF* and *NRAS* mutations are less frequent in mucosal melanomas (6.4% and 13.8%, respectively) than in cutaneous melanomas, although the incidence of *KIT* mutations is higher; these tumors have a much lower somatic mutation burden than cutaneous melanoma.[127] Two large mucosal melanoma cohorts from Germany (N = 444) and China (N = 706)[128] have provided significant insight into the prognostic significance of various histopathologic factors. These cohorts showed that the depth of the

primary lesion, number of positive regional lymph nodes, and sites of distant metastases are important prognostic factors for overall survival.

Uveal Melanoma

The human adult choroid tissue does not have the classic lymphatic system drainage seen in other tissues. The transformation of choroidal melanocytes to melanoma leads to two possible uveal melanoma subtypes with respect to their propensity to metastasize distantly. These two types are classified as low risk (class 1) or high risk (class 2) for metastatic disease by gene expression profiling.[129] DecisionDx-UM (Castle Biosciences) is a commercially available 15-gene expression profiling diagnostic assay used for risk stratification in uveal melanoma. Another independent biomarker that was identified was *PRAME* expression, and the combination of the 15-gene expression profile and *PRAME* status has been validated in a multicenter prospective study as an integrated prognostic test for uveal melanoma.[130] Risk stratification can aid clinically in tailoring the frequency/modality of long-term surveillance in this patient population.[130]

Activating mutations in any of the two G-protein pathway–associated *GNAQ* and *GNA11* genes are present in a majority of uveal melanomas and are thought to be early events in tumorigenesis. Genetic aberrations of BAP1, an enzyme that removes single ubiquitin moieties from various substrates, including histones, are associated with the more aggressive class 2 type.[131] Gene expression analysis of 80 uveal melanomas as part of The Cancer Genome Atlas project has also shown low (ie, <15%) incidence of tumors bearing T cells expressing immune exhaustion markers. These molecular characteristics have provided the basis for several clinical trials, as discussed next in the "Treatment" section.

Once uveal melanoma becomes metastatic, the prognosis is poor, with the median overall survival ranging between 11.3 and 13.4 months.[132,133] Multivariable analysis has shown that ECOG PS of 1 or higher, high serum LDH level, and short time from primary tumor diagnosis to metastasis are poor prognostic factors for survival.

TREATMENT

Mucosal Melanoma

Management of this rare subtype often requires a multidisciplinary approach. Resection of the primary lesion with negative surgical margins is an important prognostic factor and can be curative in select cases. The utility of SLN mapping is controversial. Lymph node dissection is considered if there is clinical or radiologic evidence of nodal involvement. Postoperative radiotherapy can reduce the risk of local-regional recurrence and is considered in high-risk disease (close and positive margins, multifocal lesions, or extracapsular extension); however, it has not affected the rate of distant metastasis or overall survival.[134-136] There is a paucity of data for adjuvant immunotherapy in resected mucosal melanoma. An international retrospective study included 55 patients with resected mucosal melanoma who completed adjuvant anti–PD-1 therapy and found no statistical difference in recurrence-free survival (HR, 1.36; 95% CI, 0.69-2.68), distant metastasis–free survival (HR, 0.53; 95% CI, 0.24-1.17), or overall survival (HR, 1.1; 95% CI, 0.45-2.65) when compared with the matched historical cohort.[137] Adjuvant nivolumab and ipilimumab was tested in the multicenter phase 2 single-arm SALVO trial. Thirty-five patients with resected mucosal melanoma who received ipilimumab at 1 mg/kg and nivolumab at 3 mg/kg (flipped-dose regimen) for 4 cycles every 3 weeks, followed by maintenance nivolumab had 2-year recurrence-free survival and overall survival rates of 37% and 68%, respectively.[138]

The prognosis for patients with metastatic mucosal melanoma is poor. Even though the treatment for metastatic mucosal melanoma is largely extrapolated from randomized trials for cutaneous melanoma, the efficacy of immunotherapy in mucosal melanoma is consistently suboptimal compared to cutaneous melanoma. In a pooled analysis of six clinical trials that recruited patients with advanced mucosal melanoma, treatment with combination ipilimumab and nivolumab, nivolumab alone, and ipilimumab alone showed objective response rates of 37.1%, 23.3, and 8.3%, compared to 60.4%, 40.9%, and 21.2% for cutaneous melanoma.[139] This finding was supported by a large, international retrospective study which reported that a single-agent anti–PD-1 and or combination PD-1 and CTLA-4 blockade may result in antitumor response rates of 29% and 31%, respectively.[140] The decreased efficacy of conventional immunotherapies may be, in part, explained by the lower tumor mutation burden, lower rates of oncogenic driver mutations, and decreased PD-L1 positivity seen in these tumors.

Prospective studies have been mostly conducted in China, where there is an increased prevalence of mucosal melanoma. In a phase 2 trial, 114 Chinese patients with previously untreated advanced mucosal melanoma were randomly assigned to carboplatin and paclitaxel with bevacizumab or carboplatin and paclitaxel alone.[141] The addition of bevacizumab moderately improved the median progression-free survival (4.8 vs 3.0 months; HR, 0.461; 95% CI, 0.306-0.695) and overall survival (13.6 vs 9.0 months; HR, 0.611; 95% CI, 0.407-0.917). More recently, combination anti–PD-1 and antiangiogenic therapies were examined in two separate prospective single-arm studies in China. Both combination toripalimab (anti–PD-1 antibody) and axitinib (a vascular endothelial growth factor receptor inhibitor) and atezolizumab and bevacizumab regimens achieved an objective response rate of 45% to 48%, a median progression-free survival of 8.0 to 8.2 months, and a 1-year overall survival rate of 62.1% to 76.0% in Chinese patients with unresectable or metastatic mucosal melanoma.[142,143] Despite these promising results, these combinations remain investigational. Currently, a phase 2 study exploring the efficacy of a combination of anti–PD-1 therapy and a vascular endothelial growth factor receptor inhibitor in the United States is in progress (NCT05384496).

KIT-targeted therapies have been investigated in melanomas bearing *KIT* genetic aberrations, including the mucosal subtype. In a 25-patient phase 2 study, imatinib (400 mg administered orally once daily) was associated with a 21% incidence of confirmed antitumor response rates. All responses occurred in patients with mutations as opposed to gene amplifications. However, most responses were short (median time to progression, 3.7 months), and the median overall survival was 12.5 months.[144]

Uveal Melanoma

Historically, enucleation had been the standard-of-care treatment of select patients with uveal melanoma. The Collaborative Ocular Melanoma Study is the largest trial of patients (N = 1317) with uveal melanoma to address whether local radiation therapy is noninferior to eye enucleation. Patients with no evidence of metastatic disease were randomly assigned to eye-preserving[133] I-plaque radiation therapy versus enucleation; there was no difference in melanoma-specific overall survival.[145]

Molecular assays have enabled better identification of patients at high risk of distant metastatic uveal melanoma. Adjuvant clinical trials in this high-risk group are under way; at this time, only results from non–randomized single-arm studies are available.

Metastatic uveal melanoma has a poor prognosis. A single-institution retrospective analysis of 521 patients who were diagnosed with metastatic uveal melanoma and observed until 2011 showed poor overall survival, irrespective of whether the patient received treatment (median overall survival, 6.3 vs 1.7 months, respectively).[146] In a selected patient population, adoptive cell therapies have shown proof-of-principle efficacy, suggesting that immunotherapies can have a role in this aggressive disease.[147] Retrospective studies have shown the overall response rate of metastatic uveal melanoma to combination nivolumab and ipilimumab to be low (11.6%),[148] although higher than with single-agent PD-1/PD-L1 therapy (3.6%).[149] An increased benefit of combination immunotherapy was confirmed by two phase 2 prospective single-arm multicenter studies in patients with metastatic uveal melanoma, showing that concurrent CTLA-4/PD-1 blockade was associated with a clinical benefit inferior to that seen in cutaneous melanoma and mucosal melanoma.[150,151] Despite advances in knowledge about the biology of uveal melanoma, little clinical benefit has been demonstrated so far with targeted therapies, including MEK inhibitors.[152,153]

The first FDA-approved drug for metastatic uveal melanoma, tebentafusp, is a first-in-class bispecific fusion protein. This engineered T-cell receptor therapeutic detects the gp100 peptide presented by HLA*02:01, with the other end fused to an anti-CD3 chain that binds and activates T cells. The phase 3 IMCgp100-202 trial randomly assigned 378 patients (2:1) to tebentafusp versus investigator's choice of therapy (pembrolizumab, ipilimumab, or dacarbazine), with a primary endpoint of overall survival. A recent update with a median follow-up of 36 months showed that the median overall survival was 21.6 months for the tebentafusp arm versus 16.9 months for the investigator's choice arm (HR, 0.68; 95% CI, 0.54-0.87).[154] Tebentafusp was FDA approved for HLA-A*02:01–positive patients with unresectable or metastatic uveal melanoma in January 2022.

Liver-directed therapies can be considered for patients with liver-dominant or isolated metastatic uveal melanoma. The FOCUS trial evaluated the efficacy of HEPZATO, a percutaneous hepatic perfusion (PHP) with melphalan, in a phase 3 multicenter study of 144 patients with unresectable metastatic uveal melanoma predominantly in the liver.[155] Although this study began as a randomized trial, the control arm of best alternative care (investigator's choice of transarterial chemoembolization, pembrolizumab, ipilimumab, or dacarbazine) was stopped after accruing 42 patients because of enrollment concerns, and 59 patients were then added to the PHP arm only. Melphalan at 3 mg/kg ideal body weight, infused into the hepatic artery every 6 to 8 weeks for up to six total infusions, demonstrated a superior objective response rate (35.2% vs 12.5%; $P = .0154$) and median progression-free survival (9.03 vs 3.12 months; $P = .0007$) when compared with the control arm. The median overall survival was numerically improved in the PHP arm (20.53 vs 14.06 months) compared with best alternative care but has yet to fully mature. Subsequently, isolated hepatic perfusion with melphalan in patients with isolated uveal melanoma liver metastases showed similar clinical benefit, with an improved objective response rate (40% vs 4.5%, $P < .0001$) and median progression-free survival (7.4 vs 3.3 months, $P < .0001$), against investigator's choice of treatment in the phase 3 randomized SCANDIUM trial.[156] PHP with melphalan gained FDA approval for liver-directed therapy for patients with liver-dominant uveal melanoma in August 2023; however, its availability is restricted to programs participating in the HEPZATO KIT Risk Evaluation and Mitigation Strategy (REMS) because of the risk of periprocedural complications, including hemorrhage, thromboembolic events, and liver injury.

KEY POINTS

- Noncutaneous melanomas account for 5% of all melanomas and consist of uveal and mucosal melanomas.
- *KIT* mutations are more frequent in mucosal melanomas compared with cutaneous melanomas; the incidence of oncogenic *BRAF* and *NRAS* mutations is low.
- A commercially available 15-gene expression profile (DecisionDx-UM) and *PRAME* RNA expression were validated in a prospective study as an integrated prognostic biomarker for uveal melanomas based on their propensity to metastasize and melanoma-specific survival. Genomic information assists in tailoring surveillance plans for patients after definitive treatment of their uveal melanomas.[130]
- *GNAQ* and *GNA11* mutations are present in a majority of uveal melanomas and are thought to be early events in tumorigenesis; genetic aberrations of *BAP1* are associated with the more aggressive class 2 type.

- A novel bispecific fusion protein, tebentafusp, is the first T-cell receptor therapeutic drug developed and the first drug to significantly improve overall survival in patients with metastatic uveal melanoma who are positive for HLA*02:01. Tebentafusp has been FDA approved for HLA-A*02:01–positive patients with unresectable or metastatic uveal melanoma.
- Combination ipilimumab and nivolumab is associated with higher response rates in both uveal and mucosal melanomas compared with single-agent PD-1 inhibitors; however, the clinical benefit from immunotherapy is much lower in these rare subtypes when compared with cutaneous melanoma.

NONMELANOMA SKIN CANCERS

Nonmelanoma skin cancer can arise from any skin cell subtype. BCCs and CSCCs comprise nearly 99% of nonmelanoma skin cancers and are by far the most frequently diagnosed skin cancers. Less common (1%) skin cancer types include MCC, Kaposi sarcoma, cutaneous lymphoma, skin adnexal tumors, and various types of sarcomas (eg, carcinosarcoma and fibrosarcoma). Approximately 5.4 million BCCs and CSCCs are diagnosed each year in the United States, affecting 3.3 million Americans; an increase in diagnoses and treatments represents an increasing public health challenge.

BCC, CSCC, and MCC share common risk factors (Table 16-4), such as high UV radiation exposure, skin phototype (low Fitzpatrick skin type), male sex, advanced age, and immunosuppression. In MCC, Merkel cell polyomavirus also plays a pathogenic role. Several histopathologic analyses across the three nonmelanoma skin cancers have detected a high incidence of PD-1–positive lymphocytes that infiltrate PD-L1–expressing tumors; these studies have established the translational rationale for the successful use of PD-1/PD-L1 pathway inhibitors in each of these three cancers.[157-159] Because of the high frequency of these cancers and the increasing costs of diagnostics and treatments, considerable research on chemoprevention is ongoing. Apart from large public health care campaigns to encourage the use of broad-spectrum (UV radiation types A and B) sunscreens and adoption of sun-safe practices, large randomized clinical trials have identified a handful of chemopreventive agents that reduce the incidence of skin cancer development compared with standard-of-care practices, but those agents still have not been incorporated into routine clinical use.[160,161]

Table 16-4 **Important Characteristics of the Three Most Frequent Nonmelanoma Skin Cancers**

Characteristic	Squamous Cell Carcinoma	Basal Cell Carcinoma	Merkel Cell Carcinoma
New diagnoses	>1 million per year	Approximately 4.3 million per year	Approximately 2000 per year
Cell origin	Stem cells in the hair follicle bulge and basal layer of interfollicular epidermis	Undifferentiated $CD200^+$ basal cells of the hair follicle outer root sheath	Merkel cells in the basal epidermal layer of skin
Precursor lesion	Solar keratosis, Bowen disease, and keratoacanthoma	Not known	Not known
Risk factors	UV radiation exposure, skin phototype, ionizing radiation, chronic wounds/scars, immunosuppression, HPV infection, smoking, and genetic defects in DNA repair	UV radiation exposure, tanning bed use, skin phototype, male sex, age >50 years, immunosuppression, and basal cell nevus syndrome	UV radiation exposure, skin phototype, age >70 years, male sex, immunosuppression, and MCPyV
Biology	High somatic mutation burden (*TP53, NOTCH1/2/4, CDKN2A*, and *EGFR*), high degree of PD-1–positive tumor-infiltrating lymphocytes	Mutations in *PTCH1*, smoothened homolog, high degree of PD-1–positive tumor-infiltrating lymphocytes	Low somatic mutation burden if MCPyV positive, high somatic mutation burden if MCPyV negative, high degree of PD-1–positive tumor-infiltrating lymphocytes
Prevention	Broad-spectrum sunscreens, nicotinamide, and acitretin	Broad-spectrum sunscreens, nicotinamide, and calcipotriol + 5-fluorouracil	Broad-spectrum sunscreens
Propensity to metastasize, %	41[162]	0.0029-0.55[163]	33[164]
Median OS, if distant metastatic	2.2 years[165]	24.1 months[166]	12-17.2 months[167,168]

Abbreviations: HPV, human papillomavirus; MCPyV, Merkel cell polyomavirus; OS, overall survival.

Newly diagnosed CSCC and BCC can be stratified on the basis of relapse risk and metastatic potential according to the National Comprehensive Cancer Network guidelines. Large size (>20 mm for trunk and extremities and 10 mm for face), poorly defined borders, prior recurrence, immunosuppression, and poor histology are associated with a high risk of relapse and distant metastasis. In cases of CSCC and MCC, which have a higher propensity for metastasis, SLN mapping should be considered for complete staging. MCC staging is assigned based on tumor, node, and metastasis assessment according to the eighth edition of the American Joint Committee on Cancer staging system. CSCC staging can be assigned by American Joint Committee on Cancer staging. Of note, American Joint Committee on Cancer staging applies only to CSCC in the head and neck region because these guidelines were developed within the American Joint Committee on Cancer Head and Neck Committee and thus represent a major change from the seventh edition. The Brigham and Women's Hospital tumor staging system for CSCC was developed with the goal of providing an alternative T staging system for better risk stratification.[169-171]

Nonmelanoma skin cancers include BCC, CSCC, and MCC that are seen in older subjects and linked to excessive skin damage from sun exposure. Nonmelanoma skin cancers show infiltration by activated T lymphocytes and exhibit high tumor mutation load (except in Merkel cell polyoma virus associated MCC). Nonmelanoma skin cancers are highly curable with complete surgical resection conferring reduced risk of local relapse compared to alternative options such as cryotherapy, photodynamic therapy, radiation therapy, or local application of 5-fluorouracil and imiquimod. For lesions located on the face, Mohs micrographic surgery can provide the best cosmetic outcome. There are no standards for optimal wide-excision margins, although the National Comprehensive Cancer Network recommends excision of low-risk CSCC and BCCs with 4- to 6-mm and 4-mm clinical margins, respectively.

Radiation therapy is recommended for patients who are at high risk of local relapse following surgery and in cases in which surgery did not achieve negative margins. Radiation therapy can also be considered in patients with CSCC and MCC who have positive lymph nodes and cannot be considered for systemic chemotherapy or radical lymph node surgery.

Considerable advances in the systemic management of nonmelanoma skin cancers have been achieved since 2012; these advances have challenged the use of cytotoxic chemotherapies for these cancers, which was common practice before 2012.

BCC is a tumor arising from the keratinocyte in the basal layer of epidermis that is increasingly diagnosed in older subjects linked to cumulative sun exposure, particularly to ultraviolet radiation. Although highly curable when diagnosed early, locally advanced surgically unresectable and metastatic BCC are incurable and often result in poor outcomes with historical treatments such as radiation. Driven by the unique biology of BCC, in which constitutive activation of the hedgehog signaling pathway is seen secondary to mutations in hedgehog pathway–associated genes, eg, *PTCH1* (mutation in 90%) and *SMO* (mutation in 10%), molecularly targeted therapy is possible. Vismodegib (first-in-class) and sonidegib are two FDA-approved small-molecule inhibitors of SMO for locally advanced surgically unresectable or metastatic BCC. The approval was based on large phase 2 non–placebo-controlled clinical trials (BOLT and STEVIE).[172,173] Both targeted therapies, sonidegib (200 mg) and vismodegib (150 mg), are orally available and are administered once daily. Antitumor responses were greater than 50% for both drugs, and they are higher in patients with locally advanced disease compared with those with metastatic disease. Class-specific adverse event rates for hedgehog inhibitors are muscle spasms (49%-64%), alopecia (43%-62%), dysgeusia (38%-54%), weight loss (27%-33%), asthenia (8%-28%), appetite loss (19%-25%), diarrhea (17%-24%), nausea (16%-33%), and fatigue (16%-29%). Given the cumulative constitutional symptoms, treatment with hedgehog inhibitors is frequently interrupted or discontinued. Nevertheless, the median overall survival for the metastatic BCC cohort for vismodegib was 33.4 months, whereas it was not reached for sonidegib.

In February 2021, FDA-approved cemiplimab-rwic at a dose of 350 mg every 3 weeks for patients with locally advanced surgically unresectable or metastatic BCC who had progressed on HHI therapy, had not had an objective response after 9 months on HHI therapy, or were intolerant of prior HHI therapy or are not candidates for curative surgery or radiation therapy. The incidences of confirmed objective antitumor response in patients with metastatic BCC (n = 28) and locally advanced BCC (n = 84) were 21% and 29%, respectively. At median follow-ups of 9.5 (metastatic BCC) and 15.1 months (locally advanced BCC), the duration of response had not been reached (range, 9 to ≥23 and 2 to ≥21 months, respectively).[174,175]

CSCC: Although highly cured by surgery in early-stage disease, locally advanced surgically unresectable or metastatic CSCC is life threatening and not cured with historical treatments such as chemotherapy or epidermal growth factor antagonist cetuximab or radiation therapy. Due to exhibition of favorable biomarkers for response to immune checkpoint inhibitor therapy (such as high tumor mutation burden, increased TILs, and PD-L1 expression), locally advanced and surgically unresectable CSCC patients underwent clinical trials with anti–PD-1 agents. PD-1 inhibitors, cemiplimab, pembrolizumab, and cosibelimab were granted FDA approval for treatment of locally advanced surgically unresectable and distant metastatic CSCC on the basis of high antitumor responses and longer durability of responses. EMPOWER-CSCC-1 was a phase 1/2 study of cemiplimab (3 mg/kg administered intravenously every 2 weeks or 350 mg every 3 weeks) in patients with locally advanced and metastatic squamous cell carcinoma, reporting overall response rates of 44% and 49%, respectively.[176] At a median follow-up of 9 (locally advanced disease) and 17 months (metastatic disease), the median overall survival had not been reached.[177,178] In the KEYNOTE-629 phase 2 study, single-agent pembrolizumab led to a 34% response rate in patients with recurrent or metastatic

CSCC. At a median follow-up of 11.4 months, the median progression-free survival was 6.9 months, whereas the median overall survival had not been reached.[179] In the CARSKIN trial, single-agent pembrolizumab had a slightly higher response rate in patients with unresectable CSCC (41%). At a longer median follow-up of 22.4 months, the median progression-free survival was 6.7 months, and the overall survival had not been reached.[180] CK-301-101 was a phase 1 trial of cosibelimab, a fully humanized monoclonal antibody against PD-L1. Unique to this drug molecule is the potential for a dual function of triggering antibody-dependent cellular cytotoxicity (ADCC) in addition to the conventional mechanism of action of PD-1/PD-L1 blockade. ADCC function is mediated through the Fc region of the antibody engaging with natural killer (NK) cells to promote direct tumor lysis. Seventy-eight patients with metastatic (defined as nodal and/or distant) CSCC received cosibelimab 800 mg every 2 weeks until confirmed complete response, progressing disease, or intolerant toxicity. The primary endpoint of objective response rate was 47.4% with ongoing response in 73.0% of patients with a median follow-up of 15.4 months. Grade 3 or higher treatment-related adverse events occurred in 10.3% of participants. Overall, this study demonstrated a meaningful clinical activity without any new safety signals.[181]

There is also now emerging evidence of clinical benefit of perioperative immunotherapy for high-risk CSCC.

After surgical resection and postoperative radiotherapy, cemiplimab administered at a dose of 350mg for the first 12 weeks and then switched to 700mg every 6 weeks for additional 36 weeks demonstrated superior disease-free survival compared to placebo (HR 0.32, 95% CI 0.20 to 0.51, $P < 0.001$) in high-risk CSCC in a randomized phase 3 trial.[182] The trial defined high-risk disease as patients with in-transit metastases, radiologic or clinical evidence of perineural invasion of named nerves, T4 primary tumor (with bone invasion), or local recurrence with poorly differentiated history, nodal stage ≥N2b, ≥T3 lesion (diameter >4.0 cm). Patients with high-risk nodal disease defined as extracapsular extension with at least one node measuring at least 20 mm in diameter or at least three involved nodes regardless of extracapsular extension were also eligible for the study.

Neoadjuvant cemiplimab, administered for a maximum of four cycles at a 350-mg fixed dose, showed a promising pathologic complete response rate of 51% and radiologic RECIST response rate of 68% in an international phase 2 single-arm trial that enrolled 71 patients with resectable stage II to IV CSCC; all 15 patients who had either a pathologic complete or a major response were disease free at a median follow-up of 37.4 months.[183] A phase 3 randomized trial to evaluate neoadjuvant cemiplimab with or without adjuvant cemiplimab (pathologic response guided) compared to standard-of-care surgical resection is in progress (NCT 06568172).

PD-1/PD-L1 inhibitors were also approved by the FDA in 2017 (avelumab), 2018 (pembrolizumab), and 2023 (retifanlimab) for the treatment of metastatic MCC.[184] Although antitumor responses have been similar to those seen with metastatic melanoma and squamous cell carcinoma, overall survival has been shorter. In the JAVELIN Merkel 200 study, avelumab (10 mg/kg administered intravenously every 2 weeks) in the first-line setting was associated with a 33% confirmed overall response rate. At a median follow-up of 40.8 months, the median overall survival was 12.6 months, and the 42-month overall survival rate was 31%.[185] The clinical benefit was not significantly different when avelumab was administered to patients who had previously experienced progression after prior chemotherapy for metastatic MCC.[186] In the smaller study of pembrolizumab for patients with treatment-naive metastatic disease, MCC antitumor responses were higher (56%), and the 24-month overall survival rate was 69%.[187] Lastly, retifanlimab, a PD-1 blocking antibody (500 mg administered intravenously every 4 weeks) achieved an overall response rate of 46.2% with a disease control rate of 53.8%.[184]

KEY POINTS

- Nonmelanoma skin cancers are by far the most frequently diagnosed cancers. This has implications for increasing health care costs, particularly for BCC and squamous cell carcinoma.
- Surgery is the cornerstone therapy for management of most nonmelanoma skin cancers.
- Unlike MCC, squamous cell carcinoma and BCC have low metastatic potential.
- PD-1/PD-L1 inhibitors have been approved for patients with locally advanced or distant metastatic nonmelanoma skin cancers: pembrolizumab and cemiplimab for CSCC, avelumab and pembrolizumab for MCC, and cemiplimab for BCC.
- Neoadjuvant cemiplimab showed a high pathologic complete response rate in a phase 2 trial of stage II to IV resectable CSCC.
- In a phase 3 trial which randomized patients with resected high-risk CSCC to either adjuvant cemiplimab or placebo, the adjuvant cemiplimab group achieved significantly longer disease-free survival.
- Two hedgehog inhibitors, sonidegib and vismodegib, are approved for the treatment of advanced BCC. In practice, both can be used interchangeably, although notably, sonidegib was studied in patients with locally advanced BCC, whereas vismodegib was studied both in patients with locally advanced disease and in those with metastatic disease.

HIGH-YIELD TAKEAWAYS

Triple M overlap syndrome

- TMOS, characterized by myocarditis, myositis, and myasthenia gravis, is an oncologic emergency that can occur in patients treated with single or combination immunotherapy. Although rare, it carries a particularly high mortality rate and requires a multidisciplinary team (cardiology, neurology, and rheumatology) effort for prompt diagnosis and treatment.

Melanoma and brain metastases

- Combination nivolumab and ipilimumab at standard dosing (1 and 3 mg/kg, respectively) should be considered when deciding the upfront treatment option for patients with brain metastases as it has demonstrated meaningful intracranial and extracranial responses, particularly in patients who are neurologically asymptomatic, not receiving steroids, and have intracranial metastases 3 cm in diameter or smaller.

Resectable melanoma and treatment

- Adjuvant immunotherapy is approved for resected stage IIB/C, III, and IV melanoma.
- Adjuvant BRAF/MEK inhibitor therapy is approved for resected stage III melanoma.
- There is emerging data for neoadjuvant immunotherapy, followed by surgery for patients with resectable, macroscopic stage III or IV melanoma.

Unresectable metastatic melanoma and treatment

- Combination immunotherapy (ipilimumab and nivolumab, relatlimab and nivolumab) and anti–PD-1 monotherapy (nivolumab and pembrolizumab) are approved therapies for metastatic or unresectable melanoma.
- For patients with *BRAF* V600–mutated melanoma, combination targeted therapy (encorafenib + binimetinib, dabrafenib + trametinib, or vemurafenib + cobimetinib) is also approved.
- For patients with *BRAF* V600–mutated melanoma, combination immunotherapy is preferred over the combination targeted therapy for the first-line setting based on the improved overall survival demonstrated in the DREAMseq study.

ANTI–PD-1 refractory melanoma and treatment

- Lifileucel, TIL therapy, was recently approved for patients who have progressed on anti–PD-1 therapy and, if *BRAF* V600 mutated, BRAF/MEK inhibitors.

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

MELANOMA AND OTHER SKIN CANCERS 16

CHAPTER SUMMARY GUIDE

KEY POINTS

- Cutaneous melanoma accounts for 1.7% of all new cancer diagnoses annually worldwide; 0.7% of all cancer-related deaths are a result of cutaneous melanoma.
- Projected melanoma-specific mortality rates have been declining since 2016; overall incidence rates seem to have stabilized for men after decades of increase while continuing to increase for women.
- In 2025, about 104,960 new cases of invasive melanoma are expected to be diagnosed in the United States with about 8,430 projected deaths.
- Both cutaneous melanoma incidence and mortality rates are higher in men than in women.
- UV light exposure is the most well-characterized risk factor for cutaneous melanoma.
- Australia and New Zealand have the highest incidence of melanoma but relatively better survival outcomes, while Black Americans experience low melanoma incidence but relatively worse survival.
- Familial cutaneous melanomas represent approximately 10% of melanomas.
- Germline mutations in the *CDKN2A* and *BAP1* gene locus are associated with an increased risk of developing cutaneous and uveal melanoma.
- All patients with melanoma and a personal history or family history of cancer should be referred to genetics.
- *BRAF* V600E is the most frequent somatic mutation in sporadic melanomas, followed by mutations in *NRAS, CDKN2A, TERT*, and *NF1*.
- Population-based skin cancer screening programs have identified risk factors that can render melanoma screening cost efficient to select high-risk patients.
- The use of sunscreens has the highest level of clinical evidence for melanoma prevention.
- Clinical evaluation of a patient with newly diagnosed cutaneous melanoma should include a full medical history, including family and personal histories of melanoma and other cancers.
- Physical examination should include skin and lymph node examinations every 3 to 6 months for the first 3 to 5 years and then annually for their lifetime.
- Surgical management includes wide local excision concurrent with SLN biopsy when indicated. SLN status is an independent prognostic factor for overall survival.
- Melanoma with deep Breslow thickness (ie, ≥4.0 mm) and ulceration, even without positive regional lymph nodes (stage IIC), has a high risk of recurrence.
- Completion lymph node dissection did not improve overall survival after a positive SLN biopsy specimen in two randomized clinical trials and is not considered standard of care for all patients with clinically occult stage III melanoma. Completion lymph node dissection decreases the incidence of regional lymph node recurrence and can be considered in select patients.
- For patients with clinical stage III melanoma (clinically palpable regional lymph nodes), neoadjuvant treatment approaches preferably containing combination immunotherapy is recommended. Total lymph node dissection with or without external radiation therapy to the lymph node basin should be reserved for patients who are refractory to neoadjuvant treatment (ie, no pathologic response or minimal pathologic response) of the regional nodal basin.
- Although adjuvant radiation decreased the risk of in-field recurrence, there was no significant decrease in relapse-free survival or overall survival. Adjuvant radiation can be considered for select patients with a high risk for locoregional recurrence.
- Adjuvant pembrolizumab and nivolumab are FDA approved for patients with resected stage IIB/C melanoma because of improved relapse-free survival; however, the decision to pursue adjuvant therapy should include a careful discussion of risks and benefits.
- Combination dual targeted therapy with dabrafenib and trametinib (in *BRAF* V600–mutated disease), as well as nivolumab and pembrolizumab, is an adjuvant treatment option for patients with completely resected stage III melanoma based on improved relapse-free survival and reasonable tolerability.

- Active surveillance alone, without adjuvant therapy, is an equally acceptable option for patients with high-risk resected melanoma, given that there is no clear overall survival benefit with adjuvant anti–PD-1 monotherapy or adjuvant targeted therapy. The decision between treatment and observation requires shared decision-making between the patient and provider, including a detailed discussion of risk and potential benefit.
- Adjuvant ipilimumab and nivolumab at attenuated doses showed no clinical benefit in resected stage IIIB-IIID melanoma patients and is not a recommended adjuvant therapy of melanoma.
- The combination of nivolumab and ipilimumab in the adjuvant setting has shown overall survival benefit in the resected stage IV setting with a significantly higher immune-related adverse event rate than definitive treatment for stage IV melanoma.
- Neoadjuvant approach is relevant and effective in high-risk clinically palpable stage III and resectable stage IV melanoma.
- Status of pathologic response in an index lymph node helps determine the need for lymph node dissection and additional adjuvant treatment in high-risk stage III disease.
- Neoadjuvant and adjuvant pembrolizumab improved event-free survival compared with adjuvant pembrolizumab in a randomized phase 2 trial.
- In a phase 3 trial, neoadjuvant ipilimumab and nivolumab had superior event-free survival compared with adjuvant nivolumab. The patients who achieved major pathologic responses after two doses of neoadjuvant ipilimumab and nivolumab did not receive adjuvant therapy and had an estimated 12-month recurrence-free survival of 95.1%, highlighting the potential role of pathologic response as a predictive biomarker to personalize adjuvant therapy.
- In a smaller multi-institutional study, neoadjuvant relatlimab and nivolumab regimen was found to be effective and safe option in melanoma patients with stages IIIB, IIIC, IIID, and IV (M1a) disease.
- Surgical resection can be considered in select patients with symptomatic melanoma brain metastases and for disease control (ie, oligometastatic disease) or with palliative intent.
- Systemic therapy with immune checkpoint inhibitor-based or BRAF-directed therapy in BRAF mutation–positive melanoma should be considered for primary treatment of melanoma brain metastases.
- Stereotactic radiosurgery is a standard palliative treatment option in advanced melanoma and can be considered for disease control in select patients with oligometastatic disease or limited central nervous system disease or when the tumor is inaccessible for surgery.
- Whole-brain irradiation did not reduce distant intracranial failure and was associated with earlier decline in performance status and hence not routinely recommended.
- Concurrent administration of MAPK inhibitors with radiation therapy worsens radiation therapy–related toxicities.
- Concurrent use of immune checkpoint inhibitor treatment and stereotactic radiosurgery of melanoma brain metastases is found to be safe in retrospective studies. However, optimal sequencing of immune checkpoint inhibitor treatment and radiation therapy is under clinical investigation in patients with melanoma brain metastases.
- Dual checkpoint blockade is the preferred first-line immunotherapy treatment option in unresectable/advanced melanoma.
- Concurrent ipilimumab and nivolumab should be considered for patients with small asymptomatic central nervous system metastases; both topics are discussed later in the chapter.
- Four phase 3 randomized clinical studies in patients with *BRAF* V600–mutated metastatic melanoma have shown significant progression-free survival and overall survival benefits favoring concurrent BRAF/MEK inhibition compared with a single-agent BRAF inhibitor.
- Oncolytic viral therapy such as TVEC represents a reasonable option to control local tumor in selected patients and showed superior responses lasting at least 6 months when compared to the granulocyte-macrophage colony-stimulating factor-treated arm. However, its combination with anti–PD-1 agent did not improve progression-free or overall survival.
- Lifileucel, a one-time autologous TIL therapy, is approved by the FDA for patients with anti–PD-1 refractory melanoma and can have clinically meaningful durable effect.
- Although systemic chemotherapy is not recommended as a first-line treatment of melanoma, it may be used in selected clinical scenarios as a bridge to future treatments.
- Patients with small untreated asymptomatic parenchymal brain metastases can be safely and effectively treated with concurrent ipilimumab and nivolumab, without local surgery or radiation therapy.
- Intracranial responses are durable in patients with asymptomatic parenchymal brain metastases treated with concurrent ipilimumab and nivolumab; the combination of dabrafenib and trametinib results in less durable intracranial responses.
- The care of patients with symptomatic melanoma brain metastases remains challenging. Coordination of multidisciplinary care, including expertise in surgery and radiation therapy, is recommended for this population.
- Toxicities from immune checkpoint inhibitors are generally reversible with dose suspension and use of corticosteroids and/or other immunomodulatory agents. The exception is endocrine toxicities, which may require permanent hormone replacement. For serious adverse events, suspension or discontinuation of immune checkpoint inhibitors is recommended.

- Discontinuation of immunotherapy because of severe adverse events has not been shown to affect overall clinical benefit.
- Physicians should be aware of drug- and class-specific adverse events of the three currently FDA-approved BRAF/MEK combinations (vemurafenib and cobimetinib, dabrafenib and trametinib, and encorafenib and binimetinib), as well as appropriate dose reductions, delays, or even treatment discontinuations, if necessary.
- In treatment-naive patients with advanced *BRAF* V600–mutated melanoma, intermediate-term data show significantly improved overall survival for those who start with nivolumab and ipilimumab and then switch to dabrafenib and trametinib at the time of disease progression rather than the reverse treatment sequence.
- Although anti–PD-1 monotherapy remains a first-line option, the decision to treat with single or dual checkpoint blockade (PD-1/CTLA-4 vs PD-1/LAG-3) should be individualized on the basis of risk for immune-related toxicities, tumor burden, central nervous system disease status, performance status, tumor-associated symptoms, and patient preference.
- Immunotherapy can result in durable complete responses after stopping therapy. Treatment discontinuation of immunotherapy should be discussed with patients who have a confirmed complete response.
- Noncutaneous melanomas account for 5% of all melanomas and consist of uveal and mucosal melanomas.
- *KIT* mutations are more frequent in mucosal melanomas compared with cutaneous melanomas; the incidence of oncogenic *BRAF* and *NRAS* mutations is low.
- A commercially available 15-gene expression profile (DecisionDx-UM) and *PRAME* RNA expression were validated in a prospective study as an integrated prognostic biomarker for uveal melanomas based on their propensity to metastasize and melanoma-specific survival. Genomic information assists in tailoring surveillance plans for patients after definitive treatment of their uveal melanomas.[130]
- *GNAQ* and *GNA11* mutations are present in a majority of uveal melanomas and are thought to be early events in tumorigenesis; genetic aberrations of *BAP1* are associated with the more aggressive class 2 type.
- A novel bispecific fusion protein, tebentafusp, is the first T-cell receptor therapeutic drug developed and the first drug to significantly improve overall survival in patients with metastatic uveal melanoma who are positive for HLA*02:01. Tebentafusp has been FDA approved for HLA-A*02:01–positive patients with unresectable or metastatic uveal melanoma.
- Combination ipilimumab and nivolumab is associated with higher response rates in both uveal and mucosal melanomas compared with single-agent PD-1 inhibitors; however, the clinical benefit from immunotherapy is much lower in these rare subtypes when compared with cutaneous melanoma.
- Nonmelanoma skin cancers are by far the most frequently diagnosed cancers. This has implications for increasing health care costs, particularly for BCC and squamous cell carcinoma.
- Surgery is the cornerstone therapy for management of most nonmelanoma skin cancers.
- Unlike MCC, squamous cell carcinoma and BCC have low metastatic potential.
- PD-1/PD-L1 inhibitors have been approved for patients with locally advanced or distant metastatic nonmelanoma skin cancers: pembrolizumab and cemiplimab for CSCC, avelumab and pembrolizumab for MCC, and cemiplimab for BCC.
- Neoadjuvant cemiplimab showed a high pathologic complete response rate in a phase 2 trial of stage II to IV resectable CSCC.
- In a phase 3 trial which randomized patients with resected high-risk CSCC to either adjuvant cemiplimab or placebo, the adjuvant cemiplimab group achieved significantly longer disease-free survival.
- Two hedgehog inhibitors, sonidegib and vismodegib, are approved for the treatment of advanced BCC. In practice, both can be used interchangeably, although notably, sonidegib was studied in patients with locally advanced BCC, whereas vismodegib was studied both in patients with locally advanced disease and in those with metastatic disease.

CHAPTER TABLES AND IMAGES

Table 16-1 Recommended Wide and Deep Excision Margins for Tis to T4 Melanoma

Breslow Depth of Invasion (mm)	Wide Surgical Margin (cm)	Deep Surgical Margin
In situ	0.5-1	Excised to the depth within the adipose layer
≤1.0	1	
>1.0 and ≤2.0	1-2	Excised to the depth immediately above muscle fascia
>2.0	2

Table 16-4 **Important Characteristics of the Three Most Frequent Nonmelanoma Skin Cancers**

Characteristic	Squamous Cell Carcinoma	Basal Cell Carcinoma	Merkel Cell Carcinoma
New diagnoses	>1 million per year	Approximately 4.3 million per year	Approximately 2000 per year
Cell origin	Stem cells in the hair follicle bulge and basal layer of interfollicular epidermis	Undifferentiated $CD200^+$ basal cells of the hair follicle outer root sheath	Merkel cells in the basal epidermal layer of skin
Precursor lesion	Solar keratosis, Bowen disease, and keratoacanthoma	Not known	Not known
Risk factors	UV radiation exposure, skin phototype, ionizing radiation, chronic wounds/scars, immunosuppression, HPV infection, smoking, and genetic defects in DNA repair	UV radiation exposure, tanning bed use, skin phototype, male sex, age >50 years, immunosuppression, and basal cell nevus syndrome	UV radiation exposure, skin phototype, age >70 years, male sex, immunosuppression, and MCPyV
Biology	High somatic mutation burden (*TP53, NOTCH1/2/4, CDKN2A*, and *EGFR*), high degree of PD-1–positive tumor-infiltrating lymphocytes	Mutations in *PTCH1*, smoothened homolog, high degree of PD-1–positive tumor-infiltrating lymphocytes	Low somatic mutation burden if MCPyV positive, high somatic mutation burden if MCPyV negative, high degree of PD-1–positive tumor-infiltrating lymphocytes
Prevention	Broad-spectrum sunscreens, nicotinamide, and acitretin	Broad-spectrum sunscreens, nicotinamide, and calcipotriol + 5-fluorouracil	Broad-spectrum sunscreens
Propensity to metastasize, %	41[162]	0.0029-0.55[163]	33[164]
Median OS, if distant metastatic	2.2 years[165]	24.1 months[166]	12-17.2 months[167,168]

Abbreviations: HPV, human papillomavirus; MCPyV, Merkel cell polyomavirus; OS, overall survival.

SARCOMA 17

Ravin Ratan, MD, and Richard F. Riedel, MD

RECENT UPDATES

- Afamitresgene autoleucel, an engineered autologous T-cell receptor product targeting melanoma-associated antigen A4 (MAGE-A4), was FDA approved for adults who have select HLA-A*02 serotypes and have unresectable or metastatic MAGE-A4-expressing synovial sarcoma and have received prior chemotherapy.[1]
- The addition of neoadjuvant and adjuvant pembrolizumab to radiation therapy and surgery was shown to significantly improve disease-free survival for patients who have stage III undifferentiated pleomorphic sarcoma and pleomorphic or dedifferentiated liposarcoma of the extremity and limb girdle.[2]
- Vimseltinib, an oral colony-stimulating factor (CSF)-1R inhibitor, showed improved overall response rate and meaningful improvements in symptoms and function when compared with placebo in a randomized phase 3 trial for patients with symptomatic tenosynovial giant cell tumor.[3]
- Nirogacestat, a gamma-secretase inhibitor, demonstrated improved progression-free survival (PFS) and patient-reported outcomes over placebo for patients who have progressive desmoid fibromatosis and was FDA approved.[4]
- The combination of doxorubicin with trabectedin, followed by trabectedin single-agent therapy, improved PFS and overall survival over patients receiving doxorubicin alone for unresectable or metastatic leiomyosarcoma in a randomized phase 3 trial.[5,6]
- In March 2026, there was a voluntary manufacturer recall of tazemetostat, previously used to treat epithelioid sarcoma. This was based on emerging data from the ongoing Phase Ib/III SYMPHONY-1 trial on secondary hematologic malignancies.

OVERVIEW

Sarcomas are rare cancers that can originate in bone and soft tissues. Most sarcomas arise from mesoderm-derived cells. These cancers are uncommon, constituting less than 1% of cancers occurring in adults and approximately 15% of cancers in children. Sarcomas are heterogeneous, with more than 150 subtypes recognized in the World Health Organization classification of tumors of soft tissue and bone, with further subtyping commonplace based on modern molecular phenotyping.[7] In adults, soft tissue sarcomas (STSs) are approximately four times more common than sarcomas of bone (13,400 vs. 3,970 projected cases, respectively, in the United States in 2023).[8] Approximately 42% of patients diagnosed with sarcoma will die of their disease, with a majority dying from metastatic disease.[7]

Appropriate multidisciplinary treatment is essential for patients presenting with sarcoma. In most cases of localized sarcoma, complete surgical removal of the primary tumor is required for cure. Surgery is also used when feasible in the management of oligometastatic disease, particularly in the lung, and for diseases with more indolent growth patterns. Radiation therapy (RT) is important in many sarcoma subtypes to reduce the risk of local tumor recurrence after surgery for localized disease or for palliation of tumor-related symptoms. Stereotactic body radiotherapy also plays an increasingly important role in the treatment of oligometastatic disease. Chemotherapy in the neo/adjuvant setting plays a more controversial role in most soft tissue histologic subtypes but is critically important and well established in selected subtypes, such as osteosarcoma, Ewing sarcoma, and nonpleomorphic rhabdomyosarcoma. The role of chemotherapy in the adjuvant setting for the remaining sarcomas is determined based on patient- and disease-specific considerations, such as histology sensitivity to chemotherapy in the metastatic setting, and survival rate based on risk factors such as size, grade, location, and age. For patients who have metastatic disease, histology-guided systemic therapy is generally the primary treatment, with other modalities used in specific circumstances.

Recently, there have been important advances in the treatment of sarcoma. With appropriate multidisciplinary management, long-term survival rates of localized osteosarcoma and Ewing sarcoma have improved from less than 20% to more than 70%. Similar gains in cure rates have occurred in patients who have nonpleomorphic rhabdomyosarcoma, mostly as a result of large multicenter histology-specific cooperative group studies. Significant improvements in long-term survival rates of patients who

have metastatic gastrointestinal (GI) stromal tumor (GIST) have occurred since the introduction of tyrosine kinase inhibitor (TKI) therapy, with 20% to 30% of patients surviving 9 to 10 years after initiation of treatment.[9] However, improvements in outcomes have been less impressive in most other STS subtypes. Historically, large phase 3 trials of novel therapies have included multiple subtypes of STS and/or bone sarcoma, which has caused difficulty in interpreting subtype-specific results. Recognizing that a one-size-fits-all approach is unlikely to be feasible given the biologic and genetic heterogeneities of sarcomas, there has also been a shift toward conducting clinical trials for specific sarcoma subtypes or molecularly defined markers. This approach has led to the approval of a number of new therapies, including albumin-bound sirolimus for perivascular epithelioid cell tumor (PEComa) in 2021, atezolizumab for alveolar soft part sarcoma (ASPS) in 2022, nirogacestat for desmoid tumors in 2023, afamitresgene autoleucel for synovial sarcoma in 2024, and both pexidartinib and vimseltinib for tenosynovial giant cell tumor (TGCT) in 2019 and 2025, respectively.

EPIDEMIOLOGY AND ETIOLOGY

The most common subtypes of STS include GIST, leiomyosarcoma, liposarcoma (LPS), and undifferentiated pleomorphic sarcoma (UPS). Osteosarcoma and chondrosarcoma are the two most common bone sarcomas in adults. Although osteosarcoma can arise in soft tissue (extraskeletal osteosarcoma), it is important to note that this is a different entity and is generally treated following STS paradigms. Ewing sarcoma can arise in either bone or soft tissue, but is typically classified as a bone sarcoma and is treated identically regardless of primary location.

The most common cause of sarcoma is unknown. However, known causes are hereditary cancer predisposition syndromes or exposures to specific environmental factors. The incidence of sarcoma generally increases with age, although there are exceptions for some subtypes. Ewing sarcoma, nonpleomorphic rhabdomyosarcoma (embryonal and alveolar subtypes), and osteosarcoma occur more frequently in children and young adults.

Many hereditary syndromes are associated with sarcoma (Table 17-1). In an international genomic study of more than 1,000 patients who have sarcoma, recognized pathogenic germline variants were detected in approximately 10% of patients, and a large minority had multiple genomic variants, suggesting an interacting contribution of rare mutations to sarcoma risk.[10] People who have Li-Fraumeni syndrome are at great risk for the development of osteosarcoma or STS. In one large study of patients who have sarcoma, germline tumor protein p53 (*TP53*) mutations were present in approximately 3% of cases.[11]

Table 17-1 Genetic Syndromes Associated With Sarcoma

Syndrome	Genetic Abnormality	Associated Sarcoma Types
Li-Fraumeni syndrome	*TP53* mutation	Various types of STS and bone sarcomas
Retinoblastoma	*RB1* gene deletion	Leiomyosarcoma, osteosarcoma
Neurofibromatosis type I	*NF-1* mutation	MPNST, GIST
Gardner syndrome	*APC* mutation	Desmoid tumor
McCune-Albright syndrome	*GNAS1* mutation	Osteosarcoma
Bloom syndrome	*RECQL3* mutation	Embryonal RMS, osteosarcoma
Rothmund-Thomson syndrome	*RECQL4* mutation	Osteosarcoma
Werner syndrome	*WRN* mutation	Osteosarcoma
Costello syndrome	*HRAS* mutation	Embryonal RMS
Nijmegen breakage syndrome	*NBS1* mutation	Embryonal RMS
Carney-Stratakis syndrome	*SDH* mutation	GIST
Noonan syndrome	*PTPN11* mutation	Embryonal RMS, giant cell tumor, PVNS

Abbreviations: *APC*, APC regulator of WNT signaling pathway; GIST, gastrointestinal stromal tumor; *GNAS1*, GNAS complex locus; *HRAS*, HRAS protooncogene, GTPase; MPNST, malignant peripheral nerve sheath tumor; *NBS1*, nibrin; *NF-1*, neurofibromin-1; *PTPN11*, protein-tyrosine phosphatase, nonreceptor-type 11; PVNS, pigmented villonodular synovitis; *RB1*, RB transcriptional corepressor 1; *RECQL3/4*, RECQ protein-like 3/4; RMS, rhabdomyosarcoma; *SDH*, succinate dehydrogenase; STS, soft tissue sarcoma; *TP53*, tumor protein p53; *WRN*, Werner syndrome.

Referral for genetic counseling and testing should be considered in individuals younger than 46 years who have STS or osteosarcoma, who also have a family history of STS, osteosarcoma, breast cancer, CNS tumor, or adrenocortical carcinoma in a first- or second-degree relative occurring before 56 years.[12] Referral for genetic counseling and testing should also be considered for patients who have multiple cancers of the listed types, regardless of age at diagnosis.

Some epidemiologic evidence indicates an association between occupational exposure to vinyl chloride, pesticides, or herbicides (including Agent Orange) or exposure to the imaging agent thorotrast and development of hepatic angiosarcoma, but few other environmental exposures are linked to sarcoma.[13] A recent meta-analysis suggested an association between a woodworking occupation and STS incidence.[14]

There is also a small but measurable long-term risk of STS or bone sarcoma after exposure to therapeutic radiation, well less than 1% overall.[15] Despite their rarity, it is important to recognize symptoms concerning radiation-associated sarcoma, particularly in breast cancer survivors, as well as sarcomas occurring in pediatric patients with cancer.[16,17] It is estimated that radiation-associated sarcomas make up approximately 3% to 6% of all new sarcoma diagnoses.[18] The median latency in one series was 8.6 years (range, 6 months to 44 years).[19] Analysis of sarcoma incidence in survivors of atomic bomb blasts suggested that moderate levels of ionizing radiation, lower than typically administered for therapy, also increased the risk of bone sarcoma and STS.[20]

Other risk factors for the development of STS include lymphedema (angiosarcoma) and human herpesvirus-8 (HHV-8; Kaposi sarcoma [KS]) infection. KS is causally associated with HHV-8 and occurs in the setting of immune dysregulation—most notably HIV infection—but also classically in older Mediterranean men ("classic"), in certain parts of Africa ("endemic"), and in chronically immunosuppressed patients, including transplant recipients, in the absence of HIV.

GENETIC CHARACTERISTICS

Sarcomas exhibit a wide range of genetic abnormalities, including complex chromosomal aberrations, chromosomal translocations involving transcription factors, overexpression of ligands to receptor kinases, and gene mutations resulting in activated cellular kinases, gene amplification, and regulatory protein inactivation, among others (Table 17-2).[7] Many sarcomas have defined, recurring, specific genetic alterations that contribute to pathogenesis. These alterations are important for diagnostic purposes, especially in cases in which histologic findings do not point to a definite diagnosis.

Table 17-2 Representative Genetic Alterations in Sarcoma

Class of Alteration	Sarcoma Subtype	Genetic Change	Frequency, %
Activating mutation	GIST	*KIT* or *PDGFRA* mutation	>90
	Desmoid fibromatosis	*Beta-catenin* or *APC* mutations	85-90
	Chondrosarcoma	*IDH1/2* mutations	≥50
	PEComa	*TSC1/2* mutations	~50
Ligand expression	Dermatofibrosarcoma protuberans	*COL1A1-PDGFB* gene fusion	~100
	Giant cell tumor of the bone	*RANK* ligand	~100
Inactivation/deletion	Myxofibrosarcoma	*NF-1* mutation, *NF-1* deletion	~10-20, >90
	Malignant peripheral nerve sheath tumor		
	Epithelioid sarcoma, rhabdoid tumors	*INI1* loss	81
Gene amplification	Well-differentiated and dedifferentiated liposarcoma	CDK4, MDM2	>90
Translocation	Synovial sarcoma	*t*(*X*;18) SYT-SSX1 or SYT-SSX2	>90
	Ewing sarcoma	*t*(11;22) EWSR1-FLI1	>85
		t(21;22) *EWSR1-ERG*	5-10
	Alveolar rhabdomyosarcoma	*t*(2;13) PAX3-FOXO1	~70
		t(1;13) PAX7-FOXO1	~15
	Inflammatory myofibroblastic tumors	*ALK* fusions	50

Abbreviations: *ALK*, anaplastic lymphoma kinase; *APC*, APC regulator of WNT signaling pathway; *CDK4*, cyclin-dependent kinase 4; *EWRSR1-ERG*, fusion of EWS RNA-binding protein 1 and ETS transcription factor ERG; *EWSR1-FLI1*, fusion of EWS RNA-binding protein 1 and FLI1 protooncogene, ETS transcription factor; *FOXO1*, forkhead box O1; GIST, gastrointestinal stromal tumor; *IDH1/2*, isocitrate dehydrogenase 1/2; *INI1*, integrase interactor 1; *KIT*, KIT protooncogene, receptor tyrosine kinase; *MDM2*, MDM2 protooncogene; *NF-1*, neurofibromin-1; *PAX3/7*, paired box gene 3/7; *PDGFRA*, platelet-derived growth factor receptor, alpha; PEComa, perivascular epithelioid cell tumor; *RANK*, receptor activator of nuclear factor-kappa B; *SYT-SSX1/2*, synovial sarcoma, X-chromosome-related 1/2; *TSC1/2*, TSC complex subunit 1/2.[7,11]

Tumor genome sequencing identifies potentially actionable mutations in less than 20% of patients with STS, and the impact on survival is yet to be defined.[21] Two important low-frequency actionable genetic alterations occasionally seen in sarcoma are *NTRK* fusions and high microsatellite instability (MSI). Although most sarcomas exhibit low tumor mutational burden (TMB), identifying the subset of sarcomas with high TMB may support treatment with immunotherapy in the metastatic or relapsed setting.[22]

KEY POINTS

- Sarcomas account for approximately 1% of cancers in adults.
- STSs are three to four times more common than those of bone.
- Individuals who have certain hereditary cancer susceptibility syndromes, such as Li-Fraumeni, have an increased risk of sarcoma.
- Therapeutic radiation confers a small but definite risk for the development of sarcoma.
- HHV-8 infection is associated with KS.
- Approximately 30% to 40% of sarcomas have defined, recurring, specific genetic alterations such as chromosomal translocations, gene amplifications, or mutations that contribute to pathogenesis.

CLINICAL PRESENTATION AND DIAGNOSIS

STSs generally present as growing masses that are sometimes associated with pain, whereas bone sarcomas are often associated with pain in the region of bone involvement, with or without an associated soft tissue mass. STSs may be clinically suspected by either their clinical characteristics on physical exam (generally firm) and/or their location (typically deep to subcutaneous fat). Regardless of the clinical impression, soft tissue masses that are increasing in size, associated with symptoms, or larger than 5 cm warrant imaging before attempts at surgical resection.

Dermal vascular neoplasms, such as angiosarcoma and KS, often appear as indistinct red, purple, blue, or brown discoloration in the skin. Often, a mass-like lesion is not present. Angiosarcomas, occurring in the dermis in older adults, and KS, occurring in the setting of HIV/AIDS, frequently involve the head-and-neck region and are often multicentric. KS occurring mostly in Mediterranean men in the absence of HIV infection (often referred to as classic KS) frequently involves the legs and feet. Advanced KS (usually in the setting of AIDS) may involve the lymph nodes (resulting in severe edema), oropharynx, GI tract, or respiratory tract.

Ultrasound and cross-axial imaging (MRI or CT imaging) are useful in the evaluation of suspected sarcomas and can help differentiate benign lesions from potentially malignant masses. Core needle biopsy is the preferred method of biopsy when sarcoma is suspected, ideally in consultation with an orthopedic or surgical oncologist, to ensure an approach that can ultimately allow for resection. Fine-needle aspiration is not adequate because it does not allow for accurate assessment of subtype or grade. When diagnostic material cannot be obtained by core needle biopsy, incisional biopsy is performed with the understanding that the subsequent oncologic resection must encompass the prior biopsy site and scar.

KEY POINTS

- STSs often present as enlarging masses and may be painful or painless.
- Bone sarcomas are usually associated with pain.
- A core needle or incisional biopsy is required to obtain sufficient tumor material for definitive diagnosis and sarcoma subtype classification.
- Angiosarcoma and KS can present as dermal-only or visceral disease.

PATHOLOGIC FEATURES, STAGING, AND PROGNOSTIC FACTORS

Because of the diversity of sarcoma subtypes and their differential diagnoses, such as sarcomatoid carcinoma (which is treated as a carcinoma, not a sarcoma), uterine carcinosarcoma, melanoma, and lymphoma, the pathologist is a critical contributor to patient care. Expert review of a patient's biopsy or resection by an expert bone and soft tissue pathologist is critical for optimal outcome. Retrospective analyses report a change in diagnosis from the original reference center approximately 40% of the time with expert review.[23,24]

Important considerations for sarcoma staging include sarcoma subtype (bone or soft tissue), site, size, and tumor grade. It is important to recognize that pathologists have historically used different grading systems; however, the American Joint Committee on Cancer (AJCC) staging guidelines (ninth edition) use a three-grade classification, including 1 (low grade), 2 (intermediate to high grade), and 3 (high grade), based on degree of differentiation, mitoses, and necrosis.[25] The presence of nodal disease and distant metastases also factor into AJCC TNM staging. Nodal metastatic disease is an unfavorable prognostic feature, but it is associated with better overall survival (OS) than distant metastatic disease. Nodal metastatic disease is observed in less than 10% of patients

with STS; however, several subtypes do have a propensity for nodal spread in addition to hematologic sites, including epithelioid sarcoma, dedifferentiated liposarcoma, pediatric rhabdomyosarcoma, ASPS, angiosarcoma, myxofibrosarcoma, synovial sarcoma, clear-cell sarcoma, and myxoid liposarcoma. Sentinel-node biopsy can be considered on a case-by-case basis for specific subtypes but is not considered standard for any sarcoma. In the current staging system, lymph node metastasis is considered stage IV.

Evaluation of the local extent of sarcoma is generally accomplished by MRI or CT imaging of the primary site. For patients who have high-grade sarcoma, a chest CT scan should be performed to evaluate for the presence of lung metastases and to serve as a baseline for future comparison. A CT scan of the abdomen and pelvis is needed for the aforementioned subtypes that can spread via lymphatics in addition to the bloodstream. Myxoid liposarcoma may also spread to the spine or other bones, and additional imaging, such as whole-body MRI and total spine MRI, should be considered to fully stage the disease. In the absence of symptoms, the yield from routine imaging of the brain for patients who have tumors originating outside the head-and-neck region is low apart from high-risk histologies, including visceral angiosarcoma, ASPS, and left-sided cardiac sarcomas. For high-grade bone sarcomas, radionuclide bone scan or positron emission tomography (PET)/CT is recommended to evaluate for the presence of bone metastases. PET/CT can also be used to stage STS and evaluate response to neoadjuvant therapy, as well as to assess early response to TKI treatment of patients who have GIST, and help distinguish well-differentiated liposarcoma from dedifferentiated liposarcoma. A PET scan is notoriously not helpful for myxoid liposarcoma.

Histology, grade, size, and completeness of resection are the most important factors in determining the risk of relapse. Of primary importance in determining OS is tumor grade; OS also depends on the initial size and location of the tumor. Multiple nomograms that include factors such as tumor histology, size, location, and patient age have been developed and found to be prognostic with respect to survival outcomes.[26,27]

KEY POINTS

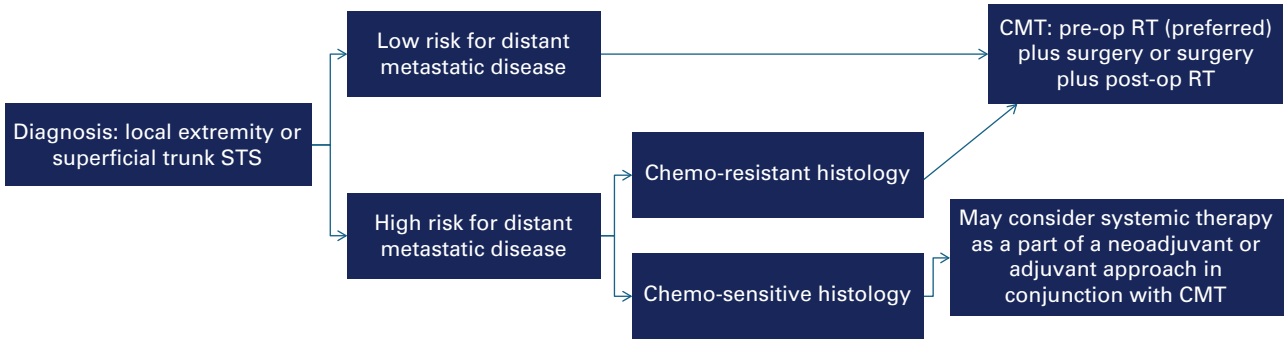
- Tumor grade is a key factor in sarcoma staging, treatment, and patient prognosis.
- Staging of extremity STSs or bone sarcomas should include the lungs, as they are the most common site for distant metastases.

TREATMENT OF LOCALIZED STS: GENERAL PRINCIPLES

SURGERY

The primary curative treatment modality for most sarcomas is surgery (Fig. 17-1). A planned oncologic resection to remove the tumor intact with a rim of normal tissue at the surgical margin (R0 resection) results in a lower risk of local relapse and better long-term patient survival than removal in which sarcoma touches the surgical margin (R1 resection) or in which gross disease remains (R2 resection).

Figure 17-1 Treatment Paradigm for Extremity and Superficial Trunk STS



Abbreviations: CMT, combined modality therapy; RT, radiation therapy; STS, soft tissue sarcoma.

RADIATION THERAPY

Radiation to the site of the primary tumor is the standard of care for all intermediate- and high-grade STS of the extremities or body wall that are larger than 5 cm (Fig. 17-1). RT greatly improves the rates of local control and reduces the need for amputation for patients who have extremity STS. RT may be considered in select cases of low-grade STS, such as situations in which reoperation for recurrence would result in substantial morbidity or for locally recurrent low-grade STS. Patients who have an STS less than 5 cm occurring in an extremity or body wall do not uniformly require adjuvant RT after an R0 resection, although it can be used to prevent local recurrence in an area that would be difficult to manage with surgery in the event of local recurrence.

For intermediate- and high-grade STS, RT can be administered either before or after surgery. Preoperative RT allows for treatment of a smaller field using a lower dosage. This is because the tumor defines the target volume rather than the entire operative bed. A Canadian randomized study of preoperative RT compared with postoperative RT demonstrated similar rates of local disease control.[28] The risk of early wound complications (eg, delayed healing, infection, or need for reoperation) was increased (most often in the leg) with preoperative RT, but the treatment field was smaller, and the radiation dosage was lower than with postoperative RT. The risk of late complications, including fibrosis and lymphedema, seems greater with postoperative RT. The timing of RT should be decided in conjunction with the orthopedic or surgical oncologist. Recently, hypofractionated courses have been reported with encouraging results.[29,30]

In contrast to the benefit of RT for STS of the extremities or body wall, the role of RT for retroperitoneal or visceral STS resected with clear or microscopically positive margins remains controversial and, historically, has not been recommended. The dosages that can be administered postoperatively for abdominal STS generally are limited by normal tissue (eg, bowel) tolerance. Although preoperative RT may be considered for high-grade or large abdominal or retroperitoneal STS, it does not clearly improve survival in these patients but may improve local control.[31]

Intraoperative RT has been used for improved local control when an STS extends to the surgical margin adjacent to critical structures or after resection of local recurrence in a previously irradiated field. Its use, however, is not widely available. Proton radiation can be useful as treatment of STS in anatomic areas with little tolerance for radiation scatter, such as the spine, sacrum, and base of the skull.

Stereotactic body RT, which provides ablative doses of radiation, is frequently used in the setting of recurrent or metastatic disease.[32] Dosage and fractionation should be determined by an experienced radiation oncologist in the setting of a multidisciplinary team.

ADJUVANT CHEMOTHERAPY

The role of chemotherapy in the curative setting for patients who have localized STS (nonrhabdomyosarcoma) has continued to evolve in recent years. Because of the rarity of this group of diseases, older studies enrolled patients who had a variety of STS histologies and were often underpowered to detect a survival benefit. The prolonged periods of time required to accrue meant that treatment regimens were often outdated at the time of study analysis and publication. Despite various conclusions being reached in individual studies, meta-analyses of conducted studies using anthracycline and later anthracycline- and ifosfamide-based regimens have suggested a small but potential survival benefit.[33,34] Modern prospective studies have reached variable conclusions, further fueling debate.

Two large, adequately powered studies prospectively studied the impact of neoadjuvant or adjuvant chemotherapy in localized STS since the most recent meta-analysis. The first, conducted by the European Organization for Research and Treatment of Cancer (EORTC), enrolled intermediate- or high-grade STSs of any size and a wide range of histologies. Patients were randomized after surgery to receive either adjuvant doxorubicin and ifosfamide or no chemotherapy. The study failed to show an OS benefit to adjuvant chemotherapy.[35] A key critique was the inclusion of intermediate-grade and smaller tumors, as both size and grade are important risk factors for the subsequent development of metastatic disease.

A subsequent study attempted to address concerns regarding heterogeneity of risk factors and potential lack of comfort with randomization to placebo, using a different design. In the neoadjuvant setting, patients with five specific sarcoma subtypes (myxoid liposarcoma, leiomyosarcoma, synovial sarcoma, UPS, and malignant peripheral nerve sheath tumor) were randomized to receive either neoadjuvant epirubicin and ifosfamide for three cycles or an active, histology-specific, nonanthracycline-based regimen, which varied for each subtype. Tumors were required to be at least 5 cm in size, high grade, and with a deep anatomic location. The study demonstrated an OS benefit for patients receiving anthracycline (epirubicin) and ifosfamide (AI) over a histology-tailored approach.[36] A critique of this study, however, was that it was not specifically designed to answer whether adjuvant chemotherapy provided a benefit compared with no chemotherapy; rather, it addressed whether a histotype-specific regimen improved outcomes of a more generic anthracycline-based regimen. In this context, it was a negative study. Of note, however, a separate analysis of these patients found that those deemed to be high risk (10-year predicted OS <60%) as determined by a sarcoma-specific nomogram had greater OS when receiving AI compared with predicted OS rates, whereas those predicted to be lower risk (10-year predicted OS ≥60%) and those who received histotype-tailored chemotherapy did not.[37]

Taken together, these studies indicate that adjuvant anthracycline and ifosfamide chemotherapy is likely associated with little benefit in low-risk groups but can potentially impact survival in patients at higher risk of mortality and those with chemotherapy-sensitive histologies. The potential benefit must be balanced against the substantial toxicity associated with these regimens, including high rates of grades 3 and 4 hematologic toxicity as well as substantial risk of nonhematologic toxicity. Although tools such as the nomogram or specific risk factors, such as size and subtype, can assist in risk assessment and selection of patients for adjuvant treatment, the heterogeneity of sarcoma subtypes and anatomic locations is not fully captured by these tools. As such, the judgment of treating physicians and local practice patterns often impact the decision to offer perioperative chemotherapy with curative intent.

More recently, in the setting of reported responses to checkpoint blockade in the metastatic setting of select histologic subtypes and high pathologic response rates with neoadjuvant radiation and checkpoint blockade, the SU2C-SARC032 clinical trial examined the role of neoadjuvant pembrolizumab in combination with preoperative RT, followed by surgical resection and adjuvant pembrolizumab compared with radiation and surgery alone in patients with UPS and pleomorphic or dedifferentiated LPS of the extremity and limb girdle.[2] The addition of pembrolizumab resulted in a significant improvement in 2-year disease-free survival (DFS) for patients who have stage III UPS and pleomorphic or dedifferentiated LPS. Notably, the majority of patients in the study had UPS, and based on subgroup analysis, the benefit appeared to be limited to those patients with grade 3 disease. Although radioimmunotherapy likely represents a significant improvement in tolerability over anthracycline- and ifosfamide-based neoadjuvant systemic therapy, the relative efficacy of the two approaches is not well understood and has not been explicitly studied. Practice patterns are more consistent for specific sarcoma subtypes that are resistant to conventional cytotoxic-based, chemotherapy-based regimens. These include ASPS, clear-cell sarcoma, extraskeletal myxoid chondrosarcoma, and solitary fibrous tumor, among others, for which adjuvant chemotherapy is not offered. By contrast, adjuvant or neoadjuvant chemotherapy has greatly improved OS for patients who have nonpleomorphic rhabdomyosarcoma (eg, embryonal and alveolar rhabdomyosarcoma) and extraskeletal Ewing sarcoma. Although these types of sarcomas are typically seen in the pediatric population and are found less frequently in adults, treatment of adults typically follows the same schedule of therapy as that for pediatric patients when feasible.

KEY POINTS

- Surgical resection remains the standard of care for most patients who have localized STS when treating with curative intent.
- Preoperative or postoperative external-beam RT is used for large (>5 cm in greatest dimension), intermediate- to high-grade STS arising in the extremity or body wall.
- The addition of neoadjuvant and adjuvant pembrolizumab to RT and surgery is shown to significantly improve 2-year DFS for patients who have stage III UPS and pleomorphic or dedifferentiated LPS of the extremity and limb girdle.
- Adjuvant RT is not routinely recommended after resection of retroperitoneal or visceral STS.
- Adjuvant or neoadjuvant chemotherapy with an anthracycline (doxorubicin or epirubicin) and ifosfamide reduces the risk of sarcoma recurrence and may improve OS in patients who have chemotherapy-sensitive STS subtypes that have a high risk for the development of metastasis.
- Patients who have localized extraskeletal Ewing sarcoma should be treated with chemotherapy as administered to patients who have skeletal Ewing sarcoma if not medically contraindicated.
- Embryonal and alveolar rhabdomyosarcomas are aggressive cancers with a propensity for nodal and distant metastases. Depending on clinical group and staging, they are typically managed using surgery, adjuvant RT, and multiagent chemotherapy at centers with experience in treating these STS.

TREATMENT OF METASTATIC STS: SYSTEMIC THERAPY OPTIONS

ANTHRACYCLINES

As single drugs or in combination, anthracyclines, such as doxorubicin and epirubicin, yield the best response rates for metastatic non-GIST STSs (rates of 10%-25% in various studies).[37] PEGylated liposomal doxorubicin has also been studied and is active in the treatment of metastatic STS.[38] Studies show varying degrees of efficacy associated with this agent. It is generally administered at lower dosages and, thus, better tolerated than conventional doxorubicin. Liposomal doxorubicin is commonly used in the treatment of older patients and those with sensitive histologies, such as those who have KS, in which higher dosages of doxorubicin are not likely to be beneficial.

IFOSFAMIDE

Ifosfamide demonstrates single-agent activity in the treatment of advanced STS. Based on available studies, it seems to have a similar degree of activity as doxorubicin. Similar to doxorubicin, there is a dosage-response relationship in the treatment of metastatic STS with increased responses seen at dosages in excess of 10 g/m^2, particularly in chemotherapy-sensitive histologies, such as synovial sarcoma.[39,40] Continuous infusional schedules may be less toxic than bolus administration with conserved activity. There is no direct evidence that such dosages improve survival compared with lower dosages administered conventionally. Ifosfamide is challenging to use and is associated with substantial side effects, including nephrotoxicity, neurologic toxicity, and hemorrhagic cystitis requiring concomitant administration of mesnaand careful monitoring.

DOXORUBICIN-BASED COMBINATIONS

A randomized EORTC trial of doxorubicin at 75 mg/m^2 combined with ifosfamide at 10 g/m^2 per cycle demonstrated an improved objective response rate (26% with the combination and 14% with doxorubicin alone) and progression-free survival (PFS; 7.4

vs. 4.6 months) in patients with advanced sarcoma, but showed OS similar to that with single-agent doxorubicin.[41] Because of toxicity, 18% of patients receiving the combination discontinued treatment before completing six cycles compared with 3% of patients receiving doxorubicin alone. The rate of death resulting from toxic effects was low (<2%) and similar in the two treatment arms. Based on these results, the authors recommended sequential single-agent therapy in the palliative setting when the patient has minimal symptoms from STS and consideration of combination therapy if sarcoma regression would relieve acute symptoms or improve the likelihood of tumor control with surgery or RT.

For patients who require a response and for whom ifosfamide is not appropriate, other doxorubicin-based combinations, including doxorubicin and dacarbazine, have been studied and are listed in national guidelines. Recently, a phase 3 trial demonstrated improved PFS (12.2 vs 6.2 months), response rate (36% vs 13%), and OS with doxorubicin and trabectedin, followed by trabectedin maintenance versus doxorubicin alone for patients with leiomyosarcoma.[5,6]

GEMCITABINE AND DOCETAXEL

Multiple phase 2 studies have evaluated and confirmed the activity of single-agent gemcitabine as well as gemcitabine and docetaxel for patients with STS. To investigate whether docetaxel (an agent with little single-agent activity against sarcoma) had synergistic activity with gemcitabine and improved activity of the regimen, a randomized study was conducted, enrolling patients who had multiple sarcoma subtypes and demonstrated improved PFS and OS for the combination of gemcitabine and docetaxel compared with gemcitabine alone. Because of the novel Bayesian statistical design, the study enrolled only 122 patients across multiple sarcoma subtypes.[42] A second randomized study was conducted in patients specifically who have soft tissue and uterine leiomyosarcoma comparing gemcitabine with gemcitabine and docetaxel. In contrast to the prior study, this second histotype-specific trial failed to demonstrate a PFS or OS benefit with the combination but did reveal a 3-month PFS of 40% for each.[43] The combination remains a treatment option for STS patients, particularly in the United States. Given conflicting data regarding the benefit and the acknowledgment that docetaxel adds substantial toxicity to the regimen, interest remains in evaluating other gemcitabine-based combinations, with examples including vinorelbine, pazopanib, and dacarbazine.[44-47]

Finally, gemcitabine and docetaxel were compared with single-agent doxorubicin in the first-line treatment of unresectable or metastatic STS in the randomized phase 3 GeDDis trial.[48] This study found no difference in the proportion of patients alive and free of disease progression at 24 weeks, but did find that gemcitabine and docetaxel were less convenient to give and associated with more toxicity when compared with doxorubicin. As a result, doxorubicin is most often used in the frontline setting for anthracycline-responsive disease (Fig. 17-2).

Figure 17-2 Treatment Paradigm for Metastatic Soft Tissue Sarcomas^

DURATION OF FRONTLINE THERAPY

No consensus is available as to the duration of frontline therapy for metastatic disease. Some physicians treat until progression or toxicity, whereas others administer a defined number of cycles or to maximum response (clinical or tumor) and then closely

observe patients after therapy for signs or symptoms of tumor progression. The use of traditional doxorubicin has historically been limited to six to eight cycles or a cumulative anthracycline dose of 450 mg/m^2 because of concerns for cardiac toxicity. Although specific guidelines and practices vary, dexrazoxane, a cardioprotectant, should be considered in patients expected to receive high cumulative doses (>250 to 300 mg/m^2) of doxorubicin. If dexrazoxane is unavailable, doxorubicin may be administered as a continuous infusion over 48 to 72 hours as an alternative way to decrease the risk of cardiotoxicity.

SECOND-LINE AND LATER CHEMOTHERAPY

Trabectedin

Trabectedin is a cytotoxic agent that was approved by the US FDA for use in patients who have unresectable or metastatic leiomyosarcoma or liposarcoma after prior treatment with an anthracycline-based chemotherapy regimen. Treatment with trabectedin led to a 45% reduction ($P < .001$) in risk of sarcoma progression or death compared with dacarbazine in a randomized, open-label, international phase 3 study.[49] Trabectedin was administered via a 24-hour infusion. The median PFS was 4.2 months with trabectedin compared with 1.5 months with dacarbazine, with no substantial difference in OS. Objective response rates were less than 10% and not substantially different between the two arms. Principal adverse effects of trabectedin are neutropenia, anemia, thrombocytopenia, increased transaminase levels, increased creatine kinase levels, fatigue, and nausea. Treatment with trabectedin led to a 1.2% incidence of rhabdomyolysis and a 2.1% incidence of treatment-related death; this did not occur in the dacarbazine-treated arm. Therefore, it is important to monitor patients with weekly CPK levels in addition to standard laboratory tests. Older patients (aged >70 years) did not have increased adverse event rates with trabectedin compared with younger individuals. Although not FDA approved for this indication, trabectedin can be considered for translocation-associated sarcomas based on a Japanese study that randomized 76 patients with translocation-associated sarcomas (one-third with myxoid liposarcoma) after progression on standard chemotherapy to receive either trabectedin or best supportive care. Patients receiving trabectedin had a median PFS of 5.6 months compared with 0.9 months in the placebo group.[50]

Eribulin

Eribulin is an antimitotic agent that inhibits microtubule function and, in a phase 3, randomized, open-label trial, improved OS compared with dacarbazine for patients who had previously treated locally advanced or metastatic leiomyosarcoma or liposarcoma.[51] A planned subgroup analysis stratified by sarcoma subtype identified a statistically significant improvement in PFS and OS for patients with liposarcoma treated with eribulin as compared with dacarbazine. There was a 1.2-month difference in median PFS and a 7-month difference in OS in favor of eribulin. No difference in PFS or OS was seen for patients who had leiomyosarcoma. Based on these results, the FDA-approved eribulin for the treatment of unresectable or metastatic liposarcoma in patients who previously received an anthracycline. Patients treated in the phase 3 study had previously received at least an anthracycline and one other chemotherapy. The most frequent adverse events were neutropenia, fatigue, nausea, alopecia, and constipation. Importantly, dacarbazine is likely a more active drug in leiomyosarcoma than liposarcoma, and the lack of benefit seen in the leiomyosarcoma cohort is best interpreted as eribulin and dacarbazine having similar efficacy rather than eribulin being inactive in leiomyosarcoma. On this basis, it is currently considered a standard agent for subsequent treatment of advanced STS beyond just liposarcoma by the National Comprehensive Cancer Network (NCCN), regardless of histology.

MOLECULARLY TARGETED THERAPY, INCLUDING TKIs

Pazopanib, an oral multikinase inhibitor that targets vascular endothelial growth factor (VEGF) receptors, platelet-derived growth factor receptor, alpha (PDGFRA), and PDGFRB, among others, is FDA approved as a treatment for patients with locally advanced or metastatic non-adipocytic STS after treatment with standard chemotherapy. This approval was based on the results of the phase 3, randomized, placebo-controlled PALETTE trial that demonstrated substantial improvement in median PFS involving patients receiving pazopanib as compared with placebo (20 vs 7 weeks).[52] The objective response rate was only 6% in the group receiving pazopanib. The median OS was not substantially different between patients receiving pazopanib compared with those receiving placebo (12.5 vs 10.7 months). Importantly, patients who had liposarcoma or GIST were not included in this trial. Notable severe toxicities associated with pazopanib included fatigue, anorexia, nausea, mucositis, hypertension, diarrhea, rash or desquamation, hypopigmentation, and decline in cardiac ejection fraction. In addition, a boxed warning exists for severe and fatal hepatotoxicity, requiring close monitoring of liver function tests. The target dose is 800 mg daily, although many patients cannot tolerate that dose. Many physicians opt for starting at a lower dose, such as 400 mg daily, with close monitoring of liver enzymes and blood pressure and titration to the full dose as tolerated.

Larotrectinib is a highly selective inhibitor of the three tropomyosin receptor kinases (TRK1, TRK2, and TRK3). The genes (*NTRK1, NTRK2*, and *NTRK3*) encoding these kinases can be constitutively activated by chromosomal translocations, which can be seen in a variety of different cancers, including a rare subset of sarcomas. Larotrectinib was FDA approved for the treatment of solid tumors with a known *NTRK* fusion without a resistance mutation. This approval was made on the basis of a 55-patient study that found this agent was associated with a 75% response rate in these cancers. Notably, this study included 18 patients

with STS.[53] Both larotrectinib and entrectinib are included in the NCCN guidelines as treatment options for sarcomas exhibiting *NTRK* fusions.[54]

Cyclin-dependent kinase 4 (*CDK4*) is frequently amplified along with *MDM2* (MDM2 protooncogene) in well-differentiated and dedifferentiated liposarcomas. Treatment of patients with well-differentiated or dedifferentiated liposarcoma using the selective CDK4 inhibitor palbociclib resulted in one objective tumor response and a median PFS of 18 weeks in a single-arm, open-label, phase 2 trial.[55] The most common adverse events were neutropenia, anemia, and thrombocytopenia. Promising activity was also observed in a phase 2 trial of abemaciclib for dedifferentiated liposarcomas,[56] which is being evaluated in an ongoing placebo-controlled phase 3 trial.[57]

Nab-sirolimus, a formulation of protein-bound particles for injectable suspension, was FDA approved for adult patients who have locally advanced unresectable or metastatic malignant PEComa after completion of a multicenter single-arm clinical trial involving 31 patients. The overall response rate was 39%, with an additional 52% of patients achieving stable disease. The median duration of response was not reached after a median follow-up for response of 2.5 years. The median PFS was 10.6 months, and the median OS was 40.8 months. Responses were seen preferentially in tumors with a *TSC2* mutation.[58] Adverse events observed were similar to those of other commercially available mTOR inhibitors.

In July 2022, the anaplastic lymphoma kinase (ALK) inhibitor crizotinib was approved by the FDA for the treatment of unresectable, recurrent, or refractory ALK-positive inflammatory myofibroblastic tumors. In 12 ALK-positive evaluable patients treated in a prospective single-arm protocol, the objective response rate was 66.7% with a median PFS of 18 months.[59]

IMMUNOTHERAPY

Immune checkpoint inhibitors blocking PD-1, PD-L1, and CTLA-4 have been studied in the treatment of advanced bone and STS. Pembrolizumab was found in a small phase 2 trial to have activity against UPS and dedifferentiated liposarcoma. This trial enrolled a total of 40 patients who had advanced STS. The response rate was 40% in the UPS cohort and 20% in the liposarcoma cohort.[60] Subsequent expansion cohorts for UPS and liposarcoma evaluated 40 patients for each subtype; the final response rates were 23% in UPS and 10% in liposarcoma.[61] There was minimal activity against synovial sarcoma, leiomyosarcoma, and bone sarcomas in this trial. Similar results were observed in a noncomparative phase 2 study of 85 patients with bone sarcomas and STS who received nivolumab (n = 43) or the combination of ipilimumab and nivolumab (n = 42).[62] Response rates were 5% for nivolumab monotherapy and 16% for ipilimumab and nivolumab. Subsequent expansion cohorts for this study included patients who had GIST (n = 18), dedifferentiated liposarcoma (n = 24), and UPS (n = 24). Final 6-month response rates were 0% for patients who have GIST, 14% for those with dedifferentiated liposarcoma, and 14% for those with UPS treated with combination ipilimumab and nivolumab.[63] Finally, a study examining the combination of durvalumab and tremelimumab showed encouraging response rates in cutaneous angiosarcoma (20%), UPS (20%), chordoma (20%), and, importantly, in 40% of patients with ASPS.[64]

A checkpoint blockade with various agents is effective in the treatment of ASPS, either alone or in combination with axitinib.[65,66] Atezolizumab, as a single agent, demonstrated activity against ASPS in a dedicated phase 2 trial with a response rate of 37%, ultimately leading to FDA approval in 2022.[66]

Cutaneous angiosarcomas often exhibit high TMB, and recently, the combination of ipilimumab and nivolumab showed a response rate of 25% in angiosarcoma, with three of five patients who had cutaneous angiosarcomas of the scalp and face achieving partial response.[67] NCCN guidelines currently list pembrolizumab as an appropriate treatment under certain circumstances for advanced or metastatic myxofibrosarcoma, UPS, cutaneous angiosarcoma, ASPS, and undifferentiated sarcomas.

Pembrolizumab is also FDA approved for the treatment of advanced cancers with high MSI or defects in mismatch repair.[68] In addition, it was recently FDA approved for the treatment of advanced cancers with high TMB. Therefore, the small subset of sarcomas that exhibit MSI, defects in mismatch repair, or high TMB should be considered for immunotherapy either as standard of care or in clinical trials. Numerous ongoing clinical trials are exploring checkpoint inhibitors in various combinations with cytotoxic chemotherapies, as well as TKIs for bone sarcomas and STS, to further improve outcomes and further elucidate uncommon subtypes that may respond. Importantly, a correlative analysis from completed trials suggests that tumor PD-L1 expression is not a reliable biomarker for potential response to checkpoint blockade, unlike in other cancers.[69]

Afamitresgene autoleucel, an engineered autologous T-cell receptor product, targeting melanoma-associated antigen A4 (MAGE-A4), was FDA approved for adults who are HLA-A*02:01P, -A*02:02P, -A*02:03P, or -A*02:06P positive, and have unresectable or metastatic MAGE-A4-expressing synovial sarcoma treated with prior chemotherapy. This was based on the single-arm, open-label, phase 2 SPEARHEAD-1 study showing an overall response rate of 39% for patients with synovial sarcoma.[1] Cytokine release syndrome and cytopenias were the most common adverse events observed.

HISTOLOGY-SPECIFIC TREATMENT

Because sarcomas are a biologically heterogeneous group of diseases, it is not surprising that specific sarcoma subtypes may be preferentially sensitive to certain agents (Table 17-3). Ifosfamide is particularly active against synovial sarcoma and seems to be less active against nonuterine soft tissue leiomyosarcomas. Dacarbazine consistently demonstrates modest activity against

leiomyosarcoma, and paclitaxel, as well as PEGylated liposomal doxorubicin, are active against cutaneous or breast angiosarcoma.[70] Studies demonstrate activity of sunitinib, pazopanib, and cediranib against ASPS.[71-73] The combination of temozolomide and bevacizumab, as well as sunitinib and pazopanib, has activity in malignant solitary fibrous tumors.[74-76] As previously noted, immunotherapy has varying activity based on histologic type.

Table 17-3 Select Histology-Specific Treatments and FDA-Approved Agents

Histology	FDA Approved	NCCN Compendia Listed Agents
Angiosarcoma		Paclitaxel; checkpoint inhibitors
ASPS	Atezolizumab	Sunitinib; pazopanib; pembrolizumab ± axitinib
Desmoid tumor	Nirogacestat	Sorafenib; pazopanib
Giant cell tumor of bone	Denosumab	
GIST	Imatinib (first line)	
	Sunitinib (second line)	
	Regorafenib (third line)	
	Ripretinib (fourth line)	
	Avapritinib (PDGFR exon 18 mutations, including D842V)	
Liposarcoma	Trabectedin	
	Eribulin	
LMS	Trabectedin	
Synovial sarcoma	Afamitresgene autoleucel	
TGCT	Pexidartinib	
UPS		Checkpoint inhibitors

Abbreviations: ASPS, alveolar soft part sarcoma; GIST, gastrointestinal stromal tumor; LMS, leiomyosarcoma; NCCN, National Comprehensive Cancer Network; TGCT, tenosynovial giant cell tumor; UPS, undifferentiated pleomorphic sarcoma.

KEY POINTS

- Doxorubicin and ifosfamide are the most active single-agent drugs for metastatic (non-GIST, non-rhabdomyosarcoma) adult STS.
- Anthracycline-based combinations have not consistently improved OS for patients who have metastatic disease, but are reasonable to consider in select patients.
- Sequential single-agent treatment of metastatic disease is a reasonable approach for many patients who have metastatic disease.
- Gemcitabine and docetaxel, as a combination, are active in advanced or metastatic STS with efficacy similar to doxorubicin but with more toxicity.
- Trabectedin is FDA approved in patients with leiomyosarcoma or liposarcoma who have received prior treatment with an anthracycline.
- Eribulin is FDA approved for the treatment of advanced liposarcoma after prior treatment with an anthracycline.
- Pazopanib is FDA approved for non-GIST, non-adipocytic STS patients who have received prior chemotherapy.
- Afamitresgene autoleucel, an engineered autologous T-cell receptor product, targeting MAGE-A4, was FDA approved for adults with select HLA-A*02 serotypes, who have unresectable or metastatic MAGE-A4-expressing synovial sarcoma and have received prior chemotherapy.
- Immune checkpoint inhibitors, for patients with metastatic disease, are under active exploration but appear to have activity in UPS and angiosarcoma, and atezolizumab is FDA approved in ASPS.
- The addition of neoadjuvant and adjuvant pembrolizumab to RT and surgery was shown to significantly improve DFS for patients with stage III UPS and pleomorphic or dedifferentiated LPS of the extremity and limb girdle.
- Treatments are becoming increasingly histology-specific.

SPECIAL CONSIDERATIONS: OTHER SOFT TISSUE NEOPLASMS

DESMOID TUMOR

Desmoid tumor, also known as aggressive fibromatosis, is a locally aggressive soft tissue tumor with no metastatic potential that can occur in the setting of familial adenomatous polyposis (FAP) or sporadically. It is important to refer desmoid patients to genetics, evaluate for somatic mutations, and/or refer for colonoscopy to rule out FAP. It follows an unpredictable course with spontaneous regressions seen in 20% of patients in one recently reported phase 3 trial[77] and 8% in another randomized study of previously progressing patients.[4] Given this unpredictable behavior, global consensus statements recommend a watch-and-wait approach ("active surveillance") with treatment reserved for patients with symptomatic and/or rapidly progressive disease.[78] Given their lack of metastatic potential, symptom palliation and prevention of anatomic complications are the key goals in the treatment of desmoid tumors, with radiographic resolution being a secondary consideration.

Surgical resection of desmoid tumors is problematic because of the high risk of recurrence and morbidity associated with surgery at some sites, and is recommended only for selected patients, generally after multidisciplinary discussion. RT is effective; however, it is associated with a small but concerning risk of secondary malignancies and seems less effective in younger patients, limiting its use for patients younger than 30.[79] Novel interventional approaches, such as cryoablation and high-intensity frequency ultrasound, are also being explored for desmoid tumors.

Until recently, the evidence supporting the activity of individual systemic agents was limited to small and/or uncontrolled case series. More recently, however, two randomized controlled trials confirmed the benefit associated with both sorafenib and pazopanib in the treatment of this disease. Sorafenib, a multitargeted tyrosine kinase targeting both RAF kinases and cell-surface kinase receptors (including VEGF receptors, among others), improved PFS compared with placebo for patients with progressive, symptomatic, or recurrent disease.[77] The study enrolled 87 patients; the median PFS was 9.4 months for placebo, and it had not yet been reached for patients treated with sorafenib. Common adverse effects associated with sorafenib included rash, hypertension, fatigue, palmar-plantar erythrodysesthesia, and pain. Of the patients treated with sorafenib, 18% had to stop treatment due to toxicity. In another clinical trial, pazopanib was compared with methotrexate and vinblastine chemotherapy in a randomized trial and improved the 6-month non-progression rate from 50% to 86%.[80]

Most recently, the results of the international, randomized, placebo-controlled, phase 3 DeFi study evaluating the use of the gamma-secretase inhibitor nirogacestat for patients with progressive desmoid tumor demonstrated a 71% decrease in the risk of tumor progression with nirogacestat, with an overall response rate of 41% versus 8% for placebo.[4] Commonly observed toxicities included diarrhea, hypokalemia, hypophosphatemia, rash, and ovarian dysfunction in women of childbearing age. Other effective agents with varying levels of evidence available in support of their efficacy include liposomal doxorubicin, doxorubicin-based combination chemotherapy, pazopanib, and the combination of methotrexate and vinblastine or vinorelbine.

TENOSYNOVIAL GIANT CELL TUMOR

Tenosynovial giant cell tumor (TGCT), previously known as pigmented villonodular synovitis and giant cell tumor (GCT) of tendon sheath, is a non-malignant, but locally aggressive neoplasm, most commonly affecting joint spaces, and is driven by translocations leading to overexpression of colony-stimulating factor (CSF) 1. It consists of a localized type, which is treated with surgery, and a diffuse type, which is characterized by multiple recurrences despite attempts at surgical resection. Pexidartinib, a selective inhibitor of CSF-1R, was approved by the FDA for the treatment of TGCT not amenable to surgical resection. This agent, in the randomized phase 3 ENLIVEN study, had a 25-week RECIST v1.1 response rate of 39% compared with 0% for placebo.[81] It is a reasonable option for selected patients but has been associated with a small risk of severe hepatotoxicity in the phase 3 clinical trial, and currently can only be prescribed via a risk evaluation and mitigation strategy program. Vimseltinib, another oral CSF-1R antagonist, has also demonstrated a significant improvement in objective response rate (40% for vimseltinib vs 0% in placebo) and clinically meaningful improvements in symptoms and function for patients who have TGCT in the recently published randomized phase 3 MOTION clinical trial (NCT 05059262).[3]

KEY POINTS

- Sorafenib, pazopanib, and nirogacestat are effective in the treatment of desmoid tumors requiring treatment based on disease progression or tumor-related symptoms. Active surveillance is recommended for most patients who are asymptomatic, have minimal symptoms, or are not at risk for anatomic complications from further progression. Nirogacestat is FDA approved for this indication.
- Strategies targeting CSF-1R, such as pexidartinib (FDA approved) and vimseltinib, are effective in TGCT that is not amenable to surgical resection.

SPECIAL CONSIDERATION: KAPOSI SARCOMA

Treatment of KS is aimed at disease control and alleviation of tumor-related symptoms and complications. No treatment is clearly curative. Specific treatment recommendations vary based on the disease extent and the presence or absence of concurrent HIV

infection. Asymptomatic lesions may be observed without direct therapy. In patients who have HIV infection and KS, introduction of antiretroviral therapy (ART), resulting in a decline in viral load and an increase in CD4 cell count, frequently leads to regression in Kaposi lesions with durable clinical response rates greater than 50%.[82] This is standard for all patients who have HIV/AIDS and is the only treatment needed in some cases. Occasionally, and sometimes dramatically, patients with KS who subsequently receive ART experience a sudden flare or burst in KS lesion growth.[83] This phenomenon, known as immune reconstitution inflammatory syndrome, resulting from immune response against pathogens, may occur within weeks to a few months after initiation of ART. In a cohort study of 150 patients who had HIV-associated KS who began ART as the sole treatment of KS, 10 (6.6%) had progressive immune reconstitution inflammatory syndrome–associated KS. In such instances, ART usually can be successfully continued, although chemotherapy may also be required for a time to control KS growth.[84] In HIV-negative patients, classic KS is often an indolent disease that is limited to the skin and managed with local therapies except in advanced cases. The decision to provide specific antitumor local or systemic treatment of KS should be based on several factors, including assessment of disease extent, site of the disease, rate of disease progression, patient-specific psychological factors, and presence of organ dysfunction.[83]

LOCAL TREATMENT

Local treatment may be possible for patients who have limited, nonbulky, and accessible lesions. Alitretinoin gel (0.1%) is the only topical patient-administered therapy approved by the FDA for the treatment of AIDS-related KS.[85]

Other local treatments for KS include alternative topicals such as imiquimod and timolol, intralesional chemotherapy, RT, laser therapy, and cryotherapy, all of which can be effective at controlling local tumor growth. RT has a role in the treatment of KS, particularly when the disease is bulky and symptomatic and when rapid tumor shrinkage is required.

SYSTEMIC THERAPY

Patients who have KS-associated edema, extensive mucocutaneous disease, or symptomatic pulmonary or GI disease need a rapid response, which is best achieved with systemic therapy. Liposomal formulations of doxorubicin and daunorubicin are the standard frontline treatments for patients who have extensive or advanced disease or for those who require rapid tumor shrinkage. For HIV-related KS, each of the two available liposomal anthracyclines proved superior to conventional chemotherapy (bleomycin and vincristine with or without non-liposomal doxorubicin) in terms of response rate and toxicity profile based on the results of randomized prospective clinical trials.[86-88] Liposomal doxorubicin also has substantial activity in classic KS.[88] Patients who have KS whose tumors initially respond well to this treatment may require additional therapy. Low-dose weekly paclitaxel is an established second-line therapy for KS and shows efficacy even for patients who have HIV-associated KS and anthracycline-resistant disease.[89] Pomalidomide is shown to be effective for both HIV-positive and -negative patients. In one representative study, it was administered at a dose of 5 mg once daily on days 1 through 21 of a 28-day cycle. The overall response rate was 73% in the HIV-positive cohort and 100% in the HIV-negative cohort.[90] Based on the results of this trial and other studies, pomalidomide was FDA approved for the treatment of adult patients who have AIDS-related KS after failure of highly active ART, and also for the treatment of KS in adult patients who are HIV negative. More recently, pembrolizumab has demonstrated activity for patients who have classic or endemic KS with a best overall response rate of 71% in a single-arm, phase 2 trial.[91] Oral etoposide, vinorelbine, gemcitabine, bevacizumab, and imatinib have also been evaluated individually for patients who have anthracycline-treated KS and have demonstrated objective responses.

KEY POINTS

- KS may be observed without the use of antineoplastic therapy when the disease burden is limited and asymptomatic.
- ART is the standard frontline treatment of all patients who have HIV-associated KS.
- Immune reconstitution after introduction of ART for patients who have HIV-associated KS may result in tumor flare in 5% to 10% of cases.
- Liposomal anthracycline is the standard first-line chemotherapy for patients requiring systemic treatment of KS because of tumor growth, symptoms, or involvement of visceral organs.
- Paclitaxel is active in anthracycline-resistant KS.
- Pomalidomide is FDA approved for the treatment of advanced KS in both HIV-positive and -negative patients.

SPECIAL CONSIDERATION: GIST

BIOLOGY AND PRESENTATION

GISTs are the most common sarcoma subtype and are characterized by the presence of the CD117 (KIT protooncogene, receptor tyrosine kinase [*KIT*]) and/or DOG-1 (discovered on GIST-1) immunohistochemical markers; most express the stem cell marker CD34. Most GISTs have activating mutations in the *KIT* or *PDGFRA* gene. Approximately 10% to 15% of GISTs use alternative mechanisms for pathogenesis, including loss of function of the succinate dehydrogenase (*SDH*) complex, inactivating mutations

in neurofibromin-1 (*NF-1*), and activating mutations in *BRAF*.[92] Rarely, *NTRK* fusions can also be seen in these tumors.[93] These latter three types of GIST, those without *KIT* or *PDGFRA* mutations, were previously referred to as wild-type GIST.

GISTs are thought to arise from the interstitial cells of Cajal, the pacemaker cells of the GI tract. Approximately 65% of GISTs occur in the stomach, 25% in the small bowel, and the remainder in other sites along the GI tract or in the abdomen. GISTs occurring in the setting of neurofibromatosis predominantly appear in the small intestine, including the duodenum, as multifocal tumors and frequently exhibit a low mitotic rate.[94]

In some cases, GISTs are found unexpectedly during an endoscopy study in the absence of symptoms. Often, symptoms are nonspecific, such as bloating and early satiety. They can also present with bleeding, causing substantial anemia, and less commonly can cause frank bowel obstruction. CT is the imaging study of choice, and an endoscopic biopsy for localized disease is the standard of care for determining a diagnosis, particularly if neoadjuvant therapy is planned.

The primary treatment of localized GIST is surgery, although surveillance with periodic endoscopic ultrasound can be considered for gastric GISTs less than 2 cm in size that do not have high-risk features by endoscopic ultrasound. High-risk features include irregular borders, cystic spaces, ulceration, echogenic foci, or internal heterogeneity.[95] The most common sites for metastatic recurrence are the peritoneum and liver. Nodal, bone, and pulmonary metastases from GIST have been described but are rare.

Tumors are staged on the basis of size, location in the GI tract, mitotic rate, involvement of lymph nodes, and presence of metastasis. The involvement of lymph nodes (rare) or the presence of metastasis is classified as stage IV disease. GIST is graded by mitotic rate. A low mitotic rate is 5 or fewer mitoses per 5 mm^2 (50 microscopic fields using 40× magnification); a high mitotic rate is more than 5 mitoses per 5 mm^2. The occurrence of tumor rupture before or during surgery is associated with a high risk of GIST recurrence.

LOCALIZED DISEASE

Adjuvant Therapy

Imatinib is a standard adjuvant treatment for patients who have resected GIST at an elevated risk of recurrence. It was initially FDA approved based on the Z9001 study, which showed improved recurrence-free survival (RFS) when administered for 1 year in comparison with no adjuvant treatment.[96] The SSG XVIII trial, a large, randomized, open-label trial, examined the use of imatinib administered for 1 year compared with 3 years after complete resection of high-risk GIST.[97,98] High risk was defined by a tumor size larger than 10 cm, a mitotic count of more than 10 per 50 high-power field (hpf), a tumor size larger than 5 cm with a mitotic count of more than 5 per 50 hpf, or tumor rupture. The study revealed improvements in both RFS and OS. Most recently, the multicenter, open-label, randomized phase 3 IMADGIST study explored the use of 6 years of adjuvant imatinib compared to 3 years in patients with a recurrence risk of at least 35%. An improvement in RFS was observed, but data on OS were premature.[98]

Imatinib therapy can be associated with intolerable adverse effects, and one-quarter of the patients assigned to take imatinib for 3 years discontinued treatment early for reasons other than disease recurrence. Periorbital edema, muscle cramps, leukopenia, and elevation in serum creatinine level were more common in patients assigned to 3 years of imatinib. Based on the information currently available, it is reasonable to discuss adjuvant imatinib therapy for at least 3 years with patients who are at high risk of tumor relapse. Importantly, adjuvant imatinib is not recommended for patients with imatinib-insensitive disease, including wild-type (non-*KIT*, non-*PDGFRA* mutated) GIST or those with a *PDGFRA* exon 18 D842V mutation.

Neoadjuvant Therapy

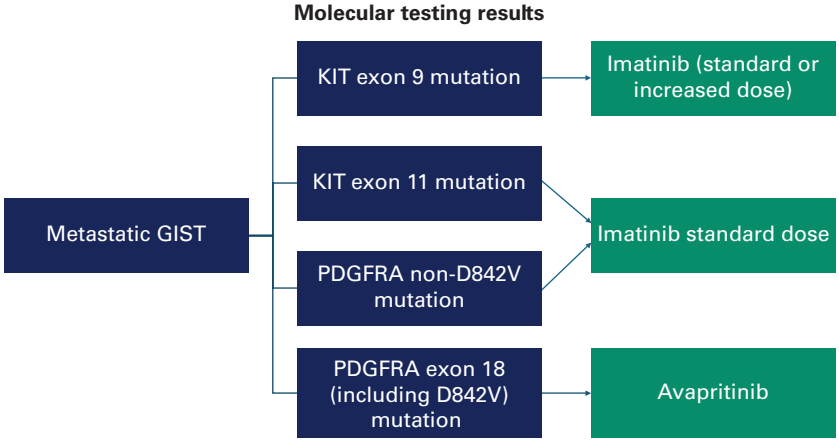
The primary treatment of localized GIST is surgery. Imatinib can be considered as neoadjuvant therapy for patients who have high predicted morbidity associated with primary surgery, though this has not been prospectively studied. In that setting, optimal response to imatinib can take up to 12 months based on data in advanced disease. No evidence is available that neoadjuvant imatinib improves outcomes compared with adjuvant imatinib, but it may help extent of surgery eventually required. If neoadjuvant or adjuvant therapy is considered, mutation testing to confirm the presence of a responsive *KIT*/*PDGFRA* mutation is recommended beforehand to ensure the tumor is likely to respond. If neoadjuvant therapy is pursued, risk stratification for further adjuvant therapy should be done based on the pretreatment biopsy, as treatment with imatinib is likely to lower the observed mitotic rate.

Advanced Disease

Cytotoxic chemotherapy is ineffective for the treatment of GIST. However, imatinib has remarkable activity against most *KIT* or *PDGFRA* mutation-positive GISTs. In early-phase studies of imatinib therapy for metastatic GIST, response rates were approximately 54%, with an additional 28% of patients achieving stable disease.[99] In randomized phase 2 and 3 studies, a once-daily dose of 400 mg was as effective as 600 or 800 mg of imatinib daily.[99,100] As a result, 400 mg daily of oral imatinib is the standard treatment of metastatic GIST (Fig. 17-3). The *KIT* genotype of a GIST predicts the responsiveness of the tumor to imatinib. Patients who have mutations in exon 11 of *KIT* have a greater chance of response to imatinib than patients with exon 9 *KIT* mutations or wild-type *KIT*.[101] Tumors that harbor the *PDGFRA* mutation D842V are particularly insensitive to imatinib, although other mutations in *PDGFRA* are imatinib sensitive. Avapritinib is a TKI directed against the *PDGFRA* D842V mutation.

In the phase 1 NAVIGATOR clinical trial, this agent yielded an impressive 88% response rate in the treatment of patients with this previously highly resistant mutation.[102] Based on these data, avapritinib was FDA approved for the treatment of unresectable or metastatic GIST harboring a *PDGFRA* exon 18 mutation, including the D842V mutation.

Figure 17-3 GIST Treatment Options Algorithm in the First-Line Setting



Abbreviation: GIST, gastrointestinal stromal tumor.

Patients with GIST harboring an activating mutation in exon 9 of *KIT* may benefit from a higher starting dose of imatinib (400 mg twice daily). A meta-analysis of two large, randomized trials comparing 400 mg of imatinib daily with 400 mg twice daily in the treatment of advanced or metastatic GIST confirmed a small PFS advantage and detected a higher objective response rate associated with the higher dose for patients with exon 9 *KIT* mutations.[103] However, with a median follow-up of more than 40 months, there was no improvement in OS. There was no difference in outcome between the standard and high-dose groups among patients who had the more common exon 11 *KIT* mutations.

After disease progression with 400 mg of imatinib daily, a conventional approach is to increase the dosage to a total daily dose of 800 mg (or 600 mg if the higher dose is not tolerated). Approximately one-third of patients may have some degree of tumor control after escalation of imatinib dosage.[99,104]

For patients with imatinib-refractory disease or patients intolerant to imatinib, sunitinib is the standard second-line therapy based on a randomized, phase 3 study, showing improved PFS compared with placebo.[105] The median duration of PFS in the sunitinib arm was 24 weeks compared with 6 weeks for patients treated with placebo. OS was superior in the sunitinib arm. Objective tumor responses, however, were infrequent (less than 10% of patients). The most frequently reported adverse effects of sunitinib were fatigue, diarrhea, skin discoloration, and nausea, each occurring in more than 20% of patients. Patients with *KIT* exon 9 mutations appear to have more clinical benefit in terms of response rate and PFS with sunitinib compared with those with *KIT* exon 11 mutations.[106] Hypertension and hypothyroidism are also known toxicities of sunitinib and should be closely monitored and treated immediately when identified. Rare cases of fatal liver and cardiac events have been reported.

Regorafenib, at a dose of 160 mg daily for 3 of every 4 weeks, is approved for the treatment of GIST after the development of resistance to imatinib and sunitinib based on the results of a randomized, blinded, placebo-controlled trial.[107] The median PFS was 5 months for patients receiving regorafenib compared with 1 month for patients receiving placebo. The most common severe adverse events related to regorafenib were hypertension and hand-foot skin reaction, which occurred in 24% and 20% of patients, respectively.

Ripretinib is a novel TKI that targets not only *KIT* but also *PDGFRA* mutations commonly found in advanced GIST. In the phase 3 INVICTUS trial, this agent was compared with placebo for patients with metastatic GIST who had been previously treated with imatinib, sunitinib, and regorafenib.[108] Patients treated with ripretinib had a median PFS of 6.3 months compared with 1.6 months in the placebo group. Based on these data, it was FDA approved in May 2020 for the treatment of advanced GIST for patients who have received three or more TKIs. Given that ripretinib is active against mutations in the activation loop of *KIT*, it was hoped that earlier-line use of this agent would yield improved PFS compared with sunitinib. Unfortunately, this was not demonstrated in the recent phase 3 randomized INTRIGUE study despite patients on ripretinib experiencing fewer severe adverse events.[109] However, an exploratory subgroup analysis indicated that certain resistance mutations (*KIT* exon 11 with secondary 17/18 mutations) were associated with longer PFS in patients who received ripretinib. Of note, an increase from standard dose ripretinib (150 mg daily) to dose-escalated (150 mg twice daily) therapy can be considered upon progression.[110,111]

Surgery and Other Local Therapies

Surgery and other local therapies can play a potential role in the setting of limited, progressive, metastatic disease.[112] In some patients who have multifocal metastatic disease, progression is identified in a limited number of sites with other sites remaining under control. Patients with this pattern of disease progression can be treated successfully with resection of progressing sites coupled with continued TKI therapy. In the liver—the most common site of metastasis—ablation and other types of liver-directed therapy can be considered for oligoprogression when surgery is not feasible. It is essential to continue TKI therapy in such patients because of the risk of rapid progression without systemic treatment. Patients who have multiple sites of disease progression, indicative of generalized resistance to systemic therapy, are not appropriate candidates for local therapies because they almost universally experience additional progression soon afterwards.

PRESENTING CASE STUDY

A 60-year-old woman presents to her primary care physician with a long-standing history of persistent iron-refractory iron-deficiency anemia and ongoing fatigue; she has no other pertinent past medical history. Gastrointestinal testing reveals a 4.8-cm submucosal small bowel tumor associated with ulceration but without stigmata of recent bleeding. Endoscopic biopsy identifies a spindle cell tumor that is positive for *KIT* (CD117) and DOG-1, consistent with a diagnosis of gastrointestinal stromal tumor (GIST). The patient undergoes primary surgical resection with partial small bowel resection. Pathology confirms GIST with 18 mitoses/50 hpf. *KIT* gene sequencing demonstrates a mutation in exon 11. She is referred to medical oncology for consideration of adjuvant therapy.

Based on the characteristics of this patient's tumor, what is the next best step?

Surgical resection is the standard of care for patients with localized GIST. This patient exhibits high-risk features for recurrent disease, including a non-gastric primary location and a mitotic rate greater than 10 mitoses/50 hpf. Based on the SSGXVIII/AIO study, 3 years of adjuvant imatinib improved both recurrence-free and OS compared to 1 year of adjuvant therapy. *KIT* exon 11 mutations are predicted to be sensitive to imatinib. As a result, adjuvant imatinib is the next best step. Although the optimal duration of adjuvant therapy is unknown, data would currently support at least 3 years. Recently published data from the IMADGIST study, comparing 6 years to 3 years of adjuvant imatinib, revealed an improvement in recurrence-free survival, while data for OS were premature.

Two years after completing therapy, imaging reveals multifocal hepatic disease; biopsy indicates metastatic GIST. Molecular testing again reveals a *KIT* exon 11 mutation with no evidence of secondary mutations. How would you proceed based on these findings?

Resumption of systemic therapy with imatinib (400 mg, once daily) would be the most appropriate next step. Lifelong therapy with a KIT-targeted tyrosine kinase inhibitor (TKI) is now recommended, as trials exploring discontinuation have universally shown more rapid progression of metastatic disease off TKI-based therapy.

KEY POINTS

- Most GISTs have activating mutations in the *KIT* or *PDGFRA* gene.
- Surgery is the best curative treatment of primary GIST, although surveillance is an option for small gastric GISTs without high-risk features on endoscopic ultrasound.
- For patients who have localized GIST at high risk of recurrence, 400 mg of imatinib daily for at least 3 years after surgery delays time to recurrence and improves OS.
- Imatinib at a dosage of 400 mg daily is the standard of care in first-line therapy for metastatic GIST with sensitive mutations. Dose escalation can be considered upon progression.
- Patients with *KIT* exon 9–mutated GISTs may benefit from a higher initial starting dose of imatinib (eg, 400 mg twice daily).
- GISTs with *PDGFRA* exon 18 D842V mutations are resistant to imatinib but highly responsive to avapritinib.
- Sunitinib is FDA approved as a second-line therapy for patients with imatinib-refractory GIST or who cannot tolerate imatinib.
- Regorafenib is FDA approved for third-line treatment of GIST after failure of imatinib and sunitinib.
- Ripretinib is FDA approved for fourth-line treatment of GIST after treatment with at least three prior TKIs. Dosage escalation can be considered upon progression.
- Local therapies (eg, surgery, liver-directed therapy) may be appropriate in conjunction with continued TKI therapy for patients with limited progression of metastatic disease.

BONE SARCOMAS

OSTEOSARCOMA

Osteosarcomas are the most common primary tumors of bone, with two peaks of incidence: one between ages 10 and 20 years and a smaller peak between ages 60 and 80 years. Disease in the latter age group is sometimes associated with Paget's disease of bone. Osteosarcomas generally arise in the metaphysis of the bone (between the bone end [epiphysis] and the shaft [diaphysis]). They are characterized by lytic and blastic features in admixed bone. If the tumors extend to soft tissue, they can cause both a periosteal reaction and ossification in a pattern perpendicular to the surface of the bone (Fig. 17-4).

Figure 17-4 Osteosarcoma of the Right Distal Femur With Characteristic Cortical Destruction and Bone Formation

(A) At diagnosis. (B) After three cycles of neoadjuvant doxorubicin and cisplatin with coarsening of calcification consistent with response to therapy.

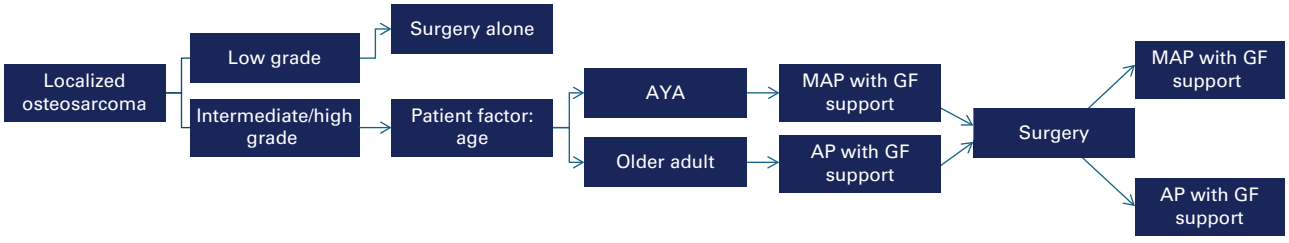
Neoadjuvant and adjuvant chemotherapy are the standard of care for most patients who have osteosarcomas (Fig. 17-5). It has resulted in significant improvement in 5-year survival rates from approximately 20% with surgery alone to as high as 80% in patients with responsive disease. Neoadjuvant chemotherapy is often preferred because it allows for assessment of histologic response, which is a major prognostic factor in localized high-grade osteosarcoma. Nearly all patients with localized osteosarcoma benefit from chemotherapy. The exception is superficial low-grade osteosarcomas for which adjuvant chemotherapy is not indicated. For conventional osteosarcomas, six cycles of cisplatin and doxorubicin were found to be as effective as a more complex seven-drug regimen in one randomized multicenter study.[113]

Figure 17-5 Treatment Paradigm for Localized Osteosarcoma



Abbreviations: AP, doxorubicin, cisplatin; AYA, adolescent and young adult; GF, growth factor; MAP, methotrexate, doxorubicin, cisplatin.

Data regarding the use of methotrexate remains somewhat controversial in adult patients. However, the combination of doxorubicin, cisplatin, and high-dose methotrexate (methotrexate, doxorubicin, cisplatin [MAP] chemotherapy) is a standard therapy in young patients who have normal cardiac and renal function based on pediatric osteosarcoma studies. In older adults,

high-dose methotrexate is associated with delayed clearance, increased risk of nephrotoxicity, and acute lung injury. Given these risks and the unclear benefit associated with this agent, methotrexate is not routinely considered a standard component of the treatment of adults.

The response of osteosarcomas to neoadjuvant chemotherapy is best assessed by pathologic examination at the time of surgery. This examination assesses the percentage of viable tumor in the total volume of the resection specimen. Presently, there is no evidence that changing therapy improves OS for patients who have osteosarcoma and have a poor response to preoperative chemotherapy. EURAMOS-1, a large, international, randomized, phase 3 trial, evaluated the addition of ifosfamide and etoposide (IE) for patients with ≥10% viable tumor (poor histologic response) after two cycles of MAP. Of note, the addition of IE resulted in increased toxicity with no improvement in event-free survival (EFS). The 3-year EFS rate was 55% in the control group and 53% in the group receiving IE.[114] Because patients with poorly responding osteosarcoma treated with full-course chemotherapy have higher survival rates than patients who do not receive additional chemotherapy, all patients should be offered adjuvant chemotherapy for treatment of primary osteosarcoma, regardless of histologic response.

RT is not commonly used as an adjuvant or neoadjuvant treatment of localized high-grade osteosarcoma. It can, however, be considered for patients who have undergone positive-margin surgery (such as a head-and-neck osteosarcoma) for whom additional surgery may result in significant morbidity. Of note, it has no role for those who have undergone negative-margin surgery.

Osteosarcomas typically metastasize to the lung. Resection of pulmonary metastases (stage IVA disease) can be curative in a substantial minority of patients.[115] Patients with fewer than three pulmonary metastases who are more than 2 years from diagnosis to the development of lung metastasis have the best survival rates after metastasectomy.

IE has activity in relapsed osteosarcoma.[116,117] Gemcitabine (with or without docetaxel) also has some activity in this setting.[118] More recently, TKIs have demonstrated activity in the treatment of advanced osteosarcoma. Regorafenib was compared with placebo in two randomized, phase 2 clinical trials for patients with known progressive disease, many of whom had previously been treated with chemotherapy for metastatic disease. In the REGOBONE study, the median PFS was 16.4 weeks in the regorafenib group compared with 4.1 weeks for those on placebo.[119] In the SARC024 study, the median PFS was 3.6 months with regorafenib compared with 1.7 months for placebo.[120] The most common toxicities encountered were hypertension, hand-foot syndrome, asthenia, and diarrhea. Sorafenib and cabozantinib have also shown activity in osteosarcoma.[121,122]

EWING SARCOMA

Ewing sarcoma typically occurs in the bones of children and less commonly in adults. Radiographically, skeletal Ewing sarcoma usually affects the shaft of the bone in an infiltrative pattern called onion skinning, which is easily visible on CT scans and X-rays (Fig. 17-6). On microscopy, Ewing sarcoma appears as monotonous sheets of small, round, blue cells that express high levels of a cell-surface glycoprotein (CD99) and the nuclear factor FLI-1, which can be detected using immunohistochemistry. However, expression of CD99 and FLI-1 is not specific for Ewing sarcoma, and molecular studies may be performed to detect the characteristic chromosome translocations present in the disease. Most Ewing sarcomas have reciprocal translocation involving *EWSR1* and *FLI-1*, with a small minority involving *EWSR1* and *ERG* or other less commonly seen partners. A small percentage have alterations that do not involve *EWSR1*.

Recently, other undifferentiated round cell sarcomas, specifically those harboring *CIC-DUX4* and *BCOR-CCNB3* translocations, have been identified. These tumors, although previously grouped within the Ewing sarcoma family of tumors (ESFT) and often treated similarly to Ewing sarcoma, likely have their own distinct biology, responsiveness to treatment, and prognosis.[123]

Localized Disease

Multimodality therapy with surgery, chemotherapy, and RT is the standard of care for localized ESFT and results in greater than 50% cure rates (Fig. 17-7). Local treatment of the primary site of disease is usually performed after an initial 12 to 18 weeks of multiagent chemotherapy. Complete resection of the tumor is preferred when feasible. RT is administered as an adjuvant for the treatment of microscopic residual tumor or as definitive local therapy if surgery cannot be performed with acceptable morbidity.

The combination of vincristine, doxorubicin, and cyclophosphamide (VDC) with IE is the current standard chemotherapy regimen used and showed improvements in relapse-free survival and OS when compared with VDC alone in a study performed primarily in pediatric patients with nonmetastatic Ewing sarcoma.[124] Of note, a randomized trial of VDC alternating with IE every 2 weeks (known as interval-compressed therapy) for a total of 14 cycles, as compared with the standard every 3-week dosing schedule in patients aged younger than 50 years with localized Ewing sarcoma, demonstrated an improvement in RFS.[125] The toxicity profile and frequency did not differ between arms, and secondary malignancies, including acute leukemia, osteosarcoma, and lymphoma, occurred in approximately 3% of patients. Whereas interval-compressed therapy has become a reasonable standard for adolescent and young adult patients, a minority of adult patients (12% of the study population) were enrolled in this study.

Late recurrence of Ewing sarcoma, more than 5 years after initial diagnosis, occurs in approximately 10% to 15% of children and adolescents, with approximately 25% of the late recurrences developing more than 10 years after diagnosis.[126] As a result, long-term surveillance is recommended.

Metastatic Disease

For metastatic Ewing sarcomas, the addition of IE to VDC in the upfront setting did not appear to improve survival outcomes over VDC alone, although the study was likely underpowered to identify a survival difference in the metastatic patient population.[124] In the relapsed setting, the phase 3 rEECur study examined the activity of several frequently used salvage regimens, including high-dose ifosfamide, cyclophosphamide in combination with topotecan, irinotecan in combination with temozolomide, and gemcitabine in

combination with docetaxel, using a Bayesian approach and multiple pairwise comparisons. Among the regimens examined, gemcitabine in combination with docetaxel appears to be the least favored, whereas high-dose ifosfamide appeared to be the most favored.[127]

CHONDROSARCOMA

Chondrosarcomas are the second most common primary tumor of bone and usually affect patients aged 60 years or older. On radiographs, chondrosarcomas generally appear as a radiolucent area with obvious bony destruction and a moderate number of discrete calcified areas. They most often involve the medullary cavity and have scalloped edges consistent with a multinodular growth pattern. Metastases from conventional chondrosarcoma often involve the lung, follow a relatively indolent growth rate, and may be managed by surgery if limited in number.

There is no role for traditional chemotherapy in the management of most conventional chondrosarcomas, as they are highly resistant to chemotherapy. Patients who have unresectable metastatic or recurrent chondrosarcoma are best served by clinical trial participation when available. Chondrosarcomas may have activating mutations in different receptor tyrosine kinases as well as mutations in isocitrate dehydrogenase 1 (*IDH1*) and isocitrate dehydrogenase 2 (*IDH2*). The NCCN guidelines list the IDH1 inhibitor ivosidenib as a potential option for *IDH1*-mutated chondrosarcomas.[128] Pazopanib is additionally listed based on a phase 2 prospective study revealing a disease control rate at 16 weeks of 43%, a median PFS of 7.9 months, and a median OS of 17.6 months.[129] Finally, dasatinib can be considered based on more limited data.

Dedifferentiated chondrosarcoma is generally a high-grade variant and occasionally responds to chemotherapy used for osteosarcoma. Patients who have mesenchymal chondrosarcoma, another high-grade variant that resembles Ewing sarcoma on routine staining, may benefit from chemotherapy used for the treatment of Ewing sarcoma. Extraskeletal myxoid chondrosarcoma is not a cartilaginous tumor, but rather a soft tissue malignancy that often occurs in deep soft tissue and is characterized by chromosomal translocations involving *NR4A3*. It has a relatively indolent growth rate, a high risk of dissemination, and is relatively resistant to chemotherapy.[130,131]

GCT OF BONE

GCT of bone is a rare, primary tumor of bone composed of malignant stromal cells that secrete receptor activator of nuclear factor-kappa B (RANK) ligand and recruit multinucleated osteoclast-like cells that result in bone lysis. Although considered largely benign, metastatic disease can occur in a small number of cases (primarily to the lungs).

Patients usually present with lytic bone destruction, pain, and restricted mobility of the joint adjacent to the lesion. Management of primary disease typically involves complete curettage of the lesion, often followed by intralesional adjuvant therapy with heat, freezing, or chemicals (eg, phenol). Approximately 10% to 20% of tumors recur locally, often necessitating joint resection and replacement; metastasis occurs in approximately 1% of cases. The use of denosumab, an inhibitory monoclonal antibody to RANK ligand, administered subcutaneously during the first month on days 1, 8, and 15, followed by day 1 monthly dosing thereafter, resulted in a lack of tumor progression in the large majority of patients in a phase 2 trial.[132] Substantial adverse events that occurred during denosumab treatment included osteonecrosis of the jaw in 1% of patients, hypocalcemia in 5%, and hypophosphatemia in 3%. Based on the high rate of tumor control and relatively low rate of adverse effects from denosumab treatment of GCT of bone, the FDA-approved denosumab as treatment of patients with unresectable GCT of bone or in situations in which complete resection would result in severe morbidity in adults and skeletally mature adolescents.

KEY POINTS

- Chemotherapy is critical for curative intent treatment of localized osteosarcoma.
- Doxorubicin and cisplatin are commonly used as standard therapy in adult patients, and high-dose methotrexate (MAP chemotherapy) is added in the treatment of children and young adults with normal renal function.
- The addition of IE does not improve survival for individuals who have a poor response to initial MAP chemotherapy.
- Resection of lung metastases (metastasectomy) should be considered for patients with osteosarcoma.
- TKIs, such as regorafenib, show activity in patients with metastatic osteosarcoma.
- Multimodality therapy, including multiagent chemotherapy, surgery, and/or RT, is critical in the management of patients who have localized Ewing sarcoma.
- Interval-compressed VDC/IE is the standard treatment approach for adolescents and young adults who have localized disease.
- Conventional chondrosarcomas are generally low to intermediate grade and are resistant to chemotherapy. There is no currently FDA-approved therapy.
- Denosumab, a monoclonal antibody targeting RANK ligand, is FDA approved for the treatment of GCT of bone that is deemed unresectable or for which surgery would likely result in severe morbidity.

SURVIVORSHIP

Survivors of childhood cancer are at risk for the development of secondary cancers, including sarcomas. The Childhood Cancer Survivor Study identified a ninefold higher risk of a secondary sarcoma among survivors of childhood cancer compared with the general population.[133] Moreover, the great improvement in long-term survival rates of children and adults with sarcoma, especially Ewing sarcoma, osteosarcoma, and rhabdomyosarcoma, from multimodality treatment comes at a high cost for a minority of patients. Serious late effects of treatment include secondary malignancy, infertility, cardiomyopathy, nephropathy, neuropathy, hearing impairment, and limb dysfunction. The cumulative incidence of secondary malignancy in children treated for sarcoma is approximately 1% to 3% at 10 to 20 years, with the highest risk for patients who received chemotherapy and RT. Children treated for sarcoma have a threefold to sixfold higher risk of secondary cancer than those in the age-matched general population.[134,135]

Adults who have sarcoma treated with chemotherapy and/or RT are also at risk for long-term complications, including secondary malignancies and radiation-induced fibrosis and lymphedema. Symptomatic cardiomyopathy develops in approximately 1% to 2% of patients treated for sarcoma with doxorubicin and ifosfamide, and renal tubular and/or glomerular dysfunction develops in 5% to 10%, with the risk related to the cumulative dose received. Infertility is most often related to exposure to alkylating agents and affects postpubescent men more often than women. The Children's Oncology Group has guidelines for the long-term follow-up of survivors of childhood, adolescent, and young adult cancers (http://www.survivorshipguidelines.org).

HIGH-YIELD TAKEAWAYS

- The treatment of metastatic GIST follows a clear sequence of sequential TKI-based therapy (see the following) based on drug approvals, although specific mutations may confer differential sensitivity to various agents. This applies to *KIT* and *PDGFRA* mutant GIST, with the exception of *PDGFRA* D842V mutant GIST, for which avapritinib is the only FDA-approved therapy.

Line of Treatment	Agent
First	Imatinib
Second	Sunitinib
Third	Regorafenib
Fourth	Ripretinib

- Patients who have localized GIST should be considered for adjuvant therapy with imatinib if their tumors are at high risk for recurrence. Risk factors that suggest high risk include a non-gastric primary location, a tumor size larger than 10 cm, a mitotic rate of more than 10 per 50 hpf, a tumor size larger than 5 cm with a mitotic rate of more than 5 per 50 hpf, or tumor rupture. The optimal duration of adjuvant therapy is unknown, but at least 3 years is recommended for high-risk disease. Given the extremely high risk for disease recurrence after tumor rupture, some advocate long-term therapy for this situation.
- Patients who have most subtypes of metastatic STS are generally treated with doxorubicin-based chemotherapy in the first line.
- Ewing sarcoma and osteosarcoma are both chemosensitive tumors with high metastatic potential. Nonmetastatic tumors are treated with chemotherapy both before and after local control interventions (surgery, RT, or both).

SARCOMA 17

CHAPTER SUMMARY GUIDE

KEY POINTS

- Sarcomas account for approximately 1% of cancers in adults.
- STSs are three to four times more common than those of bone.
- Individuals who have certain hereditary cancer susceptibility syndromes, such as Li-Fraumeni, have an increased risk of sarcoma.
- Therapeutic radiation confers a small but definite risk for the development of sarcoma.
- HHV-8 infection is associated with KS.
- Approximately 30% to 40% of sarcomas have defined, recurring, specific genetic alterations such as chromosomal translocations, gene amplifications, or mutations that contribute to pathogenesis.
- STSs often present as enlarging masses and may be painful or painless.
- Bone sarcomas are usually associated with pain.
- A core needle or incisional biopsy is required to obtain sufficient tumor material for definitive diagnosis and sarcoma subtype classification.
- Angiosarcoma and KS can present as dermal-only or visceral disease.
- Tumor grade is a key factor in sarcoma staging, treatment, and patient prognosis.
- Staging of extremity STSs or bone sarcomas should include the lungs, as they are the most common site for distant metastases.
- Surgical resection remains the standard of care for most patients who have localized STS when treating with curative intent.
- Preoperative or postoperative external-beam RT is used for large (>5 cm in greatest dimension), intermediate- to high-grade STS arising in the extremity or body wall.
- The addition of neoadjuvant and adjuvant pembrolizumab to RT and surgery is shown to significantly improve 2-year DFS for patients who have stage III UPS and pleomorphic or dedifferentiated LPS of the extremity and limb girdle.
- Adjuvant RT is not routinely recommended after resection of retroperitoneal or visceral STS.
- Adjuvant or neoadjuvant chemotherapy with an anthracycline (doxorubicin or epirubicin) and ifosfamide reduces the risk of sarcoma recurrence and may improve OS in patients who have chemotherapy-sensitive STS subtypes that have a high risk for the development of metastasis.
- Patients who have localized extraskeletal Ewing sarcoma should be treated with chemotherapy as administered to patients who have skeletal Ewing sarcoma if not medically contraindicated.
- Embryonal and alveolar rhabdomyosarcomas are aggressive cancers with a propensity for nodal and distant metastases. Depending on clinical group and staging, they are typically managed using surgery, adjuvant RT, and multiagent chemotherapy at centers with experience in treating these STS.
- Doxorubicin and ifosfamide are the most active single-agent drugs for metastatic (non-GIST, non-rhabdomyosarcoma) adult STS.
- Anthracycline-based combinations have not consistently improved OS for patients who have metastatic disease, but are reasonable to consider in select patients.
- Sequential single-agent treatment of metastatic disease is a reasonable approach for many patients who have metastatic disease.
- Gemcitabine and docetaxel, as a combination, are active in advanced or metastatic STS with efficacy similar to doxorubicin but with more toxicity.
- Trabectedin is FDA approved in patients with leiomyosarcoma or liposarcoma who have received prior treatment with an anthracycline.
- Eribulin is FDA approved for the treatment of advanced liposarcoma after prior treatment with an anthracycline.
- Pazopanib is FDA approved for non-GIST, non-adipocytic STS patients who have received prior chemotherapy.
- Afamitresgene autoleucel, an engineered autologous T-cell receptor product, targeting MAGE-A4, was FDA approved for adults with select HLA-A*02 serotypes, who have unresectable or metastatic MAGE-A4-expressing synovial sarcoma and have received prior chemotherapy.

- Immune checkpoint inhibitors, for patients with metastatic disease, are under active exploration but appear to have activity in UPS and angiosarcoma, and atezolizumab is FDA approved in ASPS.
- The addition of neoadjuvant and adjuvant pembrolizumab to RT and surgery was shown to significantly improve DFS for patients with stage III UPS and pleomorphic or dedifferentiated LPS of the extremity and limb girdle.
- Treatments are becoming increasingly histology-specific.
- Sorafenib, pazopanib, and nirogacestat are effective in the treatment of desmoid tumors requiring treatment based on disease progression or tumor-related symptoms. Active surveillance is recommended for most patients who are asymptomatic, have minimal symptoms, or are not at risk for anatomic complications from further progression. Nirogacestat is FDA approved for this indication.
- Strategies targeting CSF-1R, such as pexidartinib (FDA approved) and vimseltinib, are effective in TGCT that is not amenable to surgical resection.
- KS may be observed without the use of antineoplastic therapy when the disease burden is limited and asymptomatic.
- ART is the standard frontline treatment of all patients who have HIV-associated KS.
- Immune reconstitution after introduction of ART for patients who have HIV-associated KS may result in tumor flare in 5% to 10% of cases.
- Liposomal anthracycline is the standard first-line chemotherapy for patients requiring systemic treatment of KS because of tumor growth, symptoms, or involvement of visceral organs.
- Paclitaxel is active in anthracycline-resistant KS.
- Pomalidomide is FDA approved for the treatment of advanced KS in both HIV-positive and -negative patients.
- Most GISTs have activating mutations in the *KIT* or *PDGFRA* gene.
- Surgery is the best curative treatment of primary GIST, although surveillance is an option for small gastric GISTs without high-risk features on endoscopic ultrasound.
- For patients who have localized GIST at high risk of recurrence, 400 mg of imatinib daily for at least 3 years after surgery delays time to recurrence and improves OS.
- Imatinib at a dosage of 400 mg daily is the standard of care in first-line therapy for metastatic GIST with sensitive mutations. Dose escalation can be considered upon progression.
- Patients with *KIT* exon 9–mutated GISTs may benefit from a higher initial starting dose of imatinib (eg, 400 mg twice daily).
- GISTs with *PDGFRA* exon 18 D842V mutations are resistant to imatinib but highly responsive to avapritinib.
- Sunitinib is FDA approved as a second-line therapy for patients with imatinib-refractory GIST or who cannot tolerate imatinib.
- Regorafenib is FDA approved for third-line treatment of GIST after failure of imatinib and sunitinib.
- Ripretinib is FDA approved for fourth-line treatment of GIST after treatment with at least three prior TKIs. Dosage escalation can be considered upon progression.
- Local therapies (eg, surgery, liver-directed therapy) may be appropriate in conjunction with continued TKI therapy for patients with limited progression of metastatic disease.
- Chemotherapy is critical for curative intent treatment of localized osteosarcoma.
- Doxorubicin and cisplatin are commonly used as standard therapy in adult patients, and high-dose methotrexate (MAP chemotherapy) is added in the treatment of children and young adults with normal renal function.
- The addition of IE does not improve survival for individuals who have a poor response to initial MAP chemotherapy.
- Resection of lung metastases (metastasectomy) should be considered for patients with osteosarcoma.
- TKIs, such as regorafenib, show activity in patients with metastatic osteosarcoma.
- Multimodality therapy, including multiagent chemotherapy, surgery, and/or RT, is critical in the management of patients who have localized Ewing sarcoma.
- Interval-compressed VDC/IE is the standard treatment approach for adolescents and young adults who have localized disease.
- Conventional chondrosarcomas are generally low to intermediate grade and are resistant to chemotherapy. There is no currently FDA-approved therapy.
- Denosumab, a monoclonal antibody targeting RANK ligand, is FDA approved for the treatment of GCT of bone that is deemed unresectable or for which surgery would likely result in severe morbidity.

CHAPTER TABLES AND IMAGES

Table 17-1 Genetic Syndromes Associated With Sarcoma

Syndrome	Genetic Abnormality	Associated Sarcoma Types
Li-Fraumeni syndrome	*TP53* mutation	Various types of STS and bone sarcomas
Retinoblastoma	*RB1* gene deletion	Leiomyosarcoma, osteosarcoma
Neurofibromatosis type I	*NF-1* mutation	MPNST, GIST
Gardner syndrome	*APC* mutation	Desmoid tumor
McCune-Albright syndrome	*GNAS1* mutation	Osteosarcoma
Bloom syndrome	*RECQL3* mutation	Embryonal RMS, osteosarcoma
Rothmund-Thomson syndrome	*RECQL4* mutation	Osteosarcoma
Werner syndrome	*WRN* mutation	Osteosarcoma
Costello syndrome	*HRAS* mutation	Embryonal RMS
Nijmegen breakage syndrome	*NBS1* mutation	Embryonal RMS
Carney-Stratakis syndrome	*SDH* mutation	GIST
Noonan syndrome	*PTPN11* mutation	Embryonal RMS, giant cell tumor, PVNS

Abbreviations: *APC*, APC regulator of WNT signaling pathway; GIST, gastrointestinal stromal tumor; *GNAS1*, GNAS complex locus; *HRAS*, HRAS protooncogene, GTPase; MPNST, malignant peripheral nerve sheath tumor; *NBS1*, nibrin; *NF-1*, neurofibromin-1; *PTPN11*, protein-tyrosine phosphatase, nonreceptor-type 11; PVNS, pigmented villonodular synovitis; *RB1*, RB transcriptional corepressor 1; *RECQL3/4*, RECQ protein-like 3/4; RMS, rhabdomyosarcoma; *SDH*, succinate dehydrogenase; STS, soft tissue sarcoma; *TP53*, tumor protein p53; *WRN*, Werner syndrome.

Table 17-2 **Representative Genetic Alterations in Sarcoma**

Class of Alteration	Sarcoma Subtype	Genetic Change	Frequency, %
Activating mutation	GIST	*KIT* or *PDGFRA* mutation	>90
	Desmoid fibromatosis	*Beta-catenin* or *APC* mutations	85-90
	Chondrosarcoma	*IDH1/2* mutations	≥50
	PEComa	*TSC1/2* mutations	~50
Ligand expression	Dermatofibrosarcoma protuberans	*COL1A1-PDGFB* gene fusion	~100
	Giant cell tumor of the bone	*RANK* ligand	~100
Inactivation/deletion	Myxofibrosarcoma	*NF-1* mutation, *NF-1* deletion	~10-20, >90
	Malignant peripheral nerve sheath tumor		
	Epithelioid sarcoma, rhabdoid tumors	*INI1* loss	81
Gene amplification	Well-differentiated and dedifferentiated liposarcoma	CDK4, MDM2	>90
Translocation	Synovial sarcoma	*t*(*X*;18) SYT-SSX1 or SYT-SSX2	>90
	Ewing sarcoma	*t*(11;22) EWSR1-FLI1	>85
		t(21;22) *EWSR1-ERG*	5-10
	Alveolar rhabdomyosarcoma	*t*(2;13) PAX3-FOXO1	~70
		t(1;13) PAX7-FOXO1	~15
	Inflammatory myofibroblastic tumors	*ALK* fusions	50

Abbreviations: *ALK*, anaplastic lymphoma kinase; *APC*, APC regulator of WNT signaling pathway; *CDK4*, cyclin-dependent kinase 4; *EWRSR1-ERG*, fusion of EWS RNA-binding protein 1 and ETS transcription factor ERG; *EWSR1-FLI1*, fusion of EWS RNA-binding protein 1 and FLI1 protooncogene, ETS transcription factor; *FOXO1*, forkhead box O1; GIST, gastrointestinal stromal tumor; *IDH1/2*, isocitrate dehydrogenase 1/2; *INI1*, integrase interactor 1; *KIT*, KIT protooncogene, receptor tyrosine kinase; *MDM2*, MDM2 protooncogene; *NF-1*, neurofibromin-1; *PAX3/7*, paired box gene 3/7; *PDGFRA*, platelet-derived growth factor receptor, alpha; PEComa, perivascular epithelioid cell tumor; *RANK*, receptor activator of nuclear factor-kappa B; *SYT-SSX1/2*, synovial sarcoma, X-chromosome-related 1/2; *TSC1/2*, TSC complex subunit 1/2.[7,11]

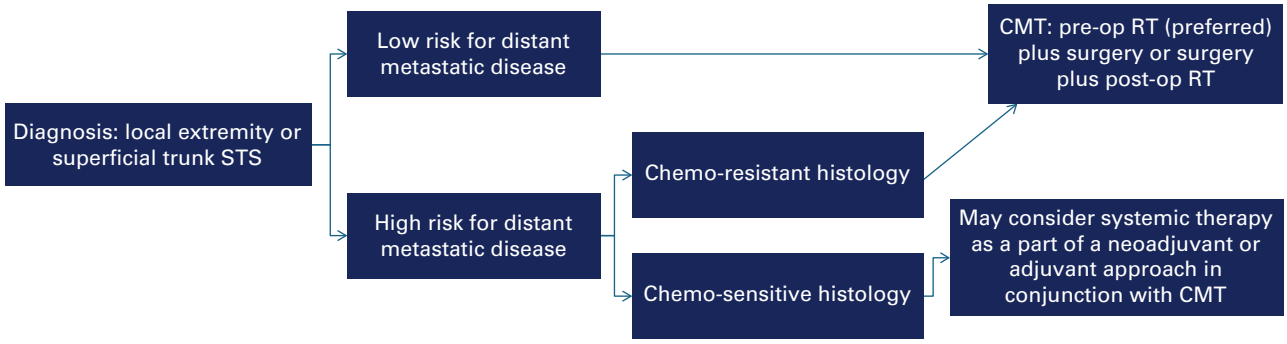
Table 17-3 **Select Histology-Specific Treatments and FDA-Approved Agents**		
Histology	**FDA Approved**	**NCCN Compendia Listed Agents**
Angiosarcoma		Paclitaxel; checkpoint inhibitors
ASPS	Atezolizumab	Sunitinib; pazopanib; pembrolizumab ± axitinib
Desmoid tumor	Nirogacestat	Sorafenib; pazopanib
Giant cell tumor of bone	Denosumab	
GIST	Imatinib (first line)	
	Sunitinib (second line)	
	Regorafenib (third line)	
	Ripretinib (fourth line)	
	Avapritinib (PDGFR exon 18 mutations, including D842V)	
Liposarcoma	Trabectedin	
	Eribulin	
LMS	Trabectedin	
Synovial sarcoma	Afamitresgene autoleucel	
TGCT	Pexidartinib	
UPS		Checkpoint inhibitors

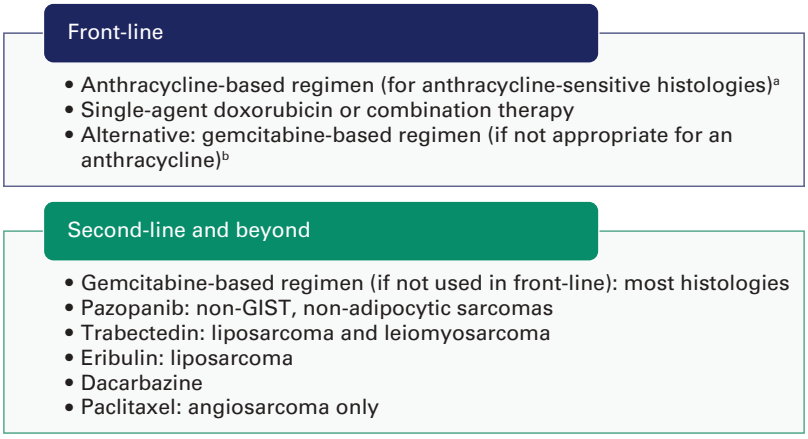
Abbreviations: ASPS, alveolar soft part sarcoma; GIST, gastrointestinal stromal tumor; LMS, leiomyosarcoma; NCCN, National Comprehensive Cancer Network; TGCT, tenosynovial giant cell tumor; UPS, undifferentiated pleomorphic sarcoma.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 17-1 Treatment Paradigm for Extremity and Superficial Trunk STS



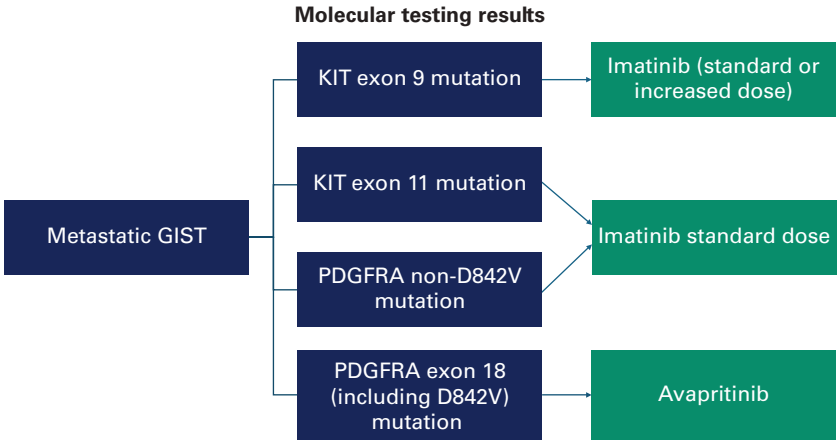
Abbreviations: CMT, combined modality therapy; RT, radiation therapy; STS, soft tissue sarcoma.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 17-2 Treatment Paradigm for Metastatic Soft Tissue Sarcomas^



Abbreviations: GIST, gastrointestinal stromal tumor; LMS, leiomyosarcoma.
^Excluding GIST, pediatric rhabdomyosarcoma, and most indolent histologies.
[a]Doxorubicin/ifosfamide (most histologies), doxorubicin/dacarbazine (most histologies), doxorubicin/trabectedin (LMS only).
[b]Gemcitabine/docetaxel (preferred), gemcitabine/dacarbazine, gemcitabine/vinorelbine.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 17-3 GIST Treatment Options Algorithm in the First-Line Setting

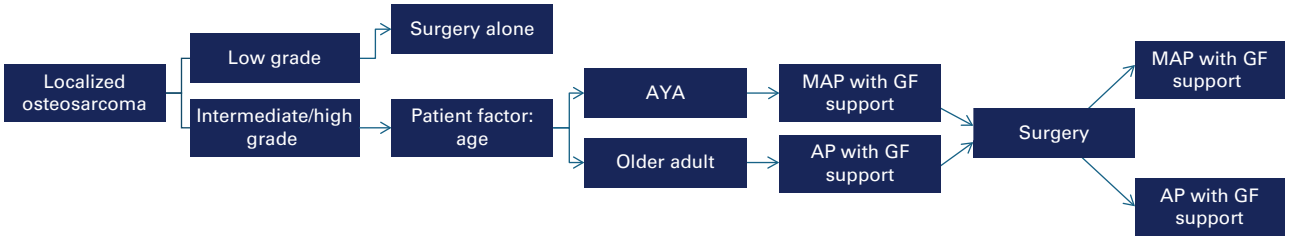


Abbreviation: GIST, gastrointestinal stromal tumor.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 17-4 Osteosarcoma of the Right Distal Femur With Characteristic Cortical Destruction and Bone Formation

(A) At diagnosis. (B) After three cycles of neoadjuvant doxorubicin and cisplatin with coarsening of calcification consistent with response to therapy.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 17-5 Treatment Paradigm for Localized Osteosarcoma

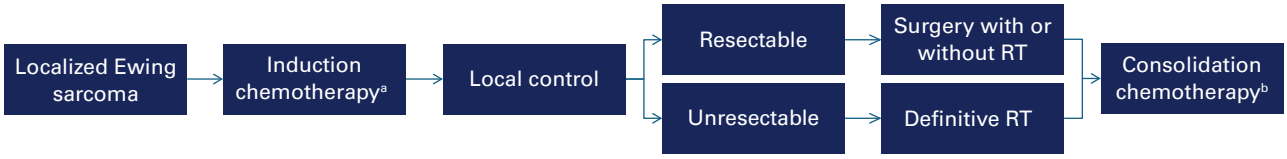


Abbreviations: AP, doxorubicin, cisplatin; AYA, adolescent and young adult; GF, growth factor; MAP, methotrexate, doxorubicin, cisplatin.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 17-6 Characteristic Changes in Tibial Ewing Sarcoma

Onion skin changes are seen along the tibial diaphysis in this radiograph in the area of the associated soft tissue mass.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 17-7 Treatment Paradigm for Localized Ewing Sarcoma



Abbreviations: GF, growth factor; IE, ifosfamide and etoposide; RT, radiation therapy; VDC, vincristine, doxorubicin, and cyclophosphamide.
[a]Four to six cycles of interval compressed (Q2W) VDC/IE with GF support.
[b]Complete a total of 14 cycles of interval compressed VDC/IE, as tolerated.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

CENTRAL NERVOUS SYSTEM TUMORS

18

Stephen J. Bagley, MD, MSCE, and Karisa C. Schreck, MD, PhD

RECENT UPDATES

- For patients who have grade 2 non-enhancing *IDH*-mutated astrocytoma or oligodendroglioma confirmed by biopsy or more extensive surgery, vorasidenib is an FDA-approved agent based on the randomized phase 3 INDIGO study, which demonstrated that it extends progression-free survival (27.2 months vs. 11.1 months in control) and time to next therapy.[1]
- For patients aged 6 months or older with relapsed/refractory pediatric low-grade glioma having a *BRAF* rearrangement or V600E alteration, tovorafenib is approved by the FDA (51% response rate and duration of response 13.8 months).[2]

OVERVIEW

Primary central nervous system (CNS) tumors consist of a diverse range of pathologic entities. Metastatic tumors represent the most common CNS tumor diagnosis. Among primary brain cancers, tumors of neuroepithelial tissue include most of the malignant primary CNS tumors, such as infiltrating glial tumors (including glioblastoma *IDH* wild type (*IDH*wt), astrocytoma *IDH* mutant, and oligodendroglioma) and embryonal tumors (eg, medulloblastoma). The last two editions of the World Health Organization Classification of Tumors of the Central Nervous System (WHO Classification of Tumors of the CNS) have included molecular diagnostics, with the most recent (fifth edition published in 2021) introducing major changes that advance the role of molecular diagnostics in CNS tumor classification.[3] The treatment of cancers within the CNS presents specific challenges, including relatively low incidence, drug delivery because of the blood-brain barrier, immunosuppressed tumor microenvironment, and highly infiltrative nature of many of these tumors. Surgery and radiation therapy have remained the mainstays in many CNS tumors; however, the role of systemic therapy has evolved in several of these cancers. The current understanding and evidence-based treatment of the most common cancers of the CNS as they are encountered in clinical oncology practice are outlined in this chapter.

EPIDEMIOLOGY
