Primary malignant CNS tumors are the most common solid tumors in children and are the leading cause of death as a result of cancer in children. CNS tumors are the second leading cause of cancer-related death for those in the adolescent and young adult population (aged 15-39 years). The average age-adjusted incidence rate for primary brain tumors is 6.02 cases per 100,000 population per year in children and 11.8 and 43.7 cases per 100,000 population for individuals ages 15 to 39 years and 40 years or older, respectively. In all people, the average annual age-adjusted incidence rate of all malignant and non-malignant brain and other CNS tumors was 25.3 per 100,000 population. Of all primary CNS tumors, approximately one-third are meningiomas, one-third are gliomas, and the remainder are a variety of other benign and malignant tumors. Gliomas occur more frequently in men, whereas meningiomas are more common in women. Of all gliomas, approximately two-thirds are glioblastomas. In children, embryonal tumors, such as medulloblastoma, are the most common CNS tumors.[4]

It has been difficult to identify environmental factors associated with primary brain tumors. Ionizing radiation is the only environmental risk factor reliably considered to increase the risk of brain tumors, with young age at treatment and increased dosage conferring a higher risk.[5] The risk of primary CNS lymphoma but not other types of primary brain tumors is increased for patients who have immunodeficiency conditions, such as post-transplant immunosuppression or HIV infection.[6]

Genetic predisposition to primary CNS tumors is relatively uncommon, although they may be associated with several familial cancer syndromes.[7,8] For example, astrocytoma *IDH* mutant and glioblastoma *IDH*wt are associated with Li-Fraumeni syndrome, neurofibromatosis type 1, and Lynch syndrome. *IDH* mutant gliomas are associated with Maffucci syndrome and Ollier's disease. Medulloblastoma is associated with Li-Fraumeni syndrome, basal cell nevus syndrome, and familial

adenomatous polyposis. CNS hemangioblastomas are the most common manifestation of von Hippel-Lindau (VHL) disease. Recent genomic sequencing studies have identified an inheritable predisposition to the development of glioma in approximately 5% of patients who have glioblastoma.[9]

KEY POINTS

- Exposure to ionizing radiation is a well-established risk factor for primary CNS tumors.
- Most patients who have primary CNS tumors have no identifiable risk factor. The exceptions are patients who have a primary CNS tumor associated with one of the familial cancer syndromes, including neurofibromatosis type 1, Li-Fraumeni syndrome, Lynch syndrome, and familial adenomatous polyposis. Other, less common, inherited genomic risks are emerging.
- Immunodeficiency is a risk factor for primary CNS lymphoma.

PRESENTATION

The presenting symptoms of a brain tumor are related to mass effect, parenchymal infiltration, hydrocephalus, and/or tissue destruction. This may cause patients to present with seizures, altered mental status, focal neurologic deficits, or headache, among other symptoms.

DIAGNOSIS AND STAGING

DIAGNOSTIC IMAGING

MRI with and without contrast is more sensitive than CT imaging for confirming the presence of a brain tumor. Different types of brain tumors exhibit distinct imaging characteristics on MRI. The most crucial sequences for their evaluation are T1-weighted images with and without contrast, as well as T2-weighted and/or fluid-attenuated inversion recovery (FLAIR) sequences. Contrast enhancement is indicative of blood-brain barrier disruption and/or angiogenesis, and it usually increases with higher grades of malignant disease. However, there are a number of low-grade (WHO grade 1) tumors that are robustly enhancing as well. Heterogeneous enhancement is characteristic of glioblastoma and is a consequence, in part, of central tumor necrosis. Conversely, some high-grade tumors may not exhibit contrast enhancement. Contrast enhancement may not reflect the true extent of the disease because the blood-brain barrier may remain intact at the rim of the infiltrating tumor. Although MRI is generally much more helpful in evaluating brain tumors, non-contrast CT imaging can be useful in certain situations, such as evaluating hemorrhage, calcification, or tumor involvement of the bone.

DIAGNOSTIC PATHOLOGY

For nearly all patients, the definitive diagnosis of a CNS tumor requires a surgical biopsy or resection with histologic and molecular examination of the tissue. However, some patients, for example, those with brainstem gliomas, may not be optimal candidates for biopsy because of the operative risk, and imaging can be diagnostic in some cases. Minimally invasive methods that evaluate circulating tumor cells or DNA in plasma or cerebrospinal fluid (CSF) are yet to be validated for CNS tumors.

Primary CNS tumors typically remain localized to the brain and spinal cord, and a staging system, as is common in systemic cancers, does not exist, with medulloblastoma being an exception. Starting in 1993, the WHO classification system traditionally used a four-tiered histologic grading system based on degree of malignancy, with grade 1 tumors having the lowest proliferative potential and grade 4 tumors demonstrating the highest degree of cytologic malignancy and mitotic activity, often with necrosis and microvascular proliferation.

The 2021 WHO Classification of Tumors of the CNS incorporates both histologic and molecular features to generate a grade and integrated diagnosis for each patient.[3] This major update to brain tumor classification aims to group tumors based on biologic and molecular features rather than purely on histologic appearance, which enables clinicians to have a better understanding of the prognosis and optimal therapy for patients who have specific CNS tumors. Some of the most important changes involve the classification of gliomas, including differentiation of gliomas that occur primarily in adults from those that occur primarily in children, as well as the molecular criteria that define a glioblastoma, *IDH*wt. Key takeaways from the 2021 WHO classification system are discussed for each tumor type in the respective sections of this chapter. The following are techniques for assessing important CNS tumor biomarkers:

- Pathogenic point mutations
  - Immunohistochemistry (*IDH1* R132H; *BRAF* V600E; H3K27M)
  - Single-gene sequencing or next-generation sequencing (NGS)
- Chromosomal alterations (eg, 1p/19q codeletion, Chr. 7 gain, Chr. 10 loss)
  - Fluorescence in situ hybridization (FISH)
  - Single-nucleotide polymorphism arrays
  - NGS

- Pathogenic fusion alterations (KIAA-BRAF, FGFR-TACC, NTRK-fusions, etc.)
  - RNA sequencing
  - DNA or RNA fusion panels
  - FISH
- *MGMT* promoter methylation
  - Bisulfite sequencing
  - Methylation array

The 2021 WHO Classification includes tumors defined exclusively by their DNA methylation profile. This includes high-grade astrocytoma with piloid features and diffuse glioneuronal tumor with oligodendroglioma-like features and nuclear clusters.

PATHOGENESIS

CLINICALLY RELEVANT MARKERS IN GLIOMAS

Research in the past decade has rapidly increased understanding of the pathobiology of diffuse gliomas. Several molecular abnormalities have been discovered that play key roles in glioma development, and precise molecular characterization of diffuse gliomas is still subject to discussion and extensive research. The 2021 WHO Classification of Tumors of the CNS defines three broad categories of adult diffuse gliomas based on histopathology, mutational spectrum, and copy number alterations (Fig. 18-1).[3]

OLIGODENDROGLIOMA, *IDH* MUTANT, AND 1P/19Q CO-DELETED

These gliomas can be grade 2 or 3. The presence of both a pathogenic *IDH* mutation and codeletion of Chr. 1p and 19q is required for diagnosis. This category of tumors, compared with the other two groups of gliomas, is associated with a more favorable overall prognosis and better response to radiation therapy and chemotherapy. The 5-year survival rate of patients who have these tumors typically ranges from 50% to 80%, although, with aggressive treatment consisting of radiation therapy and chemotherapy, a median survival of ~12 to 18 years has been observed.

ASTROCYTOMA, *IDH* MUTANT

These gliomas can be grade 2, 3, or 4. The presence of a pathogenic *IDH1* or *IDH2* alteration is required, and *ATRX* is also frequently mutated.[3] The 5-year survival rate for patients who have these tumors typically ranges from 25% to 50%. In the 2021 WHO Classification of Tumors of the CNS, the grade 4 tumors in this category are no longer referred to as glioblastoma and are instead referred to as astrocytoma, IDH mutant, WHO grade 4. Some molecular features can impact grading, such as *CDKN2A*/B deletion, which portends an inferior prognosis and is sufficient to classify the tumor as grade 4, irrespective of microscopic features.

GLIOBLASTOMA, *IDH* WILD TYPE

Glioblastoma may be diagnosed by histopathologic criteria or by molecular criteria (Fig. 18-1). Tumors that appear to be low-grade glioma but lack *IDH1/2* or *BRAF* alterations should have molecular testing performed to evaluate for gain of chromosome (Chr) 7 and loss of Chr 10, *EGFR* amplification, or *TERT* promoter mutations.[10] Compared with the two categories above, these gliomas overall have a less favorable prognosis and are less responsive to chemotherapy. The 5-year survival rate for patients who have these tumors is approximately ~10% to 14%.

PEDIATRIC TYPE DIFFUSE HIGH-GRADE GLIOMA

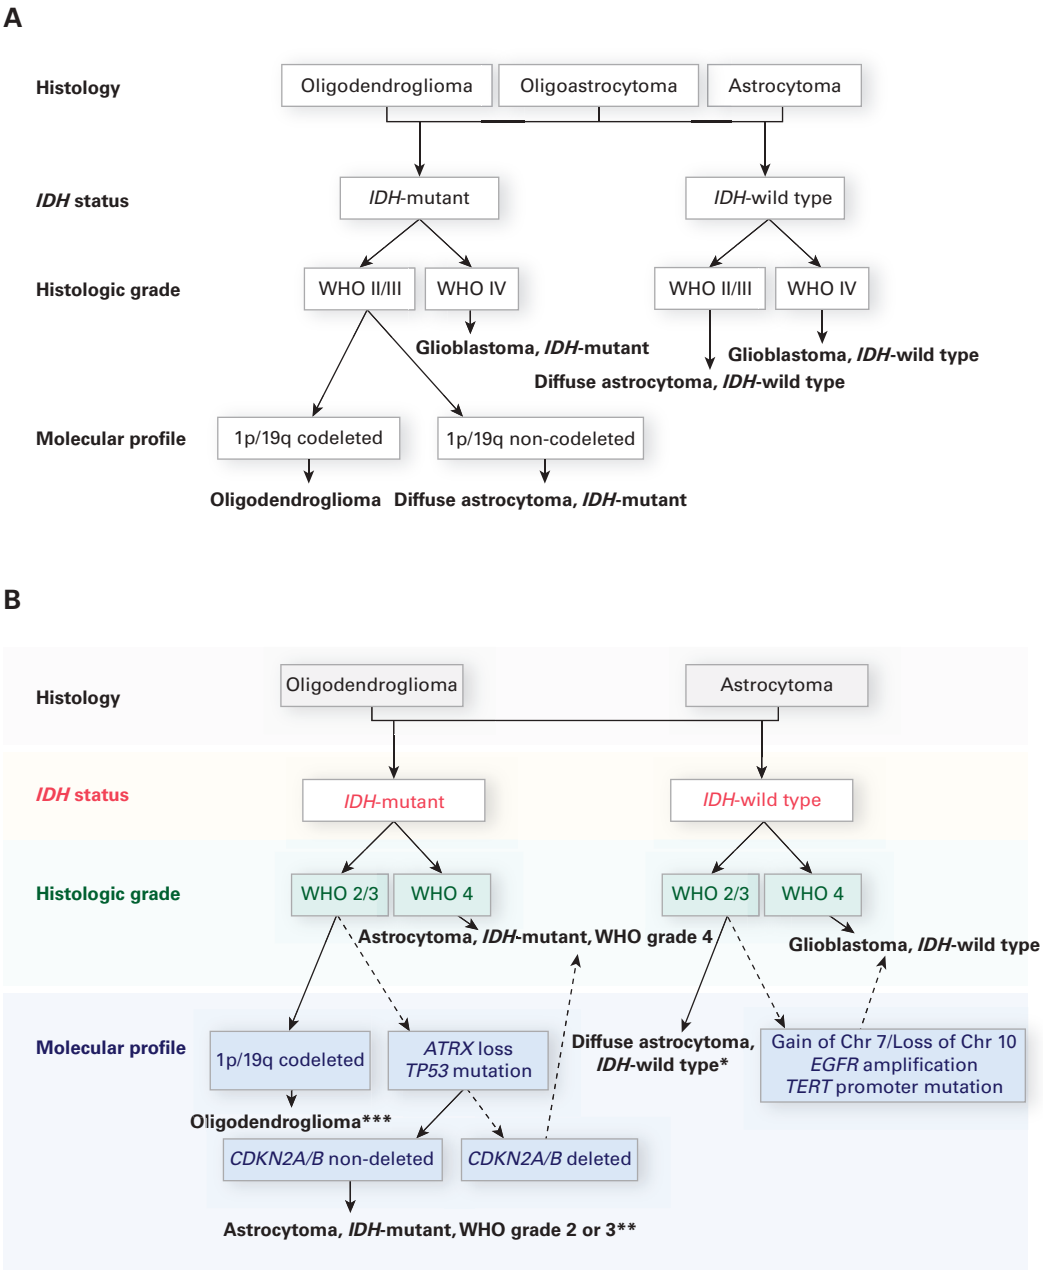
Diffuse midline gliomas (DMGs) are aggressive gliomas arising primarily from the pons and other midline sites in children and young adults. The presence of an H3K27 alteration is sufficient to make this diagnosis, which is classified as grade 4. Adults may present with DMG, often in the thalamus or diffuse hemispheric gliomas, having H3G34 alterations. In children, these gliomas are highly aggressive and poorly responsive to therapy.[11] In adults, the clinical course is more heterogeneous.[12] Standard treatment involves ionizing radiation, but the role of upfront systemic therapy is less clear. Dordaviprone (ONC201) recently received accelerated approval by the FDA for progressive disease in patients with *H3 K27M* mutations.[13]

IDH MUTATION

Mutations in the *IDH1* or *IDH2* genes are early genetic abnormalities in glioma development. *IDH* mutations result in the excess accumulation of 2-hydroxyglutarate, an oncometabolite, which contributes to the formation of and may participate in the progression of gliomas.[14,15] *IDH* mutations have been found in most WHO grade 2 and 3 gliomas and are a clear indicator of a favorable prognosis in high-grade glioma.[16]

In addition, *IDH* mutations have been demonstrated to independently predict survival benefit from the addition of chemotherapy to radiation therapy for patients who have grade 3 glioma.[17]

Figure 18-1 The Classification of Diffuse Gliomas



(A) WHO 2016. (B) WHO 2021.
Abbreviations: Chr, chromosome; CNS, central nervous system; *EGFR*, epidermal growth factor receptor.
Simplified diagnostic algorithm for adult diffuse gliomas based on the 2021 WHO classification of CNS tumors. Dashed lines denote changes compared with the 2016 WHO classification.
*Diffuse astrocytoma, *IDH* wild type without molecular features of glioblastoma, is a rare entity. Molecular testing for gain of *Chr* 7 and loss of Chr 10, *EGFR* amplification, and *TERT* promoter is required to exclude glioblastoma, *IDH* wild type, grade 4. In the absence of molecular features of glioblastoma, additional testing should be considered (eg, *BRAF* alterations, histone mutations, methylome profiling).
**Astrocytoma, *IDH* mutant, can be diagnosed as grade 2, 3, or 4 based on histopathologic grading criteria and *CDKN2A/B* status.
***Oligodendroglioma, *IDH* mutant with codeletion of the short arm of chromosome 1 and the long arm of chromosome (1p19q), can be diagnosed as grade 2 or 3 based on histopathologic features.

1P/19Q CODELETION

Oligodendrogliomas show a combined loss of the short arm of chromosome 1 (1p) and the long arm of chromosome 19 (19q) in addition to an *IDH* mutation. This codeletion of 1p/19q is secondary to an unbalanced pericentromeric translocation event and

seems to be instrumental in the development of oligodendrogliomas.[18] Several candidate genes have been identified, including *CIC* and *FUBP1*, which may represent the genetic alteration underlying the 1p/19q codeletion.[19]

Many studies demonstrate that 1p/19q codeletion is associated with a favorable prognosis in glioma.[18] 1p/19q codeletion has been determined to predict improved survival with the addition of combination chemotherapy (ie, procarbazine, lomustine, and vincristine [PCV]) to radiation therapy compared with radiation therapy alone.[20,21]

BRAF ALTERATIONS

Pathogenic alterations in the *BRAF* gene are probably early genetic abnormalities in glioma development. *BRAF* alterations result in increased signaling through the MAPK signaling cascade, resulting in proliferation, neovascularization, and increased survival. The most common *BRAF* alteration is a single-nucleotide variant p.V600E that enables *BRAF* to function as a single, aberrantly active protein molecule. *BRAF* V600E mutations are observed in a variety of non-CNS tumors, and in CNS tumors, primarily occurring in low-grade glioma, pleomorphic xanthoastrocytoma, ganglioglioma, and epithelioid glioblastoma, although they have been identified in many other CNS tumors of grades 1 to 4. The effect of *BRAF* V600E alterations on prognosis differs by grade and among pediatric and adult gliomas.[22-24] The FDA has approved targeted therapy for glioma with *BRAF* V600E alterations.

The second most common *BRAF* alteration is a rearrangement causing various gene fusions that result in increased activation through MAPK signaling dependent on dimerization. The FDA has approved a type II BRAF inhibitor, tovorafenib, for pediatric-type low-grade glioma with a *BRAF* fusion and V600 mutation.[2]

MGMT PROMOTER METHYLATION

MGMT (O6-methylguanine-DNA methyltransferase) is an enzyme that plays a crucial role in DNA repair. Alkylating agents, such as temozolomide, lead to methylation of nucleotide bases in genomic DNA. Although some of these lesions are fixed by base excision repair, O6-methylguanine requires MGMT for its repair.

Hypermethylation of the MGMT promoter–associated CpG island has been described in approximately 30% to 40% of glioblastomas. MGMT promoter methylation prevents transcription of the *MGMT* gene and subsequent expression of the DNA repair enzyme. Consequently, patients who have MGMT promoter–methylated tumors are expected to receive more benefit from temozolomide than those with tumors that lack it. The more favorable prognosis of patients who have MGMT promoter–methylated glioblastoma is well described, along with its association with a greater magnitude of benefit from temozolomide.[25] MGMT methylation has not been shown to be predictive of benefit from temozolomide in other grades of CNS tumors or in other tumor types.

KEY POINTS

- *IDH* mutations are central aspects of defining astrocytoma IDH mutant and oligodendroglioma, two types of adult diffuse gliomas.
- *IDH* mutations are most common in grade 2 and 3 gliomas but can also be seen in grade 4 astrocytomas.
- Regardless of grade, *IDH* mutations in glioma are associated with younger age, increased sensitivity to treatment, and comparatively favorable prognosis.
- Oligodendrogliomas are defined by the presence of both *IDH* mutation and 1p/19q codeletion and have improved response to chemotherapy and prognosis compared with other gliomas.
- Tumors that are *IDH* mutated without 1p/19q codeletion are referred to as astrocytoma, *IDH* mutant, and commonly harbor a mutation in *ATRX*.
- *BRAF* alterations, which may have an impact on available therapeutic options, occur in a range of CNS tumors, but at this time are not pathognomonic for any WHO CNS tumor type.
- According to the 2021 WHO Classification of Tumors of the CNS, glioblastoma is by definition *IDH* wild type.
- In glioblastoma, being MGMT promoter–methylated is both prognostic and predictive of the magnitude of benefit from temozolomide.

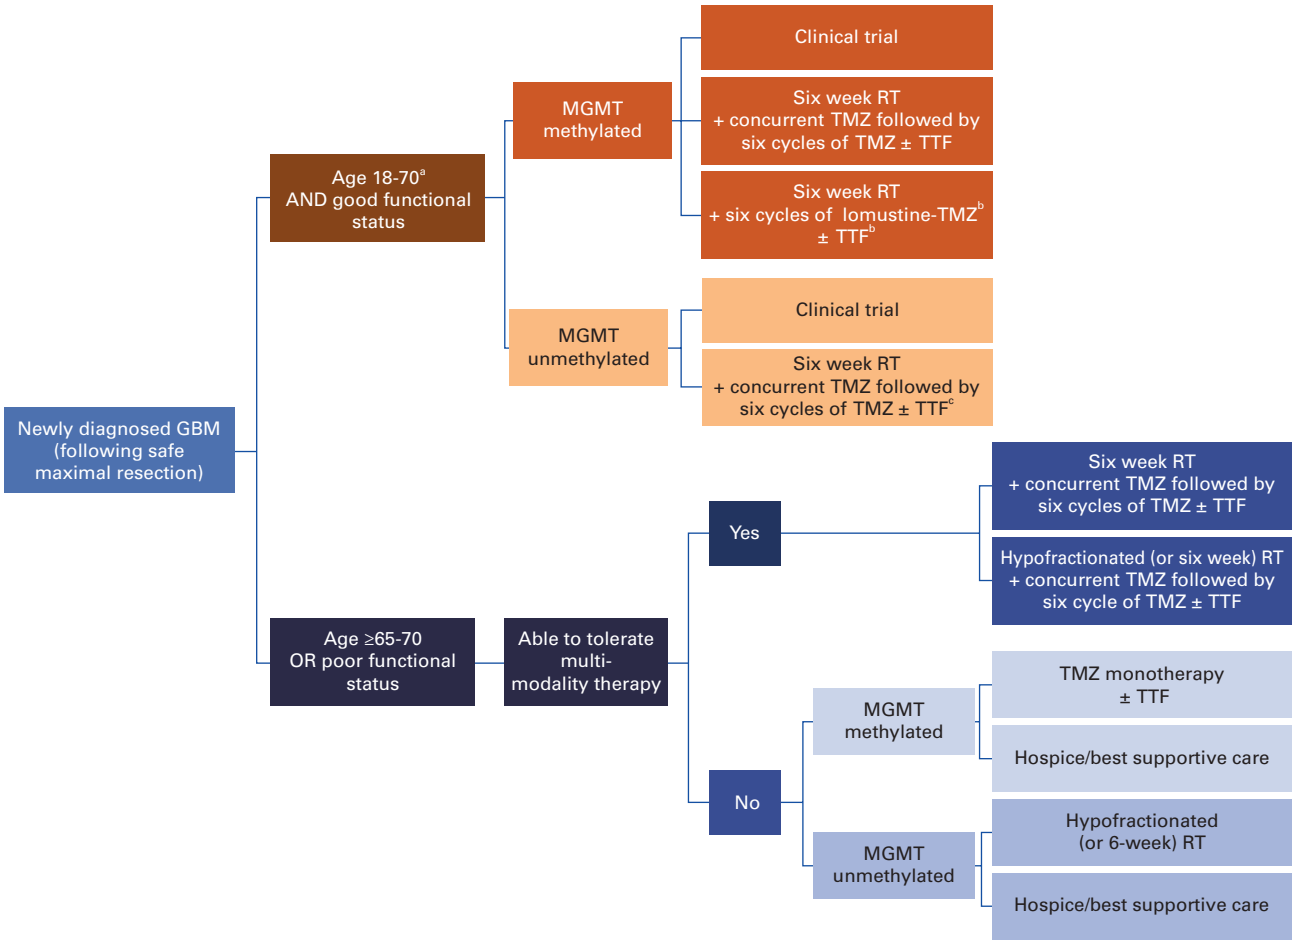
GLIOBLASTOMA, *IDH* WILD TYPE

Glioblastomas are the most common primary malignant brain tumors in adults. Histopathologic hallmarks include increased cellularity, nuclear pleomorphism, frequent mitoses, pseudopalisading necrosis, and neovascularization. The median age at diagnosis is approximately 65 years.[8] In the 2021 WHO Classification of Tumors of the CNS, glioblastoma is, by definition, *IDH* wild type and is formally referred to as glioblastoma, *IDH* wild type.[7] Traditionally, glioblastomas were diagnosed based on the histologic findings of microvascular proliferation and/or necrosis. Although these features continue to result in a diagnosis of glioblastoma under the 2021 classification system, the current classification also allows for a diagnosis of glioblastoma, *IDH* wild type, even in the absence of histologic features of glioblastoma if one or more of three genetic parameters are present in an *IDH* wild-type glioma: *TERT* promoter mutation, *EGFR* gene amplification, or combined gain of entire chromosome 7 and loss of entire chromosome 10 (+7/−10). This important change is based on several articles demonstrating that astrocytomas that appear

to be lower grade histologically but lack an *IDH* or *BRAF* alteration (eg, gliomas formerly referred to as *IDH* wild-type diffuse astrocytoma or *IDH* wild-type anaplastic astrocytoma) have similarly poor survival outcomes compared with histologically defined glioblastoma if any of these molecular alterations are present.[10,26]

Glioblastoma *IDH* wild type has a real-world median overall survival (OS) of approximately 12 to 15 months with standard treatment,[4,27,28] although recent phase 3 clinical trials suggest that the median OS may be closer to 18 to 21 months in selected populations with good performance status.[29,30] MGMT promoter methylation is associated with a prolonged survival of patients who have glioblastoma compared with those without methylation (18.2 months vs. 12.2 months; $P < .001$).[25] Guidelines for treatment of glioblastoma were released in 2021 by the ASCO and the Society for Neuro-Oncology.[31] Key elements of treatment are outlined in the following sections and are summarized in Figure 18-2.

Figure 18-2 Standard-of-Care Treatment Paradigm for Patients Who Have Newly Diagnosed or Recurrent Glioblastoma



Abbreviations: GBM, glioblastoma; MGMT, O6-methylguanine-DNA methyltransferase; RT, radiation therapy; TMZ, temozolomide; TTF, tumor-treating fields.
[a]In elderly patients with good performance status, standard 6-week daily radiation therapy plus TMZ can be considered.
[b]It is unclear whether lomustine plus TMZ is preferred over TMZ alone.
[c]Because MGMT methylation status is predictive of the efficacy of TMZ, TMZ can be withheld in select patients who have MGMT-unmethylated tumors, especially in the context of clinical trials or when the risks of TMZ outweigh the benefits.

Glioblastoma in adults: a Society for Neuro-Oncology (SNO) and European Society of Neuro-Oncology (EANO) consensus review on current management and future directions. *Neuro Oncol*. 2020;22(8):1073-1113, by permission of Society for Neuro-Oncology and Oxford University Press.

SURGERY

The initial step of treatment is the best possible safe neurosurgical resection. In general, the overall outcome is better in patients who can undergo a gross total resection (removal of all contrast-enhancing tissue assessed on an MRI scan performed within 48 hours after surgery), but because of tumor location and comorbidities, many tumors are amenable only to a partial resection or biopsy.[32] There are data to support a survival benefit from supramaximal resection (resection beyond the contrast enhancement) for newly diagnosed glioblastoma.[33] Unfortunately, even in the absence of residual contrast enhancement, the extremely

infiltrative nature of this tumor makes true complete surgical resection impossible, and all patients have residual cancer that requires additional therapy.

RADIATION THERAPY

Radiation therapy has remained the backbone of the treatment of newly diagnosed glioblastoma. Currently, focal brain radiation therapy (only to areas of tumor involvement, not the whole brain), consisting of 60 Gy delivered in 30 fractions, is considered standard. Shorter courses of hypofractionated radiation over 1 to 3 weeks have been evaluated in phase 3 clinical trials of older or frail patients who have glioblastoma because of the poorer prognosis of these patients. These trials demonstrate that a shorter course of radiation produces outcomes similar to or better than those seen with standard radiation (60 Gy in 30 fractions) in older or frail patients.[34-36] Multiple attempts to improve the therapeutic efficacy of radiation therapy by using altered fraction schemes have not produced substantially better results so far.

CHEMOTHERAPY

Temozolomide chemotherapy is the standard of care for newly diagnosed glioblastoma. A landmark phase 3 trial randomly assigned 573 patients aged 18 to 70 years to receive involved-field radiation therapy alone or radiation therapy plus concurrent once-per-day temozolomide (75 mg/m^2 per day) followed by up to six cycles of adjuvant temozolomide (cycle 1, 150 mg/m^2 once per day for 5 days of a 28-day cycle; cycles 2-6, 200 mg/m^2 once per day for 5 days of a 28-day cycle if blood counts are acceptable).[37] The addition of temozolomide to radiation therapy improved the median OS compared with radiation therapy alone (14.6 months vs. 12.1 months; hazard ratio [HR], 0.63; 95% CI, 0.53-0.75). With long-term follow-up, the survival rate continued to be superior in the temozolomide arm at 2 years (27% vs. 11%) and 5 years (10% vs. 2%).[38]

As described in the "MGMT Promoter Methylation" section, MGMT promoter methylation is predictive of benefit from temozolomide. Patients whose MGMT promoter is unmethylated may not benefit from temozolomide.[25] Subsequent trials have attempted to further improve outcomes in patients who have MGMT-methylated tumors by combining lomustine with temozolomide during and after radiation therapy in a randomized study.[39] In the modified intent-to-treat analysis (n = 129), the median OS was improved from 31.4 months (95% CI, 27.7-47.1) with temozolomide to 48.1 months (95% CI, 32.6 months to not assessable) with lomustine and temozolomide (HR, 0.60; 95% CI, 0.35-1.03). Grade 3 or 4 hematologic toxicity and nausea were more common with combination therapy. Although these results are intriguing, additional studies (such as the ongoing NRG BN011 phase 3 trial) are warranted to determine whether dual therapy with temozolomide and lomustine in combination with radiation therapy should be used routinely for patients who have MGMT-methylated glioblastoma.

Bevacizumab, an intravenous monoclonal anti-vascular endothelial growth factor (VEGF) antibody, has been evaluated for the treatment of patients with newly diagnosed glioblastoma with no improvement in survival, precluding routine use.[40,41] The effect on quality of life was mixed, but it may provide a benefit in select patients.[40] In contemporary practice, this agent is often used to treat symptomatic cerebral edema, often with shorter courses than what was described in the pivotal trials.

When considering chemotherapy in older patients who have glioblastoma, a careful assessment of the patient's overall clinical status and comorbidities is critical. For adults aged 65 years or older who have glioblastoma treated with hypofractionated radiation (40 Gy in 15 fractions), randomized phase 3 trial data demonstrate that OS is improved by the addition of concurrent and adjuvant temozolomide (median OS, 13.5 months vs. 7.7 months; HR, 0.53; 95% CI, 0.38-0.73).[42] For older patients who are not candidates for a combined-modality approach because of poor performance status or comorbidities, MGMT methylation status may be helpful for decision-making. In such patients who have MGMT-unmethylated tumors, a short course of radiation therapy without temozolomide may be reasonable. In such patients who have MGMT-methylated tumors, temozolomide alone (without radiation therapy) is supported by phase 3 data.[35,43]

TUMOR-TREATING FIELDS

Tumor-treating fields are a form of treatment from a device that delivers alternating electromagnetic fields through electrodes placed on the shaved scalp. It is approved by the FDA for use in the treatment of patients who have newly diagnosed (as maintenance therapy in combination with temozolomide after concurrent chemoradiotherapy) and recurrent glioblastoma (as monotherapy), as well as some non-CNS malignancies. A randomized phase 3 trial of maintenance temozolomide cycles with or without tumor-treating fields enrolled 695 patients who had completed concurrent chemoradiotherapy and not yet experienced tumor progression. The final data demonstrated a significant increase in the median OS of patients treated concurrently with temozolomide and tumor-treating fields compared with patients treated with temozolomide alone (21 months vs. 16 months; $P < .00062$).[44] Although tumor-treating fields are part of the National Comprehensive Cancer Network guidelines, incorporation into routine clinical care has been mixed for a variety of reasons.

PSEUDOPROGRESSION

It is essential to consider so-called pseudoprogression before initiating alternative therapy. Pseudoprogression is best described in gliomas as a radiographic increase in enhancement or edema on MRI after chemoradiotherapy, often within a few months of

completing treatment, and this can raise concern for tumor progression. Pseudoprogression can mimic true tumor growth, especially in patients whose tumors exhibit MGMT promoter methylation.[45] On MRI, both progression and pseudoprogression are characterized by increased contrast enhancement, T2-weighted signal abnormality, and mass effect with or without clinical deterioration (Fig. 18-3). Advanced imaging techniques such as perfusion-weighted imaging, chemical exchange saturation transfer (CEST) imaging, or MR spectroscopy may be helpful, though not definitive. Amino acid PET shows high diagnostic accuracy for differentiating recurrence versus pseudoprogression, although it is not widely available.[46,47] Post-radiation therapy changes that are within the radiation treatment field can often be observed initially (typically for the first 3 months after radiation therapy) to assess whether the changes represent pseudoprogression rather than actual tumor growth.[48] Repeated tissue biopsy may be required to more definitively determine whether the patient has an active or progressive tumor or treatment effect or necrosis, but it can be challenging, and its value may be limited because tissues often comprise a mixture of treatment effect and necrosis of tumor, which can lead to significant interobserver variability in diagnosis.[49] Dexamethasone can be used for symptomatic relief from cerebral edema caused by treatment effect, generally with good responses. Bevacizumab may also be useful in this setting, particularly for patients who are symptomatic or intolerant of steroids.

PRESENTING CASE STUDY

A 49-year-old woman presents to the emergency room with 1 week of worsening headaches, and an MRI reveals a 4 cm × 4 cm contrast-enhancing mass in the right frontal lobe. Pathology from surgical resection identifies a glioma without necrosis or microvascular proliferation, and immunohistochemical staining is negative for the *IDH1* R132H mutation.

Given the patient's age, what is the most important next test to order?

Since this patient is under 55 years old, it is critical to determine whether this glioma harbors an *IDH* mutation. Although immunohistochemistry for *IDH1* R132H, the most common *IDH* mutation in glioma, is negative in this case, next-generation sequencing (NGS) is the gold standard for establishing *IDH* mutational status. It is imperative that NGS is performed on this tumor to confirm that there are no variants in *IDH1* or *IDH2*.

NGS revealed that this tumor was negative for any mutations in *IDH1* or *IDH2*. However, epidermal growth factor receptor (*EGFR*) amplification and a *PTEN* mutation were detected.

How do these results inform your decisions regarding next steps?

Although this patient's tumor did not exhibit histologic hallmarks of glioblastoma (ie, necrosis and/or microvascular proliferation), a diagnosis of glioblastoma was established because the tumor is *IDH* wild type and has *EGFR* amplification.

In an *IDH* wild-type glioma, the presence of any one of the following molecular alterations establishes a diagnosis of glioblastoma: *EGFR* amplification, *TERT* promoter mutation, or gain of chromosome (Chr) 7 and loss of Chr 10 (+7/−10).

Now that the diagnosis of glioblastoma has been established, are there any other tests to order on this tumor that could impact treatment and prognosis?

O6-methylguanine-DNA methyltransferase (MGMT) promoter methylation can be very informative. MGMT is an enzyme that is responsible for DNA repair after alkylating-agent chemotherapy. In approximately 40% of glioblastomas, the *MGMT* gene is silenced by methylation of its promoter, thereby preventing DNA damage repair and increasing the potential effectiveness of alkylating-agent chemotherapy. Multiple clinical studies confirm that MGMT promoter methylation is prognostic of improved survival independent of established clinical factors. MGMT promoter methylation is also predictive of responsiveness to temozolomide in patients with glioblastoma. PD-L1 testing is not ordered routinely for patients who have glioblastoma because PD-1/PD-L1 immune checkpoint inhibitors have not demonstrated efficacy in this disease. Testing for tumor mutational burden (TMB) is also not indicated for most patients diagnosed with glioblastoma because TMB is almost uniformly low in this population. Rare exceptions include patients with Lynch syndrome or other inherited germline defects in DNA repair genes.

How would finding out that the patient's tumor is positive for MGMT promoter methylation affect further management?

Radiation with concomitant temozolomide chemotherapy, followed by six cycles of maintenance temozolomide, is the most appropriate treatment option for this patient. If the patient's tumor had been MGMT unmethylated, a clinical trial of radiation plus an experimental agent that does not include temozolomide chemotherapy could have been considered. Patients who have MGMT-unmethylated tumors have a poor prognosis and response to standard therapies and are encouraged to participate in clinical trials.

RECURRENCE

No uniform standard of care exists for the treatment of recurrent glioblastoma. Treatment options are tailored to the individual clinical setting. Participation in clinical trials should be considered. Unfortunately, all standard therapies have limited benefit, and a focus on symptom control with end-of-life care may be appropriate.

Of note, radiographic pseudoprogression may mimic tumor progression in patients who have glioblastoma treated with radiation therapy with or without temozolomide and should be considered before switching therapy, especially in patients who have MGMT promoter–methylated tumors (see the "Pseudoprogression" section).

For patients who have resectable disease with good neurologic function and performance status, a second resection may be reasonable.[50] Nitrosoureas, including lomustine and carmustine, which are FDA-approved agents for recurrent glioblastoma, may be used but have not demonstrated consistent efficacy and are associated with significant myelosuppresion.[51] Nonetheless, they form a cornerstone of non-clinical trial treatment of progressive glioblastoma *IDH*wt.[52] In 2009, the FDA approved bevacizumab for the treatment of recurrent glioblastoma after treatment with radiation therapy and temozolomide failed, although there were no data showing that bevacizumab improved OS.[53] A phase 3 clinical trial demonstrated that the addition of bevacizumab to lomustine did not improve survival compared with lomustine alone, although crossover may confound the results.[54] The use of bevacizumab can be of benefit to some patients who have significant symptomatic edema and mass effect, who have difficulty tolerating high doses or a long course of steroids. Because of these steroid-sparing and antiedema effects on the brain, tumor appearance on MRI can be dramatically improved for a period of time, and bevacizumab remains a key component of modern neuro-oncologic care. Bevacizumab in combination with reirradiation is also a viable option for select patients, although it does not improve survival over bevacizumab alone.[55] Complicating considerations for bevacizumab include that patients need a long washout period (ideally ≥4-6 weeks) after being considered for repeated surgery and that the drug increases the risks of hemorrhage, bowel perforation, venous thromboembolism, hypertension, and nephrotic syndrome. The initial bevacizumab patent (Avastin) expired several years ago, which resulted in the approval of several biosimilars with no known difference in safety or efficacy compared with bevacizumab.

Tumor-treating fields are also approved by the FDA for the treatment of recurrent glioblastoma. Results from a phase 3 randomized trial of tumor-treating fields compared with physician choice of chemotherapy for patients who have recurrent glioblastoma demonstrated no difference in OS. Although it did not provide a survival advantage, survival with tumor-treating fields was considered comparable to that with chemotherapy or bevacizumab and was associated with fewer serious adverse effects and

better quality of life.[56] However, the benefit of tumor-treating fields for recurrent glioblastoma remains uncertain because no evidence from phase 3 clinical trials is available to demonstrate that chemotherapy itself extends survival in this patient population.

Most recently, data from several phase 2 basket trials demonstrate benefit from targeted therapies in select patients with targetable biomarkers across numerous different solid tumors, including brain tumors. The benefit from the combination of dabrafenib and trametinib was shown in the phase 2 open-label ROAR trial,[57] which included 45 patients who had recurrent or progressive high-grade gliomas (69% had glioblastoma) who harbored *BRAF* V600E mutations and were previously treated with radiation therapy and first-line chemotherapy. With a median follow-up of 12.7 months, the objective response rate (ORR) was 31% (three complete responses and 11 partial responses), and the median duration of response was 13.6 months. The median progression-free survival (PFS) was 4.5 months, and the median OS was 17.6 months. Based on these and other data, the combination of dabrafenib plus trametinib was granted tissue-agnostic approval by the FDA in June 2022 in patients aged 6 years or older with unresectable or metastatic *BRAF* V600E–mutated solid tumors that had progressed with previous treatment. Similarly, basket trials of tropomyosin receptor kinase (TRK) inhibitors larotrectinib,[58] entrectinib,[59] and repotrectinib[60] have shown benefit in *TRK* fusion–positive solid tumors, and a basket trial of the RET (rearranged during transfection) kinase inhibitor selpercatinib showed benefit in solid tumors containing a *RET* fusion gene.[61] These studies led to tissue-agnostic, accelerated approvals of these agents by the FDA for patients who have any solid tumor with the appropriate molecular profile (ie, *TRK* fusion for larotrectinib, entrectinib, and repotrectinib; *RET* fusion for selpercatinib). Although additional studies are required to estimate the efficacy of these targeted agents more precisely in patients who have glioblastoma with targetable alterations and their optimal sequencing with standard-of-care therapies, these drugs represent FDA-approved treatment options for a small subset of patients who have glioblastoma.

It is important to note that immune checkpoint inhibitors have not demonstrated efficacy in the vast majority of patients who have glioblastoma, but two negative phase 3 trials have been completed in the first-line setting.[62,63] The anti-PD1 monoclonal antibody pembrolizumab is approved by the FDA for the treatment of adult and pediatric patients who have any unresectable or metastatic solid tumor that is microsatellite instability-high, mismatch repair deficient, and/or tumor mutational burden (TMB)-high as determined by an FDA-approved test.[64] Pembrolizumab is, therefore, an approved option for the rare cases of glioblastoma (approximately 1% or fewer) that harbor these phenotypes in the setting of a germline mutation related to DNA repair (eg, *MSH6, PMS2, POLE*, or others).[65]

KEY POINTS

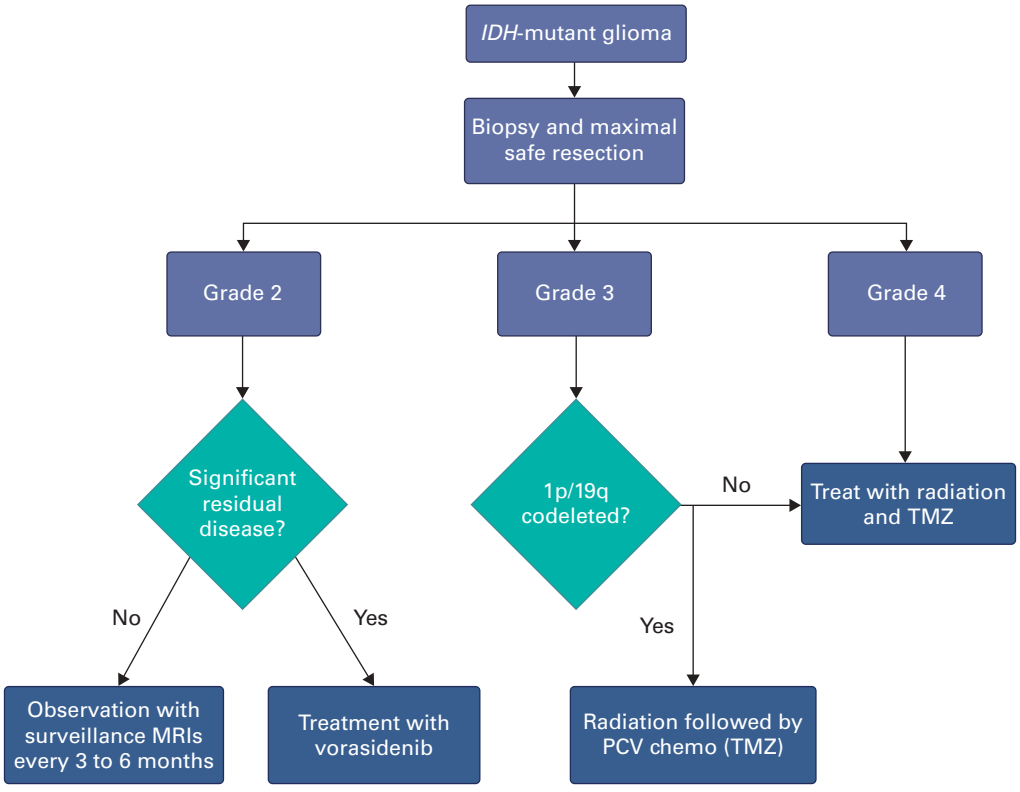
- The current standard of treatment of glioblastoma in patients younger than 70 years is maximal safe resection followed by radiation therapy with concurrent and adjuvant temozolomide, with consideration of tumor-treating fields.
- Phase 3 data also support the use of concurrent chemoradiotherapy in older adults based on the results of a trial with hypofractionated radiation therapy plus temozolomide versus treatment with hypofractionated radiation therapy alone.
- Pseudoprogression may mimic tumor progression in patients who have glioblastoma treated with radiation therapy and should be considered before switching therapy, especially in patients who have MGMT-methylated tumors.
- Tumor-treating fields are FDA approved for newly diagnosed and recurrent glioblastoma.
- Bevacizumab is effective as a steroid-sparing agent for symptom management in select patients who have glioblastoma, although evidence for improvement in OS is lacking.
- When detected in patients who have glioblastoma, *BRAF* V600E mutation, *TRK* fusion, and *RET* fusion are potentially actionable and can be targeted with drugs that have been granted accelerated approval by the FDA in a tissue-agnostic, genotype-specific manner.

ASTROCYTOMA, *IDH* MUTANT

In the current WHO Classification of Tumors of the CNS, all *IDH*-mutated diffuse astrocytic tumors are considered as a single type (*IDH*-mutant astrocytoma) and are then graded as WHO CNS grade 2, 3, or 4. Therefore, the terms "diffuse" and "anaplastic" are no longer used. Grade 2 *IDH*-mutant astrocytomas show an infiltrative diffuse growth pattern (perineuronal and/or perivascular satellitosis, subpial spread), have a variable degree of nuclear atypia and pleomorphism, and have no or few mitoses. Grade 3 *IDH*-mutant astrocytomas (formerly anaplastic) have increased cellularity and mitotic activity. Both these tumors have a high propensity to transform into higher grades over time. Grade 4 *IDH*-mutant astrocytomas may be diagnosed based on histologic findings of necrosis and/or microvascular proliferation. However, in the new 2021 classification system, the presence of *CDKN2A/B* homozygous deletion in an *IDH*-mutant astrocytoma automatically results in a CNS grade 4 classification even in the absence of histologic grade 4 features (microvascular proliferation or necrosis).

Prospective trials have yet to specifically study these molecularly defined groups based on the 2021 WHO integrated diagnostic criteria. All available clinical trial data on *IDH* mutation and 1p/19q codeletion status are either indirect or from subgroup analyses that incorporated post hoc categorization of patients. Within these limitations, guidelines for therapy for *IDH*-mutated astrocytoma were released in December 2021 by ASCO and the Society for Neuro-Oncology.[31] Key elements of treatment are outlined in the following sections and summarized in Figure 18-4.

Figure 18-4 Management of *IDH*-Mutant Glioma



Abbreviations: PCV, procarbazine, lomustine, and vincristine; TMZ, temozolomide.
For patients who have grade 2 *IDH*-mutant astrocytoma or oligodendroglioma, vorasidenib is approved in the first-line setting for patients following biopsy or resection. For patients who have oligodendroglioma (*IDH*-mutated, 1p/19q codeleted), radiation followed by PCV chemotherapy is also standard of care, but TMZ may be considered if toxicity is a concern. For patients who have grade 2 to 3 *IDH*-mutant astrocytoma, radiation with TMZ (12 cycles adjuvant, consider concurrent) can be used, although PCV may be considered. Patients who have grade 4 astrocytoma should be treated with radiation and concurrent TMZ as first-line therapy, followed by six cycles of adjuvant TMZ.

SURGERY

As in glioblastoma, the initial step of treatment of a presumed grade 2 or 3 glioma is maximal safe neurosurgical resection. As with glioblastoma *IDH*wt, there appears to be a benefit from supramaximal resection in these tumors as well.[66] For tumors that enhance, removal of all contrast-enhancing tissue is a common goal. Grade 2 *IDH*-mutant astrocytomas can be indolent tumors; however, they tend to eventually progress to high-grade astrocytomas. Although the surgical management of small and asymptomatic grade 2 gliomas is more controversial, maximal safe surgical resection, when possible, is associated with improved survival.

IDH-INHIBITOR THERAPY

For patients who have grade 2 *IDH*-mutant glioma, the IDH1/2 inhibitor vorasidenib is approved by the FDA as a first-line therapy. The INDIGO phase 3 trial randomly assigned participants with residual or recurrent grade 2 *IDH*-mutant glioma who had received a surgical diagnosis between 1 and 5 years before enrollment, received no previous treatment, had no contrast-enhancing disease, and had a residual tumor measuring at least 1 cm × 1 cm in the two longest dimensions to be treated with vorasidenib 40 mg once per day or placebo.[1] PFS, the primary trial endpoint, was significantly improved to 27.7 months in the vorasidenib arm compared with 11.1 months for placebo (HR, 0.39; 95% CI, 0.27-0.56). Prespecified subgroup analysis demonstrated a benefit in patients who have 1p/19q codeleted and non-codeleted tumors. Grade 3 or higher toxicity was seen in 23% of patients, most commonly elevated liver function test results. Because the trial included patients who were 1 to 5 years beyond diagnosis, the optimal time to implement this therapy is still unclear; long-term survival data are not available, and it remains acceptable to monitor for radiographic or symptomatic tumor growth.

RADIATION THERAPY

As in patients who have glioblastoma, postoperative radiation therapy with chemotherapy is demonstrated to prolong survival in patients who have grade 3 astrocytoma and is a standard component of treatment.[67] Most practitioners currently treat with

54 to 60 Gy in 1.8- to 2.0-Gy fractions. Radiation therapy likely improves OS for grade 2 *IDH*-mutated astrocytoma as well, although the optimal timing for initiating treatment remains uncertain. A phase 3 clinical trial evaluated the role of immediate radiation therapy versus delayed radiation therapy in patients who have low-grade glioma and demonstrated no improvement in median OS with immediate treatment compared with delayed radiation therapy (7.4 years vs. 7.2 years; $P = .87$).[68] The study did demonstrate that early treatment extends the time to recurrence and reduces seizures compared with delayed radiation therapy at the time of tumor progression (median PFS, 5.3 years vs. 3.4 years; $P < .0001$). Thus, a rationale exists for delaying radiation therapy in an attempt to prevent radiation therapy–induced neurologic damage in patients who have grade 2 *IDH*-mutant astrocytoma, particularly in those with favorable prognostic factors (eg, complete resection, younger age). Importantly, however, the RTOG 9802 phase 3 trial of radiation therapy alone versus radiation therapy followed by chemotherapy with PCV demonstrated minimal long-term neurotoxicity. In fact, a majority of patients showed improvement in neurocognitive testing over time.[69] Therefore, for patients who have WHO grade 2 *IDH*-mutant astrocytoma and who have minimal symptoms, including well-controlled seizures, it is acceptable to either treat at the time of initial diagnosis or defer radiation therapy and chemotherapy until evidence of symptomatic tumor growth is observed. A trial of vorasidenib before treatment with radiation is considered appropriate in patients with low-grade *IDH* mutant astrocytoma or oligodendroglioma.

CHEMOTHERAPY

For patients who have WHO grade 3 *IDH*-mutant astrocytoma, the current standard of care is to offer adjuvant temozolomide after radiation therapy. Temozolomide can also be offered concurrently with radiation therapy. The EORTC 26053 (CATNON trial) phase 3 international trial randomly assigned patients who have grade 3 glioma without 1p/19q codeletion to either radiation therapy alone or radiation therapy with temozolomide during and/or after radiation therapy using a factorial design.[70] In the subgroup of 444 patients who have *IDH*-mutant tumors, concurrent temozolomide was not significantly associated with improved OS (HR, 0.80; 95% CI, 0.58-1.10), whereas adjuvant temozolomide showed an OS HR of 0.48 (95% CI, 0.35-0.67). Based on these data, it is considered standard to offer adjuvant temozolomide with or without concurrent temozolomide during radiation.

Observation is historically favored for patients who have low-risk, low-grade (WHO grade 2) glioma, loosely defined as patients aged younger than 40 years who have undergone surgical gross total resection. Such patients are, therefore, excluded from most clinical trials of chemotherapy. However, when the decision was made to treat patients who have WHO grade 2 *IDH*-mutant astrocytoma with radiation therapy, the preponderance of the evidence favored adding chemotherapy (either PCV or temozolomide). Although studies support improved survival with PCV in *IDH*-mutant 1p/19q non-codeleted tumors (5.5 years vs. 3.3 years), the survival advantage seems less pronounced than in 1p/19q codeleted tumors (ie, oligodendrogliomas)[17] (see the "Oligodendroglioma, *IDH* Mutant, and 1p/19q Codeleted" section for details). Given this observation, as well as the lower toxicity and probable efficacy of temozolomide in this setting (based on data from the CATNON study), adjuvant temozolomide rather than PCV is a reasonable treatment option for patients who have grade 2 *IDH*-mutant astrocytoma.

RECURRENCE

As with patients who have glioblastoma, no uniform therapy is available for patients who have *IDH*-mutant astrocytoma that has relapsed after radiation therapy and alkylating chemotherapy, and treatment options are tailored to the individual clinical setting. Repeated surgery may be considered in select cases for either diagnostic purposes (eg, possible progression to a higher grade, differentiation of active tumor vs. treatment effect) and/or for debulking. Retreatment with temozolomide or nitrosourea-based regimens may be an option. Bevacizumab is an option for recurrent high-grade disease with associated symptoms. In addition, repeated radiation therapy with or without concomitant temozolomide is considered in certain situations. IDH inhibitors may be considered for non-enhancing recurrent disease, although prospective randomized data that confirm a benefit are lacking.

KEY POINTS

- In the 2021 WHO Classification of Tumors of the CNS, all *IDH*-mutant diffuse astrocytic tumors are considered as a single entity (*IDH*-mutant astrocytoma) and are then graded as grade 2, 3, or 4. These tumors are 1p/19q non-codeleted.
- Initial treatment of grade 3 *IDH*-mutant astrocytomas is maximal safe resection followed by radiation therapy with chemotherapy. Adjuvant temozolomide provides a clear survival benefit, and concurrent temozolomide may be considered given the potential benefit and limited risk of harm.
- Grade 2 *IDH*-mutant astrocytomas can be indolent tumors; however, they tend to eventually progress to high-grade astrocytomas.
- Maximal safe resection is recommended, especially if a presumed glioma is large and/or symptomatic.
- The IDH inhibitor vorasidenib is an FDA-approved agent for grade 2, *IDH*-mutant astrocytomas following surgery.
- Radiation therapy with adjuvant chemotherapy (temozolomide or PCV) provides a clear survival benefit in grade 2 *IDH*-mutant astrocytoma regardless of whether treatment was administered just after diagnosis or at the time of tumor progression. Definitive therapy may be deferred until radiographic or symptomatic progression occurs in individuals with positive prognostic factors (eg, complete resection, younger age) or who elect first-line IDH-inhibitor therapy.

OLIGODENDROGLIOMA, *IDH* MUTANT, AND 1P/19Q CO-DELETED

Oligodendrogliomas are relatively uncommon, accounting for only ~8% of gliomas. Nevertheless, they are important to note because of their unique natural history, comparatively favorable prognosis, and sensitivity to chemotherapy. Key histologic features include monomorphic, rounded nuclei with artifactual, clear perinuclear halos on paraffin-processed tissues (fried-egg pattern), and delicate capillary vascular networks (chicken-wire vessels); requisite molecular features include *IDH* mutation and 1p/19q codeletion.

Grade 3 oligodendrogliomas typically demonstrate high cellularity, nuclear pleomorphism, and frequent mitoses. Abundant endothelial proliferation and tumor necrosis may also be seen, but these tumors are graded differently; a grade 4 does not exist for oligodendrogliomas. In the current WHO classifications, oligodendrogliomas, which are always *IDH* mutated, are also defined by the presence of a 1p/19q codeletion. Mass effect or seizures are typically seen at presentation. MRI scans reveal a variably contrast-enhancing mass in most patients. The disease course of grade 2 oligodendrogliomas is more indolent than that of grade 2 astrocytomas.

SURGERY

As previously described for *IDH*-mutant astrocytomas (see the "Astrocytoma, *IDH* Mutant" section), the initial step of treatment of a presumed grade 2 or 3 oligodendroglioma is the best-possible safe neurosurgical resection. For tumors that enhance, the removal of all contrast-enhancing tissue is performed as a common goal. The surgical management of small and asymptomatic gliomas is more controversial. Either first-line surgical resection or a watch-and-wait approach may be considered.

IDH INHIBITORS

The IDH1/2 inhibitor vorasidenib is an FDA-approved agent as first-line therapy for *IDH*-mutant astrocytomas and oligodendrogliomas based on the results of a double-blind randomized placebo-controlled phase 3 study as described in the "Astrocytoma, *IDH* Mutant" section.[71] For patients who have non-enhancing residual grade 2 oligodendroglioma who had received surgery within 1 to 5 years before enrollment, there was a clear improvement in PFS (HR, 0.32; 95% CI, 0.18-0.57) and time to next therapeutic intervention (HR, 0.14; 95% CI, 0.05-0.4). Given the indolent natural history of oligodendroglioma, it remains unclear at what point in the disease trajectory IDH inhibitor therapy should be implemented. Effects on OS, family planning, and quality of life are not yet clear. These factors should be considered with patients when initiating therapy.

RADIATION THERAPY AND CHEMOTHERAPY

For grade 3 oligodendrogliomas, surgical debulking is typically followed by radiation therapy with chemotherapy. Support for the use of chemotherapy and radiation therapy after resection of grade 3 (formerly anaplastic) oligodendrogliomas comes from two phase 3 trials, one conducted in North America (RTOG 9402) and one in Europe (EORTC 26951). In the North American trial, patients who had anaplastic oligodendrogliomas or anaplastic oligoastrocytomas were randomly assigned to receive PCV for four cycles before radiation therapy or radiation therapy alone.[20] Patients who have *IDH*-mutated 1p/19q co-deleted tumors benefited from the addition of PCV to radiation therapy (median survival, 14.7 years vs. 6.8 years).

In the European trial, patients received PCV after radiation therapy. Results were similar to those of the North American trial. Some long-term results demonstrated a longer median survival in patients who had 1p/19q co-deleted tumors who received both radiation therapy and PCV compared with those who received radiation therapy alone. Taken together, these two randomized trials support the standard use of radiation therapy and chemotherapy with PCV for patients who have grade 3 oligodendrogliomas.

In patients who have grade 2 oligodendroglioma, considerations regarding timing of therapy are similar to those for patients who have WHO grade 2 *IDH*-mutant astrocytoma (see the "Astrocytoma, *IDH* Mutant" section). If adjuvant therapy is chosen, the preponderance of the evidence is in favor of offering both radiation therapy and chemotherapy to patients who have WHO grade 2 *IDH*-mutant 1p/19q co-deleted oligodendroglioma. The phase 3 RTOG 9802 clinical trial defined patients as being at high risk of early progression if they were 40 years or older and/or if they were younger than 40 years and had undergone subtotal resection or biopsy instead of a gross total resection. Patients meeting these eligibility criteria were then randomly assigned to receive either radiation therapy alone or radiation therapy followed by chemotherapy with PCV. The study showed that the addition of chemotherapy with PCV significantly improved survival.[69] Subgroup analyses support trends that patients who have tumors with 1p/19q codeletion may, in fact, be the patients who derive the most benefit from chemotherapy.[72]

Radiation therapy with PCV may be superior to radiation therapy and concomitant temozolomide for patients who have grade 3 oligodendroglioma, based on a large retrospective cohort study.[71] Temozolomide is overall better tolerated, and patients are commonly treated with radiation therapy and temozolomide as well. The CODEL ongoing prospective trial is comparing radiation therapy followed by PCV with chemoradiotherapy with temozolomide followed by adjuvant temozolomide in patients who have oligodendrogliomas (both grade 2 and grade 3). This study will eventually answer the question of how the two regimens compare.

KEY POINTS

- Oligodendroglial tumors are characterized by both *IDH* mutation and 1p/19q codeletion and have a more indolent course than astrocytomas.
- After surgery for debulking and maximal safe resection, patients who have WHO grade 3 *IDH*-mutant 1p/19q co-deleted oligodendroglioma should be offered radiation therapy in combination with PCV because the addition of PCV after radiation therapy significantly improves OS compared with radiation therapy alone. TMZ is a reasonable alternative to PCV when toxicity is a concern.
- For patients who have WHO grade 2 *IDH*-mutant 1p/19q co-deleted oligodendroglioma, maximal safe resection is recommended if the tumor is large and/or symptomatic.
- The IDH inhibitor vorasidenib is an FDA-approved agent for grade 2 oligodendroglioma before radiation therapy, though the effect on survival is unknown.
- Radiation therapy and adjuvant PCV provide a clear survival benefit in grade 2 *IDH*-mutant 1p/19q co-deleted oligodendroglioma; however, no clear OS advantage is seen with immediate postoperative radiation therapy compared with delayed radiation therapy. Definitive therapy may be deferred until radiographic or symptomatic progression in individuals with positive prognostic factors (eg, complete resection, younger age) or who elect first-line IDH-inhibitor therapy.

RARE, TARGETABLE CNS TUMORS

DIFFUSE MIDLINE GLIOMA (H3K27M-MUTATED)

The role of chemotherapy in DMG has historically been unclear, given the lack of clinical trial data supporting efficacy. In 2025, the FDA granted accelerated approval of the protease activator dordaviprone for progressive disease following prior therapy in patients aged 1 year or older with DMG harboring an H3K27M mutation. This recommendation was based on a select subgroup of 50 patients from five non-randomized clinical trials in adults and children with gliomas.[13,73] In that select population, the overall response rate was 22% (including partial and minor responses) with a median duration of response lasting 10.3 months. It was well tolerated, with fatigue being the most common treatment-related grade 3 toxicity (10%; see Table 18-1).

Table 18-1 **Rare, Targetable CNS Tumors**

Rare, Targetable Nervous System Tumors	Grade	Tumor Characteristics	Common Alterations	Targeted Therapy	References
Pilocytic astrocytoma	1	Primarily pediatric. Frequently appear as a cyst with a mural nodule in the cerebellum. Can be cured by surgery if removed completely	*KIAA1549-BRAF* fusion	Tovorafenib	2,74
Subependymal giant cell astrocytoma	1	Periventricular, 1:10 in patients who have tuberous sclerosis	*TSC1* or *TSC2*	Everolimus	75
CNS hemangioblastoma	1	Highly vascular, 25% associated with VHL	*VHL*	Belzutifan (for VHL-associated)	76
Plexiform neurofibroma	1	Occur on peripheral nerves and can undergo malignant transformation	*NF1*	Selumetinib (for NF1-associated)	77
Pleomorphic xanthoastrocytoma	2 or 3	Primarily adolescent and young adult, predilection for cerebrospinal fluid dissemination	*BRAF*	Dabrafenib/ trametinib	78
Diffuse midline glioma	4	Primarily pediatric	*K3K27M*	Dordaviprone	13

Abbreviations: CNS, central nervous system; VHL, von Hippel-Lindau.

KEY POINTS

- Grade 1 astrocytomas are more common in children and young adults. Surgical resection is often curative.
- Everolimus is an FDA-approved agent for the treatment of SEGAs.
- Low-grade astrocytomas with *BRAF* V600E or *BRAF* rearrangements may be amenable to *BRAF*- or *MEK*-targeted therapy.

MEDULLOBLASTOMA

Medulloblastoma is the most common malignant brain tumor in children, but young adults and older adults are also at risk, although at a lower frequency. Medulloblastomas develop in the posterior fossa. They may be located in either the cerebellar hemispheres or the vermis and may involve the fourth ventricle. Obstructive hydrocephalus is relatively common because of the proximity of the tumor to the fourth ventricle. Symptoms at presentation may include loss of balance, incoordination, diplopia, dysarthria, and signs of hydrocephalus such as headache, nausea, vomiting, and gait instability.

Molecular pathology studies demonstrate discrete subtypes of medulloblastoma that have variable prognoses. The following genetically defined subtypes are included in the WHO Classification of Tumors of the CNS[79]:

- WNT activated: best prognosis with long-term survival in more than 90% of patients
- Sonic hedgehog (SHH) activated: intermediate prognosis
- Group 3: overexpression of *MYC*; worst prognosis
- Group 4: intermediate prognosis

Although the molecular characterization has not yet resulted in specific therapies, the aberrant pathways identified may eventually lead to targeted treatments for the respective entities.

Maximal surgical resection is important because residual tumor after surgery confers a worse prognosis. A worse prognosis is also seen with positive CSF cytology or the presence of leptomeningeal metastases on MRI scans. Surgery alone is not curative; however, surgical resection followed by radiation to the craniospinal axis with a boost to the site of the primary tumor may be curative.

Post-radiation chemotherapy is a mainstay of treatment in children who have medulloblastoma, particularly because it limits the total dose of radiation required to treat the still-developing CNS. Based on this experience and data from retrospective studies in adults suggesting that adjuvant chemotherapy is associated with improved survival compared with craniospinal radiation alone, even after adjusting for potential confounders, adults with medulloblastoma are usually offered chemotherapy if post-radiation therapy blood cell counts permit. However, no prospective data show an added benefit from chemotherapy in adults who received full-dose craniospinal irradiation. Chemotherapy regimens for adult patients are often modeled after the experience in pediatric patients. Once-per-week treatment with vincristine during radiation therapy, frequently used in children, is often omitted in adults because of poor tolerability of the drug and concerns about lack of efficacy. Adjuvant chemotherapy regimens include cisplatin, cyclophosphamide, and vincristine[80] or cisplatin, lomustine, and vincristine,[80] but there is no unifying standard of care, and the role for chemotherapy after craniospinal irradiation remains controversial.

Vismodegib, a small-molecule inhibitor of the SHH pathway, has demonstrated activity in patients who have recurrent SHH-type medulloblastoma,[81] and high-dose chemotherapy with autologous stem cell transplantation may result in longer survival in some selected patients.[82,83] With appropriate initial therapy, 5-year event-free survival is achieved in more than 80% of patients who have average-risk medulloblastoma and in 36% of patients who have disseminated disease at diagnosis.[80]

KEY POINTS

- Medulloblastomas typically occur in the cerebellum in children, but they can also present in adults.
- Treatment of medulloblastoma includes maximal safe resection followed by irradiation of the craniospinal axis (with a boost to the tumor bed). Platinum-based chemotherapy regimens are considered, especially in higher-risk patients, if post-radiation therapy blood cell counts permit.

MENINGIOMA

Meningiomas are usually benign (grade 1) and originate in the dura covering the brain and spinal cord. Patients who have meningiomas may present with typical features of mass lesions in the brain, including seizures or focal neurologic deficits. Asymptomatic meningiomas may also be incidentally detected on CT or MRI scans that are obtained for other reasons. The tumors have a characteristic appearance on MRI scans, usually consisting of uniform contrast enhancement along the dura and distinct separation from brain parenchyma. Due to tumoral somatostatin receptor (SSTR) expression, there has been an increased use of DOTATATE-PET in the evaluation of these tumors though its optimal role has yet to be defined.

Many incidentally discovered meningiomas do not require treatment. For patients who have an asymptomatic presumed WHO grade 1 meningioma, observation may be appropriate. Epidemiologic evidence suggests that as many as two-thirds of these patients will not have symptoms over time.[84]

In cases of substantial mass effect and/or symptoms, the treatment of choice is usually complete resection. Surgery is often feasible if the meningioma is located over the cortical convexity, olfactory groove, anterior sagittal sinus, or posterior fossa. However, the possibility of resection may be limited for tumors in other sites, including sphenoid, parasagittal, orbital, tentorial, or clival locations. For those situations, external beam radiation therapy or focal stereotactic radiation therapy may be useful for tumor control.

Meningiomas may have more aggressive histologic or molecular features. Patients who have WHO grade 2 (previously atypical) meningiomas or WHO grade 3 (previously anaplastic) meningiomas are commonly treated with surgical resection followed by radiation therapy: either external beam radiation therapy or stereotactic radiosurgery. Those who experience relapse despite optimal surgery and radiation therapy often have progressive debilitation before death. Although several pharmaceutical approaches have been assessed, they have had limited, if any, efficacy.[85] Clinical trials should be considered for these patients.

KEY POINTS

- For many patients who have meningioma, observation is appropriate. For patients who are symptomatic, surgical removal of the tumor is the most common treatment.
- Meningiomas that are WHO grade 2 or 3 are rare but have a more aggressive course with recurrences that may require repeated resection and radiation therapy.
- Currently, systemic regimens have limited, if any, efficacy for the treatment of meningiomas.

HEMANGIOBLASTOMA

Hemangioblastoma is a rare, slow-growing tumor of the CNS that occurs most commonly in the posterior fossa or spinal cord. These tumors can occur sporadically or as a part of VHL disease, an inherited autosomal dominant syndrome characterized by numerous benign and malignant tumors, such as hemangioblastomas, retinal angiomas, endolymphatic sac tumors, renal cell carcinoma, pheochromocytomas, pancreatic cysts, and pancreatic neuroendocrine tumors.

Sporadic hemangioblastomas are typically solitary, whereas multiple tumors within the neuraxis should raise concern for VHL.[86] When hemangioblastomas are symptomatic, they typically result in local symptoms by compression of neural structures or as a result of bleeding. Surgical resection offers definitive therapy for sporadic, isolated hemangioblastomas. Radiation therapy is also an option in patients who have surgically inaccessible tumors. However, the role of surgery and/or radiation in patients who have VHL disease is less well defined because of the frequent occurrence of additional lesions. In these patients, the HIF2α inhibitor belzutifan is an additional treatment option.[87] In the LITESPARK-004 study, belzutifan demonstrated an ORR of 44% in the 50 patients with VHL disease who have CNS hemangioblastomas, with median duration of response and median PFS not reached after a median follow-up time of 38 months.[2] The drug is now FDA approved for adult patients who have VHL disease who require therapy for CNS hemangioblastoma and do not require immediate surgery. Patients must be monitored carefully for anemia and hypoxia.

KEY POINTS

- Surgery and/or radiation are definitive options for sporadic, isolated hemangioblastoma.
- For patients who have VHL-associated CNS hemangioblastoma, belzutifan represents an effective systemic treatment option.

PRIMARY CNS LYMPHOMA

Primary CNS lymphoma is a variant of non-Hodgkin lymphoma that involves the CNS without evidence of systemic disease. More than 95% of primary CNS lymphomas are diffuse large B-cell lymphomas with the remaining cases comprising T-cell lymphomas, low-grade lymphomas, or Burkitt lymphoma. Primary CNS lymphomas constitute approximately 2% to 3% of all brain tumors. The tumor is slightly more common in men, and the median age at diagnosis in immunocompetent patients is approximately 67 years.[88] Most patients diagnosed with primary CNS lymphoma are immunocompetent; however, patients who have a compromised immune system (eg, those who have undergone solid organ transplantation, have congenital immunodeficiency, or have HIV infection) are at increased risk of this disease. Epstein-Barr virus is frequently associated with primary CNS lymphoma in immunocompromised individuals, and Epstein-Barr virus DNA may be found within the tumor.

Patients present with a variety of symptoms characteristic of either focal or multifocal mass lesions. MRI scans usually show homogeneous contrast-enhanced tumors within the periventricular deep white matter. Multifocality is common because these tumors grow diffusely. Heterogeneous contrast enhancement is sometimes seen, especially in patients who have a compromised immune system or after exposure to immunosuppressant agents, such as corticosteroids. It is important to consider CNS lymphoma in the differential diagnosis of brain tumors because treatment of CNS lymphoma differs significantly from treatment of other primary brain cancers. Administration of corticosteroids may result in the complete disappearance of the contrast-enhancing lesion, making diagnosis difficult. Consequently, when CNS lymphoma is considered in the differential diagnosis, corticosteroids should be avoided unless mass effect is causing serious and immediate complications. Often, even in those settings, other means can be utilized to decrease intracranial pressure. Obtaining specimens of suspected lesions by biopsy is critically important because many malignant and non-malignant CNS conditions can mimic CNS lymphoma. As with systemic lymphoma, the role of surgery is restricted primarily to obtaining appropriate tissue for diagnosis.

Staging evaluation includes slit-lamp examination of the eyes (to assess for ocular lymphoma, which is present at diagnosis in approximately 25% of patients); MRI scans of the spine; PET/CT imaging or CT scan of the chest, abdomen, and pelvis; testicular ultrasound to rule out lymphoma; lumbar puncture if safe; and HIV testing. Primary CNS lymphomas typically do not involve the bone marrow, and the role of a bone marrow biopsy as part of the standard workup is controversial. Age and performance status are the strongest independent predictors of OS in patients who have primary CNS lymphoma.

High-dose methotrexate-based regimens with typical doses between 3.5 and 8 g/m^2 have remained the backbone of the treatment of CNS lymphoma. Several combination regimens are used in clinical practice, including high-dose methotrexate with rituximab; with rituximab plus temozolomide; with rituximab, vincristine, and procarbazine; or with rituximab, thiotepa, and high-dose cytarabine.[89-92] The different regimens have not been formally compared in prospective trials, and comparative efficacy cannot be conclusively defined. ORRs for the different regimens are reported to be between 35% and 95%. A substantial percentage of durable complete responses with many of these patients likely cured. However, late relapses, even after 10 years or more, can occur.

Controversy still remains regarding the role of consolidation therapy for patients who have responded to induction with high-dose methotrexate-based therapy. Encouraging data are reported with the use of thiotepa-based conditioning regimen followed by autologous stem cell transplantation, although prospective comparative trial data are sparse. A recently reported trial comparing autologous transplantation with high-dose chemotherapy as consolidation therapy in newly diagnosed primary CNS lymphoma (CALGB-51101) revealed that 2-year PFS was superior in the transplantation arm, although there was a statistically higher number of patients who had primary refractory disease on the high-dose chemotherapy arm during induction before consolidation. When comparing 2-year PFS from the start of consolidation, there was a trend toward improvement with transplantation (HR, 0.58; 95% CI, 0.25-1.36). The estimates of 3-year survival were similar between groups (83% for transplantation and 72% for high-dose chemotherapy).[93]

A possible role of low-dose whole-brain radiation therapy for consolidation in patients who have newly diagnosed primary CNS lymphoma has also been studied.[94] This approach is generally used only in patients who have responsive disease and preserved functional status but who are not candidates for high-dose chemotherapy based on organ dysfunction or patient preference.

A number of additional drugs show promising activity in primary CNS lymphoma, including ibrutinib and lenalidomide, and possibly immunotherapies, including chimeric antigen receptor (CAR) T cells and PD-1 inhibitors.[95] Additional research is needed to determine the best clinical use of these new agents.

Strategies for the treatment of recurrent disease include reinduction with high-dose methotrexate-based regimens and, in select cases, high-dose chemotherapy with autologous stem cell transplantation, temozolomide, ibrutinib, lenalidomide, CAR T cells, combinations with rituximab, and whole-brain radiation therapy.[96] Additional studies are needed to determine the optimal choice and sequence of these therapies for patients with recurrent disease.

The aforementioned doses of methotrexate (3.5-8.0 g/m^2) are potentially lethal if not followed by active measures to reduce associated toxicity. Multiple doses of leucovorin must be administered starting approximately 24 hours after treatment to minimize toxicity to normal cells (ie, leucovorin rescue), and hyperhydration with urinary alkalinization with intravenous fluids is used to enhance methotrexate excretion. Methotrexate levels must be monitored to confirm effective elimination. Prolonged exposure may be secondary to the accumulation of methotrexate in third-space fluid collections (eg, pleural effusions). Such fluid collections should be drained before treatment with methotrexate if possible. In patients who are unable to clear methotrexate quickly enough, administration of glucarpidase can be considered, which cleaves methotrexate and neutralizes its toxic effect.

KEY POINTS

- Primary CNS lymphomas are usually diffuse large B-cell lymphomas.
- Epstein-Barr virus is frequently associated with primary CNS lymphoma in immunocompromised individuals.
- When CNS lymphoma is considered in the differential diagnosis, corticosteroids should be held before biopsy, if clinically feasible, because they can lead to nondiagnostic biopsy results, which, in turn, can delay treatment.
- High-dose methotrexate-based chemotherapy has remained the backbone of therapy for newly diagnosed primary CNS lymphoma.
- Autologous stem cell transplantation can be considered for consolidation in patients who have good functional status and who respond to a methotrexate-based chemotherapy regimen.

METASTATIC DISEASE TO THE NERVOUS SYSTEM

BRAIN METASTASES

Brain metastases from systemic cancers are more common than those from primary brain tumors. The incidence of brain metastases has been reported as 9% to 17% in various studies; autopsy series suggest that the true incidence of brain metastases in adults may be greater than 20%, although these numbers may represent end-stage disease without direct clinical therapeutic relevance. Brain metastases are most associated with lung cancer, breast cancer, melanoma, or an unknown primary cancer. These lesions

generally result from hematogenous spread and are most common at the junction of the gray and white matter, at which the caliber of blood vessels narrows, thereby trapping tumor emboli. A total of 80% of brain metastases occur in the cerebral hemispheres, 15% in the cerebellum, and 5% in the brainstem.[97] It is reported that more than 80% of people with brain metastases have more than one, and approximately 50% have three or more brain metastases seen on MRI scans.[98] Interestingly, the incidence of metastases to the parenchyma of the spinal cord is low.

The management of brain metastases requires an individualized approach because these patients have highly heterogeneous primary disease processes. Considerations for therapy depend on multiple variables, such as the number and location of the brain metastases, histology of the primary cancer, tumor molecular characteristics, degree of extracranial disease, and performance status. Whole-brain radiation therapy remains a primary treatment modality for patients who have a high intracranial tumor burden, and the routine role of whole-brain radiation therapy as adjunctive therapy in patients who are candidates for stereotactic radiosurgery or surgical resection has evolved. Randomized trials show that, despite improved rates of intracranial disease control, adjunctive whole-brain radiation therapy does not improve OS and may decrease quality of life as a result of adverse effects and neurocognitive decline. Techniques such as hippocampal avoidance whole brain radiotherapy (WBRT; discussed below) or stereotactic radiosurgery (also discussed below) can mitigate the toxicity of radiation. In addition, the integration of systemic therapy into the management of brain metastases has increased considerably over the past decade because improved systemic therapies with significant brain penetration have begun to offer greater potential for intracranial disease control for certain cancer types and genotypes.[99]

SURGERY

For patients who have a single, surgically accessible metastasis that is large or associated with significant edema and mass effect, surgical resection achieves rapid symptom relief and local control. Surgery (or stereotactic biopsy for inaccessible tumors) is also favored for single lesions when there is uncertainty regarding the histologic diagnosis based on either clinical grounds or radiographic findings.

RADIATION THERAPY

For patients who receive surgery, radiation to the resection cavity with stereotactic radiosurgery is shown to decrease local recurrence compared with surgery alone. One phase 3 trial randomly assigned 132 patients who had undergone a complete resection of one to three brain metastases (maximum diameter of resection cavity <4 cm) to either stereotactic radiosurgery of the resection cavity or observation.[100] Freedom from local recurrence at 1 year was 43% in the observation group and 72% in the stereotactic radiosurgery group (HR, 0.46; $P = .015$), indicating that stereotactic radiosurgery significantly lowers local recurrence. Stereotactic radiosurgery may be preferred as an independent treatment in patients who have surgically inaccessible lesions and cannot undergo craniotomy because of the operative risk. Limitations include the inability to obtain tissue diagnosis or reduce mass effect; in addition, lesions must generally be less than 3 to 4 cm to be safely treated. Furthermore, stereotactic radiosurgery may increase cerebral edema, resulting in a mass effect that requires either corticosteroid treatment or resection of necrotic tissue.

Historically, stereotactic radiosurgery was used primarily in patients with 10 or fewer small (<3 cm) brain metastases.[101,102] However, recent practice has evolved such that patients with a greater number of small brain metastases are commonly managed with stereotactic radiosurgery. Local control rates with stereotactic radiosurgery are high, ranging from 80% to 90%.[103] In patients who have undergone stereotactic radiosurgery for up to 10 small brain metastases, there is no longer a role for adjunctive whole-brain radiation therapy. In a phase 3 clinical trial, patients who had one to three brain metastases were treated with either surgery or stereotactic radiosurgery and then randomly assigned to either whole-brain radiation therapy (30 Gy in 10 fractions) or observation. Whole-brain radiation therapy reduced the incidence of intracranial progression (48% vs. 78%; $P < .001$) and death resulting from neurologic factors (28% vs. 44%; $P < .002$); however, OS was similar in the two groups (10.97 months vs. 10.7 months; $P = .89$).[104] This study and many others also raise concerns regarding cognitive impairment with the addition of whole-brain radiation therapy. Nonetheless, whole-brain radiation remains the standard approach to initial treatment in most patients who have a very high overall tumor burden, including those with multiple large tumors. When whole-brain radiation therapy is used, data from a placebo-controlled phase 3 clinical trial suggest that concurrent use of memantine may delay cognitive decline.[105] A subsequent unblinded randomized phase 3 trial[106] shows that use of whole-brain radiation therapy with hippocampal avoidance led to an additional 26% relative reduction in risk of cognitive toxicity compared with conventional whole-brain radiation therapy; both groups received memantine during whole-brain radiation therapy and for 6 months afterward.

SYSTEMIC THERAPY

Classic chemotherapy plays a limited role in the treatment of brain metastases, in part because of poor drug delivery through the blood-brain barrier and blood-tumor barrier. However, chemotherapy may be curative in specific tumors, such as lymphoma and germ cell tumors; chemotherapy may be incorporated into the treatment plan for both brain tumors and systemic metastatic disease in these patients, often in combination with radiation therapy. Another unique situation is extensive-stage small-cell lung

cancer presenting with brain metastases; these patients may be treated with initial systemic therapy if their intracranial disease is asymptomatic and with whole-brain radiation therapy upon completion of induction therapy.

A growing body of evidence shows intracranial efficacy of molecularly targeted small molecules and/or immune checkpoint inhibitors in cancers in which the respective agents are known to be effective systemically. In select cases with small and asymptomatic or minimally symptomatic brain metastases, a closely monitored trial of systemic therapy with intracranial efficacy and deferral of locoregional CNS therapy is an increasingly acceptable treatment approach.[107] Key examples of effective systemic therapies across the solid tumors that most commonly metastasize to the CNS are displayed in Table 18-2.[108-127]

Table 18-2 Key Systemic Agents With Intracranial Activity in Patients With Brain Metastases

Primary Tumor	Drug(s)	Intracranial Response Rate(s) (95% CI) %	References
NSCLC, driver mutation negative, PD-L1 positive	Pembrolizumab	30 (16-47)	108
EGFR-mutant NSCLC	Osimertinib	91 (71-99)	109
ALK-rearranged NSCLC	Alectinib	81 (58-95)	110
	Brigatinib	78 (52-94)	111
	Lorlatinib	82 (57-96)	112
ROS1-positive NSCLC	Entrectinib	79 (60-93)	113
	Repotrectinib	89 (52-100)	60
RET-fused NSCLC	Selpercatinib	82 (57-96)	114
	Pralsetinib	70 (35-93)	115
MET exon-14 skipping mutation NSCLC	Capmatinib	54 (17-77)	116
	Tepotinib	55 (23-83)	117
KRAS G12C-mutant NSCLC	Adagrasib	42 (20-67)	118
	Sotorasib	25 (13-41)	119
Small cell lung cancer	Tarlatamab	63 (30-100)	128
HER2-positive breast cancer	Lapatinib and capecitabine	66 (50-80)	120
	Neratinib and capecitabine	49 (32-66)	121
	Tucatinib, capecitabine, and trastuzumab	47 (34-61)	122
	Fam-trastuzumab deruxtecan (T-Dxd)	46 (19-75)	123
Melanoma, *BRAF* V600E mutant	Dabrafenib and trametinib	58 (46-69)	124
Melanoma	Ipilimumab and nivolumab	54 (43-64)	125
	Pembrolizumab	22 (7-48)	126
	Nivolumab	20 (7-41)	127
Renal cell carcinoma	Cabozantinib	55 (36-73)	128
	Ipilimumab and nivolumab	32 (15-54)	129

Abbreviations: EGFR, epidermal growth factor receptor; NSCLC, non–small cell lung cancer.

In addition, the FDA has approved the use of three TRK inhibitors, larotrectinib, entrectinib, and repotrectinib, for *NTRK* fusion–positive solid tumors regardless of tumor type.[60,61,130,131] The activity of these drugs has also been demonstrated in patients who have brain metastases. Entrectinib and repotrectinib are also FDA-approved agents for metastatic *ROS1*-positive non–small cell lung cancer, and there has been activity of these drugs for *ROS1*-positive non–small cell lung cancer brain metastases.

ANTIEPILEPTIC PROPHYLAXIS AND CORTICOSTEROIDS

A recently published guideline review by a panel of experts from ASCO and the Society for Neuro-Oncology focused on anticonvulsant prophylaxis and corticosteroid use in adults with metastatic brain tumors. Prophylactic antiepileptic drugs were not recommended for routine use in patients without a seizure history. Corticosteroids (dexamethasone) were recommended for symptomatic relief for patients who have signs of, and neurologic symptoms related to mass effect from their brain metastases.[132]

KEY POINTS

- Brain metastases as a group are the most common brain tumors.
- Stereotactic radiosurgery is increasingly being used in addition to or in place of surgery for patients with brain metastases.
- When whole-brain radiation therapy is used for the treatment of brain metastases, the use of hippocampal avoidance intensity-modulated radiation therapy and memantine together has been demonstrated in a randomized trial to decrease the risk of neurocognitive toxicity.
- Small molecules and immunotherapies are increasingly used in the treatment of brain metastases from cancers in which the respective medications are effective systemically.

LEPTOMENINGEAL METASTASES

Leptomeningeal metastases occur in approximately 5% of patients who have cancer and are more frequently recognized as patients who have cancer live longer, and as diagnostic studies improve.[133] Leptomeningeal disease is most common with breast cancer, lung cancer, and melanoma. The tumor may reach the leptomeninges by hematogenous spread or by direct extension from preexisting tumor deposits within the dura or brain parenchyma. Tumor cells are disseminated throughout the neuraxis by the flow of CSF. Patients present with signs and symptoms referable to one or more of the following: local injury to nerves traveling through the spinal fluid (cranial nerve palsies, weakness, paresthesias, or pain); direct invasion into the brain or spinal tissues or interruption of blood supply to those tissues (focal findings or seizures); obstruction of normal CSF flow pathways, increased intracranial pressure, and hydrocephalus (headache, nausea, vomiting, and dizziness); and interference with cognitive function (encephalopathy).

Diagnosis is made by MRI scanning or CSF analysis. Initial analysis of CSF demonstrates malignant cells in ~50% of affected patients; however, in nearly 10% of patients who have leptomeningeal involvement, the cytologic examination remains persistently negative.[134] Increasing the number of lumbar punctures (up to six) and the volume of CSF removed (10 mL per lumbar puncture) increases the yield of positive cytology. CSF analysis often demonstrates mild protein elevation, pleocytosis, and possible low glucose concentrations. Radiographic studies may demonstrate diffuse and/or nodular contrast enhancement of the leptomeninges or hydrocephalus without a mass lesion. More recently, the use of CSF advanced analyses (circulating tumor cells or cell-free DNA) is becoming incorporated into the assessment of patients. Their exact role is yet to be defined and validated.

In patients who have leptomeningeal disease from solid tumors, the median survival without therapy is typically short, often between 4 and 12 weeks, depending on the tumor type.[135] Death results from progressive neurologic dysfunction. Palliative care may be the most appropriate for patients who have poor performance status, significant neurologic dysfunction, and/or uncontrolled systemic disease. Corticosteroids and analgesics may offer limited temporary improvement. Radiation therapy, especially whole-brain radiation therapy, should be considered for the treatment of symptomatic sites. Ventriculoperitoneal shunting can be considered for palliative relief of refractory symptomatic hydrocephalus.

For patients who have minimal systemic disease, no significant neurologic deficits, and an acceptable performance status, a more aggressive approach may be considered. Unfortunately, no specific treatment has definitively demonstrated an improvement in OS. Imaging to assess for normal CSF flow should be considered before intrathecal therapy is given because blockage of flow by tumor deposits in the subarachnoid space reduces drug delivery and increases the risk of toxicity of intrathecal therapy. In the presence of CSF flow abnormalities, radiation therapy may be attempted to attain normal CSF flow. Radiation therapy may also be used to treat areas of bulky disease and other symptomatic sites. When available, proton craniospinal radiation therapy, which has an improved toxicity profile compared with photon craniospinal radiation therapy, is an option in selected patients who have a better prognosis and adequate functional status. This is based on a randomized phase 2 trial of proton craniospinal radiation therapy versus involved-field radiation therapy in 63 patients who have leptomeningeal disease from either breast cancer or non–small cell lung cancer, in which proton craniospinal radiation therapy improved both median CNS PFS (7.5 months vs. 2.3 months) and OS (9.9 months vs. 7.5 months) compared with involved-field radiation therapy with no difference in the rate of serious adverse effects.[136]

If CSF flow is normal, intrathecal chemotherapy or monoclonal antibodies, such as rituximab or trastuzumab, may provide some disease control in patients who have non-bulky leptomeningeal involvement of their cancer. Drugs can be administered intrathecally through an Ommaya reservoir or by repeated lumbar punctures, although certain drugs cannot be given by lumbar puncture because of toxicity.

For patients who have a systemic therapy option that has both efficacy against the primary tumor and a reasonable likelihood of CNS penetration or activity, systemic therapy can be offered. Key examples include osimertinib in *EGFR*-mutated non–small cell lung cancer or alectinib or lorlatinib in *ALK*-positive non–small cell lung cancer. Of note, leptomeningeal involvement

from hematologic malignancies may have a much better response to systemic (eg, high-dose methotrexate in secondary CNS lymphoma) and intrathecal chemotherapy.

KEY POINTS

- Leptomeningeal metastases are manifested by progressive symptoms and signs of injury to brain parenchyma, cranial nerves, and/or spinal nerves.
- Treatment of leptomeningeal metastases from solid tumors is often limited to symptom control. Radiation to symptomatic areas and, in select patient cases with symptomatic hydrocephalus, shunt placement may alleviate symptoms. Proton craniospinal radiation therapy, when available, should be considered for patients who have a better prognosis and adequate functional status.
- Intrathecal chemotherapy or systemic therapies can be offered to select patients.

COMPLICATIONS AND IMPORTANT SUPPORTIVE CARE AGENTS IN CNS TUMORS

CEREBRAL EDEMA

Corticosteroids, antiepileptic drugs, and anticoagulant drugs are important ancillary agents for the treatment of patients who have brain tumors. Corticosteroids are indispensable for controlling cerebral edema. Unfortunately, the long-term use of these agents can result in substantial toxic effects, including myopathy, hyperglycemia, peripheral edema, and Cushing syndrome. Dexamethasone is often the drug of choice because of its minimal mineralocorticoid activity and long half-life. Corticosteroids are generally recommended for temporary relief of symptoms and should be started at the minimum dose necessary and tapered as quickly as deemed possible, especially in asymptomatic patients. Patients on ≥4 mg of dexamethasone per day for at least 4 weeks should be given prophylaxis for pneumocystis jirovecii pneumonia. Bevacizumab may also be considered in select cases to control severe edema, including edema secondary to radiation necrosis.[137]

SEIZURES

Antiepileptic drugs are administered for the treatment of seizures. Clinical trials demonstrate that some antiepileptic agents, including phenytoin, phenobarbital, and carbamazepine, induce common hepatic enzyme systems, such as CYP450 enzymes. Induction of these enzymes results in decreased exposure to chemotherapy agents and other drugs metabolized by the same enzyme systems, including warfarin and small-molecule inhibitors. By contrast, valproate inhibits CYP450 and may reduce chemotherapy metabolism with a consequent increase in toxicity. Newer antiepileptic drugs, such as levetiracetam, zonisamide, lacosamide, lamotrigine, topiramate, and pregabalin, do not typically interact with current treatment regimens. These agents are preferred when feasible because they may help patients avoid the enzyme interactions previously noted.

Clinical trials have not demonstrated a discernible benefit for the use of routine prophylactic antiepileptic therapy for patients who have no history of seizures.[138] Similarly, no clear evidence supports the efficacy or lack of efficacy of antiepileptic therapy in the post-craniotomy setting.[138] Prospective randomized trials demonstrate a lack of efficacy of perioperative seizure prophylaxis[139]; however, the heterogeneity of included patients and the use of older antiepileptic agents in these trials have led to limited acceptance of these results. If antiepileptics are initiated perioperatively, current practice is to discontinue use after a few weeks. Patients who have had a seizure should generally continue to receive antiepileptic therapy indefinitely.

VENOUS THROMBOEMBOLISM

Clinically apparent venous thromboembolism or pulmonary emboli that require anticoagulation may occur in 20% to 30% of patients who have primary brain tumors. The reason for this high risk is likely multifactorial and includes hypercoagulability of malignancy as well as the immobility of many patients who have brain tumors. Presumably, the surgical injury of brain parenchyma also results in the release of procoagulant proteins that lead to a higher risk of thrombosis. Spontaneous bleeding during anticoagulation occurs in only 2% of patients who have malignant gliomas and does not seem to be higher than the rate seen in patients who are not treated with anticoagulants.[140] Low-molecular-weight heparin is generally considered more effective than warfarin in patients who have active malignancy.[141] Patients who have CNS tumors should receive anticoagulation for established venous thromboembolism as recommended for other patients who have cancer. Anticoagulation should be avoided in the setting of active intracranial bleeding (or especially hemorrhagic brain tumors), thrombocytopenia, or coagulopathy. Prospective clinical trials evaluating newer direct oral anticoagulants, including factor Xa inhibitors (eg, apixaban, edoxaban, rivaroxaban) and direct thrombin inhibitors (eg, dabigatran), have not yet conclusively assessed the safety of these drugs in patients who have brain tumors. However, accumulating retrospective data suggest that a direct oral anticoagulant is a reasonable alternative to low-molecular-weight heparin for patients who desire oral therapy; one large retrospective study demonstrated significantly lower rates of intracranial hemorrhage in patients who have glioblastoma-associated venous thromboembolism treated with direct oral anticoagulants compared with low-molecular-weight heparin.[142] Additional prospective clinical evaluation is warranted.

HIGH-YIELD TAKEAWAYS

- Surgical resection is the gold standard for diagnosis of primary CNS tumors, and testing for *IDH1/2* mutations and *MGMT* promoter methylation is critical for accurate diagnosis, treatment selection, and overall prognosis in glioma.
- Radiation and concomitant temozolomide followed by six cycles of temozolomide is the standard of care for *IDH*-WT glioblastoma and grade 4 *IDH*-mutant astrocytoma.
- Radiation followed by PCV is highly effective and is the standard of care for oligodendrogliomas (*IDH*-mutant, 1p/19q co-deleted) of all grades.
- A range of targeted therapies is increasingly available for metastatic CNS cancers and should be considered when appropriate.
- High-dose methotrexate-based chemotherapy has remained the backbone of therapy for newly diagnosed primary CNS lymphoma; autologous stem cell transplantation can be considered for consolidation in patients who have good functional status.
- Stereotactic radiosurgery is increasingly being used in addition to or in place of surgery for patients who have a single or a limited number of brain metastases.

CENTRAL NERVOUS SYSTEM TUMORS

18

CHAPTER SUMMARY GUIDE

KEY POINTS

- Exposure to ionizing radiation is a well-established risk factor for primary CNS tumors.
- Most patients who have primary CNS tumors have no identifiable risk factor. The exceptions are patients who have a primary CNS tumor associated with one of the familial cancer syndromes, including neurofibromatosis type 1, Li-Fraumeni syndrome, Lynch syndrome, and familial adenomatous polyposis. Other, less common, inherited genomic risks are emerging.
- Immunodeficiency is a risk factor for primary CNS lymphoma.
- *IDH* mutations are central aspects of defining astrocytoma IDH mutant and oligodendroglioma, two types of adult diffuse gliomas.
- *IDH* mutations are most common in grade 2 and 3 gliomas but can also be seen in grade 4 astrocytomas.
- Regardless of grade, *IDH* mutations in glioma are associated with younger age, increased sensitivity to treatment, and comparatively favorable prognosis.
- Oligodendrogliomas are defined by the presence of both *IDH* mutation and 1p/19q codeletion and have improved response to chemotherapy and prognosis compared with other gliomas.
- Tumors that are *IDH* mutated without 1p/19q codeletion are referred to as astrocytoma, *IDH* mutant, and commonly harbor a mutation in *ATRX*.
- *BRAF* alterations, which may have an impact on available therapeutic options, occur in a range of CNS tumors, but at this time are not pathognomonic for any WHO CNS tumor type.
- According to the 2021 WHO Classification of Tumors of the CNS, glioblastoma is by definition *IDH* wild type.
- In glioblastoma, being MGMT promoter–methylated is both prognostic and predictive of the magnitude of benefit from temozolomide.
- The current standard of treatment of glioblastoma in patients younger than 70 years is maximal safe resection followed by radiation therapy with concurrent and adjuvant temozolomide, with consideration of tumor-treating fields.
- Phase 3 data also support the use of concurrent chemoradiotherapy in older adults based on the results of a trial with hypofractionated radiation therapy plus temozolomide versus treatment with hypofractionated radiation therapy alone.
- Pseudoprogression may mimic tumor progression in patients who have glioblastoma treated with radiation therapy and should be considered before switching therapy, especially in patients who have MGMT-methylated tumors.
- Tumor-treating fields are FDA approved for newly diagnosed and recurrent glioblastoma.
- Bevacizumab is effective as a steroid-sparing agent for symptom management in select patients who have glioblastoma, although evidence for improvement in OS is lacking.
- When detected in patients who have glioblastoma, *BRAF* V600E mutation, *TRK* fusion, and *RET* fusion are potentially actionable and can be targeted with drugs that have been granted accelerated approval by the FDA in a tissue-agnostic, genotype-specific manner.
- In the 2021 WHO Classification of Tumors of the CNS, all *IDH*-mutant diffuse astrocytic tumors are considered as a single entity (*IDH*-mutant astrocytoma) and are then graded as grade 2, 3, or 4. These tumors are 1p/19q non-codeleted.
- Initial treatment of grade 3 *IDH*-mutant astrocytomas is maximal safe resection followed by radiation therapy with chemotherapy. Adjuvant temozolomide provides a clear survival benefit, and concurrent temozolomide may be considered given the potential benefit and limited risk of harm.
- Grade 2 *IDH*-mutant astrocytomas can be indolent tumors; however, they tend to eventually progress to high-grade astrocytomas.
- Maximal safe resection is recommended, especially if a presumed glioma is large and/or symptomatic.
- The IDH inhibitor vorasidenib is an FDA-approved agent for grade 2, *IDH*-mutant astrocytomas following surgery.
- Radiation therapy with adjuvant chemotherapy (temozolomide or PCV) provides a clear survival benefit in grade 2 *IDH*-mutant astrocytoma regardless of whether treatment was administered just after diagnosis or at the time of tumor

progression. Definitive therapy may be deferred until radiographic or symptomatic progression occurs in individuals with positive prognostic factors (eg, complete resection, younger age) or who elect first-line IDH-inhibitor therapy.

- Oligodendroglial tumors are characterized by both *IDH* mutation and 1p/19q codeletion and have a more indolent course than astrocytomas.
- After surgery for debulking and maximal safe resection, patients who have WHO grade 3 *IDH*-mutant 1p/19q co-deleted oligodendroglioma should be offered radiation therapy in combination with PCV because the addition of PCV after radiation therapy significantly improves OS compared with radiation therapy alone. TMZ is a reasonable alternative to PCV when toxicity is a concern.
- For patients who have WHO grade 2 *IDH*-mutant 1p/19q co-deleted oligodendroglioma, maximal safe resection is recommended if the tumor is large and/or symptomatic.
- The IDH inhibitor vorasidenib is an FDA-approved agent for grade 2 oligodendroglioma before radiation therapy, though the effect on survival is unknown.
- Radiation therapy and adjuvant PCV provide a clear survival benefit in grade 2 *IDH*-mutant 1p/19q co-deleted oligodendroglioma; however, no clear OS advantage is seen with immediate postoperative radiation therapy compared with delayed radiation therapy. Definitive therapy may be deferred until radiographic or symptomatic progression in individuals with positive prognostic factors (eg, complete resection, younger age) or who elect first-line IDH-inhibitor therapy.
- Grade 1 astrocytomas are more common in children and young adults. Surgical resection is often curative.
- Everolimus is an FDA-approved agent for the treatment of SEGAs.
- Low-grade astrocytomas with *BRAF* V600E or *BRAF* rearrangements may be amenable to *BRAF*- or *MEK*-targeted therapy.
- Medulloblastomas typically occur in the cerebellum in children, but they can also present in adults.
- Treatment of medulloblastoma includes maximal safe resection followed by irradiation of the craniospinal axis (with a boost to the tumor bed). Platinum-based chemotherapy regimens are considered, especially in higher-risk patients, if post-radiation therapy blood cell counts permit.
- For many patients who have meningioma, observation is appropriate. For patients who are symptomatic, surgical removal of the tumor is the most common treatment.
- Meningiomas that are WHO grade 2 or 3 are rare but have a more aggressive course with recurrences that may require repeated resection and radiation therapy.
- Currently, systemic regimens have limited, if any, efficacy for the treatment of meningiomas.
- Surgery and/or radiation are definitive options for sporadic, isolated hemangioblastoma.
- For patients who have VHL-associated CNS hemangioblastoma, belzutifan represents an effective systemic treatment option.
- Primary CNS lymphomas are usually diffuse large B-cell lymphomas.
- Epstein-Barr virus is frequently associated with primary CNS lymphoma in immunocompromised individuals.
- When CNS lymphoma is considered in the differential diagnosis, corticosteroids should be held before biopsy, if clinically feasible, because they can lead to nondiagnostic biopsy results, which, in turn, can delay treatment.
- High-dose methotrexate-based chemotherapy has remained the backbone of therapy for newly diagnosed primary CNS lymphoma.
- Autologous stem cell transplantation can be considered for consolidation in patients who have good functional status and who respond to a methotrexate-based chemotherapy regimen.
- Brain metastases as a group are the most common brain tumors.
- Stereotactic radiosurgery is increasingly being used in addition to or in place of surgery for patients with brain metastases.
- When whole-brain radiation therapy is used for the treatment of brain metastases, the use of hippocampal avoidance intensity-modulated radiation therapy and memantine together has been demonstrated in a randomized trial to decrease the risk of neurocognitive toxicity.
- Small molecules and immunotherapies are increasingly used in the treatment of brain metastases from cancers in which the respective medications are effective systemically.
- Leptomeningeal metastases are manifested by progressive symptoms and signs of injury to brain parenchyma, cranial nerves, and/or spinal nerves.
- Treatment of leptomeningeal metastases from solid tumors is often limited to symptom control. Radiation to symptomatic areas and, in select patient cases with symptomatic hydrocephalus, shunt placement may alleviate symptoms. Proton craniospinal radiation therapy, when available, should be considered for patients who have a better prognosis and adequate functional status.
- Intrathecal chemotherapy or systemic therapies can be offered to select patients.

CHAPTER TABLES AND IMAGES

Table 18-1 Rare, Targetable CNS Tumors

Rare, Targetable Nervous System Tumors	Grade	Tumor Characteristics	Common Alterations	Targeted Therapy	References
Pilocytic astrocytoma	1	Primarily pediatric. Frequently appear as a cyst with a mural nodule in the cerebellum. Can be cured by surgery if removed completely	*KIAA1549-BRAF* fusion	Tovorafenib	2,74
Subependymal giant cell astrocytoma	1	Periventricular, 1:10 in patients who have tuberous sclerosis	*TSC1* or *TSC2*	Everolimus	75
CNS hemangioblastoma	1	Highly vascular, 25% associated with VHL	*VHL*	Belzutifan (for VHL-associated)	76
Plexiform neurofibroma	1	Occur on peripheral nerves and can undergo malignant transformation	*NF1*	Selumetinib (for NF1-associated)	77
Pleomorphic xanthoastrocytoma	2 or 3	Primarily adolescent and young adult, predilection for cerebrospinal fluid dissemination	*BRAF*	Dabrafenib/ trametinib	78
Diffuse midline glioma	4	Primarily pediatric	*K3K27M*	Dordaviprone	13

Abbreviations: CNS, central nervous system; VHL, von Hippel-Lindau.

Table 18-2 **Key Systemic Agents With Intracranial Activity in Patients With Brain Metastases**

Primary Tumor	Drug(s)	Intracranial Response Rate(s) (95% CI) %	References
NSCLC, driver mutation negative, PD-L1 positive	Pembrolizumab	30 (16-47)	108
EGFR-mutant NSCLC	Osimertinib	91 (71-99)	109
ALK-rearranged NSCLC	Alectinib	81 (58-95)	110
	Brigatinib	78 (52-94)	111
	Lorlatinib	82 (57-96)	112
ROS1-positive NSCLC	Entrectinib	79 (60-93)	113
	Repotrectinib	89 (52-100)	60
RET-fused NSCLC	Selpercatinib	82 (57-96)	114
	Pralsetinib	70 (35-93)	115
MET exon-14 skipping mutation NSCLC	Capmatinib	54 (17-77)	116
	Tepotinib	55 (23-83)	117
KRAS G12C-mutant NSCLC	Adagrasib	42 (20-67)	118
	Sotorasib	25 (13-41)	119
Small cell lung cancer	Tarlatamab	63 (30-100)	128
HER2-positive breast cancer	Lapatinib and capecitabine	66 (50-80)	120
	Neratinib and capecitabine	49 (32-66)	121
	Tucatinib, capecitabine, and trastuzumab	47 (34-61)	122
	Fam-trastuzumab deruxtecan (T-Dxd)	46 (19-75)	123
Melanoma, *BRAF* V600E mutant	Dabrafenib and trametinib	58 (46-69)	124
Melanoma	Ipilimumab and nivolumab	54 (43-64)	125
	Pembrolizumab	22 (7-48)	126
	Nivolumab	20 (7-41)	127
Renal cell carcinoma	Cabozantinib	55 (36-73)	128
	Ipilimumab and nivolumab	32 (15-54)	129

Abbreviations: EGFR, epidermal growth factor receptor; NSCLC, non–small cell lung cancer.

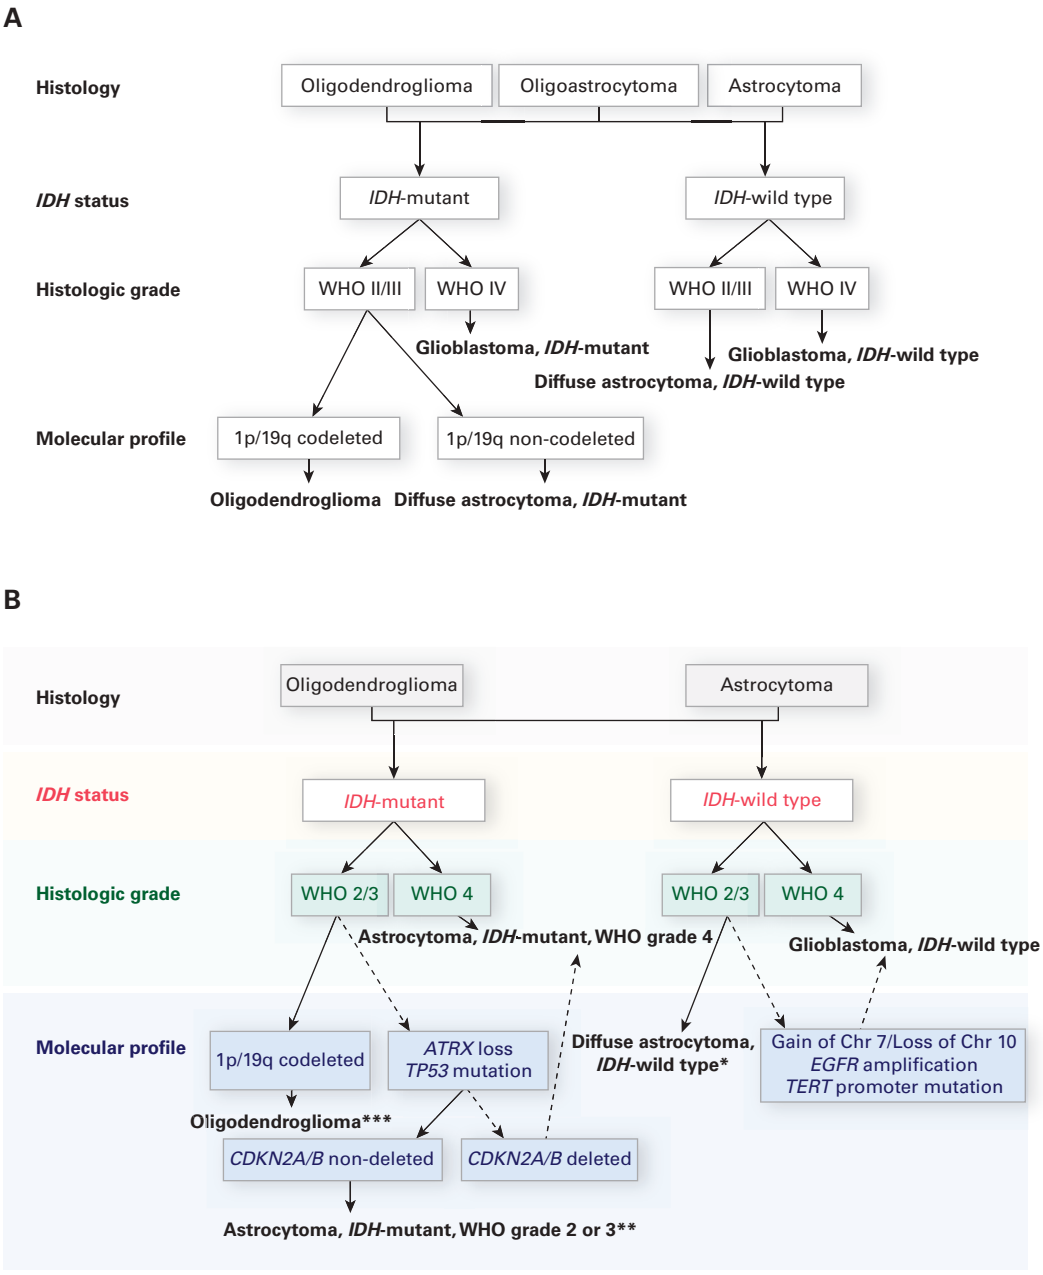
Figure 18-1 The Classification of Diffuse Gliomas



(A) WHO 2016. (B) WHO 2021.
Abbreviations: Chr, chromosome; CNS, central nervous system; *EGFR*, epidermal growth factor receptor.
Simplified diagnostic algorithm for adult diffuse gliomas based on the 2021 WHO classification of CNS tumors. Dashed lines denote changes compared with the 2016 WHO classification.
*Diffuse astrocytoma, *IDH* wild type without molecular features of glioblastoma, is a rare entity. Molecular testing for gain of *Chr* 7 and loss of Chr 10, *EGFR* amplification, and *TERT* promoter is required to exclude glioblastoma, *IDH* wild type, grade 4. In the absence of molecular features of glioblastoma, additional testing should be considered (eg, *BRAF* alterations, histone mutations, methylome profiling).
**Astrocytoma, *IDH* mutant, can be diagnosed as grade 2, 3, or 4 based on histopathologic grading criteria and *CDKN2A/B* status.
***Oligodendroglioma, *IDH* mutant with codeletion of the short arm of chromosome 1 and the long arm of chromosome (1p19q), can be diagnosed as grade 2 or 3 based on histopathologic features.

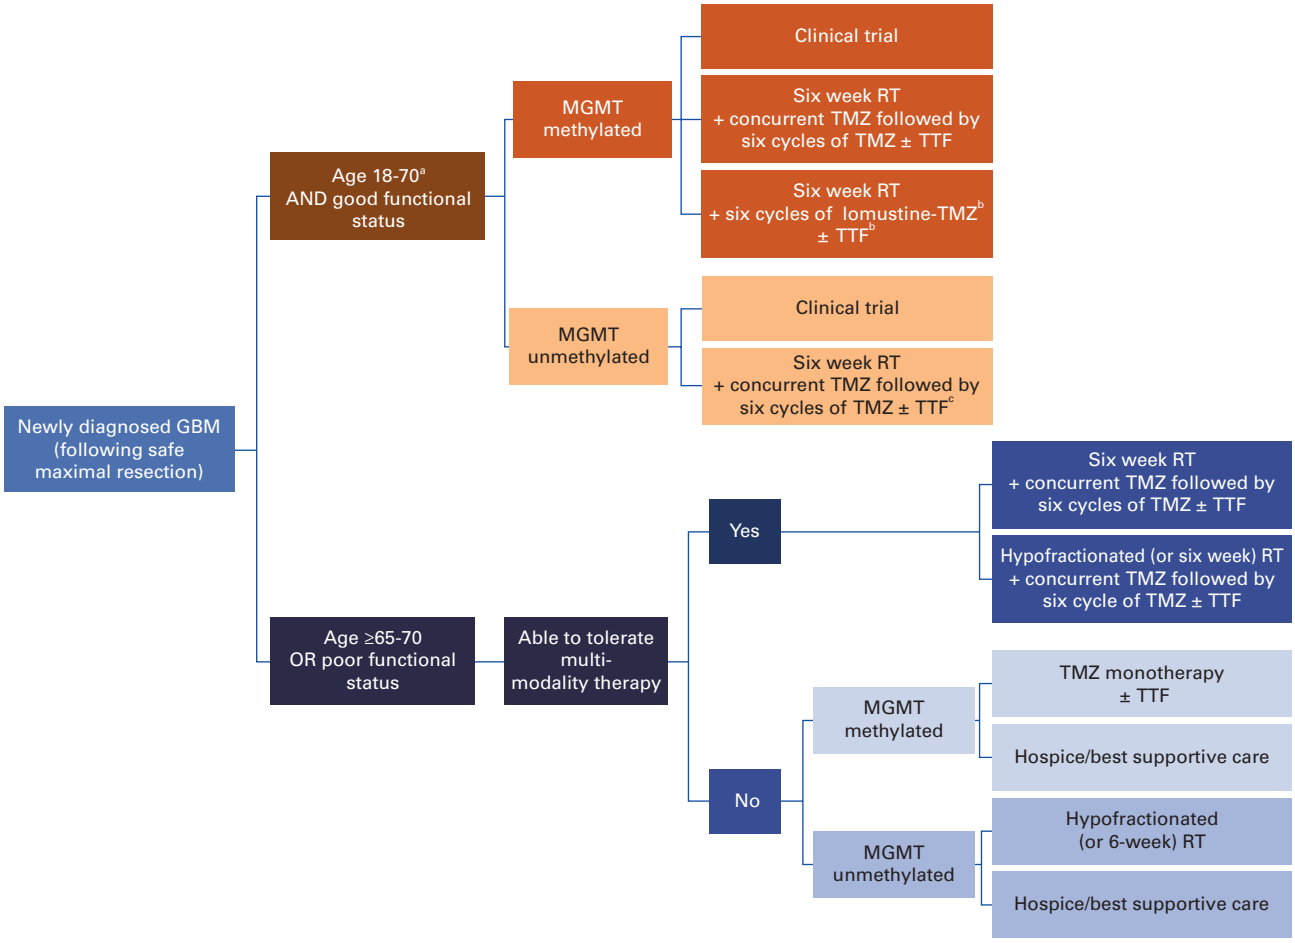
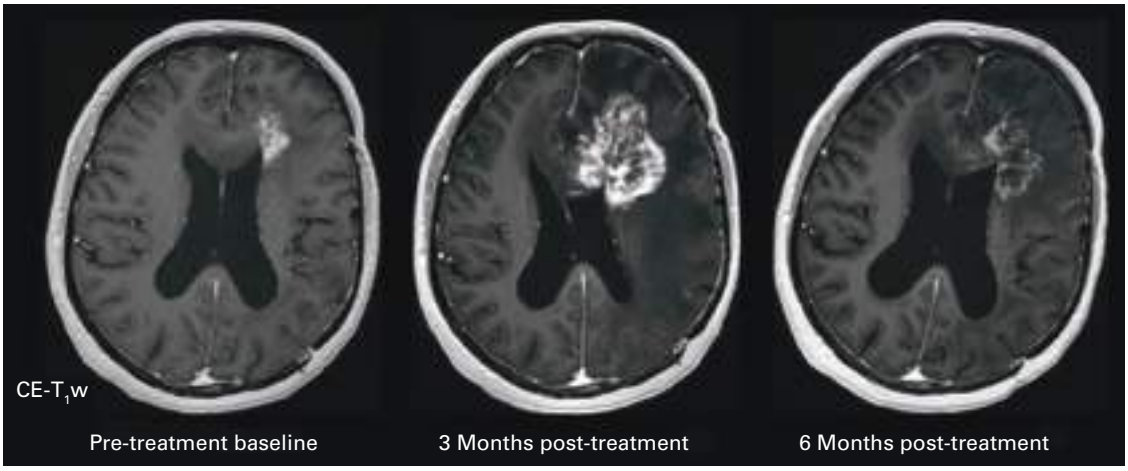
Figure 18-2 Standard-of-Care Treatment Paradigm for Patients Who Have Newly Diagnosed or Recurrent Glioblastoma



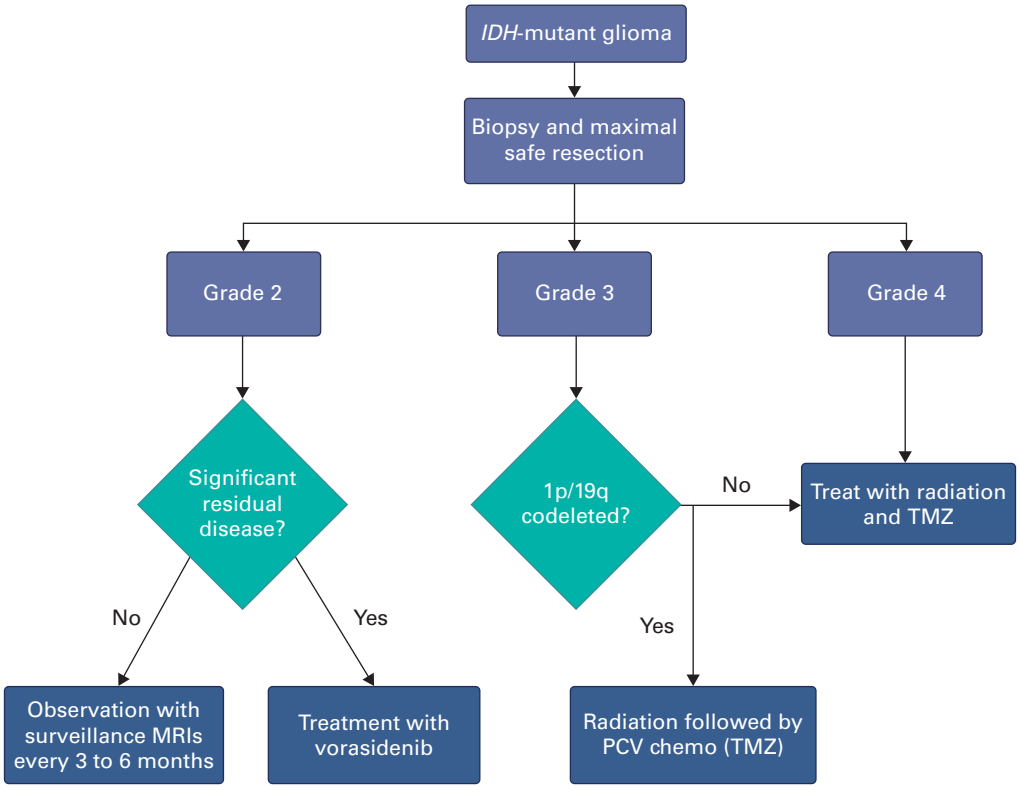
Abbreviations: GBM, glioblastoma; MGMT, O6-methylguanine-DNA methyltransferase; RT, radiation therapy; TMZ, temozolomide; TTF, tumor-treating fields.
[a]In elderly patients with good performance status, standard 6-week daily radiation therapy plus TMZ can be considered.
[b]It is unclear whether lomustine plus TMZ is preferred over TMZ alone.
[c]Because MGMT methylation status is predictive of the efficacy of TMZ, TMZ can be withheld in select patients who have MGMT-unmethylated tumors, especially in the context of clinical trials or when the risks of TMZ outweigh the benefits.
Reprinted from Wen PY, Weller M, Lee EQ, et al. Glioblastoma in adults: a Society for Neuro-Oncology (SNO) and European Society of Neuro-Oncology (EANO) consensus review on current management and future directions. *Neuro Oncol*. 2020;22(8):1073-1113, by permission of Society for Neuro-Oncology and Oxford University Press.

Figure 18-3 Pseudoprogression Following Radiation in Glioblastoma



Abbreviations: CE, contrast-enhanced; T_1w, T_1-weighted.
Serial CE T_1w imaging showing an increase 3 months and spontaneous decrease 6 months after combined radiotherapy and temozolomide of contrast-enhancement, edema, and mass effect.
Reproduced under Creative Commons under the terms of the http://creativecommons.org/licenses/by-nc-nd/4.0/license. Source: Thust SC, van den Bent MJ, Smits M. Pseudoprogression of brain tumors. *J Magn Reson Imaging*. 2018;48(3):571-589. doi:10.1002/jmri.26171, figure 1.

Figure 18-4 Management of *IDH*-Mutant Glioma



Abbreviations: PCV, procarbazine, lomustine, and vincristine; TMZ, temozolomide.
For patients who have grade 2 *IDH*-mutant astrocytoma or oligodendroglioma, vorasidenib is approved in the first-line setting for patients following biopsy or resection. For patients who have oligodendroglioma (*IDH*-mutated, 1p/19q codeleted), radiation followed by PCV chemotherapy is also standard of care, but TMZ may be considered if toxicity is a concern. For patients who have grade 2 to 3 *IDH*-mutant astrocytoma, radiation with TMZ (12 cycles adjuvant, consider concurrent) can be used, although PCV may be considered. Patients who have grade 4 astrocytoma should be treated with radiation and concurrent TMZ as first-line therapy, followed by six cycles of adjuvant TMZ.

LEUKEMIAS AND OTHER MYELOID NEOPLASMS

19

Jane L. Liesveld, MD, and Brittany K. Ragon, MD

RECENT UPDATES

The fifth edition of the World Health Organization (WHO) classification of hematolymphoid tumors and the first version of the International Consensus Classification (ICC) of myeloid neoplasms and acute leukemias were made available in 2022, and clinicians continue to optimize those classifications for diagnostic reporting and therapeutic decision-making.[1-3]

Acute Myeloid Leukemia

- Menin inhibition in patients who have acute myeloid leukemia (AML) with rearrangement of the *KMT2A (KMT2Ar)*, nucleoporin 98 (*NUP98r*) genes, or mutation of the nucleophosmin 1 gene (*NPM1*) was demonstrated to be safe and effective as monotherapy or in combination. Many menin inhibitor trials are ongoing in patients who have newly diagnosed and relapsed or refractory (relapsed/refractory) AML with *KMT2Ar*, *NUP98r*, or *NPM1* mutation.[4,5]
- Following the results of the AUGMENT-101 trial, the menin inhibitor revumenib was approved for relapsed or refractory acute leukemia with a *KMT2A* rearrangement or *NPM1* mutation.[6]
- Based on safety and efficacy demonstrated in the phase 1/2 KOMET-001 registration trial, ziftomenib was also approved for relapsed/refractory patients with *NPM1*-mutated AML.[7]
- The National Comprehensive Cancer Network (NCCN) guidelines now recommend gilteritinib, a *FLT3* inhibitor, as the preferred agent for post-transplant maintenance in patients with *FLT3*-ITD–mutated AML who are in first complete remission with measurable residual disease (MRD) by ultrasensitive peri-transplant assays. This recommendation is based on results from the Blood and Marrow Transplant Clinical Trials Network (BMT CTN) 1506 Morpho trial, which compared maintenance gilteritinib versus placebo post-transplantation and demonstrated a strong correlation between gilteritinib use and improved outcomes in patients with *FLT3*-ITD MRD detected by next-generation sequencing.[8]
- With observed limitations in European LeukemiaNet (ELN) genetic risk classifications from 2022 for older patients treated with less intensive therapies, new genetic risk classifications are offered by ELN 2024 for patients receiving less-intensive therapies, with *TP53* mutations defining the adverse risk group.[7,9]

Chronic Myeloid Leukemia

- Asciminib, an allosteric inhibitor of the myristoyl site of the BCR-ABL1 protein, was the first approved STAMP inhibitor for chronic-phase chronic myeloid leukemia (CP-CML) with resistance to at least two previous tyrosine kinase inhibitors (TKIs) and CP-CML with a *T315I* mutation.[10,11]
- Based on results of the ASC4FIRST trial, asciminib also received FDA approval for frontline use in newly diagnosed CP-CML.[12]

Myeloid Precursor Conditions (Clonal Hematopoiesis)

- With updates in the WHO 5th edition, clonal hematopoiesis is recognized for the first time as a category of precursor myeloid disease states, and clonal hematopoiesis of indeterminate potential and clonal cytopenia of undetermined significance are formally defined.[1]

- The clonal hematopoiesis risk score was published,[13] and it provided a simple and reproducible tool for assessing the risk of clonal hematopoiesis progressing to a myeloid malignancy. Based on clinical and molecular characteristics, patients with clonal hematopoiesis are categorized into three risk groups: low, intermediate, or high risk of progression to myeloid malignancy. Among clonal hematopoiesis risk score groups, the respective 5- and 10-year cumulative incidences of myeloid malignancy were 0.234% and 0.674% for low-risk, 2.59% and 7.34% for intermediate-risk, and 23.6% and 50.6% for high-risk myeloid malignancy, respectively.[13] Another score for clonal cytopenia of uncertain significance has also been developed.[14]

Myelodysplastic Syndromes

- Among the updates regarding myelodysplastic syndrome (MDS) classification is the novel entity MDS/AML in the ICC (but not recognized by the 2022 WHO classification), defined as 10% to 19% blasts in the peripheral blood and/or bone marrow in the absence of AML-defining recurrent genetic abnormalities. Specific emphasis is placed on genetically defined subtypes, such as MDS with deletion of 5q [del(5q)], MDS-SF3B1, and MDS with biallelic TP53 inactivation. Criteria for tp53 AML include blasts >10%, which is also not recognized by the classification system in the 2022 WHO. By contrast, hypoplastic MDS and MDS with fibrosis are formally included in the 2022 WHO but not recognized by the 2022 ICC.[1,3]
- A mutation-based risk assessment tool, the molecular International Prognostic Scoring System (IPSS-M), was published in 2022 and is the most accurate risk stratification tool.[15] It combines the prognostic impact of 31 gene mutations with traditional predictors (eg, blood counts, blast percentage, and karyotype) and improves prognostication compared with the revised IPSS (IPSS-R).
- In a phase 3 clinical trial in lower-risk MDS, decitabine given on days 1 to 3 of a 28-day cycle led to red blood cell transfusion independence and complete response (CR) in 41% and 36% of patients, respectively.[16] Luspatercept was approved as of August 28, 2023, for first-line treatment of anemia in adults with very low-risk to intermediate-risk MDS who are red cell transfusion-dependent. It had previously been approved in 2019 for use in patients with MDS after erythropoiesis-stimulating agents (ESA) failure, and or if there was a low likelihood of response due to erythropoietin level (>500). This expanded approval was based on results from the phase 3 COMMANDS trial. Luspatercept resulted in increased transfusion independence and increased hemoglobin levels compared with erythropoietin. This benefit was not demonstrated in MDS patients without ring sideroblasts (this subset showed equal response rates).[17]
- Hypomethylating-agent monotherapy with azacitidine or decitabine remains the standard of care for patients who have higher-risk MDS. To date, no phase 3 trials have demonstrated a benefit for adding an additional agent to azacitidine or decitabine. One of the most recent studies, the VERONA trial (NCT04401748), examined azacitidine with placebo versus azacitidine plus the Bcl-2 inhibitor, venetoclax, which fell short of meeting its primary clinical endpoint of overall survival (OS). Concerns about more frequent dose reductions of azacitidine in the combination arm as compared to the placebo arm may be a significant contributor to the outcome of this study (reference GGManero SOHO 2025).[18,19]
- On October 24, 2023, ivosidenib monotherapy was approved by the FDA for patients who have relapsed/refractory MDS based on data from the AG120-C-100 trial. The CR rate in 18 patients who had relapsed/refractory MDS was 38.9%, and the median duration of CR was not estimable (1.9-81 months).[20]
- Imetelstat, an oligonucleotide telomerase inhibitor, was approved by the FDA on June 6, 2024, for adults with low-to-intermediate-1 risk MDS for treatment of anemia in patients who had required four or more red cell transfusions over 2 months or who had not responded to ESAs. This was based on the IMerge randomized, double-blind, placebo-controlled trial in 178 patients. The rate of 8-week transfusion independence was 39.8% in the imetelstat group and 15% in the placebo group.[21]

Myeloproliferative Neoplasms

- In the WHO 5th edition, the main types of myeloproliferative neoplasms (MPNs) remain unchanged from the previous edition; however, there are several changes for the MDS/MPN overlap syndromes. Chronic myelomonocytic leukemia diagnostic criteria underwent major revisions, including lowering the cutoff for absolute monocytosis, adopting myelodysplastic and myeloproliferative subtypes, and eliminating the chronic myelomonocytic leukemia category 0. Atypical chronic myelomonocytic leukemia was renamed MDS/MPN with neutrophilia. MDS/MPN

with ring sideroblasts and thrombocytosis was redefined on the basis of an SF3B1 mutation and renamed MDS/MPN with SF3B1 mutation and thrombocytosis. Luspatercept is FDA approved for the treatment of anemia in adult patients with MDS/MPN-RS-T who require regular transfusions.[1]

- In November 2023, the FDA approved momelotinib for the treatment of intermediate- or high-risk myelofibrosis. This was based on the MOMENTUM study and a subset of patients who had anemia from the SIMPLY-1 phase 3 trial.[22,23]

Acute Lymphoblastic Leukemia

- The randomized phase 3 ECOG-ACRIN E1910 study demonstrated that blinatumomab added to conventional post-remission therapy significantly improved OS (median OS, not reached vs 71.4 months; hazard ratio [HR], 0.42; 95% CI, 0.24-0.75; two-sided $P = .003$) and recurrence-free survival (RFS) for patients who have newly diagnosed B-cell acute lymphoblastic leukemia (ALL) in MRD-negative first complete remission, leading to FDA approval for blinatumomab in this setting.[24]
- On March 19, 2024, the FDA approved ponatinib in adult patients who have newly diagnosed Philadelphia chromosome–positive (Ph+) ALL for use in combination with chemotherapy. This was based on the phase 3 PhALLCON trial.[25]
- Based on results of the FELIX trial, obecabtagene autoleucel is now approved for relapsed/refractory B-cell precursor ALL in adults.[25]
- With promising long-term results of the D-ALBA trial exploring dasatinib with blinatumomab and similarly positive results from a single institution phase 2 trial of ponatinib with blinatumomab, the chemotherapy-free regimen of tyrosine kinase inhibitor and blinatumomab is an offered induction strategy for Ph+ ALL in the NCCN guidelines.[26,27]

Chronic Lymphocytic Leukemia

- A phase 3 study comparing acalabrutinib with ibrutinib for patients who have treatment-naive chronic lymphocytic leukemia (CLL) showed acalabrutinib to be noninferior to ibrutinib for progression-free survival (PFS) but with reduced rates of atrial fibrillation (9.4% vs 16.0%; $P = .02$).[28] The acalabrutinib/enetoclax combination with or without obinutuzumab for 14 cycles was found to significantly prolong PFS compared with chemoimmunotherapy in fit patients who had not had prior CLL treatment in the AMPLIFY study.[29] A randomized trial of ibrutinib versus fixed-duration venetoclax and obinutuzumab or fixed-duration venetoclax and ibrutinib has now been published as an abstract, and this demonstrated noninferiority of the fixed-dose combinations.[30]
- The phase 3 SEQUOIA trial randomly assigned adults with treatment-naive CLL without del(17p)/*TP53* mutation to receive zanubrutinib or bendamustine and rituximab. PFS was superior for zanubrutinib (HR, 0.29 one-sided $P = .0001$). For the del(17p)/*TP53*-mutated arm that was not randomly assigned, 24-month PFS was 92% with zanubrutinib.[31,32]
- Update of a phase 3 study comparing zanubrutinib with ibrutinib for relapsed/refractory CLL showed zanubrutinib to be superior to ibrutinib for PFS and OS rates.[33]
- Lisocabtagene maraleucel (liso-cel), a CD19-directed chimeric antigen receptor T-cell therapy, was approved for use in patients who have CLL with previous exposure to both Bruton tyrosine kinase inhibitors and anti-BCL-2, based on the TRANSCEND CLL 004 study. The CR rate was 18%, and the median duration of response in all responders was 35.3 months.[34]

Hairy Cell Leukemia

- A phase 2 study of ibrutinib in relapsed classic and variant hairy cell leukemias showed a best overall response rate of 54% and 3-year PFS and OS rates of 73% and 85%, respectively.[35]
- A phase 2 study of the BRAF inhibitor vemurafenib and rituximab in relapsed/refractory hairy cell leukemia showed a complete response rate of 87% (65% MRD negative) and an RFS rate of 85% at a median follow-up of 34 months.[36]

OVERVIEW

The term *leukemia* describes a number of related cancers characterized by increased growth and/or impaired maturation of the blood-forming organs. Leukemias are classically defined by their rapidity of growth (acute vs chronic) and by the origin of the normal cell the leukemia most resembles (myeloid vs lymphoid). Thus, the four major forms of leukemia are acute myeloid

leukemia (AML), acute lymphoid leukemia (ALL), chronic myeloid leukemia (CML), and chronic lymphoid leukemia (CLL). Other leukemias include some of the mature B-cell, T-cell, or natural killer (NK)–cell neoplasms, such as hairy cell leukemia and chronic T-cell leukemias. Approximately 66,890 new cases of leukemia were expected in the United States in 2025, with 23,540 leukemia-related deaths.[37,38]

In addition to these four major forms of leukemia, in this chapter, we also discuss myelodysplastic syndrome (MDS) and myeloproliferative neoplasms (MPNs), which, together with AML, encompass disorders the World Health Organization (WHO) has classified as myeloid neoplasms. MDS encompasses a heterogeneous group of clonal stem cell disorders characterized by peripheral blood cytopenias and an inherent tendency toward transformation to AML. MPNs are clonal stem cell diseases with excess proliferation of one or more hematopoietic cell lineages. In addition to CML, the classic MPNs include polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (MF).[1] Chronic neutrophilic leukemia, chronic eosinophilic leukemia, and unclassifiable MPNs are other diseases currently recognized by WHO as MPNs.

In 2022, the WHO 5th edition classification of hematolymphoid tumors was released,[1,2] providing several key updates for leukemias and other myeloid neoplasms (Tables 19-1 and 19-2). Simultaneously, the International Consensus Classification (ICC) of myeloid neoplasms and acute leukemias was also published, providing mostly overlapping but occasionally conflicting disease definitions.[3] Updates to disease definitions are discussed in each respective disease section.

Table 19-1 2022 WHO Classification of AML[1,2]

Type of Leukemia	Classification
AML	
With defining genetic abnormalities	APL with *PML::RARA* fusion
	AML with *RUNX1::RUNX1T1* fusion
	AML with *CBFB::MYH11* fusion
	AML with *DEK::NUP214* fusion
	AML with *RBM15::MRTFA* fusion
	AML with *BCR::ABL1* fusion
	AML with *KMT2A* rearrangement
	AML with *MECOM* rearrangement
	AML with *NUP98* rearrangement
	AML with *NPM1* mutation
	AML with *CEBPA* mutation
	AML, myelodysplasia-related
	AML with other defined genetic alterations
Defined by differentiation	AML with minimal differentiation
	AML without maturation
	AML with maturation
	Acute basophilic leukemia
	Acute myelomonocytic leukemia
	Acute monocytic leukemia
	Acute erythroid leukemia
	Acute megakaryoblastic leukemia
Acute leukemia of ambiguous lineage	
With defining genetic abnormalities	Mixed-phenotype acute leukemia with *BCR::ABL1* fusion
	Mixed-phenotype acute leukemia with *KMT2A* rearrangement
	Acute leukemia of ambiguous lineage with other defined genetic alterations
	• Mixed-phenotype acute leukemia with *ZNF384* rearrangement
	• Acute leukemia of ambiguous lineage with *BCL11B* rearrangement
Immunophenotypically defined	Mixed-phenotype acute leukemia, B/myeloid
	Mixed-phenotype acute leukemia, T/myeloid

Type of Leukemia	Classification
	Mixed-phenotype acute leukemia, rare types
	Acute leukemia of ambiguous lineage, NOS
	Acute undifferentiated leukemia
B-lymphoblastic leukemia/lymphoma	
	B-lymphoblastic leukemia/lymphoma, NOS
	B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
	B-lymphoblastic leukemia/lymphoma with t(9;22)(q34.1;q11.2); *BCR-ABL1*
	B-lymphoblastic leukemia/lymphoma with t(v;11q23.3); *KMT2A* rearranged
	B-lymphoblastic leukemia/lymphoma with t(12;21)(p13.2;q22.1); *ETV6-RUNX1*
	B-lymphoblastic leukemia/lymphoma with hyperdiploidy
	B-lymphoblastic leukemia/lymphoma with hypodiploidy
	B-lymphoblastic leukemia/lymphoma with t(5;14)(q31.1;q32.3); *IL3-IGH*
	B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3); *TCF3-PBX1*
	Provisional entity: B-lymphoblastic leukemia/lymphoma, *BCR-ABL1*-like
	Provisional entity: B-lymphoblastic leukemia/lymphoma with *iAMP21*

Abbreviations: AML, acute myeloid leukemia; APL, acute promyelocyte leukemia; NOS, not otherwise specified; WHO, World Health Organization.

Table 19-2 **Tests and Procedures for Patients With AML**[39]

Test	Procedure
Diagnostic tests	CBC and differential count
	Bone marrow aspirate
	Bone marrow trephine biopsy
	Immunophenotyping, flow cytometry, next-generation sequencing for myeloid mutation panel, and RNA gene re-expression
Genetic analyses	Cytogenetics[a]
	Screening for these gene mutations[b]: *NPM1*, *CEBPA*, *IDH1*, *IDH2*, *FLT3*, *TP53*, *ASXL1*, *BCOR*, *EZH2*, *RUNX1*, *SF3B1*, *SRSF2*, *STAG2*, *U2AF1*, *ZRSR2*, *DDX41*
	Screening for these gene rearrangements: *PML-RARA*, *CBFB-MYH11*, *RUNX1-RUNX1T1*, *BCR-ABL1*, other fusion genes (if available)
Additional tests/procedures at diagnosis	Demographics and medical history[c]
	Detailed family history[d]
	Patient bleeding history[e]
	ECOG performance status
	Analysis of comorbidities
	Biochemistry, coagulation tests, urine analysis[f]
	Serum pregnancy test[g]
	Information on oocyte and sperm cryopreservation[h]
	Eligibility assessment for allo-SCT (including HLA typing)[i]
	Hepatitis A, B, C; HIV-1 testing
	Chest radiograph, 12-lead electrocardiogram, and echocardiography or MUGA (on indication)
	Lumbar puncture[j]
	Biobanking[k]

Test	Procedure
Sensitive assessment of response to treatment (MRD) by RT-qPCR or MFC[l]	RT-qPCR[m,n] for *NPM1* mutation, *CBFB-MYH11*, *RUNX1-RUNX1T1*, *BCR-ABL1*, other fusion genes (if available)
	MFC[n,o]

Abbreviations: allo-SCT, allogeneic stem cell transplantation; AML, acute myeloid leukemia; CBC, complete blood count; ECOG, Eastern Cooperative Oncology Group; HLA, human leukocyte antigen; MFC, multiparameter flow cytometry; MRD, measurable residual disease; MUGA, multigated acquisition (scan); RT-qPCR, reverse transcription quantitative polymerase chain reaction.
[a]Results from cytogenetics should be obtained preferably within 5 to 7 days. At least 20 bone marrow metaphases are needed to define a normal karyotype and are recommended to describe an abnormal karyotype. Abnormal karyotypes may sometimes be diagnosed from blood specimens.
[b]Results from *NPM1* and *FLT3* mutational screening should be available within 48 to 72 hours (at least in patients eligible for intensive chemotherapy), along with results from additional molecular genetics within the first treatment cycle. Screening for gene mutations is an evolving field of research; screening for single genes is now frequently replaced by gene panel diagnostics.
[c]Including race or ethnicity, previous exposure to toxic agents, previous malignancy, therapy for previous malignancy, and information on smoking.
[d]Thorough family history is needed to identify potential myeloid neoplasms with germline predisposition.
[e]History of bleeding episodes may inform cases of myeloid neoplasms with germline predisposition and preexisting platelet disorders.
[f]Biochemistry: levels of glucose, sodium, potassium, calcium, creatinine, aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, lactate dehydrogenase, bilirubin, urea, total protein, uric acid, total cholesterol, total triglycerides, and creatinine phosphokinase. Coagulation tests: prothrombin time; international normalized ratio, where indicated; activated partial thromboplastin time. Urine analysis: pH, and levels of glucose, erythrocytes, leukocytes, protein, and nitrite.
[g]In women with childbearing potential.
[h]Cryopreservation to be done in accordance with the wishes of the patient.
[i]HLA typing and cytomegalovirus testing should be performed in those patients eligible for allo-SCT.
[j]Required in patients who have clinical symptoms suspected of central nervous system involvement; the patient should be evaluated by an imaging study for intracranial bleeding, leptomeningeal disease, and mass lesion; lumbar puncture is considered optional in other settings (eg, high white blood cell count).
[k]Pretreatment leukemic bone marrow and blood samples for research studies are recommended.
[l]Sensitive assessment of response can be performed at early time points, for example, after induction and consolidation courses to assess remission status and determine kinetics of disease response, and sequentially beyond consolidation to detect impending morphologic relapse. No generally applicable time points can be defined because the kinetics of MRD response differ by treatment given, marker analyzed, and method used.
[m]Monitoring of response by RT-qPCR is recommended in clinical trials and clinical practice.
[n]Sensitivity of response assessment varies by method used and by marker tested; the test used and sensitivity of the assay should always be reported; analyses should be done in experienced laboratories (centralized diagnostics).
[o]Increasing evidence that response assessment by multiparameter flow cytometry qualitatively provides a better remission status than morphologic assessment and is of high prognostic value.

ETIOLOGY

The cause of leukemia is usually unknown. However, in addition to a familial or genetic predisposition in some individuals, exposure to certain infectious pathogens, radiation, chemicals, and chemotherapeutic agents has been associated with an increased incidence of leukemia.

GENETIC PREDISPOSITION

Genetic predisposition for the development of leukemia is well established. Single germline mutations in several genes (eg, *GATA2*, *RUNX1*, *CEBPA*, *DDX41*, *TP53*, and *SRP72*) have been identified as causes of familial nonsyndromic MDS/AML predisposition syndromes.[40] Syndromes characterized by defective DNA repair, such as Fanconi anemia, ataxia telangiectasia, and Bloom syndrome, also have an increased incidence of acute leukemia. Similarly, bone marrow failure syndromes associated with ribosomal abnormalities, including Diamond-Blackfan anemia and Schwachman-Diamond syndrome, and disorders of telomere maintenance, such as dyskeratosis congenita, also have an increased incidence of AML and MDS. It seems that the prevalence of germline predisposition for AML and MDS has long been underestimated, given that only some patients present with typical syndromic findings on physical examination. For instance, a recent large analysis of adult patients who have MDS showed that 2.7% were found to have a mutation in the telomerase reverse transcription (*TERT*) gene without carrying a previous clinical diagnosis of a telomere biology disorder.[41]

RADIATION

Ionizing radiation is leukemogenic. The incidences of AML, CML, and ALL increased in individuals who received radiation therapy for ankylosing spondylitis and in survivors of the atomic bomb blasts at Hiroshima and Nagasaki.[42] The highest rates of leukemia were associated with higher doses of radiation, particularly if the radiation was absorbed over a shorter time. Younger individuals seem to be more susceptible to the leukemogenic effects of radiation. The incidence of leukemia peaks between 5 and 10 years after radiation exposure, regardless of patient age.

CHEMICALS

Extensive occupational exposure to benzene and benzene-containing compounds may lead to marrow damage that eventually can manifest as aplastic anemia, MDS, or AML. Benzene is widely used in industry, particularly as a starting material

for chemicals used to make plastics, resins, synthetic fibers, dyes, detergents, drugs, and pesticides, and it is a component of crude oil, gasoline, and cigarette smoke. Other associations between occupational exposure to chemicals and subsequent leukemia are not as persuasive. Most studies have found a small but consistent increase in the development of AML among cigarette smokers.[43]

THERAPY-RELATED LEUKEMIAS

Therapy with antineoplastic agents is a major identifiable cause of acute leukemia, with alkylating agents being most commonly associated with therapy-related leukemia. Among the various alkylating agents, melphalan (frequently used in autologous stem cell transplantation [ASCT]) and the nitrosoureas seem to be particularly associated with increased risk; however, all alkylating agents are likely leukemogenic, with an increased incidence of leukemia observed after prolonged exposure and dose-intensive regimens.

The leukemias associated with alkylating agents often present initially as MDS before progressing to AML; they have no other distinct morphologic features and, on cytogenetic examination, frequently exhibit whole or partial loss of chromosomes 5 or 7 or, less often, trisomy 8. These leukemias typically develop 5 to 7 years after chemotherapy.

Patients treated with topoisomerase II inhibitors are also at risk for therapy-related leukemia. In contrast to leukemias associated with alkylating agents, disease caused by topoisomerase II inhibitors tends to have a shorter latency period (1-3 years), lacks a myelodysplastic phase, carries a monocytic morphology, and frequently involves 11q23.3 abnormalities; less commonly, translocations of 21q22 are involved. Acute promyelocytic leukemia (APL) has been associated with previous exposure to leukemogenic agents as well. A growing body of evidence also suggests that some cases of ALL are related to previous treatments with chemotherapy or radiation therapy.[44] As the use of chimeric antigen receptor (CAR) T-cell therapy increases, some cases of second primary myeloid neoplasms have been identified,[45,46] although ongoing investigation is needed regarding the actual incidence or any identifiable risk factors.

ONCOGENIC VIRUSES

Human T-cell lymphotropic virus type 1 is a causative agent of adult T-cell leukemia and lymphoma. This enveloped single-stranded RNA virus is found in patients in geographic clusters in southwestern Japan, the Caribbean, intertropical Africa, the Middle East, South America, and Papua New Guinea. It spreads horizontally by sexual contact or through blood products or vertically from mother to fetus. Although it is endemic in these geographic areas, adult T-cell leukemia develops in only 3% to 5% of patients infected with the virus, and it has a long latency period, estimated to be 30 years or more.[47] Epstein-Barr virus is associated with the endemic African form of Burkitt lymphoma and leukemia.[48] The immunodeficiency-related type of Burkitt lymphoma is seen most often in patients who have HIV infection and is more common when the CD4 T-cell count is greater than 200/mcL, that is, early in the progression of HIV infection. The association of HIV with the endemic form of Burkitt lymphoma is less clear.[49]

Overall, approximately 50% of patients who have therapy-related neoplasms have adverse cytogenetics, and approximately one-third have *TP53* mutations, which partly explains why these neoplasms tend to have lower therapeutic response rates than *de novo* disease.[50]

KEY POINTS

- Leukemias, MDSs, and MPNs encompass a diverse group of clonal diseases of the hematopoietic system.
- Familial or genetic predisposition and exposure to certain infectious pathogens, radiation, chemicals, and therapeutic agents have been associated with an increased incidence of these hematopoietic neoplasms.

ACUTE MYELOID LEUKEMIA

PATHOGENESIS

AML is a clonally derived hematologic malignancy that originates from an aberrant hematopoietic stem cell that has an increased capacity for self-renewal and profoundly altered patterns of differentiation. The current understanding is that disturbed gene expression in hematopoietic stem cells causes a differentiation block and increased self-renewing capacity, which gives rise to a leukemic stem cell. The clonal evolution of AML starts from the leukemic stem cells, in which founder or so-called driver mutations arise that initiate the leukemogenesis process, but lack the entire arsenal of mutations required for leukemogenesis. Genes such as *DNMT3A*, *TET2*, and *ASXL1* involved in the regulation of DNA modification and the chromatin state are present in the preleukemic stem and progenitor cells.[51-53] Progression to AML is accompanied by a stepwise accumulation of additional mutations and sometimes chromosomal abnormalities, including those assumed to be part of the pathogenesis of the disease (the drivers) and random mutations (so-called passengers) that confer a strong proliferative advantage to the leukemic stem cells and the blasts derived therefrom. The acquisition of individual mutations and subsequent clonal evolution are highly dynamic

processes. This is indicated by studies of relapsed AML, in which typically either the founding clone gained additional mutations and evolved into the relapsed clone or a subclone present at diagnosis survived chemotherapy, acquired additional mutations, and expanded at relapse.[48,54] Although debulking chemotherapy helps reduce the percentage of blasts and may cure AML, newer targeted therapies are often directed toward the mutations that ensure the survival and proliferative advantage of the leukemic stem cells, possibly increasing cure rates.

Advancements in genomic profiling have expanded our understanding of AML and transformed treatment approaches.[55] These findings, along with the development of targeted therapy, allow for the reclassification of disease subgroups by AML-related genetic changes, inform treatment decisions (eg, use of FLT3 and IDH1/2 inhibitors), and provide clues for the ordinal nature of mutations (eg, *DNMT3A* followed by *NPM1* and another AML disease allele).

CLINICAL PRESENTATION AND DIAGNOSIS

Fatigue, bruising, bleeding, fever, and infection are common presentations reflecting a state of bone marrow failure. Ten percent of patients present with white blood cell (WBC) counts greater than 100×10^9/L and are at an increased risk of tumor lysis syndrome and leukostasis. Leukostasis may manifest as altered mental status, dyspnea, and chest pain.[56] These are medical emergencies that need to be recognized immediately, and treatment should be instituted promptly.

Other physical findings may include organomegaly, lymphadenopathy, and infiltration of extramedullary sites, including gingiva, skin (leukemia cutis), and soft tissue (chloromas or myeloid sarcomas), by leukemic cells, and this is more common in monocytic variants. A consumptive coagulopathy resembling disseminated intravascular coagulation is a common presentation in APL (see "Acute Promyelocytic Leukemia" section for more details), but may occur in other types of AML as well.

The major signs and symptoms of AML result from decreased normal hematopoiesis because of bone marrow involvement and infiltration of organs by leukemic blasts. The WBC count may be elevated, normal, or low, but most patients will have granulocytopenia, placing them at risk for severe bacterial and fungal infections.

Examination of the peripheral blood and a bone marrow aspirate are part of the routine diagnostic workup for a patient who has suspected AML and evaluation for morphology consistent with APL.[57] A lumbar puncture is required for patients who have clinical symptoms that suggest central nervous system (CNS) involvement. Before a lumbar puncture, brain imaging should generally be performed in patients who are symptomatic to assess for possible mass lesions. Cytogenetics and fluorescence in situ hybridization (FISH), as well as molecular studies, are essential for risk stratification. At a minimum, testing for mutations in *c-KIT*, *FLT3*-ITD/tyrosine kinase domain (TKD), *NPM1*, *CEBPA*, *IDH1*, *IDH2*, *ASXL1*, *RUNX1*, and *TP53* should be obtained. Multiplex gene panels and next-generation sequencing (NGS) analysis should be used to obtain a more comprehensive prognostic assessment when possible (Table 19-2).[58]

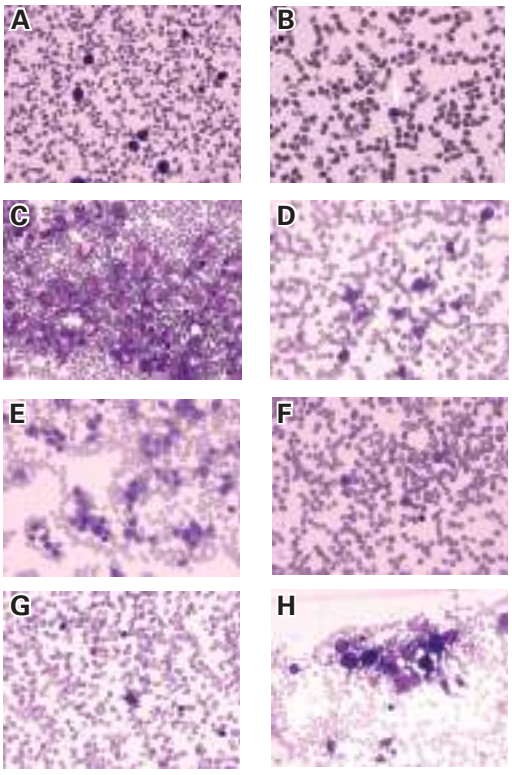
Historically, a myeloid neoplasm was classified as AML if 20% or more blasts were present in the peripheral blood or bone marrow.[59] The 2022 WHO classification and the 2022 ICC were recently introduced.[1,3,60] Although the 20% blast threshold was retained by the 2022 WHO classification, the 2022 ICC introduced a new category of MDS/AML with 10% to 19% blasts in the bone marrow or peripheral blood in recognition of the similarities in biology and prognosis between these patients and those with 20% or more myeloblasts.[1,3]

In the 2016 WHO classification, exceptions to the 20% or more blast cutoff rule included neoplasms with translocation of chromosomes 8 and 21 [t(8;21)](q22;q22.1)], inversion of chromosome 16 [inv(16)](p13.1q22), t(16;16)(p13.1;q22)], or APL, which are considered AMLs regardless of the blast percentage.[59] The 2022 WHO classification and 2022 ICC broadened the genetic abnormalities that define specific AML groups and recognized both *NPM1* and *CEBPA* as AML-defining mutations. Although ICC recognizes *TP53* (Variant allele frequency [VAF] > 10%)-mutated AML as a distinct entity, WHO does not.[1,3] In addition, AML with *BCR*::*ABL1* was added as a formal AML-defining lesion with the requirement of blasts of 20% or more, and not 10% or more, to differentiate it from CML in the accelerated phase. Importantly, the WHO classification and ICC use different blast thresholds to define AML. Although there is no minimum threshold in the 2022 WHO criteria for AML with defining genetic abnormalities (except 20% required for AML with *BCR*::*ABL1* and AML with a *CEBPA* bZIP [basic leucine zipper] mutation), the ICC requires at least 10% blasts in the bone marrow or peripheral blood for defining AML with recurrent genetic abnormalities (except 20% or more in AML with *BCR*::*ABL1*).[3]

Morphology and Immunohistochemistry

AML cells are typically 12 to 20 mm in diameter and have fine nuclear chromatin, multiple nucleoli, and azurophilic granules in the cytoplasm (Fig. 19-1). Specific patterns of reactivity with immunohistochemical stains, particularly myeloperoxidase (MPO) and nonspecific esterase, can be used to assign AML blasts to one (or more) cell lineage(s). Although the French-American-British Cooperative Group classified AML on the basis of morphology and immunohistochemistry, cytochemical stains have largely been replaced by immunophenotypic analyses of AML cells. Auer rods are coarse linear collections of cytoplasmic granules that sometimes obscure the nuclei that can be seen in AML blasts and are especially common in APL.

Figure 19-1 Morphologic Spectrum of AMLs



(A) Acute myeloblastic leukemia (AML) with minimal maturation. The cells are myeloblasts with dispersed chromatin and variable amounts of agranular cytoplasm; some display medium-sized, poorly defined nucleoli. (B) AML with maturation. Some of the blasts contain azurophilic granules, and there are promyelocytes. Note the Auer rod (arrow). (C) Acute promyelocyte leukemia. All of these cells are promyelocytes containing coarse cytoplasmic granules that sometimes obscure the nuclei. (D) Acute myelomonocytic leukemia. Promonocytes with indented nuclei are present with myeloblasts; the dense nuclear staining is unusual. (E) Acute monoblastic leukemia. These characteristic monoblasts have round nuclei with delicate chromatin and prominent nucleoli that stain intensely with nonspecific esterase (not shown); cytoplasm is abundant. (F) Acute monocytic leukemia. Most of the cells in this field are promonocytes; monoblasts and an abnormal monocyte are also present. (G) Acute erythroid leukemia. Dysplastic multinucleated erythroid precursors with megaloblastoid nuclei are present. (H) Acute megakaryoblastic leukemia. In this marrow biopsy specimen, there are large and small blasts as well as atypical megakaryocytes. Photographs and permission provided by Dr. Farid Barakat.

Immunophenotype

Most cases of AML express antigens characteristic of neutrophilic or monocytic differentiation, including precursor cell markers, such as CD34, CD117, CD33, CD13, and HLA-DR, and granulocytic markers, such as MPO and CD65. Leukemias with monocytic features express CD14 together with other monocyte-associated antigens, such as CD36 and CD64. Erythroid leukemias frequently express CD36, CD71, and CD235a (glycophorin A), whereas megakaryocytic leukemias express CD41 and CD61. In 10% to 20% of cases, the AML blasts also express lymphoid antigens, which are usually restricted to B-, T-, or NK-cell lineages, especially CD2, CD7, CD19, and CD56.

PROGNOSTIC FACTORS

AML is heterogeneous, and responses to AML therapy vary substantially among individual patients. An accurate risk stratification of the patient's disease is essential to make an informed decision on the treatment strategy for each patient.

Multiple factors have been independently associated with not achieving remission with intensive chemotherapy and/or with experiencing shortened survival. These include older age, poor performance status, previous cytotoxic chemotherapy or radiation therapy (ie, therapy-related AML), and disease evolution from an antecedent hematologic disorder (ie, secondary AML). By contrast, extramedullary disease, although common, is not an independent prognostic factor.

In current clinical practice, AML is risk-stratified according to the European LeukemiaNet (ELN) risk classification into favorable-, intermediate-, and adverse-prognosis groups based on the cytogenetic and molecular profiles of the disease.[57] The 2017 ELN molecular risk classification was updated in 2022 and includes several new mutational characteristics with updates highlighted in Table 19-3.[57,60] In 2024, for older patients treated with less intensive therapies, new genetic risk classifications were

described by ELN, acknowledging prognostication may differ for patients managed with hypomethylating-based combinations. The adverse risk group was defined by patients harboring *TP53* mutations.[9]

Table 19-3 2022 ELN Cytogenetic and Molecular Risk Stratification of AML[39]

Risk Level	Subset
Favorable	t(8;21)(q22;q22.1)/*RUNX1::RUNX1T1*[a,b]
	inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB::MYH11*[a,b]
	Mutated *NPM1*[a,c] without *FLT3*-ITD
	bZIP in-frame mutated *CEBPA*[d]
Intermediate	**Mutated *NPM1*[a,c] with FLT3-ITD**
	Wild-type *NPM1* with *FLT3*-ITD (without adverse-risk genetic lesions)
	t(9;11)(p21.3;q23.3)/*MLLT3::KMT2A*[a,e]
	Cytogenetic and/or molecular abnormalities not classified as favorable or adverse
Adverse	t(6;9)(p23.3;q34.1)/*DEK::NUP214*
	t(v;11q23.3)/*KMT2A*-rearranged[f]
	t(9;22)(q34.1;q11.2)/*BCR::ABL1*
	t(8;16)(p11.2;p13.3)/*KAT6A::CREBBP*
	inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2*, *MECOM* (*EVI1*)
	t(3q26.2;v)/*MECOM* (*EVI1*)-rearranged
	−5 or del(5q); −7; −17/abn(17p)
	Complex karyotype,[g] monosomal karyotype[h]
	Mutated *ASXL1*, ***BCOR***, ***EZH2***, *RUNX1*, ***SF3B1***, ***SRSF2***, ***STAG2***, ***U2AF1***, and/or ***ZRSR2***[i]
	Mutated *TP53*[j]

Abbreviations: AML, acute myeloid leukemia; bZIP, basic leucine zipper; ELN, European LeukemiaNet.
Frequencies, response rates, and outcome measures should be reported by risk category and, if sufficient numbers are available, by specific genetic lesions indicated.
Bold text indicates the latest changes for AML.
[a]Mainly based on results observed in intensively treated patients. Initial risk assignment may change during the treatment course on the basis of the results from analyses of measurable residual disease.
[b]Concurrent *KIT* and/or *FLT3* gene mutation does not alter risk categorization.
[c]AMLs with *NPM1* mutation and adverse-risk cytogenetic abnormalities are categorized as adverse risk.
[d]Only in-frame mutations affecting the bZIP region of *CEBPA*, irrespective of whether they occur as monoallelic or biallelic mutations, have been associated with a favorable outcome.
[e]The presence of t(9;11)(p21.3;q23.3) takes precedence over rare, concurrent adverse-risk gene mutations.
[f]Excluding *KMT2A* partial tandem duplication.
[g]Complex karyotype: ≥3 unrelated chromosome abnormalities in the absence of other class-defining recurring genetic abnormalities; excludes hyperdiploid karyotypes with three or more trisomies (or polysomies) without structural abnormalities.
[h]Monosomal karyotype: presence of two or more distinct monosomies (excluding loss of X or Y), or one single autosomal monosomy in combination with at least one structural chromosome abnormality (excluding core-binding factor AML).
[i]For the time being, these markers should not be used as an adverse prognostic marker if they co-occur with favorable-risk AML subtypes.
[j]*TP53* mutation at a variant allele fraction of at least 10%, irrespective of the *TP53* allelic status (mono- or biallelic mutation); *TP53* mutations are significantly associated with AML with complex and monosomal karyotype.

Response to treatment and long-term survival of patients are largely dependent on disease genetics, as described in the 2017 and 2022 ELN molecular risk classifications, and the age of the patient.[57,61] The 2017 ELN molecular risk classification was validated in a large cohort of 1,116 patients who had newly diagnosed AML treated with intensive induction chemotherapy during two phase 3 trials run by the German AML Cooperative Group.[61] Among patients younger than 60 years, 31% had ELN adverse-risk AML. By contrast, half the patients older than 60 years had adverse-risk AML. Although favorable-risk AML was associated with a complete remission rate of 72%, only 41% of patients who have adverse-risk AML achieved complete remission. The 5-year survival differed significantly based on ELN risk and was 54%, 31%, and 12% in patients who had favorable-, intermediate-, and adverse-risk AML, respectively. Importantly, patients older than 60 years had significantly worse 5-year survival rates than younger patients, with 37.4% versus 64.2% of patients who had favorable-risk AML and 6.4% versus 20.1% of patients who had adverse-risk AML and were alive at 5 years after treatment start. These data emphasize the poorer prognosis of older patients who have AML.

Outcomes for older patients treated with less intensive treatments for AML were difficult to discriminate using the 2017 and 2022 ELN risk classifications. Therefore, a bioinformatic algorithm was applied to a pooled analysis of the phase 3 VIALE-A trial and phase 1b study of venetoclax in combination with a hypomethylating agent in patients with AML ineligible for intensive induction, identifying new molecular signatures that were better able to differentiate survival outcomes for patients treated with azacitidine and venetoclax. This culminated in the ELN 2024 genetic risk classification incorporating a four-gene signature into three prognostic groups (favorable, intermediate, and adverse). The overall survival (OS) for the favorable-risk group was greater than 24 months, with those in the adverse-risk group, defined by mutations in *TP53*, having an OS of 5 to 8 months, and this prognostic tool applies to patients receiving hypomethylating monotherapy, hypomethylating agents with venetoclax, and azacitidine with ivosidenib for *IDH1*-mutated AML.[62]

Cytogenetics

Among patients younger than 60 years who have AML, core binding factor leukemias make up 10% to 15% of cases and have a favorable prognosis, along with APL.[63] Core binding factor leukemias consist of t(8;21) causing the fusion gene *RUNX1::RUNX1T1* and inv(16) or t(16;16), resulting in *CBFB::MYH11* fusion. The t(8;21) translocation is frequently accompanied by loss of a sex chromosome (particularly Y) or del(9q). Inv(16)/t(16;16) may be accompanied by trisomies, commonly involving chromosomes 22, 8, or 21.

Adverse cytogenetic features include inv(3)(q21;q26)/t(3;3)(q21;q26); *KMT2A* (*MLL)* rearrangements other than t(9;11), –5, –7, del(5q), del(7q); abnormalities involving chromosome 17; and a complex karyotype (three or more unrelated chromosomal abnormalities).[39] Patients who have complex or monosomal karyotypes (presence of two monosomies excluding X or Y loss or one monosomy with a structural chromosome abnormality) have a poor prognosis. Elucidation of the biological role of the menin-*KMT2A* interaction has facilitated the advent of menin inhibitors, now approved for patients with relapsed or refractory *KMT2A* rearranged AML.

In the 2022 ELN molecular risk classification, additional disease-defining cytogenetic abnormalities are considered adverse risk, including inv(3)/t(3;3) and t(3;21) involving the *MECOM* gene and t(8;16)(p11;p13), which is associated with *KAT6A*::*CREBBP*.[57,60] By contrast, hyperdiploid karyotypes with multiple trisomies (or polysomies) are no longer considered complex karyotypes and are excluded from the adverse-risk group.[39]

Mutations

Of patients aged 16 to 60 years who have AML, 35% to 40% have a normal karyotype at presentation. These patients may have accompanying mutations in *FLT3*, *NPM1*, *CEBPA*, *IDH1*, *IDH2*, *ASXL1*, and *TP53* in validated assays and a host of other mutations on comprehensive profiling.[64]

Biallelic mutations in *CEBPA* were previously reported as a favorable prognostic feature when patients were treated with chemotherapy alone.[65] In the 2022 ELN molecular risk classification, the good prognosis associated with *CEPBA* mutations was further defined as being limited to in-frame mutations affecting the bZIP region, irrespective of whether mono- or biallelic mutations were present.[57] *NPM1* mutations occur concurrently with *FLT3*-ITD in 60% of patients who have *FLT3* mutations. *NPM1* mutations occur by themselves in 30% of cytogenetically normal AMLs and are associated with a good prognosis. Although mutations in *NPM1* generally confer a favorable prognosis, patients with refractory or relapsed AML with *NPM1* mutations have poor outcomes. Advances in our understanding of the menin complex and its interaction with *NPM1* have enabled the FDA approval of menin inhibitors for patients with relapsed or refractory *NPM1*-mutated AML.

Approximately one-third of patients who have newly diagnosed AML have mutations in the *FLT3* gene. In all, 20% to 25% of patients who have AML harbor the *FLT3*-ITD gene, which is associated with a more proliferative phenotype, increased blast percentage, higher risk of relapse, and inferior OS compared with *FLT3* wild-type disease after combination chemotherapy. In all, 5% to 10% of patients who have newly diagnosed AML have a *FLT3*-TKD mutation. The prognostic impact of *FLT3*-TKD mutations is currently unclear. The presence of a coexisting *NPM1* mutation is associated with a decreased risk of relapse and improved survival in *FLT3*-ITD–mutated AML, especially in patients who have a low *FLT3*-ITD allele burden. The allelic ratio of *FLT3*-ITD:*FLT3* wild type strongly influences outcomes after induction chemotherapy that does not include an FLT3 inhibitor. A ratio of 0.5 or greater is associated with worse survival compared with a lower ratio. However, this is not the case any longer with the addition of FLT3 inhibitors to intensive chemotherapy.[66] Therefore, in the 2022 ELN molecular risk classification, *FLT3*-ITD allelic ratio is no longer incorporated into the risk classification, and all patients who have *FLT3*-ITD–mutated AML are included in the intermediate-risk group irrespective of their allelic ratio or presence of *NPM1* mutation.[57] *IDH1* and *IDH2* mutations occur in 6% to 10% and 9% to 13% of patients who have AML, respectively.[67] These mutations result in the accumulation of the oncometabolite 2-hydroxyglutarate. The prognostic relevance of these mutations is unclear, and other co-occurring mutations affect patient prognosis. Notably, drugs targeting IDH1 and IDH2 were recently approved by the FDA for first-line treatment of relapsed/refractory AML with an *IDH1* mutation or an *IDH2* mutation.

TP53 mutations are found in 70% of patients who have AML with complex cytogenetic abnormalities and are an independent poor prognostic factor in this AML subset. In addition, mutations in *SRSF2*, *SF3B1*, *U2AF1*, *ZRSR2*, *ASXL1*, *EZH2*, *BCOR*, or *STAG2*

were more than 95% specific for the diagnosis of a secondary ontogeny of AML, even if the morphologic bone marrow examination did not show evidence of previous MDS or MPNs.[68] Importantly, as in morphologically defined secondary AML, the presence of these mutations is associated with worse clinical outcomes, including a lower complete remission rate, more frequent need for reinduction, and decreased event-free survival (EFS). Therefore, in the updated 2022 ELN molecular risk classification, these mutations are included in the adverse-risk disease category.[57]

Measurable Residual Disease

Measurable residual disease (MRD) refers to residual disease that remains detectable after therapy with the help of highly sensitive techniques in the absence of morphologically detectable disease in the bone marrow. Detection of MRD at the time of remission after completion of induction chemotherapy, whether detected by multiparameter flow cytometry or molecular studies (eg, polymerase chain reaction [PCR] or NGS), is associated with increased rates of relapse and worse survival.[58,69-71] MRD detected concurrently by both flow cytometry and molecular studies confers the highest risk of disease relapse, whereas persistence of so-called DTA mutations (mutations in *DNMT3A*, *TET2*, and *ASXL1*), which are often present in individuals with age-related clonal hematopoiesis, is not correlated with an increased relapse rate.[69,70] Persistent MRD before allogeneic stem cell transplantation (allo-SCT) is associated with an increased risk of relapse and worse OS after transplantation, although this may be ameliorated by the use of myeloablative conditioning.[72,73] As maintenance strategies are explored after intensive induction or transplantation, MRD may be used to guide maintenance therapy. In the Blood and Marrow Transplant Clinical Trials Network (BMT CTN) 1506 Morpho trial evaluating gilteritinib maintenance for patients who have *FLT3*-ITD–mutated AML post-transplant, the quantity of *FLT3*-ITD MRD by PCR was highly correlated with outcome, and MRD was eradicated with gilteritinib maintenance in some cases, resulting in inclusion in the National Comprehensive Cancer Network (NCCN) guidelines as the preferred agent in this clinical setting.[3,8]

TREATMENT

Overview of AML Treatment

Patient-related factors, such as age, comorbidities, and performance status, and disease-specific factors, such as the molecular profile of the disease, presence of preexisting MDS, and previous leukemogenic therapy, typically influence the induction strategy (Table 19-2). In clinical practice, physiologic age is the more important benchmark of overall fitness for induction compared with an absolute age cutoff, although age 75 years is often considered a differentiating point. The goal of treatment is the eradication of leukemia, which is known as remission. Once remission is achieved, consolidative approaches are attempted to maintain a long-term remission and potentially offer a chance for cure (such as high-dose chemotherapy consolidation in favorable-risk patients or allo-SCT in eligible patients who have intermediate- or adverse-risk disease). If consolidative approaches cannot be offered, non-curative maintenance regimens may be used to extend OS.

Treatment of fit patients who have AML typically involves an induction chemotherapy phase and a post-remission treatment phase. The post-remission treatment phase consists of consolidation chemotherapy alone (for patients who have ELN favorable risk), allo-SCT (for transplant-eligible patients who have ELN intermediate or adverse risk), or consolidation and maintenance therapy without transplantation (for transplant-ineligible patients who have ELN intermediate or adverse risk) (Fig. 19-2).

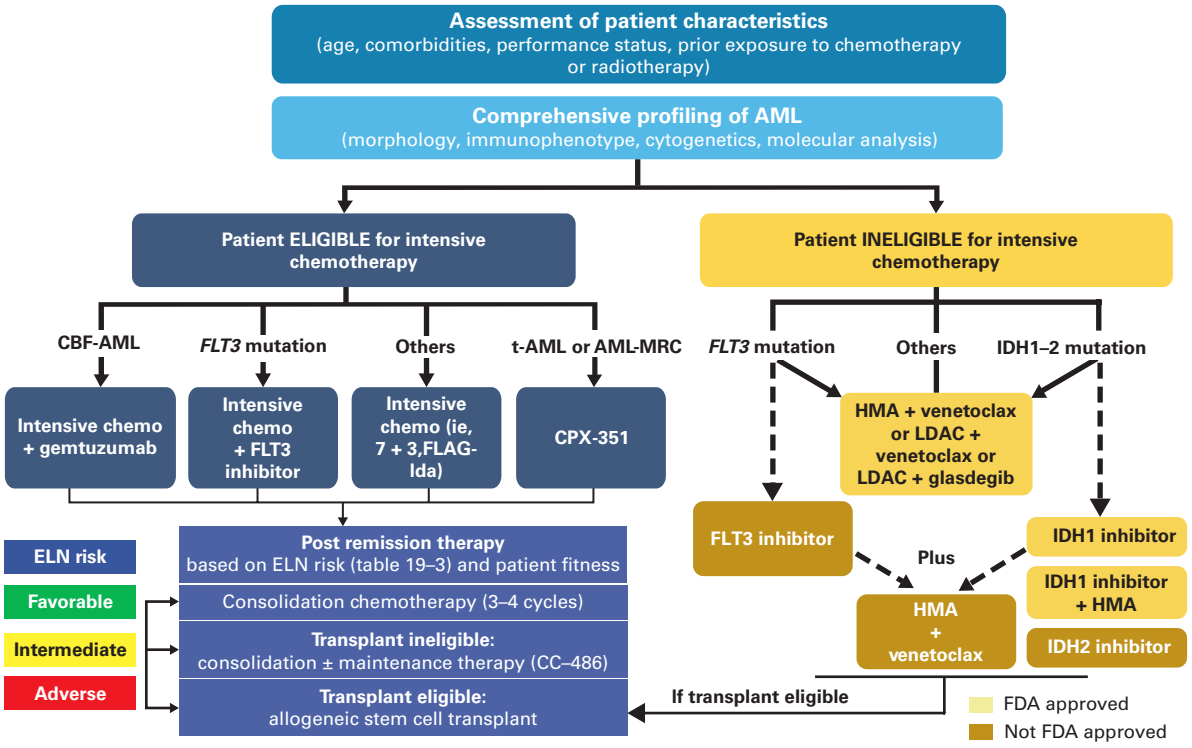
Treatment options for older patients or patients with comorbidities who are unfit for standard intensive induction therapy have improved. Treatment options now include the combination of the hypomethylating agents (HMAs, eg, azacitidine and decitabine) or low-dose cytarabine with the BCL-2 inhibitor venetoclax,[74-76] or targeted therapy.[77]

First-Line Treatment of Patients Eligible for Intensive Induction Chemotherapy

Standard intensive induction therapy uses an anthracycline for 3 days in combination with infusional cytarabine for 7 days (known as 3 + 7 or 7 + 3) with recent modifications based on cytogenetics, mutational profile, or cell-surface marker expression. ELN and NCCN consensus panels also recommend enrolling patients younger than 60 years who have AML in a clinical trial with curative intent.

Daunorubicin at 60 to 90 mg/m^2 and idarubicin at 12 mg/m^2 once per day for 3 days are the anthracyclines most used in combination with 7 days of continuously infused cytarabine at 100 to 200 mg/m^2 once per day. Daunorubicin and idarubicin at these dosage levels are comparable in terms of outcomes. A phase 3 Eastern Cooperative Oncology Group (ECOG) trial demonstrated an improved complete remission rate for daunorubicin at a dose of 90 mg/m^2 once per day for 3 days compared with 45 mg/m^2 once per day for 3 days; there was a survival benefit for patients who have a favorable- or intermediate-risk karyotype (median OS, 34 vs 21 months, respectively; $P = .004$) and for those aged younger than 50 years (median OS, 34 vs 19 months, respectively; $P = .004$). Patients aged 50 to 60 years with *FLT3*-ITD and *NPM1* mutations also had improved OS with daunorubicin at 90 mg/m^2 once per day.[39] In a randomized study based on a double-induction treatment strategy, however, no advantage was found for the 90 mg/m^2 once-per-day dose of daunorubicin compared with a dose of 60 mg/m^2 once per day in the first treatment cycle, except in patients who have *FLT3*-ITD–mutated AML.[78] Some experts recommend beginning a second cycle of chemotherapy in patients who still have more than 5% blasts in a more than 10% cellular marrow 7 to 10 days after the last dose of chemotherapy. The role of planned double induction in improving OS in AML is still not obvious, and more evidence from prospective studies is required in this regard.

Figure 19-2 First-Line Treatment Algorithm for AML



Abbreviations: AML, acute myeloid leukemia; AML-MRC, AML with myelodysplasia-related changes; CBF, core binding factor; CBF-AML, core binding factor AML; CC-486, oral azacitidine; chemo, chemotherapy; CPX-351, liposomal formulation of cytarabine and daunorubicin coencapsulated at a fixed molar ratio (5:1); ELN, European LeukemiaNet; FLAG-Ida, fludarabine, cytarabine, and granulocyte colony-stimulating factor with idarubicin; FL3, fms-like tyrosine kinase 3; HMA, hypomethylating agent; IDH, isocitrate dehydrogenase; LDAC, low-dose Ara-C (cytarabine); t-AML, therapy-related AML.
Dotted lines indicate alternative considerations.

For patients who have *FLT3*-mutated AML, midostaurin or quizartinib is added to standard first-line induction chemotherapy. In a randomized phase 3 trial for patients who had AML with *FLT3* mutations, midostaurin, a multikinase inhibitor with activity against mutated *FLT3*-ITD and TKD, improved OS compared with placebo in patients up to age 60 (hazard ratio [HR], 0.77; 95% CI, 0.63-0.95; $P = .007$), leading to FDA approval of midostaurin for this indication.[66] In addition to midostaurin, based on the QuANTUM-First trial, quizartinib, an oral, highly potent, selective type 2 FLT3 inhibitor, was approved in combination with 7 + 3 for induction in *FLT3*-ITD–positive newly diagnosed AML based on OS improvement compared with placebo. Importantly, this trial enrolled patients up to age 75 years.[57]

Gemtuzumab ozogamicin is approved for newly diagnosed $CD33^+$ AML in combination with daunorubicin and cytarabine based on the reduced risk of relapse and improved OS compared with chemotherapy alone.[79] These benefits seem to be restricted to patients who have favorable- or intermediate-risk disease (median EFS, 17.3 vs 9.5 months for gemtuzumab ozogamicin and standard chemotherapy arms, respectively; HR, 0.56; $P < .001$). Gemtuzumab ozogamicin is associated with increased risk of hepatotoxicity, including possible severe and fatal hepatic veno-occlusive disease, especially in the allo-SCT setting.

In patients aged 60 to 75 who have untreated AML and a history of cytotoxic treatment, antecedent MDS, or chronic myelomonocytic leukemia, another therapeutic option is CPX-351. CPX-351 is a liposomal formulation of cytarabine and daunorubicin coencapsulated at a fixed molar ratio (5:1) to maximize synergy between these two agents at a dose of 100 mg/m^2 of cytarabine and 44 mg/m^2 of daunorubicin once per day on days 1, 3, and 5. In this patient population, CPX-351 significantly showed improved OS, EFS, and response rates without an increase in the 60-day mortality rate or adverse events compared with 7 + 3 therapy.[80] However, CPX-351 treatment was associated with a longer time to neutrophil and platelet count recovery. The survival benefit in the CPX-351 group was especially pronounced in patients undergoing allo-SCT because of lower nonrelapse mortality (NRM) compared with 7 + 3.

Patients who have underlying poor cardiac function can be treated with a nonanthracycline-based induction regimen, such as clofarabine, cladribine, or fludarabine with high-dose cytarabine with or without gemtuzumab ozogamicin (eg, granulocyte colony-stimulating factor [G-CSF] priming, clofarabine, and high-dose cytarabine [GCLAC], cladribine plus cytarabine plus G-CSF [CLAG], or fludarabine, arabinofuranosyl cytidine [cytarabine/ara-C], and G-CSF [FLAG]).

Consolidation and Maintenance Therapy

Most consensus panels recommend three or four cycles of high-dosage cytarabine consolidation for patients aged younger than 60 years with favorable-risk cytogenetics [t(8;21), inv(16)/t(16;16)] or favorable-risk mutational patterns. Results from a randomized study suggest that high-dose cytarabine at 3 g/m^2 once every 12 hours on days 1, 3, and 5 improves outcomes in patients aged younger than 60 years[81] in comparison with standard-dose cytarabine (100 or 400 mg/m^2 by continuous infusion for 5 days).[82] This benefit was not seen in patients older than 60 because of excess toxicity, particularly neurotoxicity. High-dose cytarabine carries an increased risk of chemical conjunctivitis (12.4%) compared with standard-dose cytarabine (0.5%). Alternative accelerated dosing schedules have been explored, including HiDAC administered on days 1, 2, and 3 (HiDAC-123) with comparable outcomes to conventional dosing and potentially reduced toxicity.[83] In addition, recently, intermediate-dose cytarabine (IDAC) was determined to be noninferior to high-dose cytarabine in AML patients between 18 and 60 years old.[81,84] High-dose cytarabine and midostaurin or quizartinib consolidation therapy is used for patients who have *FLT3*-mutation–positive AML.[57,66] By contrast, matched-sibling or alternate-donor allo-SCT should be considered for patients who have intermediate- or adverse-risk AML who are considered eligible to receive such therapy.[57,85]

Oral azacitidine (CC-486) was approved as maintenance therapy in patients who have AML and have achieved complete remission after intensive induction chemotherapy but who are not able to complete intensive consolidation therapy (eg, allo-SCT). In a randomized placebo-controlled phase 3 study, CC-486 showed improved OS (24.7 vs 14.8 months) and RFS (10.2 vs 4.8 months) compared with placebo.[86,87]

Allogeneic Stem Cell Transplantation for AML

Allo-SCT offers a strong antileukemic effect and continues to be the treatment of choice for medically fit patients younger than age 70 to 75 with an available donor except those with favorable cytogenetic or molecular risk profiles (ie, patients who have APL, core binding factor AML, biallelic *CEPBA* mutations, *NPM1* mutation without *FLT3*-ITD, or who achieve an early first complete remission and have no evidence of MRD after induction).[57] If no human leukocyte antigen (HLA)-matched related or unrelated donors are available, alternative donor sources (haploidentical donors, cord blood) are considered.

For patients who have intermediate-risk AML, the absolute benefit of allo-SCT in first complete remission is less marked than that for patients who have adverse-risk disease, and controversy remains regarding whether equivalent survival may be achieved by delaying transplantation until after the first relapse.[57,85]

The optimal intensity of pretransplantation conditioning chemotherapy for AML has been the subject of extensive study. Data from a major randomized trial showed significantly higher rates of relapse and shorter RFS with reduced-intensity conditioning compared with myeloablative conditioning in patients aged 18 to 65.[88] Myeloablative conditioning, therefore, should be prioritized if the patient is considered a suitable candidate. For patients older than age 40, the combination of busulfan and fludarabine is associated with lower transplantation-related mortality rates, but it retains antileukemic effects compared with busulfan and cyclophosphamide.[89] However, there continues to be a limited role for myeloablative regimens in treating older patients who have AML. Nonmyeloablative or reduced-intensity conditioning regimens have been developed to reduce the rate of NRM in older or less medically fit patients. Reduced-intensity conditioning in older patients has demonstrated a survival benefit and improved RFS.[90-92] The BMT CTN 1704 trial prospectively evaluated the Composite Health Risk Assessment Model (CHARM) in an effort to predict 1-year NRM for adults older than age 60 receiving an allo-SCT. The CHARM score, which comprises albumin, C-reactive protein, hematopoietic cell transplantation comorbidity index, and weight loss, predicted NRM within 1 year of transplantation, with each point increase in the CHARM score being associated with an HR of 2.83 (95% CI, 2.12-3.78; $P < .0001$) for NRM.[93]

Importantly, a study performed MRD analysis using ultra-deep error-corrected sequencing for 13 commonly mutated genes in blood samples before allo-SCT from patients treated in the BMT CTN 0901 phase 3 clinical trial. The trial randomly assigned adult patients who had AML in morphologic complete remission to myeloablative conditioning or reduced-intensity conditioning.[73] In patients who had detectable MRD before allo-SCT, reduced-intensity conditioning was significantly associated with increased relapse, decreased RFS, and decreased OS compared with myeloablative conditioning, whereas there was no difference between the two conditioning approaches for patients without detectable MRD. These data argue strongly for considering the pretransplantation MRD status of patients in making decisions about which conditioning regimen to use.

The low likelihood of response to salvage chemotherapy for patients for whom primary induction failed has led to attempts to use allo-SCT as first salvage therapy. Although the post-transplantation relapse rate is high, the 20% to 25% long-term OS rate with allo-SCT for patients who experience primary induction failure is better than what would be expected with additional chemotherapy.[94]

First-Line Treatment of Patients Ineligible for Intensive Induction Chemotherapy

Historically, patients who were not considered fit enough to receive intensive chemotherapy because of advanced age or comorbidities received either low-intensity therapy with HMAs or supportive care only. However, FDA approval of the BCL-2 inhibitor venetoclax has greatly improved the treatment of this patient population and is part of the standard of care in the current treatment era. Venetoclax in combination with HMAs or low-dose cytarabine has shown impressive activity in patients older than age

75 or unfit patients in clinical trials.[75,95] The landmark VIALE-A trial was a randomized phase 3 trial demonstrating improved OS with venetoclax plus azacitidine compared with azacitidine alone (14.7 vs 9.6 months; $P < .001$).[74] Long-term follow-up of VIALE-A demonstrated continued survival advantage with azacitidine/venetoclax-treated patients surviving 14.7 months (95% confidence interval [CI], 12.1-18.7) versus 9.6 months with azacitidine alone.[96]

The combination of venetoclax and HMAs or low-dose cytarabine is approved by the FDA as treatment for patients who have AML and are aged 75 years or older or patients who are unfit for standard induction therapy. In the VIALE-C phase 3 trial of venetoclax plus low-dose cytarabine (LDAC) versus LDAC alone, the combination resulted in numerically prolonged OS without reaching statistical significance (7.2 vs 4.1 months; $P = .11$).[75] Of note, an unplanned analysis with an additional 6 months of follow-up showed a statistically significantly longer OS with the combination treatment (7.2 vs 4.1 months; $P = .04$). Long-term follow-up of this trial demonstrated a persistent improvement in OS for the LDAC/venetoclax-treated patients versus those receiving LDAC alone (8.4 vs 4.1 months).

Venetoclax can cause tumor lysis syndrome, and appropriate preventive measures are required to avoid this complication. Venetoclax is metabolized by the CYP3A4 cytochrome system, and the dose needs to be adjusted when administered concurrently with CYP3A4 inhibitors, such as the antifungal agents, posaconazole and voriconazole. Given the FDA approval of gilteritinib, ivosidenib, and enasidenib for *FLT3*-, *IDH1*-, and *IDH2*-mutated relapsed/refractory AML (see "Treatment of Relapsed/Refractory AML or Persistent Disease" section), respectively, these targeted therapies have also been studied in the first-line treatment setting for patients who are ineligible for intensive chemotherapy either as monotherapy or in combination with HMAs.

The IDH1 inhibitor ivosidenib received FDA approval for the first-line treatment of *IDH1*-mutated AML in combination with azacitidine in patients older than 75 years or patients who are medically unfit for intensive induction.[77] By contrast, the IDH2 inhibitor enasidenib remains approved by the FDA only as treatment of *IDH2*-mutated relapsed/refractory AML. Recently, two phase 3 clinical trials directly compared the combination of the IDH inhibitor ivosidenib plus azacitidine or enasidenib plus azacitidine versus azacitidine monotherapy in the first-line treatment of *IDH1*- or *IDH2*-mutated AML, respectively. The AGILE trial showed both a higher overall response rate (ORR) (63% vs 19%; $P < .0001$) and improved median OS (24 vs 7.9 months; $P = .0005$) with the combination of ivosidenib and azacitidine compared with azacitidine alone.[97] By contrast, the AG221-AML-005 trial showed a higher ORR (74% vs 36%; $P = .0003$) but no improvement in OS with enasidenib plus azacitidine compared with azacitidine alone.[4] Likewise, the phase 3 LACEWING trial comparing gilteritinib plus azacitidine with azacitidine alone showed an improvement in the composite complete remission rate but no improvement in OS.[5]

Despite a high response rate, the absence of a survival advantage for enasidenib and gilteritinib in combination with azacitidine argues against using these combinations in routine clinical practice. Instead, venetoclax and an HMA or low-dose cytarabine is typically used in these patients instead. Whether to treat patients carrying an *IDH1* mutation with ivosidenib plus an HMA or venetoclax plus an HMA as first-line therapy remains an open question, given that both approaches are predicted to result in high response rates and improved OS. In frail patients who are thought to be potentially unable to tolerate the prolonged myelosuppression induced by venetoclax, single-agent ivosidenib (approved by the FDA for this indication) for *IDH1*-mutated AML, enasidenib for *IDH2*-mutated AML, or gilteritinib for *FLT3*-mutated AML may be considered. However, it is important to remember that enasidenib and gilteritinib are not approved in the first-line setting, and individual drug approval could depend on specific insurance coverage in the United States.

More encouraging results were reported recently from a phase 1/2 trial combining gilteritinib and azacitidine with venetoclax, with a median follow-up of 19.3 months, the median OS for patients who had newly diagnosed *FLT3*-mutated disease had not been reached, with an OS rate of 72%. Investigation of this triplet combination is ongoing.[98]

Treatment of Relapsed/Refractory AML or Persistent Disease

Relapsed/refractory AML may have new mutations or lose previous mutations at the time of relapse compared with the dominant clone at initial diagnosis, and in such cases, this information can be used to guide therapy. Therefore, genomic profiling should be repeated at the time of relapse. For those fit enough to receive intensive chemotherapy, regimens containing a purine analog (ie, fludarabine, cladribine, or clofarabine) have resulted in remission rates of 30% to 45% in the relapsed/refractory setting. Some common regimens for relapsed/refractory AML are mitoxantrone, etoposide, and cytarabine (MEC); FLAG or FLAG-Ida; and cladribine, cytarabine, and G-CSF with or without mitoxantrone (CLAG-M). High-dose cytarabine can also be administered in relapsed/refractory AML if it has not been given previously.

IDH1 mutations occur in 6% to 10% of patients, and *IDH2* mutations occur in 10% to 15% of patients who have relapsed/refractory AML. These mutations result in the accumulation of the oncometabolite 2-hydroxyglutarate, which alters the epigenetic profile of AML blasts. The IDH1 inhibitors ivosidenib and olutasidenib and the IDH2 inhibitor enasidenib block the enzymatic activity of mutated *IDH1* and *IDH2*, respectively, lowering the levels of the oncometabolite 2-hydroxyglutarate.

The IDH1 inhibitor ivosidenib has demonstrated an ORR of 42% at 500 mg taken orally once per day in relapsed/refractory AML.[99] Olutasidenib, which is another selective IDH1 inhibitor, was approved in 2022 for relapsed/refractory *IDH1*-mutated AML.[100] Based on the approval summary by the FDA,[98] the complete remission and complete remission with partial hematologic recovery rates among 147 patients who had relapsed/refractory *IDH1*-mutated AML was 35% (51 of 147). Because ivosidenib is

approved for the same patient population, and olutasidenib was not directly compared with ivosidenib, both IDH1 inhibitors can be used for relapsed/refractory *IDH1*-mutated AML. The IDH2 inhibitor enasidenib has demonstrated an ORR of 40.3% and OS of 9.3 months at a dose of 100 mg taken orally once per day.[101] Both ivosidenib and enasidenib are associated with a differentiation syndrome that occurs in 10% to 14% of all patients and is clinically characterized by fever, dyspnea, pulmonary infiltrates, and hypoxia. Leukocytosis often accompanies differentiation syndrome. Early recognition is important because it can be fatal if untreated. Patients for whom there is a clinical suspicion of differentiation syndrome should be treated with systemic corticosteroids and close monitoring of hemodynamic status.

Gemtuzumab ozogamicin is approved for the treatment of relapsed/refractory AML as monotherapy administered at 6 mg/m^2 once per day on days 1 and 3 mg/m^2 once per day on day 8. Patients who have no evidence of disease progression and no significant toxicities can continue receiving treatment of up to eight courses at a reduced dosage (2 mg/m^2 once every 4 weeks). Another regimen is single-agent gemtuzumab ozogamicin at 3 mg/m^2 administered intravenously once per day on days 1, 4, and 7.

Gilteritinib, a highly selective FLT3 inhibitor, has been approved for *FLT3*-ITD–positive relapsed/refractory AML at 120 mg taken orally once per day. In the phase 3 ADMIRAL trial, gilteritinib led to improved OS compared with salvage therapy in fit and unfit patients (9.3 vs 5.6 months; $P < .001$).[102]

After the discovery that menin is an essential oncogenic cofactor for *MLL*-associated leukemogenesis, menin inhibitors are promising targeted therapeutic agents for AML with rearrangement of the *KMT2A* gene (also known as *MLL*) and *NPM1*-mutated AML (with a gene expression profile similar to the *KMT2A* rearrangement [*KMT2Ar*]). Revumenib (SNDX-5613), a potent, selective small-molecule inhibitor of the menin-histone-lysine N-methyltransferase 2A (*KMT2A*) interaction, is safe and effective as monotherapy in patients who have relapsed/refractory *KMT2Ar* AML (investigated in the phase I/II AUGMENT-101 trial) and in combination in patients who have relapsed/refractory AML with *KMT2Ar* or *NPM1* mutation.[4,5] Revumenib has now been FDA approved as monotherapy in relapsed/refractory AML with *KMT2Ar* or *NPM1* mutations based on results from AUGMENT-101.[6] An alternative menin inhibitor, ziftomenib, is also now FDA approved for relapsed/refractory *NPM1*-mutated AML based on results of the phase 1/2 KOMET-001.[103]

Investigational Approaches for the Treatment of AML

The approval of venetoclax for first-line treatment of AML has paved the way for multiple ongoing trials evaluating the combination of venetoclax with chemotherapy and targeted therapy. Although response rates to combination approaches are promising, it remains to be seen whether this will also translate into improved survival. Currently, none of these trials has studied the addition of venetoclax in a randomized controlled design. Therefore, the addition of venetoclax to chemotherapy other than HMAs, low-dose cytarabine, or targeted therapy remains investigational.

Overall, the combination of venetoclax with various chemotherapy combinations shows promising results with high composite response rates. Venetoclax in combination with FLAG-Ida showed a high composite complete remission rate in both newly diagnosed and relapsed/refractory AML (90% and 67%, respectively).[104] Similarly, in the CAVEAT trial, the combination of cytarabine and idarubicin with venetoclax resulted in a complete remission for both combinations, with an incomplete recovery rate of 72% (97% in de novo AML and 43% in secondary AML).[105] In addition, venetoclax combined with alternating courses of cladribine and low-dose cytarabine and azacitidine resulted in a complete remission for both combinations, with an incomplete recovery rate of 94%.[106]

As with chemotherapy, the addition of targeted therapy (IDH1/2 and FLT3 inhibitors) to the azacitidine and venetoclax backbone results in high response rates, with some reports also demonstrating high MRD-negative response rates.[98,107-110] However, outcomes in these trials frequently include so-called composite complete remission rates, including complete remission and additional remission definitions with incomplete or complete absence of count recovery. It is currently unclear whether remission without complete count recovery will lead to an improvement in survival, given that complete remission remains the response most consistently associated with a survival advantage.

With success in treating relapsed/refractory AML with *KMT2Ar* or *NPM1* mutations, menin inhibition is currently being investigated in combination with intensive and less intensive treatment combinations for patients with newly diagnosed *KMT2Ar* or *NPM1*-mutated AML.

In an effort to offer a trial for every patient with AML, the National Cancer Institute is supporting a precision medicine clinical trial platform called MyeloMATCH, to match patients to targeted therapies based on the molecular profile of their disease. Currently, MyeloMATCH is enrolling with several studies in Tier 1, aimed at induction therapies for newly diagnosed patients stratified into younger and older age groups.[111]

Supportive Care During AML Therapy

Transfusions, tumor lysis syndrome prophylaxis, growth factor support, anti-infective prophylaxis, and correction of coagulopathies are the crux of supportive care during AML therapy. Leukocyte-depleted blood products are preferred for all transplantation-eligible candidates. Standard tumor lysis syndrome prophylaxis administered during treatment includes hydration, diuresis, and treatment with allopurinol and/or rasburicase. Rasburicase is a genetically engineered urate oxidase that can

rapidly decrease uric acid levels by conversion to the highly soluble allantoin and should be strongly considered for tumor lysis syndrome treatment and prophylaxis in the presence of a rapidly increasing blast count, high uric acid levels, and impaired renal function. Testing for glucose-6-phospate dehydrogenase deficiency is important to help prevent hemolysis associated with rasburicase in this population.

Monitoring for cerebellar and renal toxicities should be performed concurrently with treatment using high-dose cytarabine. If signs of neurologic toxicity are detected, high-dose cytarabine should be discontinued immediately, and only standard-dose cytarabine should be used from that point onward in treatment. Steroid eye drops are also provided while patients receive high-dose cytarabine to prevent conjunctivitis.

Growth factors such as G-CSF can decrease the duration of neutropenia and decrease the risk of life-threatening sepsis during treatment. Growth factors should be discontinued 1 week before a planned bone marrow biopsy, given that they can affect marrow interpretation and determination of remission status.

Although CNS leukemia is rare in AML, patients who have monocytic differentiation, biphenotypic leukemia, *FLT3* mutation, or WBC count greater than 40,000/mL at presentation should be screened for the presence of CNS leukemia with a lumbar puncture. Patients who have nerve palsies are presumed to have CNS involvement even in the absence of leukemic cells in the cerebrospinal fluid. Intrathecal chemotherapy should be incorporated into the treatment regimen if CNS leukemia is detected.[57,112]

PRESENTING CASE STUDY

A 60-year-old man presents to the emergency department with easy bruising and fevers for 2 weeks. Complete blood count revealed a leukocyte count of 120,000 cells/mcL, hemoglobin level of 7 g/dL, and platelet count of 8,000 cells/mcL. Peripheral blood differential reveals 80% blasts.

How do the observed circulating blasts and clinical presentation inform your decision on which tests to obtain?

The next best step is to order a bone marrow biopsy with aspirate. From the biopsy and aspirate, the following analyses should be performed, including morphology; immunophenotyping; cytogenetics; gene rearrangements in *PML-RARA*, *CBFB-MYH11*, *RUNX1-RUNX1T1*, *BCR-ABL1*, and other fusion genes; and a NGS panel.

These tests provide the necessary information to inform an acute myeloid leukemia (AML) diagnosis and allow for categorization by the 2022 WHO Classification and prognostication using ELN 2022 Risk Classification. Understanding the molecular characteristics of an AML diagnosis allows for appropriate therapeutic selection.

While awaiting bone marrow biopsy results, additional history can be obtained, and testing can be performed to determine family history, comorbidities, coagulation abnormalities, pulmonary and cardiovascular baseline testing, and Eastern Cooperative Oncology Group (ECOG) performance status to help inform appropriate therapy selection.

Additional testing revealed that the patient has AML with a mutation in *FLT3-ITD*. The patient reports a medical history of hypertension that is controlled with losartan. Echocardiogram revealed a normal ejection fraction of 60% with no other reported abnormalities. ECG demonstrated a corrected QT of 270 ms. No coagulopathy was identified on additional workup. His family history is significant for a father with prostate cancer at 80 years old. His ECOG performance status is 1.

Based on what you have learned thus far regarding this patient's characteristics, what treatment could be considered at this time?

There are now several targeted FLT3 inhibitors approved in combination with standard first-line intensive induction that should be offered to patients with *FLT3-ITD*–mutated AML who are fit for intensive chemotherapy. The patient in this case would be described as fit, with an ECOG of 1 and normal cardiac function with well-controlled comorbidities. Midostaurin, a multikinase inhibitor that has activity against FLT3-ITD and FLT3-TKD, was approved in combination with an intensive chemotherapy backbone (7 + 3) for patients with newly diagnosed *FLT3*-mutated AML. In addition, quizartinib, a selective type 2 FLT3 inhibitor, has also been approved for use in combination with 7 + 3 induction for patients with newly diagnosed *FLT3-ITD*–mutated AML. Both of these agents have been shown to improve OS in combination with intensive induction compared with intensive induction and placebo. It is now the standard of care to provide an FLT3 inhibitor in the frontline setting for patients with AML harboring an *FLT3* mutation.

SECONDARY AML AND THERAPY-RELATED MYELOID NEOPLASMS

Secondary AML evolves from a previous myeloid neoplasm, commonly MDS. Therapy-related myeloid neoplasms (MDS, AML) arise after previous chemotherapy and/or radiation therapy, typically for the treatment of a previous malignancy or autoimmune disorder. Previous exposure to alkylating agents predisposes patients to chromosome losses or deletions, commonly involving chromosomes 5 and 7. MDS or AML typically arises 5 to 7 years after exposure. Topoisomerase II inhibitors can cause balanced translocations commonly involving the *KMT2A* (*MLL*) gene at chromosome 11q23, leading to AML with a shorter latency period of 1 to 3 years. Mutations in *TP53* are particularly common in therapy-related myeloid neoplasms (21%-38%) and are associated with a poor prognosis. The presence of a mutation in *SRSF2*, *SF3B1*, *U2AF1*, *ZRSR2*, *ASXL1*, *EZH2*, *BCOR*, or *STAG2* is more than 95% specific for the diagnosis of secondary AML.[68]

The outcomes with standard therapy are poor, with an estimated median survival in the range of 8 to 16 months. Allo-SCT is currently the best treatment option for most patients who have therapy-related AML or MDS, although some with favorable-risk genetics may do well without SCT.[57,112] CPX-351 is approved for patients who have secondary or therapy-related AML.[80] The approval of the menin inhibitor revumenib in R/R *KMT2Ar* AML offers another treatment modality with promising outcomes and provides a potential bridge to transplantation.[6] With success in the relapsed/refractory setting, menin inhibitors are being investigated in the frontline setting in combination with intensive and less-intensive therapies.

ACUTE PROMYELOCYTIC LEUKEMIA

APL is a distinct subtype of AML with unique clinical, morphologic, and cytogenetic features. In more than 95% of patients, APL has the characteristic t(15;17) translocation. This translocation gives rise to the PML::RARA fusion product. As a result, an aberrant retinoic acid receptor recruits corepressor complexes that cause a differentiation arrest of the myeloid cells at the promyelocyte stage.

APL occurs more frequently in patients who are young, Hispanic, and obese. It has a typical morphology characterized by abnormal cytoplasmic granules and multiple Auer rods. Coagulopathy is a clinical hallmark of the disease, and it typically presents with hypofibrinogenemia, decreased coagulation factors, increased fibrin degradation products, and platelet consumption similar to disseminated intravascular coagulation. A unique feature of APL is its high sensitivity to treatment with all-trans retinoic acid (ATRA) and arsenic trioxide (ATO).[113]

More than 80% to 90% of patients are expected to be cured with a combination of ATRA, ATO, and/or chemotherapy; however, early death, defined as death within the first 30 days of presentation, remains the major cause of treatment failure in APL. Early death is often caused by consumptive coagulopathy leading to intracerebral, gastrointestinal, and pulmonary hemorrhages and, less commonly, infection and differentiation syndrome.[114] Therefore, it is important to make an early diagnosis of APL and institute immediate treatment with ATRA without waiting for molecular or cytogenetic confirmation of the disease.[115]

The treatment of APL is informed by risk stratification based on WBC count at presentation. Patients who have an initial WBC count of 10×10^9/L or less are considered low risk (if platelets are >40,000/mcL) or intermediate risk (if platelets are ≤40,000/mcL), whereas patients who have a WBC count greater than 10×10^9/L are considered high risk.[116] Typically, low- and intermediate-risk groups are combined into a low-/intermediate-risk category for treatment choice.

Low- and Intermediate-Risk APL

The APL 0406 study demonstrated that patients who have low- or intermediate-risk APL can be treated with ATRA and ATO alone, with more sustained antileukemic efficacy and better survival than that seen with a regimen of ATRA plus chemotherapy.[117,118] Indeed, ATRA and ATO are the preferred regimens for induction and consolidation for low- and intermediate-risk APL. Maintenance therapy is not required after arsenic and ATRA therapy.

During induction therapy with either ATRA or ATO, it is important to monitor for the development of differentiation syndrome, which is manifested by fever, weight gain, respiratory distress, pulmonary infiltrates, episodic hypotension, and renal failure. This condition is believed to be related to the sudden maturation of promyeloblasts and usually responds to dexamethasone, which should be initiated immediately upon suspicion of this condition. Temporary discontinuation of ATRA or ATO is required for patients in poor clinical condition as a result of severe renal or pulmonary impairment. Prophylactic steroids to prevent differentiation syndrome are generally recommended for high-risk APL, whereas for low-risk APL, they are optional but have been used in some protocols even in lower-risk APL.[117]

Treatment with ATO can be complicated by QT-interval prolongation and, rarely, by sudden cardiac death. Therefore, before initiating treatment, any electrolyte imbalances should be corrected, especially hypomagnesemia and hypocalcemia, and other drugs that can prolong the QT interval should be discontinued.

High-Risk APL

The standard of care for patients who have high-risk APL is induction therapy using ATRA in combination with daunorubicin and cytarabine or ATRA in combination with ATO and idarubicin.[119,120] Induction treatment is then followed by consolidation therapy with ATRA plus daunorubicin or ATRA and ATO, which again is followed by maintenance therapy. If administered consistently,

these treatment regimens lead to excellent clinical outcomes. For instance, in the APML4 trial, the combination of ATRA, ATO, and idarubicin followed by ATRA and ATO consolidation and ATRA, 6-mercaptopurine, and methotrexate maintenance therapy led to excellent outcomes with a 5-year OS rate of 87%.[120] Recently, anthracycline-free regimens have shown excellent long-term outcomes for patients who have high-risk APL by adding gemtuzumab ozogamicin (an anti-CD33 monoclonal antibody conjugated to the anthracycline antibiotic calicheamicin) to ATRA and ATO.[121,122]

Molecular remission status is assessed during therapy and thereafter by reverse-transcription PCR monitoring for the PML-RARA transcript. A small fraction of patients who have APL morphology will have a different translocation and fusion partner for RARA, such as t(11;17), which is associated with a poor response to ATRA and ATO.[123]

KEY POINTS

- In 60% of patients who have AML, at least one clonal abnormality in chromosome number or structure can be found. These cytogenetic abnormalities, in combination with age and performance status, are the most important prognostic factors in AML and are indispensable in making therapeutic decisions.
- Genome-wide sequencing has identified more than 50 genes that are recurrently mutated in AML. Testing for mutations in *FLT3, NPM1, CEBPA, IDH1, IDH2, KMT2A, NPM1,* and *TP53*, among other genes, is important in making treatment decisions for patients who enter first remission.
- On the basis of cytogenetic and molecular markers, AML can be divided into several categories with distinct disease risk.
- Standard induction therapy for those eligible for intensive chemotherapy in AML involves the use of an anthracycline and cytarabine.
- All patients aged 70 to 75 years or younger who achieve complete remission, except those with a favorable-risk cytogenetic or molecular profile who achieve an early first complete remission and have no evidence of MRD after induction, should be considered for allo-SCT, particularly if the SCT comorbidity index score is low and a donor is available. Myeloablative conditioning is preferred for patients up to age 60 to 65 years.
- Patients who are considered unfit to receive chemotherapy because of age or medical comorbidities are treated with venetoclax in combination with an HMA or low-dose cytarabine. Studies of multiple novel combination therapies combining venetoclax with chemotherapy or targeted therapy are ongoing.
- The prognosis is poor for patients who have recurrent AML, and the likelihood of achieving a second remission is predicted by the length of the first remission. Individuals who have remained in remission for more than 1 year can be induced with the same chemotherapy administered for the first complete remission. Because of this poor outcome, transplantation should be considered for most patients who have recurrent AML and who are appropriate candidates.
- Genetic analysis should be repeated at the time of disease progression or relapse, given that multiple targeted therapies are currently approved in this setting. Gilteritinib is approved for relapsed/refractory *FLT3*-ITD–mutated AML, and ivosidenib, olutasidenib, and enasidenib are approved for *IDH1*- and *IDH2*-mutated relapsed/refractory AML. Revumenib is approved for relapsed/refractory AML with *KMT2Ar*. In addition, both revumenib and ziftomenib are approved for relapsed/refractory *NPM1*-mutated AML.
- The suspicion of APL in a patient who has newly diagnosed acute leukemia should trigger the immediate administration of ATRA to reduce the risk of early death resulting from hemorrhage.
- Patients who have APL should receive ATRA and ATO as part of induction and/or consolidation therapy.

CHRONIC MYELOID LEUKEMIA

CML accounts for approximately 15% of all adult leukemias with a median age at presentation of 67 years. The Ph chromosome created by t(9;22)(q34;q11) results in a fusion of two genes, *BCR* (on chromosome 22) and *ABL1* (on chromosome 9), creating the abnormal fusion oncoprotein BCR-ABL1, a dysregulated and constitutively active tyrosine kinase (p210). Another BCR-ABL1 fusion oncoprotein, p190, more common in the setting of Ph+ ALL, is detected in only 1% of patients who have CML. The BCR-ABL1 fusion protein manifests clinically with uncontrolled production of granulocytes (ie, neutrophils, eosinophils, and basophils) in various states of maturation.

CLINICAL PRESENTATION AND DIAGNOSIS

Historically, CML has been described as having three different phases—chronic phase, accelerated phase, and blast phase (blast crisis)—with the disease presenting in the chronic phase more than 90% of the time. Up to 50% of patients are diagnosed incidentally during routine blood testing. Untreated chronic-phase chronic myeloid leukemia (CP-CML) will progress to advanced-stage disease in 3 to 5 years.[124] Symptoms of CML include fatigue, night sweats, malaise, weight loss, bone aches, and abdominal discomfort from splenomegaly. Patients typically have leukocytosis, thrombocytosis, and moderate anemia at the time of presentation. The marrow is virtually always hypercellular with granulocytic hyperplasia. Ph positivity is observed in more than 90% of patients. In the remaining patients, cryptic or complex translocations leading to *BCR*::*ABL1* can be detected by FISH or PCR

assays. Both WHO and ELN have developed criteria to distinguish the phases of CML, with the most recent WHO update describing a biphasic scheme that recognizes only chronic and blast phases.[1,125] The blast cutoff value differs between WHO and ELN criteria, with the more commonly used WHO criteria defining blast phase as 20% blasts or more, whereas the ELN criteria define blast phase as 30% blasts or more.[1,125]

The recent WHO 2022 update for CML disease classification placed greater emphasis on high-risk features of progression and omitted the classification of accelerated phase. High-risk features of CML progression include, but are not limited to, the development of new additional chromosomal abnormalities, excess blasts (10%-19%) in the bone marrow or peripheral blood, and/or treatment failure in the effort to achieve complete hematologic response to the first tyrosine kinase inhibitor (TKI). The most common cytogenetic changes associated with CML evolution are additional Ph chromosomes, trisomy 8, isochromosome 17q, and trisomy 19.

In more than 60% of patients in blast crisis, the blasts are of myeloid lineage as determined by morphology and cell-surface markers. In 25% to 30% of patients, the blasts are of lymphoid lineage. In the remaining patients, blasts may be biphenotypic or undifferentiated. Determination of the blast lineage is useful for selecting appropriate therapy.

PROGNOSTIC FACTORS

With the advent of potent BCR-ABL1–selective TKIs, the prognosis of CML has improved dramatically compared with the pre-TKI era, with the life expectancy of patients who have CML now approaching that of the general population. Several prognostic models have been developed to assess prognosis and aid the selection of a TKI for the initial therapy for CML, including the Sokal, Euro (Hasford), and European Treatment Outcome Study scores. The most frequently used Sokal scoring system has been used to stratify risk for patients who have CML into low-, intermediate-, and high-risk groups for clinical trials evaluating TKIs. The Sokal score is based on the patient's age, spleen size, platelet count, and percentage of blasts in the peripheral blood.[126]

TREATMENT

Oral highly effective TKIs are now the first-line therapy for CML. Before the advent of TKIs, hydroxyurea, interferon alfa (IFN-α) with or without cytarabine, busulfan, omacetaxine, and allo-SCT were used in the management of CML. These therapies continue to be used in a limited manner. Omacetaxine was recently removed from the US drug market. Response to therapy in CML is assessed by measuring the hematologic, cytogenetic, and molecular responses to TKI treatment (Table 19-4).

Table 19-4 NCCN Criteria for Hematologic, Cytogenic, and Molecular Response and Relapse[127]

Complete hematologic response	Complete normalization of peripheral blood counts with a leukocyte count $<10 \times 10^9$/L
	Platelet count $<450 \times 10^9$/L
	No immature cells, such as myelocytes, promyelocytes, or blasts, in peripheral blood
	No signs or symptoms of disease with the disappearance of palpable splenomegaly
Cytogenetic response[a]	Complete cytogenetic response: no Ph+ metaphases
	Major cytogenetic response: 0%-35% Ph+ metaphases
	Partial cytogenetic response: 1%-35% Ph+ metaphases
	Minor cytogenetic response: >35%-65% Ph+ metaphases
Molecular response	Early molecular response: *BCR-ABL1* (IS) ≤ 10% at 3 and 6 months
	Major molecular response: *BCR-ABL1* (IS) ≤ 0.1% or a 3-log reduction in *BCR-ABL1* mRNA from the standardized baseline, if qPCR (IS) is not available
	Deep molecular response:
	MR4.0: *BCR-ABL1* (IS) ≤ 0.01% or
	MR4.5: *BCR-ABL1* (IS) ≤ 0.0032%
	Complete molecular response is variably described and is best defined by the assay's level of sensitivity (eg, MR4.5)
Relapse	Any sign of loss of hematologic response or loss of CCyR
	A 1-log increase in *BCR-ABL1* transcript levels with loss of MMR should prompt bone marrow evaluation for loss of CCyR, but is not itself defined as relapse (eg, hematologic or cytogenetic relapse)

Abbreviations: CCyR, complete cytogenic response; IS, International Scale; MMR, major molecular response; MR4.0, molecular response 4.0; mRNA, messenger RNA; NCCN, National Comprehensive Cancer Network; Ph+, Philadelphia chromosome–positive; qPCR, quantitative polymerase chain reaction.
[a]A minimum of 20 metaphases should be examined.

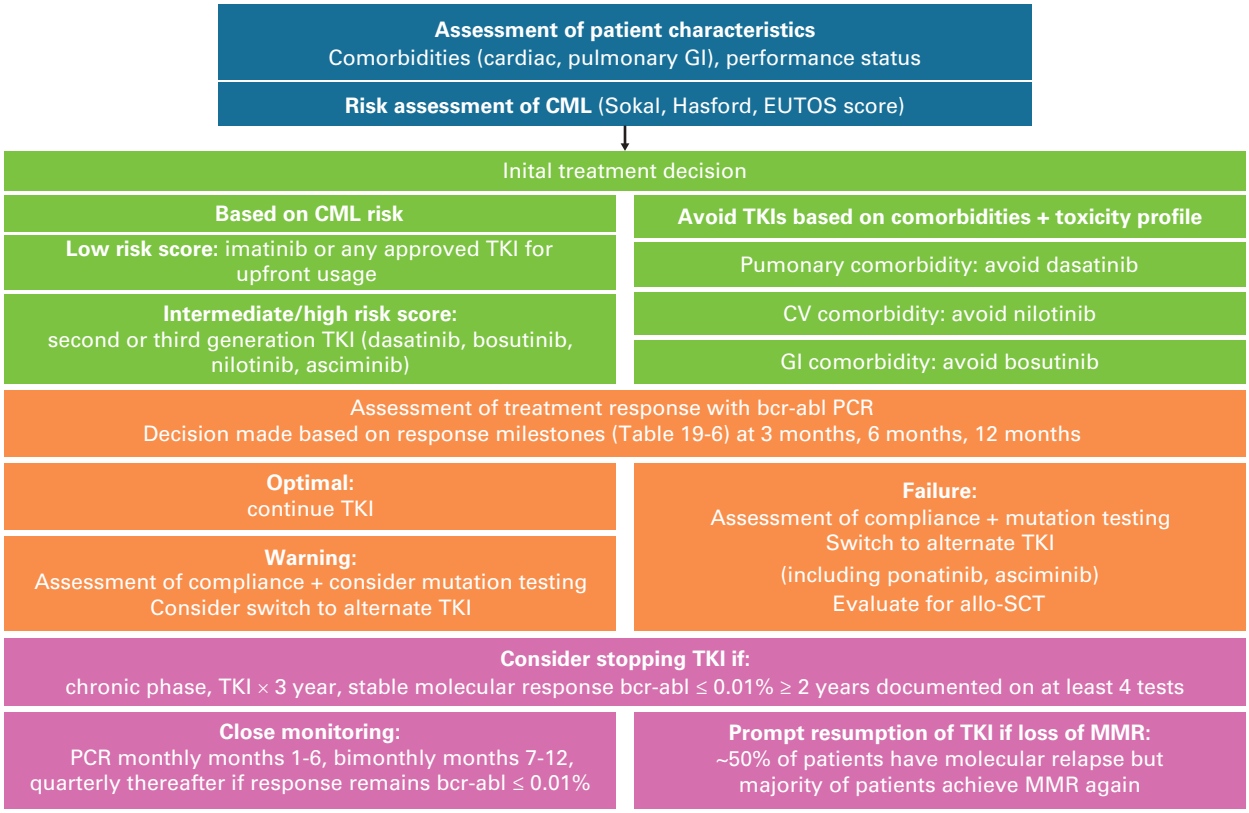
A simplified treatment algorithm for CP-CML based on the NCCN and ELN guidelines for the treatment of newly diagnosed CML is shown in Figure 19-3. The NCCN and ELN guidelines currently recommend initial therapy for CP-CML with the first-generation TKI imatinib (400 mg once per day) or a second-generation TKI, such as nilotinib (300 mg twice per day), dasatinib (100 mg once per day), or bosutinib (400 mg once per day). Recently, asciminib (80 mg once daily or 40 mg twice daily) has also been added to the NCCN guidelines as initial therapy.[125,128]

Figure 19-3 Treatment Algorithm for CP-CML Adapted From NCCN and ELN Guidelines[32,36,40]



Abbreviations: allo-SCT, allogeneic stem cell transplantation; CP-CML, chronic phase chronic myeloid leukemia; CV, cardiovascular; ELN, European LeukemiaNet; EUTOS, European Treatment Outcome Study; GI, gastrointestinal (tract); MMR, major molecular response; NCCN, National Comprehensive Cancer Network; PCR, polymerase chain reaction; TKI, tyrosine kinase inhibitor.

For the low- and intermediate-risk groups, imatinib remains an agent of choice, but for high-risk CML, the use of a second- or third-generation TKI is generally preferred. In addition, the specific toxicity profile of each TKI and the comorbidities of the patient help guide initial treatment selection. For instance, patients who have pulmonary comorbidities such as pleural effusion or pulmonary hypertension should avoid dasatinib, whereas patients who have significant cardiovascular comorbidities and hyperglycemia are advised to avoid nilotinib, and patients who have significant luminal gastrointestinal pathology are advised to avoid bosutinib.

Although most patients have an excellent response to initial TKI therapy, careful monitoring via blood cell counts, routine cytogenetic analysis of bone marrow, and FISH and quantitative PCR analyses of peripheral blood or bone marrow is critical for identifying treatment failures and considering making a change in therapy. The NCCN and ELN guidelines have established response criteria and clear milestones of response that need to be achieved with first-line TKI therapy.[125,128] Failure of treatment to achieve any of the goals of therapy at 3, 6, and 12 months or beyond should trigger an assessment of treatment compliance and testing for potential resistance mutations as well as consideration of a switch to an alternative TKI to limit the risk of progression and death (Table 19-5). Definitions of expected responses to second-line therapy have been developed, and they are relatively similar to those for first-line therapy. Failure of second-line therapy to achieve adequate disease response or a lack of response is an indication to proceed to allo-SCT. Patients who have accelerated-phase or blast-phase CML can respond to TKIs, but responses are generally short-lived, and the disease is relatively resistant to most types of therapy, with allo-SCT recommended for most eligible patients.

Table 19-5 **ELN Definitions of Response to TKIs as First-Line Therapy**[125,128]			
Time	**Optimal**	**Warning**	**Failure**
Baseline	NA	High risk or CCA/Ph+	NA
3 Months	*BCR-ABL1* ≤10% and/or Ph+ ≤ 35%	*BCR-ABL1* >10% and/or Ph+ 36%-95%	Non-CHR and/or Ph+ >95%
6 Months	*BCR-ABL1* <1% and/or Ph+ 0	*BCR-ABL1* >1%-10% and/or Ph+ 1%-35%	*BCR-ABL1* >10% and/or Ph+ >35%
12 Months	*BCR-ABL1* ≤0.1%	*BCR-ABL1* >0.1%-1%	*BCR-ABL1* >1% and/or Ph+ >0
After 12 months	*BCR-ABL1* ≤0.1%	Or loss of ≤0.1/% (MMR)	Loss of CHR, loss of CCyR, confirmed loss of MMR,[a] new mutations, or CCA/Ph+ changes

Abbreviations: CCA/Ph+, clonal chromosomal abnormalities in Philadelphia chromosome–positive cells; CCyR, complete cytogenetic response; CHR, complete hematologic response; ELN, European LeukemiaNet; MMR, major molecular response; NA, not applicable; TKI, tyrosine kinase inhibitor.
[a]MMR: *BCR-ABL1* ≤ 0.1% or ≥3-log reduction of *BCR-ABL1*.

The ultimate confirmation of treatment efficacy is the ability to discontinue TKIs indefinitely without evidence of CML recurrence, which is referred to as treatment-free remission. Discontinuing TKI therapy seems to be safe in a select group of patients who have CML. For younger patients who are interested in reaching treatment-free remission as soon as possible, the use of a second-generation TKI instead of imatinib should be considered; second-generation TKIs induce a deeper response more rapidly than imatinib in a higher proportion of patients. However, the proportion of patients achieving deep molecular remissions beyond 8 years with first-line imatinib continues to increase, and long-term outcomes are similar between imatinib and second-generation TKIs.[129-131]

First-Generation TKI: Imatinib

Imatinib was the first TKI approved for the treatment of CML and has the longest record for safety and efficacy. At a dosage of 400 mg of imatinib once per day, a complete cytogenetic response has been achieved in 49% to 77% of patients, and a major molecular response after 1 year has been achieved in 18% to 58% of patients.[130,132] After 10 years of follow-up during the IRIS trial, 93% of patients had achieved a major molecular response, and 63% of patients had obtained a deep molecular response (MR4.5) (>4.5-log reduction in *BCR-ABL1*) with an OS of 84%.[130]

A better early response can also be obtained with higher doses of imatinib (600-800 mg once per day), but these are rarely used given the availability of alternative TKIs.[125,128] Chronic fatigue, musculoskeletal pain, and muscle cramps are common adverse effects of imatinib that are associated with a decreased quality of life. Skin hypopigmentation, bone pain, diarrhea, peripheral edema, elevated lipase and alanine transaminase (ALT) levels, and cytopenias are other reported adverse effects.

The most common identifiable reasons for resistance include poor compliance with therapy, mutations in the BCR-ABL1 kinase domain that interfere with imatinib binding, *BCR-ABL1* gene amplification or overexpression, decreased drug bioavailability, or increased drug efflux. ABL1 kinase domain mutations can be detected in samples collected before treatment, suggesting that the delayed failure of imatinib therapy may reflect the considerable amount of time required for outgrowth of these selected clones. Not all mutations in *BCR-ABL1* have the same significance; mutations causing T315I amino acid substitution and those affecting the phosphate-binding loop are believed to confer the greatest degree of imatinib resistance, whereas others can be overcome by a dose increase or are functionally irrelevant.[125,128]

Second- and Third-Generation TKIs

Compared with imatinib, second-generation TKIs, such as nilotinib, dasatinib, and bosutinib, lead to higher complete cytogenetic response and major molecular response rates after at least 1 year and sometimes later, and may slightly reduce the rate of progression or treatment failure. However, no differences in OS have been documented.[129,131] These drugs can also result in complete cytogenetic response rates in approximately 50% of patients whose disease is in the chronic phase and in whom resistance to imatinib develops; however, they are inactive against the *T315I* mutation.[125,128] Asciminib, which is also now approved for initial treatment, is active against the *T315I* mutation.

Ponatinib, a third-generation TKI, is approved for the treatment of patients who have *T315I*-mutated CML and for adults who cannot tolerate any other TKI. The adverse effect profiles of these TKIs are similar to those of imatinib, although with notable distinctions. All second- and third-generation TKIs have cardiac toxicity, and some reports highlight vascular safety issues with these agents.

Dasatinib and, less so, bosutinib can cause pleural effusions. Dasatinib has also been associated with pulmonary hypertension and significant but reversible inhibition of platelet aggregation, contributing to bleeding in some patients with accompanying

thrombocytopenia.[133] Nilotinib has been associated with QT-interval prolongation and sudden death, increased serum glucose levels and worsened diabetic control, and peripheral arterial occlusive disease.[134,135] Importantly, vascular complications, such as arterial and venous thrombosis and embolic events, have occurred with nilotinib and ponatinib. Ischemic arterial occlusive events can occur in 25% to 30% of patients or more with ponatinib at a 45 mg/day dosing schedule.[136]

Several studies have explored initiating lower dosages or dosage de-escalation of second-generation TKIs. There are several nonrandomized and retrospective analyses that detail successful efforts initiating TKIs such as bosutinib, nilotinib, or dasatinib at lower dosages or decreasing TKI dosing in closely monitored patients who have achieved optimal responses.[137] It is anticipated that these types of dosage adjustments will be used in practice to prevent and/or manage treatment-related adverse events and long-term toxicities. Newer TKIs such as olverembatinib are under investigation, and this also covers the *T315I* mutation. It can be dosed every other day.[138]

Stamp Inhibitor Asciminib

Asciminib is an allosteric BCR-ABL1 inhibitor that, instead of binding to the adenosine triphosphate (ATP) binding site, specifically targets the ABL myristoyl pocket of BCR-ABL1 (STAMP), which locks the protein in an inactive conformation. In October 2021, the FDA granted accelerated approval to asciminib for patients who have CP-CML that was previously treated with two or more TKIs (40 mg bid or 80 mg once per day) based on the ASCEMBL trial and for those who have CP-CML with a *T315I* mutation (200 mg twice daily) based on the CABL001X2101 trial.

In the ASCEMBL trial, patients who had CP-CML previously treated with two or more TKIs were randomly assigned to either asciminib or bosutinib. The primary endpoint was major molecular response at 24 weeks, which was achieved in 25.5% of patients treated with asciminib and 13.2% of patients treated with bosutinib (P = .029).[11] In the CABL001X2101 trial, asciminib was tested in patients who have CP-CML that carries a *T315I* mutation. Major molecular response was achieved in 42% of patients by 24 weeks and in 49% by 96 weeks.[139]

Several trials have evaluated asciminib in the frontline setting for newly diagnosed CP-CML. The Australasian Leukaemia and Lymphoma Group (ALLG) conducted the prospective phase 2 CML13 ASCEND-CML trial that evaluated asciminib as a first-line agent for CP-CML; enrollment was completed in December 2022. Major molecular responses at 12 months were comparable to those of other second-generation TKIs, although deeper responses seemed more rapid with asciminib.[140] Asciminib has now been FDA approved for use in newly diagnosed CP-CML based on results from the phase 3 ASC4FIRST trial, which demonstrated superior efficacy of asciminib with more frequent major molecular responses on the asciminib arm compared with investigator-selected TKI with less frequent grade 3 or higher adverse events.[12]

Allo-SCT

Allo-SCT is currently reserved for patients who have CP-CML that is resistant to TKIs, patients intolerant of all TKIs, those who have CML with a BCR-ABL1 *T315I* mutation, those who have accelerated-phase CML and poor response to TKIs, and those with blast-phase disease.[125,128] Three-year survival rates can be as high as 90%, and NRM rates lower than 10% when allo-SCT is used as second-line therapy after the failure of therapy with imatinib.[141] Patients who have accelerated-phase CML and poor response to TKIs or blast-phase CML should quickly undergo workup for allo-SCT because it is the only potentially curative therapy available to them. Results are somewhat better for patients whose disease is in the accelerated phase or blast crisis and responds to TKIs by entering a second chronic phase before SCT. Disease recurrence is the most common cause of transplantation failure in patients allografted for CML. Toxicity events from allo-SCT for CML have decreased over the last three decades, mainly because of a decrease in the number of transplantation-related deaths and, most notably, a reduction in the occurrence of chronic graft-versus-host disease. Post-transplantation maintenance therapy with TKIs is frequently used, although robust data supporting the use of TKIs in this setting are lacking.[142]

TREATMENT-FREE REMISSION

Patients may be considered for a TKI treatment-free remission attempt for multiple reasons, including TKI toxicity, cost of medication, convenience, and desire to become pregnant. However, patients need to meet strict criteria before TKI discontinuation can be considered (Table 19-6). Approximately half of patients who discontinue TKIs remain in long-term treatment-free remission.[143-145] Therefore, 10% to 15% of patients who have newly diagnosed CML are expected to achieve long-term treatment-free remission, given that half of the approximately one-third of patients who achieve sustained deep molecular remission and are eligible to attempt treatment-free remission remain in long-term treatment-free remission. Importantly, once a TKI is stopped, close monitoring of the BCR-ABL transcript by PCR is required (monthly for the first 6 months and then every 2 months for the next 18 months). If the major molecular response is lost at any time, a prompt restart of the TKI is recommended with monthly PCR monitoring until a major molecular response is recaptured. Fortunately, almost all patients who lose a molecular response are able to regain the response once TKI therapy is restarted.[143-145]

Table 19-6 **NCCN Criteria for TKI Discontinuation**[127]
Outside a clinical trial, all the following criteria should be met:
Age 18 years or older
Reliably taking TKI for ≥3 years
No previous resistance to a second-generation TKI that required switching to another agent
Previous evidence of a quantifiable *BCR-ABL1* transcript
Stable molecular response (ie, MR4; *BCR-ABL1* ≤0.01% by the IS) for ≥2 years, as documented by ≥4 separate tests performed ≥3 months apart
Access to a reliable qPCR test capable of detecting at least MR4.5, providing results within 2 weeks
Access to close monitoring: first 6 months, monthly measurement of *BCR-ABL1* by qPCR; next 18 months, measure every 2 months

Abbreviations: IS, International Scale; MR4, molecular response 4; NCCN, National Comprehensive Cancer Network; qPCR, quantitative polymerase chain reaction; TKI, tyrosine kinase inhibitor.

KEY POINTS

- TKIs such as imatinib, nilotinib, dasatinib, and bosutinib are remarkably effective in newly diagnosed CP-CML, leading to complete hematologic and cytogenetic responses for most patients with OS similar to that of age-matched controls. However, continued therapy and careful follow-up are necessary. Asciminib, an allosteric inhibitor of the myristoyl site of the BCR-ABL1 protein, is now also approved in the newly diagnosed setting.
- Second-generation TKIs (eg, dasatinib, nilotinib, and bosutinib) result in quicker cytogenetic and molecular responses compared with imatinib, with no differences in OS.
- Patients who have *T315I*-mutated CML may respond to ponatinib, although the duration of response is typically short.
- Asciminib is approved by the FDA for patients who have CP-CML with resistance to at least two previous TKIs or CP-CML with a *T315I* mutation.
- Patients who have accelerated or blast-phase CML can respond to TKIs, but responses are generally short, and the disease is relatively resistant to most types of therapy. Allo-SCT is potentially curative for these patients.

MYELOID PRECURSOR CONDITIONS

The steady increase in the use of relatively inexpensive high-throughput genetic sequencing has led to an increase in the detection of clonal myeloid precursor conditions, including clonal hematopoiesis and clonal cytopenia of undetermined significance (CCUS).[146] Clonal hematopoiesis and CCUS need to be distinguished from idiopathic cytopenia of undetermined significance (ICUS) and MDS based on the presence of clonality, cytopenias, dysplasia, and increased blasts (Table 19-7).[146] Clonal hematopoiesis with somatic mutations, sometimes called clonal hematopoiesis of indeterminate potential, is defined as the presence of a clonal blood cell population associated with a recognized hematologic neoplasm driver mutation at a VAF greater than 2% in the absence of cytopenias or a WHO-defined disorder. It is a common aging-associated biologic state (present in 20%-30% of patients older than 60 years) that further predisposes them to the development of cardiovascular disorders and hematologic malignancies such as MDS/AML. Although many clonal hematopoiesis–associated mutations are reported, *DNMT3A*, *TET2*, and *ASXL1* (so-called *DTA* mutations) are the acquired variants most often reported, which account for more than 80% of the cases, with mutations in *JAK2*, *TP53*, *SF3B1*, and *SRSF2* also seen.[147] Clonal hematopoiesis that occurs after chemotherapy or radiation therapy for a nonmyeloid malignancy is most often associated with the expansion of mutations in DNA damage response genes (*TP53*, *PPM1D*, *CHEK2*).[148] Clonal hematopoiesis–defining mutations confer a modest risk (0.5%-1%) of an increase in hematologic malignancies per year but are associated with a 40% increased risk of cardiovascular events and death as a result of myocardial infarction or stroke.[149] The current understanding regarding the causal relationship between clonal hematopoiesis and increased cardiovascular morbidity and mortality is that an accelerated development of atherosclerosis is driven by an altered function of the NLRP3 (nucleotide oligomerization domain [NOD]–like receptor pyrin domain)/interleukin-1β [IL-1β]) inflammasome in mutated monocytes and macrophages.[150]

More recently, clonal hematopoiesis was also found to be associated with and potentially to be a direct contributor to the pathophysiology of a multitude of other diseases, including chronic obstructive pulmonary disease,[151] osteoporosis,[152] gout,[153] chronic kidney disease,[154] and hemophagocytic lymphohistiocytosis.[155] In contrast to the negative association of clonal hematopoiesis with these diseases, clonal hematopoiesis is potentially beneficial in other clinical contexts. *DNMT3A* mutations detected in cells of allo-SCT donors were found to be associated with improved recipient survival as a result of a reduction in the risk of relapse after transplantation.[156] Interestingly, clonal hematopoiesis was found to be associated with a reduced risk of developing

Alzheimer's disease[157] and a reduced risk of mortality in a trial of patients who have metastatic colon cancer treated with chemotherapy (in particular, a pronounced effect was observed in those with *DNMT3A* mutations).[158] Clonal hematopoiesis has been reported after CAR T-cell therapy.[159]

Table 19-7 Myeloid Precursor Conditions

Characteristic	Myeloid Precursor Subtype			
	CHIP	ICUS	CCUS	MDS
Clonal	Yes	No	Yes	Yes
Dysplasia	No	No	No	Yes
Cytopenias	No	Yes	Yes	Yes

Abbreviations: CCUS, clonal cytopenia of undetermined significance; CHIP, clonal hematopoiesis of indeterminate potential; ICUS, idiopathic cytopenia of undetermined significance; MDS, myelodysplastic syndrome.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

ICUS is defined as single or multiple cytopenias that remain unexplained despite an appropriate evaluation, including bone marrow examination. The condition excludes patients who have a known clonal mutation. By contrast, CCUS is defined as the identification of a clonal mutation in a patient who has one or more clinically meaningful unexplained cytopenias who does not meet WHO-defined criteria for a hematologic neoplasm.[146,160] In a large study, patients who had CCUS were found to have a significantly higher probability of developing a myeloid neoplasm compared with patients who had ICUS (5- and 10-year cumulative probabilities of progression were 82% vs 9% and 95% vs 9%, respectively; $P < .001$).[160]

Clonal hematopoiesis risk scoring systems have been published,[13,14] which provide a simple and reproducible prognostic tool for assessing the risk of progressing to a myeloid malignancy over time. One study analyzed whole-exome sequencing data from 193,743 healthy volunteer participants in the United Kingdom and found that 11,337 (5.85%) had pathogenic variants in genes associated with myeloid malignancies and otherwise met criteria for clonal hematopoiesis of indeterminate potential or CCUS. Using conditional probability–based recursive partitioning analysis, the authors identified a set of variables critical for classifying patients who had CHIP or CCUS into groups with distinct risk of myeloid malignancy (mutations in *SF3B1*, *SRSF2*, *ZRSR2*, *JAK2*, *TP53*, *RUNX1*, *FLT3*, *IDH1*, and *IDH2* were classified as high-risk mutations). Based on these clinical and molecular characteristics, patients who have clonal hematopoiesis are categorized into three risk groups: low, intermediate, or high risk of progression to myeloid malignancy. This and other risk prediction models in myeloid precursor diseases continue to require real-world validation and refinement.[161] Experts currently do not recommend routine screening for clonal hematopoiesis because evidence is lacking regarding the management of cardiovascular and hematologic neoplasm risks associated with clonal hematopoiesis. Clinical trials are currently being developed that test early intervention for patients who have clonal hematopoiesis and CCUS; however, these patients should not be treated outside a clinical trial.[161] Anti-inflammatory agents such as canakinumab have been examined and have shown a reduction in cardiovascular events among patients who have *TET2*-mutated clonal hematopoiesis.[162] VEXAS syndrome (vacuoles, E1 enzyme, X-linked, autoimmune, somatic) is associated with *UBA1* mutations and can arise from existing clonal hematopoiesis. Treatments are designed to inhibit inflammatory manifestations.[163]

KEY POINTS

- Clonal hematopoiesis is defined by a hematologic neoplasm driver mutation at a VAF greater than 2% in the absence of cytopenia, dysplasia, or increased blasts. Cytopenia is present in both CCUS and ICUS; note that CCUS is associated with a clonal mutation in addition to cytopenia.
- The risk of progression to a myeloid malignancy (MDS or AML) is comparably lower for those with clonal hematopoiesis (approximately 0.5%-1% per year) or ICUS (approximately 1% per year) and higher for those with CCUS (approximately 10%-20% per year). Risk factors have now been validated, and a clonal hematopoiesis risk score can be determined.[13,14]

MYELODYSPLASTIC SYNDROMES

MDS comprises a heterogeneous group of malignant disorders characterized by disordered growth and differentiation of hematopoietic progenitors and a variable risk of transformation to AML. MDS generally affects older individuals (median age at diagnosis, 65-70 years); only 10% of patients are younger than 50 years.

PATHOGENESIS

MDS occurs as a result of the sequential acquisition of somatic mutations in hematopoietic stem cells. Clonal mutations with higher allele frequencies are more likely to be present in the disease-initiating cells of MDS. Clonal hematopoiesis and CCUS, discussed in the previous section, are now considered to be MDS precursor conditions.

Typically, early driver mutations occur in genes involved in RNA splicing and DNA methylation. Links between cytogenetic abnormalities and MDS phenotype are now well established. For example, patients who have del(5q33) (ie, the 5q-minus syndrome) generally have severe macrocytic anemia, a normal or elevated platelet count, and a relatively low rate of progression to AML. Disease in these patients frequently responds to treatment with lenalidomide. *RPS14* and casein kinase 1A1 (*CSNK1A1*) have been identified as likely candidate genes involved in the 5q-minus syndrome and its response to lenalidomide.[164]

Sequencing studies have revealed a number of recurrent point mutations beyond those involving cytogenetic abnormalities. These include, but are not limited to, RNA splicing machinery mutations (*SF3B1*, *SRSF2*, *ZRSR2*, *U2AF1*); DNA methylation genes (*TET2*, *DNMT3A*, *IDH1/2*); chromatin modulation (*ASXL1*, *EZH2*); RAS pathway genes such as *KRAS*, *NRAS*, *CBL*, *NF1*, and *PTN11*; and cohesin complex genes such as *STAG2*. *SF3B1* encodes a core component of the RNA splicing machinery and is frequently mutated in patients who have MDS with ring sideroblasts. These patients tend to have lower-stage disease and better prognosis overall.[165]

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical findings in MDS are nonspecific; are related to the reduction or dysfunction of blood cells present at diagnosis; and include fatigue, bleeding diathesis, and infections. Interestingly, concurrent systemic inflammatory and autoimmune diseases are observed in up to 25% of patients who have MDS. The diagnosis is based on the examination of the blood and bone marrow, which typically shows a hypercellular marrow with dysplastic features and, in some cases, increased numbers of blasts. The diagnostic classification of MDS was recently updated by the simultaneous publication of the 2022 WHO classification and the 2022 ICC.[1,3] The WHO classification renamed these disorders myelodysplastic neoplasms. A diagnosis of dysplasia requires morphologic dysplasia in at least 10% of cells in at least one lineage. In all, 50% to 60% of patients have an abnormal karyotype.

Although there is a generally strong consensus between the 2022 WHO classification and the ICC, there are several important and consequential differences.[166] One notable and clinically relevant difference between these two classifications is the creation of the novel entity MDS/AML in the ICC, which is applied to patients who have 10% to 19% blasts in the peripheral blood and/or bone marrow. The creation of this novel category by the ICC is supported by a growing body of evidence showing that the prognosis of patients who have oligoblastic (20%-30% blasts) AML and patients who have the WHO category of MDS-increased blast 2 (which is eliminated from the ICC but was retained by the WHO) are comparable.[1]

As the prognostic impact of mutations is increasingly appreciated, the 2022 WHO classification and the ICC define mutation-specific subtypes of MDS.[1,3,166] The presence of *SF3B1* mutations is associated with a relatively favorable prognosis; it is defined as MDS with low blasts and *SF3B1* mutation by the WHO and as MDS with mutated *SF3B1* in the ICC. The negative prognostic impact of *TP53* mutations is primarily driven by patients who have biallelic (WHO nomenclature) or multihit (ICC nomenclature) *TP53* alterations. Biallelic or multihit *TP53* loss can be caused by the presence of multiple mutations (presumably affecting both alleles), one mutation and a deletion of the *TP53* locus on 17p (often in the context of a complex karyotype), or one mutation combined with copy-neutral loss of heterozygosity. The 2022 WHO classification adds MDS, hypoplastic, and MDS with fibrosis as disease subtypes that must be distinguished from aplastic anemia and primary MF, respectively.[1]

PROGNOSIS

The most important independent prognostic factors identified in MDS were classically the percentage of bone marrow blasts, number of cytopenias, and karyotype, but more recently, attention has been given to the role of specific mutations. Monosomies 5 and 7 are associated with the shortest survival, whereas the longest survival is associated with a normal karyotype and –Y, del(11q), del(5q), or del(20q) as the sole abnormality.[167] These factors were used to develop the International Prognostic Scoring System (IPSS) and later the revised IPSS (IPSS-R), which categorizes patients who have primary MDS into five risk groups with differing survival and risk of progression to AML. Findings from additional studies suggest that the prognosis is worse for patients who have therapy-related MDS than for patients who have primary MDS. Examination for heritable germline mutations is important, particularly in younger patients. These include but are not limited to *GATA2* deficiency, Schwachman-Diamond syndrome, telomeropathies, and mutations of *DDX41*.[168]

Several mutations (*ASXL1*, *RUNX1*, *EZH2*, and *TP53*) are associated with shorter survival, whereas only one mutation, *SF3B1*, has been consistently demonstrated to confer a more favorable prognosis. *TP53* mutations are encountered in 5% to 10% of patients who have MDS, are enriched in patients who have therapy-related myeloid neoplasms, and are associated with particularly poor outcomes. Patients who have MDS who carry a *TP53* mutation have poor outcomes even if they undergo allo-SCT. In a study of 1,514 patients who had MDS, the presence of a *TP53* mutation was associated with a median OS of 0.7 years and a 3-year OS rate of only 20% after transplantation. Although younger patients who have *TP53* wild-type had significantly longer OS after transplantation compared with older patients, the presence of a *TP53* mutation predicted significantly shorter OS independent of age.[169] It is increasingly understood that not all *TP53* mutations carry equal prognostic weight and that distinct patient subpopulations exist even within the cohort of patients who have *TP53*-mutated MDS.[170] Patients who have MDS with a so-called multihit state of *TP53* mutations, defined as either two separate *TP53* mutations or loss of the remaining wild-type allele by

either chromosomal deletion or copy-neutral loss of heterozygosity, have significantly worse outcomes compared with patients who have only a single *TP53* mutation. Patients who have multihit targeting of *TP53* had a median OS of only 0.7 years with a dismal 3-year OS rate of 8%. Now, there is also evidence for nonmutational TP53 dysfunction in MDS, which is also associated with a poor prognosis.[171]

Several attempts have been made to refine prognostic scoring in MDS, with the most important systems being the WHO Prognostic Scoring System (WPSS)[172] and the revised IPSS.[167] Given the importance of mutations in the prognostication of MDS, the molecular IPSS (IPSS-M) mutation-based risk assessment tool is becoming the standard-of-care risk assessment model.[15] It combines the prognostic impact of 38 gene mutations with traditional predictors (eg, blood counts, blast percentage, and karyotype) and improves prognostication compared with the IPSS-R. Table 19-8 shows the clinical outcome based on IPSS-M risk stratification.

Table 19-8 Outcomes Based on IPSS-M Risk Stratification

Characteristic	Very Low	Low	IPSS-M Risk Category*		High	Very High
			Moderate Low	Moderate High		
Patients—No. (%)	381 (14)	889 (33)	302 (11)	281 (11)	379 (14)	469 (17)
Risk score	≤−1.5	>−1.5 to −0.5	>−0.5 to 0	>0 to 0.5	>0.5 to 1.5	>1.5
Hazard ratio (95% CI)†	0.51 (0.39-0.67)	1.0 (Reference)	1.5 (1.2-1.8)	2.5 (2.1-3.1)	3.7 (3.1-4.4)	7.1 (6.0-8.3)
Median LFS (25%-75% range)—years‡	9.7 (5.0-17.4)	5.9 (2.6-12.0)	4.5 (1.6-6.9)	2.3 (0.91-4.7)	1.5 (0.80-2.8)	0.76 (0.33-1.5)
Median OS (25%-75% range)—years	10.6 (5.1-17.4)	6.0 (3.0-12.8)	4.6 (2.0-7.4)	2.8 (1.2-5.5)	1.7 (1.0-3.4)	1.0 (0.5-1.8)

The evolution and important points regarding the following prognostic systems in MDS have been reviewed by DeZern and Greenberg.[173] An online calculator is available for clinicians to use at https://mds-risk-model.com/.

TREATMENT

The therapeutic strategy for MDS is based primarily on disease risk. The main goals for patients who have IPSS low- or intermediate-1–risk (lower risk) MDS are to reduce the consequences of cytopenias and improve quality of life, whereas for patients who have intermediate-2– or high-risk (higher risk) MDS, the focus is on disease modification with prevention of transformation into AML and prolongation of survival. Supportive care is crucial in all risk categories of MDS and encompasses transfusion support, growth factor support in select patients, management of iron overload in low-risk patients and before transplantation, and appropriate use of antibiotics for prophylaxis or treatment of infections. Deferoxamine and deferasirox are oral iron chelators that are available and can be used in those who have had 20 to 30 red blood cell (RBC) transfusions and have serum ferritin levels of 2,000 ng/mL or above, with the goal to keep the level at <1,000 ng/mL. Figure 19-4 shows a treatment algorithm for newly diagnosed MDSs.

Figure 19-4 Treatment Algorithm for Newly Diagnosed MDS

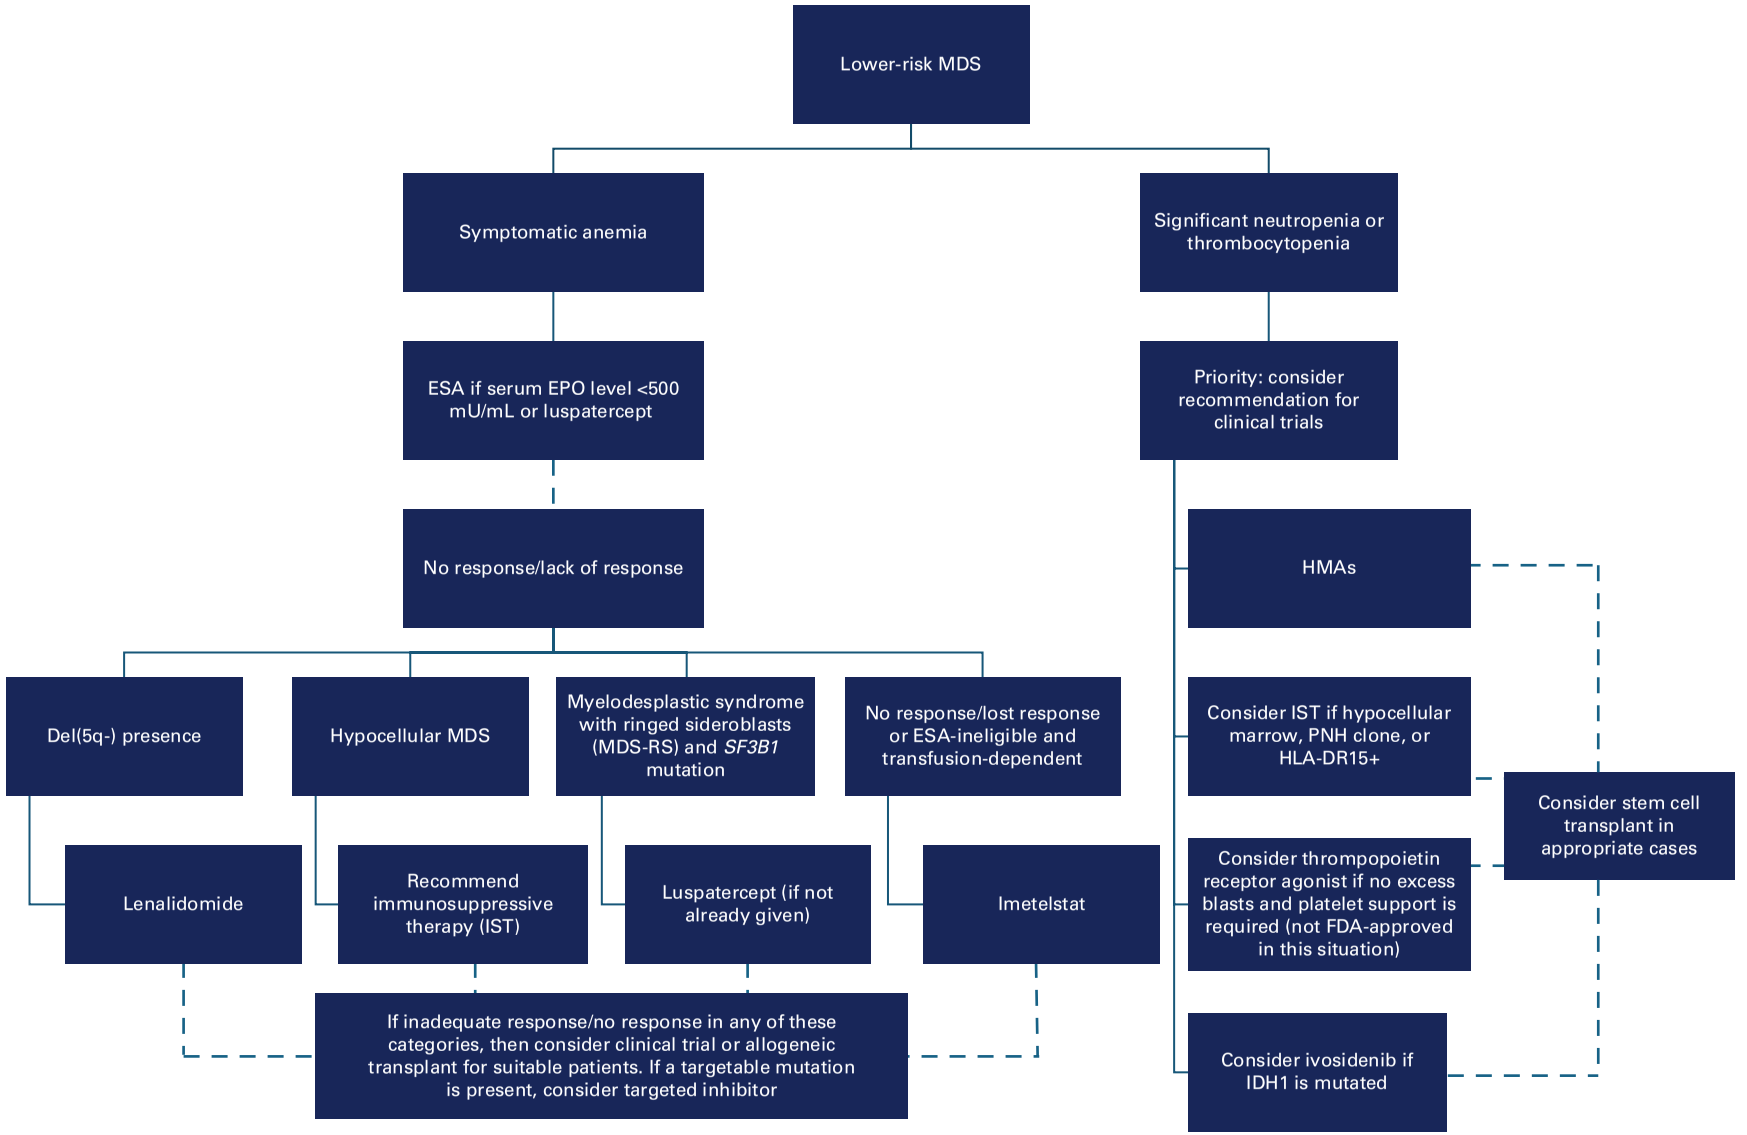

Figure 19-4 Continued

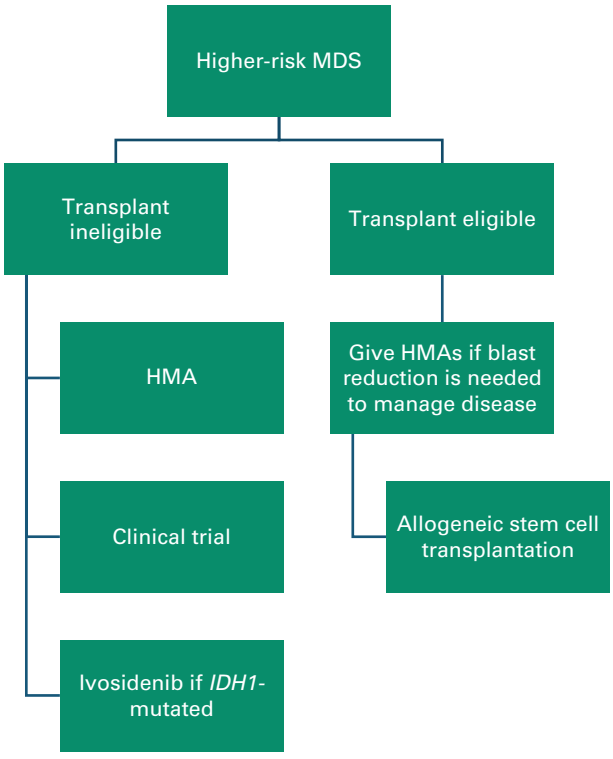

Abbreviations: EPO, erythropoietin; ESA, erythropoiesis-stimulating agents; HMA, hypomethylating agent; IDH, isocitrate dehydrogenase; IST, immunosuppressive therapy; MDS, myelodysplastic syndrome; PNH, paroxysmal nocturnal hemoglobinuria.
Dotted lines indicate alternative considerations.
Lower risk = very low and low by IPSS-R and very low, low, and moderate low by IPSS-M; higher risk = intermediate, high, and very high by IPSS-R and moderate high, high, and very high by IPSS-M.

Lower-Risk MDS

To make the best treatment decisions for patients who have lower-risk MDS, it is helpful to know the endogenous erythropoietin level of the patient, the number of transfusions the patient required in the past, and whether an isolated 5q-minus abnormality or ring sideroblasts and/or an *SF3B1* mutation are present.

ESAs can improve the anemia associated with MDS and are most effective in patients who have low endogenous erythropoietin levels (<500 U/L and ideally <200 U/L) and relatively low transfusion burden (<2 units of packed RBCs in the last month). If these favorable prognostic factors are present, the response rate to ESAs is approximately 70%; however, in the absence of these favorable prognostic factors, the response rate to ESAs is only approximately 7% to 20%. The target hemoglobin should be no higher than 12 g/dL and, in most cases, 10 g/dL. The addition of a myeloid growth factor may result in additional responses for 20% of patients; however, myeloid growth factors alone, including G-CSF, have poor responses in MDS and are currently not recommended as single agents. Thrombopoietin receptor agonists such as eltrombopag are not approved for use in MDS, but they are sometimes used in cases of severe chronic thrombocytopenia in low-risk categories.

The introduction of lenalidomide revolutionized the treatment of patients who have MDS with a 5q-minus abnormality, which is present in approximately 10% to 20% of patients who have MDS. In the phase 2 MDS-003 trial, lenalidomide yielded RBC transfusion independence for more than 8 weeks during weeks 1 to 24 in 67% of patients who have lower risk 5q-minus MDS.[174] Lenalidomide clearly showed evidence of exerting a disease-modifying effect, with cytogenetic response being achieved in 50% to 73% of patients.[175]

For patients who do not respond to ESAs or are unlikely to respond, several additional treatment options exist. First, even if patients do not have a 5q-minus abnormality, they might derive benefit from adding lenalidomide to ESA therapy. A randomized phase 2 trial showed that the combination of lenalidomide and ESAs significantly improved the erythroid response rate (39.4% vs 23.1%) in patients who have ESA-resistant lower-risk MDS compared with lenalidomide alone.[176] A phase 3 trial confirmed that lenalidomide restores sensitivity to patients who have ESA-insensitive lower risk non–5q-minus MDS, yielding a significantly higher rate and duration of major erythroid response compared with lenalidomide alone (28.3% vs 11.5%) with a longer but not statistically significant duration of response (23.8 vs 13 months).[177]

The FDA approved luspatercept in April 2020 for patients who had low- to intermediate-risk MDS with ring sideroblasts, MDS with an *SF3B1* mutation, or MDS/MPN with ring sideroblasts and thrombocytosis who have not responded to ESAs and were RBC transfusion dependent. Luspatercept is a recombinant fusion protein that contains the modified extracellular domain of the activin receptor IIB, which blocks the transforming growth factor-beta superfamily inhibitors of erythropoiesis. A phase 3 randomized double-blind study (MEDALIST) comparing luspatercept with placebo in low- to intermediate-risk patients who had MDS-related anemia, ring sideroblasts, and/or *SF3B1* mutations showed that patients treated with luspatercept had a significantly reduced transfusion burden compared with those treated with placebo (37.9% vs 13.2% reached transfusion independence for 8 weeks or longer; $P < .0001$).[178] Luspatercept response is not dependent on erythropoietin levels, and it is now approved for up-front use even before ESAs are tried on the basis of the phase 3 COMMANDS trial, in which it outperformed erythropoietin in terms of hemoglobin increases and transfusion independence. In all, 59% of patients in the luspatercept group and 31% in the ESA group reached RBC transfusion independence for at least 12 weeks with an associated increase in hemoglobin by at least 1.5 g/dL during the first 24 weeks of the study. The best responses were seen in patients who had ring sideroblasts and *SF3B1* mutations, but responses were seen in patients who had other mutations as well. The FDA has now approved it in low- and intermediate-risk patients who have MDS and are transfusion dependent.[17]

Imetelstat, a first-in-class telomerase inhibitor, improved hemoglobin levels and led to transfusion independence in patients who had lower-risk MDS and were ineligible for, had relapsed with, or were refractory to ESAs. The phase 3 IMerge trial of imetelstat versus placebo for patients with lower-risk MDS who had required four or more red cell transfusions over 8 weeks and had not responded to ESAs or were ineligible to receive them met its primary efficacy endpoint of 8-week transfusion independence (40% vs 15%), and imetelstat was granted FDA approval in June 2024. The most common grade 3 to 4 adverse effect was neutropenia.[21] The optimal sequencing of ESAs, luspatercept, and imetelstat requires further investigation, as does their role in earlier use in anemic patients not yet needing transfusions.[179]

Patients who have MDS and are positive for HLA-DR15, which is characterized by bone marrow hypoplasia, normal cytogenetics, low-risk disease, and a paroxysmal nocturnal hemoglobinuria clone, have shown prolonged responses to antithymocyte globulin, cyclosporine, or the two agents in combination.[180]

For patients who do not respond to treatment with these agents, HMAs such as azacitidine, decitabine, and the oral decitabine and cedazuridine can be used. Although the standard regimens involve 7 days of azacitidine administration and 5 days of decitabine, in a phase 3 clinical trial in lower-risk MDS, decitabine dosed on days 1 to 3 of a 28-day cycle led to RBC transfusion independence and complete response in 41% and 36% of patients, respectively.[16] A shortened 5-day course of azacitidine has also been examined.[181] Up to six cycles of azacitadine may be needed before determining a response, and the optimal duration of therapy is not known, but HMAs are usually continued until relapse occurs or toxicity intervenes. Dosage and schedule adjustments are often required because of cytopenias. Those who have mutated *IDH1* may be treated with ivosidenib after four to six cycles of an HMA have been ineffective. This treatment was approved by the FDA in 2023. The IDH1 inhibitor, olutasidenib, is also being investigated in MDS.[182] Studies are also underway to examine the effects of enasidenib in those with *IDH2* mutations, but this treatment has not yet been approved.

Platelet counts have responded to the thrombopoietin mimetics romiplostim and eltrombopag, but concern regarding proliferation of leukemic blasts remains from in vitro studies. Ongoing clinical trials with these agents will help further elucidate leukemic risk.[183] Patients who have MDS and are receiving frequent RBC supportive transfusions are at risk for iron overload and resultant end-organ (ie, heart, liver, and pancreas) complications. Iron overload is a contributing factor to early mortality and morbidity in MDS.[184] As previously noted, the iron chelators deferoxamine and deferasirox are available to treat iron overload in MDS. Deferasirox has a black-box warning for potentially fatal acute renal failure and hepatic failure.

Higher-Risk MDS

The key question for the management of a patient with higher-risk MDS is whether the patient is eligible to undergo allo-SCT. Allo-SCT is currently the only curative therapy for MDS and can lead to long-term disease-free survival (DFS) for 35% to 50% of patients, with many patients alive without evidence of disease more than 5 years after transplantation and some for as long as 25 years.

Azacitidine and decitabine are both approved as treatment of MDS (although a survival advantage was demonstrated only with azacitidine). Both are thought to have utility in MDS through their DNA demethylating activity, which leads to re-expression of key genes otherwise inactivated in MDS by hypermethylation. The effects of azacitidine were demonstrated in a phase 3 trial in which researchers found improved OS compared with conventional care (ie, supportive care alone, low-dosage cytarabine, or intensive chemotherapy as selected by investigators before random assignment) for patients who have IPSS intermediate-2– to high-risk disease.[185] Compared with the best supportive care, treatment with decitabine was reported to significantly reduce the risk of AML transformation and improve progression-free survival (PFS) in a randomized phase 3 trial in patients who have intermediate-1–, intermediate-2–, and high-risk MDS, whereas OS was not statistically significantly prolonged. Neither azacitidine nor decitabine is curative.[186]

In an oral formulation, decitabine is combined with the cytidine deaminase inhibitor cedazuridine, which prevents deactivation of decitabine by cytidine deaminase, leading to a prolonged half-life and potentially greater efficacy. Decitabine at 35 mg

plus cedazuridine at 100 mg once per day for 5 days yielded pharmacokinetic equivalence to standard decitabine at 20 mg/m^2 intravenously once per day for 5 days in patients who have MDS and chronic myelomonocytic leukemia; clinical responses were observed in 60% of treated patients with 21% of patients achieving a complete response (CR).[187] Decitabine and cedazuridine were approved by the FDA in July 2020 for the treatment of intermediate- and high-risk MDS.

Although isocitrate dehydrogenase (*IDH*) mutations are rare in MDS, ivosidenib has been approved for patients who have relapsed/refractory MDS that expresses this mutation. Eighteen adult patients received 500 mg once per day on 28-day cycles, and the CR rate was 28.9%, with all responses being CRs. Of the nine patients who were transfusion dependent, six became transfusion independent in a 56-day window after starting ivosidenib. The treatment was well-tolerated, with gastrointestinal toxicities being the most common type reported, with only rare cases of QTc prolongation noted.[20] Olutasidenib is also being studied in patients with *IDH1*-mutated MDS.

Patients who have higher-risk MDS have, in some cases, been treated with AML-like induction chemotherapy. Although response rates are lower than the rates seen in de novo AML, CRs have been reported in 40% to 60% of patients in some studies, but it is unknown whether this results in an improvement in OS. Patients who have higher risk MDS whose disease does not respond to HMAs have a poor prognosis with a median OS of 4 to 6 months, and investigational therapies should be promptly explored for this group of patients.[188]

A proposal for a revised International Working Group response criterion for higher-risk MDSs has been put forward. This will aid in the standardization of response criteria in this heterogeneous group of diseases.[189]

Allo-SCT

The BMT CTN 1102 study showed, in a biologic assignment trial, that reduced-intensity allo-SCT improved the survival rate of patients who have IPSS intermediate-2– or high-risk MDS who were aged 50 to 75 years compared with pharmacologic therapy. At 3 years, 48% of patients for whom donors were identified were alive compared with 27% of patients without donors who were treated with pharmacologic therapy alone. Similarly, leukemia-free survival was significantly higher in the donor arm (35.8%) than in the no-donor arm (20.6%; $P < .003$).[190] *ASXL1*, *RUNX*, *TP53*, and *Ras* mutations had a higher incidence of relapse and mortality, but post hoc analysis showed improved survival of *TP53* single and multihit cases. It is important to check for germline mutations because the results can impact conditioning regimens and donor selection. Allo-SCT should be considered an integral part of disease management for all patients who have advanced MDS and are fit enough to receive a transplant. There is controversy about whether treatment to reduce blasts before SCT is required.

Investigational Approaches to the Treatment of MDS

A multitude of novel therapeutics are in development in late-phase clinical trials for both lower- and higher-risk MDS. In transfusion-dependent low-risk MDS, investigators are examining the most effective sequential use of ESAs, luspatercept, and imetelstat. Several combination therapies that add novel agents to an HMA backbone have been examined in higher-risk MDS. For example, the combination of the BCL-2 inhibitor venetoclax with azacitidine, which is already approved for the treatment of AML, has also shown high response rates in MDS. In MDS, venetoclax is given for only 14 days compared with 28 days to avoid severe cytopenias. Results of the phase 3 VERONA trial (NCT04401748) have now been presented in abstract form, and this trial did not meet its primary endpoint of OS with the addition of vernetoclax to azacitidine versus azacitidine alone.[191,192] Full reports are awaited, but this would suggest that venetoclax does not improve outcomes in MDS but may be effective in blast reduction for those who have a high burden of blasts and are transplant eligible. CPX-351, the liposomal preparation of daunorubicin and cytarabine, is being examined in MDS as well.

HMA monotherapy with azacitidine or decitabine or oral decitiabine/cedazuridine remains the standard of care for patients who have higher-risk MDS and are considered ineligible for allo-SCT.

KEY POINTS

- The important prognostic factors for patients who have MDS are percentage of marrow blasts, karyotype, number of peripheral blood cytopenias, and molecular mutations.
- The therapeutic strategy for MDS is based primarily on the disease risk, with the main goals of reducing consequences of cytopenias, improving quality of life for patients who have lower risk disease, preventing transformation into AML, and improving survival for patients who have higher risk disease.
- The 5q-minus subtype responds well to therapy with lenalidomide, and administration of lenalidomide early in the disease course can delay the onset of RBC transfusion dependence.
- Luspatercept can be used in low- and intermediate-risk transfusion-dependent patients who have MDS independent of erythropoietin level, either before or after a trial with an ESA. Imetelstat is also now approved for those MDS patients with low to intermediate-1 risk who are transfusion dependent and have not responded to ESAs.
- Allo-SCT is the only curative treatment for MDS.

MYELOPROLIFERATIVE NEOPLASMS

MPNs comprise a heterogeneous group of hematologic disorders currently recognized by the WHO: PV, ET, and primary MF; mastocytosis; myeloid or lymphoid neoplasms associated with eosinophilia; and myeloid neoplasms with clinical, laboratory, and morphologic features that overlap with MDS and MPN (Table 19-9). This section focuses on the classic MPNs: PV, ET, and primary MF.

Table 19-9 2022 WHO Classification of MPNs, Myeloid Neoplasms Associated With Eosinophilia, and MDS/MPNs

Neoplasm	Classification
MPN	Chronic myeloid leukemia
	Polycythemia vera
	Essential thrombocythemia
	Primary myelofibrosis
	Primary myelofibrosis, prefibrotic or early stage
	Primary myelofibrosis, overt fibrotic stage
	Chronic neutrophilic leukemia
	Chronic eosinophilic leukemia
	Juvenile myelomonocytic leukemia
	MPN, NOS
Mastocytosis	
Myeloid and lymphoid neoplasms associated with eosinophilia and tyrosine kinase gene fusions	*PDGFRA* rearrangement
	PDGFRB rearrangement
	FGFR1 rearrangement
	JAK2 rearrangement
	FLT3 rearrangement
	ETV6::ABL1 fusion
	Other defined tyrosine kinase fusions: *ETV6*::*FGFR2*, *ETV6*::*LYN*, *ETV6*::*NTRK3*, *RANBP2*::*ALK*, *BCR*::*RET*, *FGFR1OP*::*RET*
MDS/MPN	Chronic myelomonocytic leukemia
	MDS/MPN with neutrophilia
	MDS/MPN with *SF3B1* mutation and thrombocytosis
	MDS/MPN, NOS

Abbreviations: MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; NOS, not otherwise specified; WHO, World Health Organization.

PATHOGENESIS

MPNs are characterized by stem cell–derived clonal myeloproliferation that can evolve into AML or, in the case of PV or ET, into MF (secondary [after PV/ET] MF). Multiple recurrent somatic mutations have been identified in these disorders. Most prominent among these are the usually mutually exclusive mutations in *JAK2* (primarily in exon 14 [ie, V617F] and rarely in exon 12), calreticulin (*CALR*; primarily exon 9 deletions and insertions), and myeloproliferative leukemia virus oncogene (*MPL*; primarily exon 10 mutations). *JAK2* mutations are found in almost 100% of patients who have PV, 50% to 60% of patients who have ET, and 55% to 65% of patients who have primary MF. Generally, 20% to 25% of patients who have ET and primary MF harbor *CALR* mutations, whereas *MPL* mutations are present in 3% to 4% of patients who have ET and 6% to 7% of patients who have primary MF. Increasingly, characteristic differences (eg, age at diagnosis, blood cell counts, risk of thrombosis) are recognized among these three mutations. In approximately 10% to 15% of patients who have ET or primary MF, neither *JAK2*, *CALR*, nor *MPL* mutations are found (ie, triple-negative result).[193]

In addition to these three genes, mutations in many other genes such as *LNK*, *CBL*, *DNMT3A*, *TET2*, *IDH1/2*, *EZH2*, and *ASXL1* have been described in MPNs. Several of these mutations constitutively activate cell-signaling pathways and lead to a clonal growth advantage. Other mutations affect genes involved in epigenetic regulation and are believed to cooperate with the first class of mutations. Although activation of the JAK-STAT pathway is believed to be central for MPNs, the pathophysiologic role for many of the mutations found in these disorders has yet to be determined.[193] Similarly, it is not fully understood why a single

mutation such as *JAK2* V617F can result in different clinically distinct disorders, although differences in mutant allele burden, *STAT1* signaling, order of mutation acquisition, clonal heterogeneity, and microenvironmental background may play a role.[194]

In PV, there is increasing evidence that hepcidin, the inhibitor of the cellular iron exporter ferroportin, plays a role. Iron deficiency is common in PV and is related to increased use in the production of RBCs. This is supported by the fact that patients who have certain *HFE* genes that lead to hemochromatosis and increased iron absorption, with a reduction in hepcidin, have an increased incidence of PV.[195] These and other observations have led to studies examining the use of hepcidin mimetics in PV.

CLINICAL PRESENTATION AND DIAGNOSIS

Patients may have fatigue, constitutional symptoms (eg, fever, weight loss, night sweats), microvascular symptoms (eg, headaches, erythromelalgias), pruritus, bone pain, thromboses at unusual sites (eg, portal vein, hepatic vein), early satiety, and abdominal discomfort. Subsets of patients present with a thrombotic event or have a history of thrombosis.

On physical examination, palpable splenomegaly and/or hepatomegaly can be present, and evidence of extramedullary hematopoiesis at other sites may be found. Peripheral blood studies are notable for blood counts that exceed the upper limit of normal, and changes consistent with hypermetabolism, such as elevated serum levels of lactate dehydrogenase (LDH) and uric acid, often occur. Leuko-erythroblastic changes on peripheral blood smear are characteristic of MF or primary MF. Secondary causes for erythrocytosis and thrombocytosis must be excluded.

Mutational screening is helpful to demonstrate the presence of clonal hematopoiesis. For example, with *JAK2* mutation screening and a serum erythropoietin level (below normal in PV), essentially all patients who have PV will be identified. However, the presence of a mutation alone is not required for, nor is it proof of, a diagnosis of MPN. In many cases, it is important to rule out a BCR/ABL translocation.

A bone marrow examination is important for accurate diagnosis of an MPN, but may not be necessary at diagnosis in all cases of PV and ET. Characteristic findings enable the clinician to distinguish between PV (trilineage hematopoiesis with pleomorphic megakaryocytes), ET (megakaryocyte proliferation with large and mature morphology), and primary MF (megakaryocyte proliferation and atypia as well as reticulin and/or collagen fibrosis). Marrow findings also help identify prefibrotic primary MF (bone marrow morphology consistent with primary MF but without marked fibrosis) or masked PV (bone marrow morphology consistent with PV but with blood cell counts that do not meet the criteria for PV). Table 19-10 outlines WHO diagnostic criteria for PV, ET, and MF.

PROGNOSTIC FACTORS

The median life expectancy varies considerably among patients who have ET (20 years), PV (14 years), or primary MF (6 years) because of varying risks of thrombosis, bleeding, and clonal evolution. The risk of leukemic transformation is substantially lower for PV and ET (at 20 years, <10% for PV and <5% for ET) than for primary MF. Once leukemic transformation has occurred, median survival is less than 6 months with a 3-year survival estimate of <5%.[197] An increasing number of risk factors have been recognized for shorter survival in various MPNs.

Prognostic Factors for PV

Thromboembolic events are the major cause of morbidity and mortality in PV. In the large ECLAP study of patients who had PV, two variables, being older than 65 years and having a history of previous thrombosis, were the most powerful predictors of recurrent thrombosis.[198] Although patients younger than 65 years and without previous thrombosis had an annual thrombosis risk of 2.5%, patients who had either one of the risk factors had an annual thrombosis risk of 5%, and patients who had both risk factors had an annual thrombosis risk of 11%. In the recently published REVEAL observational study of 2,510 patients who have PV, an elevated WBC count was associated with initial thromboembolic occurrence in both low-risk and high-risk patients, and this association was also found when hematocrit was controlled.[199] A prospective, multicenter study called PROSPERO is underway to validate other variables that may be associated with thromboembolic risk in PV.[200]

Prognostic Factors for ET

In the International Prognostic Score of Thrombosis scoring system for ET, patients are assigned a total score based on the following four features[201]: age older than 60 years (1 point), history of thrombosis (2 points), presence of cardiovascular risk factors (hypertension, diabetes, active tobacco use; 1 point), and presence of the *JAK2* V617F mutation (2 points). Using this model, three thrombosis risk groups were identified with different incidences of thrombosis per year: low risk (total score 0 or 1), 1% per year incidence of thrombosis; intermediate risk (total score 2), 2.4% per year incidence of thrombosis; and high risk (total score > 2), 3.6% per year incidence of thrombosis.

Prognostic Factors for Primary MF

The prognosis in primary MF is influenced by certain clinical factors (including older age, constitutional symptoms, anemia, leukocytosis, thrombocytopenia, circulating blasts, degree of bone marrow fibrosis, and transfusion dependence), specific

Table 19-10 **2016 WHO Diagnostic Criteria for PV, ET, and PMF**[196]	
Diagnosis	**Criteria Required for Diagnosis**
PV	Elevated hemoglobin concentration (men, >16.5 g/dL; women, >16.0 g/dL) or increased hematocrit (men, 49%; women, 48%) or increased red cell mass
	BM biopsy showing BM hypercellularity, trilineage hematopoiesis with prominent erythroid, granulocytic, and megakaryocyte proliferation with pleomorphic, mature megakaryocytes
	JAK2 V617F or *JAK2* exon 12 mutation; if such a mutation is absent, diagnosis of PV is still possible if there is a subnormal erythropoietin level
	Minor criterion: subnormal serum erythropoietin level
	Diagnosis of PV requires meeting either all three major criteria, or the first two major criteria and the minor criterion[a]
ET	Persistently elevated platelet count (≥450 × 10^9/L)
	BM with predominant proliferation of enlarged, mature megakaryocytes with hyperlobulated nuclei
	Not meeting diagnostic criteria for classic CML, PV, PMF, MDS, or other myeloid neoplasms
	JAK2 V617, *CALR*, or *MPL* mutation
	Minor criterion: presence of another clonal marker; if no clonal marker is present, there is no evidence of reactive thrombocytosis
	Diagnosis of ET requires meeting all four major criteria or the first three major criteria and the minor criterion
PMF	Megakaryocyte proliferation and atypia. For pre-PMF: no reticulin fibrosis grade >1, BM hypercellularity, granulocytic proliferation, and often decreased erythropoiesis. For overt PMF: grade 2-3 reticulin and/or collagen fibrosis
	Not meeting diagnostic criteria for classic CML, PV, ET, MDS, or other myeloid neoplasms
	JAK2 V617, *CALR*, or *MPL* mutation or other clonal marker; if no clonal marker is present, there is no evidence of minor reactive BM reticulin fibrosis (for pre-PMF) or reactive myelofibrosis (for overt PMF)
	Minor criteria: (1) anemia, (2) leukocytosis ≥11 × 10^9/L, (3) palpable splenomegaly, (4) LDH elevation, or (5), leuko-erythroblastosis (for overt PMF only)
	Diagnosis of overt PMF requires meeting all three major criteria and at least one minor criterion

Abbreviations: BM, bone marrow; CML, chronic myeloid leukemia; ET, essential thrombocythemia; LDH, lactate dehydrogenase; MDS, myelodysplastic syndrome; MF, myelofibrosis; PMF, primary myelofibrosis; PV, polycythemia vera; WHO, World Health Organization.
[a]Criterion number 2 (BM biopsy) may not be required in patients with sustained absolute erythrocytosis: hemoglobin levels >18.5 g/dL in men (hematocrit, 55.5%) or >16.5 g/dL in women (hematocrit, 49.5%) if major criterion 3 and the minor criterion are present. However, initial MF (present in up to 20% of patients) can be detected only by performing a BM biopsy; this finding may predict a more rapid progression to overt MF (post-PV MF).

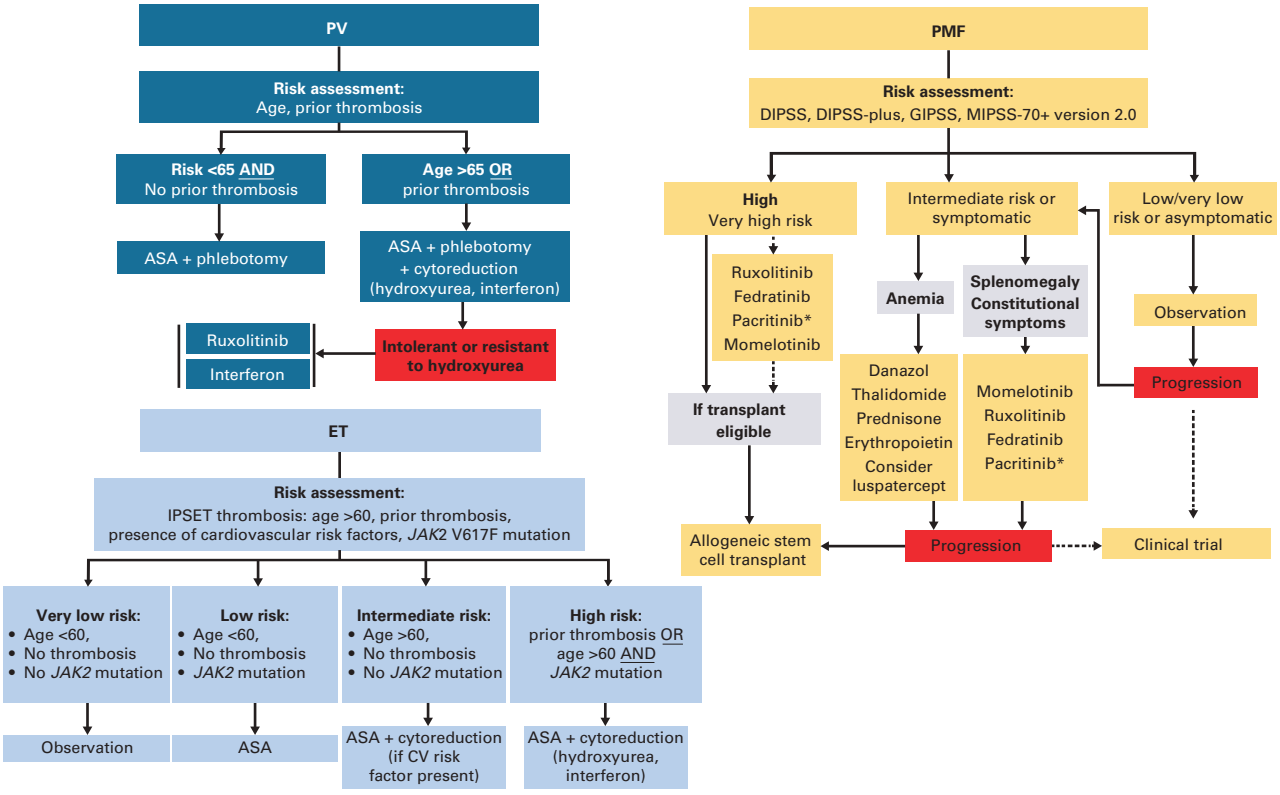
cytogenetic features, presence of driver mutations (*JAK2*, *CALR*, *MPL*), and certain high-risk molecular mutations (*ASXL1*, *SRSF2*, *U2AF1*, *EZH2*, *IDH1/2*).[202] Scoring systems are based on different combinations of these prognostic markers. The dynamic IPSS (DIPSS) is based on clinical information,[203] the DIPSS Plus is based on clinical and cytogenetic information,[204] and the mutation-enhanced IPSS and karyotype, MIPSS70 + v2.0, is based on clinical, cytogenetic, and mutational information.[205] The Genetically Inspired Prognostic Scoring System (GIPSS) is based on karyotype, absence of type 1–like *CALR* mutation, and the presence of *ASXL1*, *SRSF2*, or *U2AF1* mutations.[206] Karyotypic high-risk abnormalities include –7, inv(3), i(17q), and others, whereas +9, 20q–, and loss of the Y chromosome are some examples of favorable cytogenetics.[207] A prefibrotic early-stage MF has been defined, and in some patients, PV or ET transform to an MF state, so-called secondary MF, which can be prognosticated using the MySEC score or preferably the MIPSS70 + v2.0 score.[208]

TREATMENT

The general goals of therapy for MPNs are to alleviate symptoms, prevent thrombosis or bleeding, minimize the risk of progression to MF (for PV and ET), and, particularly in MF, reduce the risk of leukemic transformation and improve survival rates. Treatment is tailored on the basis of the individual patient's risk assessment for thrombosis and transformation into MF or AML (Fig. 19-5).

Figure 19-5 Treatment Algorithm for MPNs



Abbreviations: ASA, acetylsalicylic acid; CV, cardiovascular; DIPSS, Dynamic International Prognostic Scoring System; DIPSS Plus is based on clinical and cytogenetic information; ET, essential thrombocythemia; GIPSS, Genetically Inspired Prognostic Scoring System; IPSET, International Prognostic Score (of thrombosis) in Essential Thrombocythemia (IPSET-thrombosis); MIPSS70 + v2.0, mutation-enhanced IPSS plus karyotype is based on clinical, cytogenetic, and mutational information; MPN, myeloproliferative neoplasm; PMF, primary myelofibrosis; PV, polycythemia vera.

Therapy for PV

Patients aged 60 years or younger with no history of thrombosis are classified as low risk, whereas all others are considered high risk for a thrombotic event. Treatment for patients who have a lower risk is managed with aspirin and phlebotomy alone[209] to maintain a hematocrit target of less than 45%, but patients who have a higher risk are managed with additional cytoreductive therapy.[210] In the Cyto-PV trial, 365 patients who had PV were randomly assigned to more intensive treatment (target hematocrit, <45%) versus less intensive treatment (target hematocrit, 45%-50%). After a median follow-up of 31 months, more intensive therapy resulted in a decreased rate of cardiovascular mortality and major thrombotic events; such events were reported in 3% of the group that received more intensive treatment compared with 10% in the group that received less intensive therapy.[209] Attainment of a lower hematocrit value may be desirable in some cases, and treatment can be individualized (eg, <42% in female patients and those with progressive or residual vascular symptoms). For patients who have high-risk prognostic features and who require cytoreductive therapy, hydroxyurea is often used to lower the risk of thrombotic complications. Other reasons to consider cytoreductive therapy include symptomatic splenomegaly, constitutional symptoms, symptomatic thrombocytosis, leukocytosis, and poor compliance with or intolerance of phlebotomy.[210,211]

IFN offers an alternative to hydroxyurea as first-line cytoreductive therapy for patients who have PV, particularly for female patients who are considering becoming pregnant (teratogenicity can result from treatment with hydroxyurea). Two different formulations of IFN-α are available: pegylated IFN-α-2a and ropeginterferon-α-2b-njft. Pegylated IFN-α provides a more favorable toxicity profile than conventional IFN-α, and its prolonged activity is compatible with dosing once per week or dosing once every 2 weeks. A majority of patients treated with pegylated IFN-α-2a achieve a hematologic response with an ORR of 76.7% and a complete hematologic response rate of 48.5%.[212] In addition, pegylated IFN-α-2a has been shown to induce molecular responses with an overall molecular response rate of 54% and a complete molecular response rate of 14% shown in one study.[212] Typical adverse effects include fever, malaise, nausea, and vomiting; up to 35% of patients eventually

discontinue pegylated IFN-α therapy because of adverse effects. Ropeginterferon-α-2b-njft has an even longer duration of action and was approved by the FDA for the treatment of PV on the basis of results of the PROUD-PV/CONTINUATION-PV trial.[213] Patients were randomly assigned to receive ropeginterferon (subcutaneously once every 2 weeks) or hydroxyurea, and after 1 year, patients could opt to enter the extension part of the trial (CONTINUATION-PV). Although noninferiority to hydroxyurea was not demonstrated at the 12-month mark, response to ropeginterferon continued to increase over time, with improved responses compared with hydroxyurea at 36 months. In addition, the *JAK2* V617F variant allele fraction was decreased to a mean of 42.8% of the baseline value by month 36. In the ropeginterferon arm, there was an improvement in splenomegaly, microvascular disturbances, pruritus, and headache. After all patients on the study had been treated for 6 or more years, the EFS was significantly higher in the ropeginterferon-α-2b arm compared with the control arm. Reduction in *JAK2* V617F allele burden also continued to decrease, with 66% of ropeginterferon-α-2b patients still having 50% reduction in allele burden versus 19% in the control arm.[214,215]

Second-line treatments for individuals whose disease is resistant to or who cannot tolerate hydroxyurea include IFNs and the JAK inhibitor ruxolitinib. In the RESPONSE trial, 222 patients who had PV and were either resistant to or intolerant of hydroxyurea were randomly assigned to receive ruxolitinib (10 mg twice per day) or best available therapy.[216] Patients who received ruxolitinib showed improvement with a reduction in splenomegaly (38% vs 1%); there was also a reduction in the percentage of patients who required phlebotomy (20% vs 62%). An important limitation of this trial was the widespread use of hydroxyurea for patients assigned to best available therapy, even though documented resistance to or intolerance of this agent was an inclusion criterion for the trial. In older patients (age > approximately 75 years), oral busulfan can be used when other agents are ineffective or not tolerated. This is to be avoided in younger patients due to its leukemogenic potential.

In the phase 2 REVIVE study (NCT04057040), the hepcidin mimetic rusfertide (PTG-300) eliminated the need for phlebotomy in some patients and improved iron parameters and reduced constitutional symptoms that were a result of iron deficiency in nonerythroid compartments.[217] A phase 3 trial with this agent is underway, and preliminary results have been presented as plenary ASCO 2025 showing that 76.9% of patients on rusfertide versus 32.9% on placebo, no longer needed phlebotomy at 20 to 32 weeks[218] It is uncertain whether hepcidin modulators will have any effect on thromboembolic risk, which is intrinsic to the *JAK2* V617F mutation itself.[219]

Therapy for ET

For patients who have low-risk disease, aspirin is used to treat microvascular symptoms and may reduce the likelihood of vascular events in *JAK2*-mutated ET.[220] Younger patients who have a *CALR* or *MPL* mutation and triple-negative ET have relatively lower thromboembolic risks, and antiplatelet therapy may not affect the risk of thrombosis. If these patients are asymptomatic, their disease can be managed with observation alone. In patients who have high risk (age 60 years or older, history of vascular complications, or *JAK2* V617F mutation), hydroxyurea or IFN-α (for pregnant patients in whom hydroxyurea needs to be deferred) reduces the thrombotic risk.[220] In ET, the optimal platelet count is not known, but most treatments aim for a platelet count in the range of 400,000/mcL. Patients who have extreme thrombocytosis (eg, platelet count > 1,000,000/mcL) are not at a higher risk of thrombosis but instead might be at increased risk of hemorrhage, especially when treated with aspirin.[221] This increased risk of hemorrhage is because of the potential for development of von Willebrand syndrome as a result of the excessive adsorption of large von Willebrand multimers by platelets. Therefore, patients who have ET and extreme thrombocytosis should be screened for acquired von Willebrand syndrome, and if it is present, aspirin should be avoided, and cytoreduction should be administered to reduce the platelet count. Aspirin is relatively contraindicated if the ristocetin cofactor activity is <30%. In patients who are intolerant of hydroxyurea, anagrelide can be used; in younger patients, pegylated interferon can be used for platelet count and symptom control. IFN can cause flu-like symptoms, autoimmune disease, and psychological concerns after a long duration of therapy. Anagrelide may cause headache, fluid retention, and palpitations, and it has been suggested that it can lead to higher rates of myelofibrotic transformation.[222]

Therapy for Primary MF

Patients who have higher risk primary MF (DIPSS Plus, intermediate-2 and high risk; MIPSS70 + v2.0, high and very high risk) should be evaluated for allo-SCT; this is the only potentially curative option for primary MF. If the patient is not a candidate for allo-SCT, a JAK inhibitor can be used for symptom management or in those who are transplant eligible as a bridge to transplant. For patients who have lower risk primary MF (DIPSS Plus low and intermediate-1 risk; MIPSS70 + v2.0, very low, low, and intermediate risk), treatment decisions are guided by the nature and severity of symptoms, such as anemia, constitutional symptoms, and splenomegaly.[207] For those at low or intermediate-1 DIPSS Plus risk, observation or hydroxyurea (for constitutional symptoms or symptomatic splenomegaly) may be most appropriate. Androgens, prednisone, danazol, immunomodulatory agents (eg, thalidomide or lenalidomide), or splenectomy may be useful for symptomatic anemia, and some intermediate-1 patients may benefit from a JAK inhibitor, especially if they are not candidates for transplantation.[207]

Ruxolitinib is an inhibitor of *JAK2*, which is commonly mutated in primary MF, but its efficacy is independent of *JAK2* mutation status. The efficacy of ruxolitinib was demonstrated in two phase 3 trials, COMFORT-1 and COMFORT-2.[223,224] Ruxolitinib

significantly improved MF-related symptoms in up to half of patients and led to at least a 35% reduction in spleen volume in 28% to 42% of patients. There was also a trend in improvement in OS. However, ruxolitinib is not a specific inhibitor of the malignant clone, and it frequently results in myelosuppression, especially anemia and thrombocytopenia, as well as immunosuppression with risk of unusual infections. Ruxolitinib should not be discontinued abruptly, given that abrupt discontinuation can be associated with so-called ruxolitinib withdrawal symptoms that have potentially serious adverse effects, such as respiratory distress, shock, capillary leak, tumor lysis syndrome, splenic infarction, and/or disseminated intravascular coagulation. If ruxolitinib needs to be discontinued, it should be slowly tapered over a period of time.

Fedratinib, a JAK2-selective inhibitor, is also available for treatment of intermediate-2– or high-risk primary or secondary (post-ET, post-PV) MF. Fedratinib has been examined as both first-line (JAKARTA-1 trial)[225] and second-line (JAKARTA-2)[226] therapy for patients resistant to or intolerant of ruxolitinib. As first-line treatment, fedratinib was shown to achieve spleen volume reduction by at least 35% at week 24 in 36% of patients.[225] In patients who had MF and who were either resistant to or intolerant of ruxolitinib, a spleen response was seen in 30% of patients, and a reduction in symptoms was seen in 27%.[225,226] Wernicke encephalopathy was a rare and fatal complication of treatment. Thiamine levels should be checked before beginning treatment, and if Wernicke encephalopathy is suspected, treatment should be discontinued, and parenteral thiamine should be initiated instead. Hepatotoxicity can also be seen.

In February 2022, pacritinib received accelerated FDA approval for patients who have intermediate- or high-risk primary or secondary MF with severe thrombocytopenia (platelet count $<50 \times 10^9$/L). Pacritinib is a JAK2 and FLT3 inhibitor that also suppresses the IRAK-1 pathway but does not inhibit JAK1, resulting in less myelosuppression compared with ruxolitinib. The accelerated approval was based on results from the phase 3 PERSIST-2 study, which showed a reduction in spleen volume of at least 35% for 18% of patients treated with pacritinib versus 3% ($P < .001$) of patients who received the best available therapy, including ruxolitinib.[227] Pacritinib treatment also resulted in a statistically nonsignificant 25% reduction in total symptom score of 50% or more in the pacritinib arms versus 14% in the control group ($P = .08$). This approval of pacritinib is important because ruxolitinib is contraindicated for patients who have significant thrombocytopenia (<50,000/mcL).

In September 2023, momelotinib was approved for use in MF. It has erythropoiesis benefits because it inhibits activin A receptor type-1 (*ACVR1*) in addition to FLT3, Jak1, and Jak2. It decreases hepcidin production and mobilizes iron to improve erythroid production. It was examined in the phase 3 SIMPLIFY-1 trial in which it was compared with ruxolitinib in patients who had no previous exposure to JAK inhibitors. It was noninferior to ruxolitinib in spleen reduction potential, and it improved transfusion burden but not total symptom score.[210,228] In the phase 3 MOMENTUM trial, patients who had MF with DIPSS intermediate-1, intermediate-2, or high-risk prognostication scores were randomly assigned to momelotinib or danazol, and symptom relief, improvement in anemia, and spleen reduction were higher in the momelotinib arm.[23,209] Table 19-11 lists common adverse effects of the JAK inhibitors approved for treatment of MF.

Table 19-11 Major Adverse Effects of *JAK* Inhibitors Used in Myelofibrosis[196]

Drug	Adverse Effect
Ruxolitinib	Anemia and thrombocytopenia
	Herpes simplex and zoster reactivation (give recombinant vaccine before starting if possible)
	Tuberculosis reactivation
	Progressive multifocal leukoencephalopathy (rare)
	Reactivation of hepatitis B
	Nonmelanoma skin cancers
	Lymphoid neoplasms
	Withdrawal syndrome if stopped suddenly
	Hyperlipidemia and weight gain
Fedratinib	Diarrhea
	Liver function changes
	Wernicke encephalopathy (thiamine level should be tested before initiation)
Pacritinib	Anemia
	Thrombocytopenia (but less than with other *JAK2* inhibitors and approved in those with platelets $<50 \times 10^9$/L)
	Diarrhea
	Edema

Drug	Adverse Effect
Momelotinib	Anemia and thrombocytopenia, but less anemia and transfusion dependence with its use
	Abdominal pain
	Headache
	Neuropathy
	Asthenia
	A "first dose" effect with dizziness, hypotension, and flushing has been reported

In addition to the use of JAK inhibitors, treatments that address patient symptoms and anemia management are important in MF.[229] The MPN-Symptom Assessment Form Total Symptoms Score (MPN-SAF TSS) is an important tool for assessing symptom burden in MF; it is used in clinical trial response assessment and is a valuable tool in all patient encounters.[230] Anemia can be managed with erythropoietin, danazol, luspatercept, and transfusions when required. In certain situations, immunomodulatory drugs (IMiDs) such as thalidomide, lenalidomide, and pomalidomide have been used to treat anemia in MF.

Allo-SCT

Allo-SCT is the only curative treatment modality available for MF therapy.[231] Both myeloablative and reduced-intensity approaches are used, the former to decrease relapse and the latter to reduce toxicity. The NRM rate is high in MF at about 20% at 1 year in some series. In general, 5-year EFS and OS are about 50%. Transplantation is thought to have the most benefit for those with intermediate-2 or high risk according to the IPSS or DIPSS Plus. In lower-risk patients, benefit is not seen until after many years of follow-up. Use of alternative donors, including haplo-matched donors, is feasible, but controversy persists regarding optimal conditioning, minimizing non- or poor engraftment, and management of splenomegaly pretransplantation.[231] Post-transplant cyclophosphamide has been safely used. A recent retrospective study from the Center for International Blood and Marrow Transplant Research (CIBMTR) showed that fludarabine-busulfan–based conditioning resulted in reduced early NRM and better OS in the reduced intensity settings.[232] Ruxolitinib is commonly used to reduce spleen size before allografting.

Investigational Approaches to the Treatment of MPNS

Despite management with phlebotomy and acetylsalicylic acid (ASA), patients who have lower-risk PV still experience a higher-than-normal rate of thrombosis because they may not always have an optimally controlled hematocrit less than 45% between phlebotomy visits and can also develop symptomatic iron deficiency over time. In this context, the self-injectable hepcidin mimetic rusfertide is being evaluated as an alternative medical phlebotomy agent. Rusfertide has shown impressive early results with excellent hematocrit control without the need for phlebotomy as well as an increase in ferritin and mean corpuscular volume, which suggests a reversal of preexisting iron deficiency.[219,233]

Ropeginterferon α-2b is being assessed in patients who have ET. Ruxolitinib was examined in ET in a randomized study (MAJIC-ET), but when it was compared with the best available therapy (usually hydroxyurea), it did not result in better control of platelet counts but did reduce symptoms.[234]

Intensive efforts are ongoing to develop new classes of drugs for primary MF, such as the BET inhibitor pelabresib,[235] the BCL-XL/BCL-2 inhibitor navitoclax, the telomerase inhibitor imetelstat, the LSD1 inhibitor bomedemstat, XPO1 inhibitors such as selinexor, and the TGF-β ligand trap luspatercept for anemia improvement.[236,237] PI3Kδ inhibitors such as parsaclisib are also being examined compared with ruxolitinib.[238] Some of these agents are being used singly, and some in combination with ruxolitinib. Some have demonstrated a degree of fibrosis regression. For those patients with ET or MF who have calreticulin mutations, antibodies to calreticulin are the subject of clinical trials.

Summary of Treatment Recommendations Based on Risk Stratification in MF

Low Risk

Observation if asymptomatic.

If symptomatic,

- Ruxolitinib or other appropriate JAK2 inhibitor; switch to an alternate JAK2 inhibitor for lack of response or intolerance
- Peginterferon α-2a
- Clinical trial
- Hydroxyurea if the disease has a proliferative nature
- Consider and prepare for allo-SCT (HLA typing, watch for transfusion needs and indications of disease progression to AML), and in certain patients, begin this process early based on an adverse mutational profile

Intermediate-2 or High Risk (and Certain Intermediate-1 Cases)

- Allo-SCT if the patient is a suitable candidate
- JAK inhibitor
- Clinical trial (Fig. 19-5)

MDS/MPN OVERLAP SYNDROMES

MDS/MPN overlap syndromes are characterized by ineffective or dysplastic hematopoiesis of one or more myeloid lineages with concurrent proliferation (with or without dysplasia) of one or more myeloid lineages. In the 2022 WHO classification, there were several changes for MDS/MPN overlap syndromes.[1] The diagnostic criteria for chronic myelomonocytic leukemia underwent major revisions, including lowering the cutoff for absolute monocytosis to 0.5×10^9/L or greater and adopting myelodysplastic (WBC $<13 \times 10^9$/L) and myeloproliferative (WBC $\geq 13 \times 10^9$/L) subtypes. Atypical CML was renamed MDS/MPN with neutrophilia. MDS/MPN with ring sideroblasts and thrombocytosis was redefined on the basis of an *SF3B1* mutation and renamed MDS/MPN with *SF3B1* mutation and thrombocytosis. Patients' diseases that do not meet criteria for any of these diseases are classified as MDS/MPN unclassifiable. Clinically, these diseases can present with cytopenias in one or more lineages or as a proliferative disease accompanied by splenomegaly, hepatosplenomegaly, and/or extramedullary hematopoiesis (skin, lymph nodes, liver, gastrointestinal tract, or lungs). Patients who have MDS/MPN with ring sideroblasts and thrombocytosis may present with thromboembolism.

Chronic myelomonocytic leukemia is characterized by persistent monocytosis of 3 months or longer. The triad of *TET2*, *ASXL1*, and *SRSF2* mutations is highly specific for this disease.[239] *TET2* mutations often appear early in the course of the disease. Patients who have increased blasts and adverse prognostic factors (*ASXL1* mutation) respond to treatment with HMAs (ie, azacitidine and decitabine), which is similar to results with MDS. Hydroxyurea can be used for count control. Allo-SCT is the only potentially curative therapy available for this disease.

MDS/MPN with neutrophilia (formerly atypical CML) is rare and usually presents with high WBC counts. It has a high rate of transformation to AML, and survival in the absence of SCT is short. *SETBP1* mutations are found in 25% to 40% of patients.[240]

Patients who have MDS/MPN with *SF3B1* mutation and thrombocytosis (formerly MDS/MPN-RS-T) with ring sideroblasts and thrombocytosis have marrow ring sideroblasts of 15% or more and a persistently elevated platelet count ($\geq 450 \times 10^9$/L). Classic hotspot mutations in *SF3B1* are found in more than 80% of the patients. In addition, patients may also have mutations in *JAK2*, *CALR*, and *MPL*. The treatment is generally supportive with ESAs and transfusions. Low-dose aspirin may be administered to those patients who have *JAK2* mutations and increased cardiovascular risk. In select patients, JAK inhibition is sometimes used in combination with hypomethylating agents.

KEY POINTS

- The treatment of PV, ET, and primary MF is tailored to the likelihood of the development of venous or arterial thrombosis, bleeding, or evolution to AML, the major life-threatening and limiting complications of these MPNs. In PV and ET, cytoreductive therapy is reserved for the high-risk disease categories.
- In MF, treatment is also based on risk stratification, and multiple prognostic scoring systems are available. By using the risk levels from the MIPSS70 + v2.0 for categorizing patients, those in low-risk categories can enter a period of observation, and for patients in the high-risk categories, allo-SCT is recommended for those who are appropriate candidates. Those in intermediate-risk categories must be individualized but may benefit from JAK inhibitors and treatments to improve anemia. Transplantation is indicated for some of these patients.
- Multiple JAK inhibitors are now available for treatment of MF (ruxolitinib, fedratinib, pacritinib, and momelotinib), and they can be selected on the basis of their adverse effect profiles.
- There is increased awareness of the MPN/MDS overlap syndromes, and classification based on clinical and molecular characteristics continues to evolve, as evidenced by the changes in the 2022 WHO and ICC classifications.

BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a rare and aggressive hematopoietic neoplasm that originates from transformed plasmacytoid dendritic cells. It has a male predilection with a median age at presentation of 70 years. The disease most commonly presents with cutaneous tumors. Other sites of involvement are the spleen, bone marrow, lymph nodes, and extramedullary organs. Dual overexpression of IL-3 receptor subunit alpha (*IL3RA* or *CD123*) and *TCF4* occurs in almost all patients who have BPDCN.

The loss of multiple cell-cycle checkpoints leading to the altered G1/S transition seems to be important in the molecular pathogenesis of BPDCN. Loss-of-function mutations in *TET2* are the most commonly identified premalignant alterations in BPDCN and seem to confer resistance to UV-induced cell death in plasmacytoid dendritic cells.[241] The disease has a dismal

prognosis, with a median survival of less than 2 years without treatment. Younger age (younger than 60 years) and early allo-SCT predict superior outcomes.

Tagraxofusp-erzs, the first FDA-approved treatment of BPDCN, is a CD123-directed cytotoxin consisting of recombinant human IL-3 fused to a truncated diphtheria toxin. Given at the higher dosage of 12 mg/kg, the CR and clinical CR rate in previously untreated patients was 72% (95% CI, 53%-87%). The median time to response was 43 days (ORR, 90%). Of these patients, 45% underwent bridging treatment to allo-SCT while in complete remission. Among previously treated patients, the ORR was 67%; the median duration of response was 2.8 months, with a median time to response of 24 days.[242] Hypoalbuminemia, transaminitis, and thrombocytopenia are common adverse effects of this treatment. Tagraxofusp-erzs is also associated with capillary leak syndrome, with most cases occurring within the first cycle of treatment. Management of capillary leak syndrome includes close monitoring of volume status, necessitating aggressive intravenous fluid resuscitation or diuresis, glucocorticoids, and intravenous albumin. Other treatment strategies currently being explored in BPDCN include the combination of tagraxofusp-erzs with azacitidine and venetoclax or azacitidine plus venetoclax alone without tagraxofusp-erzs.[243]

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL occurs in children and adults with a peak incidence between ages 2 and 5 years, which declines into early adulthood and increases again with older age. Relative to childhood ALL, in which cure rates are greater than 80%, the prognosis for adult ALL is significantly worse, particularly in older individuals. Current 5-year survival rates are approximately 50% for adults but only 10% to 15% for older patients. Numerous population-based studies in multiple countries have demonstrated improvements in survival over time in all age groups except in patients older than 60 or 70 years. The improvement in survival has been attributed to the increasing use of pediatric-intensive regimens in young adults, improved risk stratification with MRD testing, improved supportive care, the advent of BCR-ABL1–targeting TKIs, and increased use of allo-SCT in middle-aged and older adults. The addition of the anti-CD20 antibody rituximab for $CD20^+$ B-cell ALL and, more recently, the addition of blinatumomab for B-cell ALL to first-line therapy are further improving survival.

PATHOGENESIS

ALL is a clonal disorder caused by genetic lesions in hematopoietic progenitor cells committed to differentiate along the B-cell or T-cell pathway. The precise sequence of events that leads to ALL is unknown, and only a minority of patients have genetic predispositions (eg, familial abnormalities in *RUNX1*, *ETV6*, *PAX5*, *IKZF*, *TP53*) or exposure to exogenous factors, such as radiation therapy or chemotherapeutic agents.

CLINICAL PRESENTATION

Patients typically present with signs and symptoms of myelosuppression-related anemia, neutropenia, and/or thrombocytopenia. Fatigue, dyspnea, and pallor are common presentations, as well as infection and bleeding. Bone pain and joint pain are commonly reported by younger patients and patients who have highly proliferative disease. Approximately 50% of patients who have ALL present with enlarged lymph nodes, hepatomegaly, and/or splenomegaly. Approximately 5% of patients have CNS involvement at diagnosis, which is associated with a worse prognosis. T-cell ALL is associated with male sex, a mediastinal mass, and disseminated lymph node involvement. Lymphoblastic lymphoma is biologically similar to ALL but lacks blood and marrow involvement. Lymphoblastic lymphoma is typically treated as ALL with or without the use of mediastinal radiation therapy for those with mediastinal masses.

DIAGNOSIS

ALL is diagnosed and categorized using morphology, immunohistochemistry, flow cytometry, cytogenetics (karyotype and FISH), and molecular features (Table 19-12).

Morphology and Immunohistochemistry

The leukemia cells in ALL are typically smaller than AML blasts and are devoid of granules and Auer rods. The French-American-British Cooperative Group developed a morphology-based classification, which, although once widely used, has largely been replaced by immunophenotyping and cytogenetic classification. ALL blasts are typically negative for myeloid and monocytic markers, such as MPO and nonspecific esterase.

Immunophenotype

A majority of ALLs have the precursor B-cell immunophenotype with expression of CD10, CD19, CD22, HLA-DR, and TDT.[244] Approximately 25% of patients have ALL with a T-cell phenotype. In 40% to 50% of adult patients, the leukemia expresses CD10 (the common ALL antigen). In approximately 10% of patients, B-cell ALL expresses cytoplasmic immunoglobulin but not surface immunoglobulin. A subset of B-cell ALL expresses CD20. In some studies, CD20 expression has been associated with a worse

Table 19-12 **Summary of WHO Classification of Lymphoid Leukemia**[196]	
	B-Lymphoblastic Leukemia/Lymphoma, NOS
B-lymphoblastic leukemia/lymphoma	B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
	B-lymphoblastic leukemia/lymphoma with t(9;22)(q34.1;q11.2); *BCR-ABL1*

outcome.[245] In 25% of patients who have ALL, a nondefinitive (ie, not MPO) myeloid antigen can be detected. As in AML, discordant combinations of antigens on leukemic blasts enable the detection of small numbers of abnormal blasts in a morphologically normal marrow using multiparameter flow cytometry. More sensitive methods for the detection of small numbers of ALL blasts involve the detection of clonally rearranged B-cell immunoglobulin genes or T-cell receptor genes by PCR or NGS.[246] PCR requires the development of individualized patient-specific probes. More recently, high-throughput NGS has been developed; it is as sensitive as PCR-based detection, but it is much less labor-intensive and more easily standardized. Unlike flow cytometry, molecular techniques require establishing the clone at diagnosis so it can be reliably followed later in therapy for the determination of MRD.

In 2% to 5% of acute leukemias, the definition of the disease as either myeloid or lymphoid is problematic because two or more distinct populations of cells exist in the same person (bilineage leukemias) or because a single population coexpresses definitive myeloid and lymphoid markers (biphenotypic leukemias). The current WHO classification combines these diseases into one diagnostic category called mixed-phenotype acute leukemia. Results of several studies suggest that patients who have this type of leukemia have a worse clinical outcome than those with either AML or ALL.[247]

Cytogenetic and Molecular Abnormalities

Cytogenetic and molecular characteristics have important prognostic significance in ALL.[248,249] In approximately 25% of patients, no cytogenetic abnormalities are found.[249] In approximately 10% of patients, an alteration in chromosome number is present without alteration in chromosome structure.[250] The most common translocation is the Ph-chromosome, seen in 20% to 30% of adults who have ALL. The Ph-chromosome results from a specific translocation, t(9;22)(q34.1;q11.2), which positions most of the *ABL1* proto-oncogene from chromosome 9 adjacent to the 5′ portion of the *BCR* gene on chromosome 22. The breakpoint on chromosome 9 is variable, whereas the breakpoints in the *BCR* gene on chromosome 22 occur within two regions: the major breakpoint cluster region (*M-bcr*) and the minor breakpoint cluster region (*m-bcr*). Rearrangements within the *M-bcr* region are transcribed into a chimeric messenger RNA that produces a hybrid 210-kd protein (p210 BCR-ABL1), whereas breaks within the *m-bcr* region express a chimeric messenger RNA that gives rise to a smaller 190-kd protein (p190 BCR-ABL1). In CML, virtually all breakpoints are mapped to the *M-bcr* region (p210 BCR-ABL1, known as CML-type Ph-chromosome). Conversely, in ALL, breakpoints are found within both the *M-bcr* and *m-bcr* regions, and those within the *m-bcr* region are called ALL-type Ph-chromosomes. The relative frequency of the two breakpoints in adult ALL has varied among studies, but overall, the two seem to be represented with equal frequency. Ph+ ALL with the CML type of *BCR-ABL1* translocation is not simply the lymphoid blast crisis phase of CML, although some cases of lymphoid blast crisis CML may mimic Ph+ ALL at diagnosis. Patients who have ALL rarely have a long prediagnostic prodrome and do not routinely have marked splenomegaly. However, an underlying CML could potentially be recognized in the patients who have p210-positive Ph+ ALL once the ALL is in remission after initial induction (ie, the lymphoblasts are no longer detected by flow cytometry, but a majority of the marrow cells still have evidence of BCR-ABL fusion by FISH or cytogenetics) or a patient develops CML after treatment of Ph+ ALL.

Another common poor-prognosis entity found in 20% to 25% of adolescents and adults is Ph-like B-cell ALL, which lacks the classic *BCR-ABL1* translocation but exhibits a gene expression profile similar to that of Ph+ ALL.[251] Kinase-activating genetic

rearrangements are characteristic of Ph-like ALL, including rearrangements of cytokine receptor–like factor 2 (*CRLF2*). *CRLF2* rearrangements are found in approximately 50% of all patients who have Ph-like ALL and are often associated with activating mutations in *JAK1/2*. In addition, ABL1/2 class fusions are seen in 10% of Ph-like ALLs. The presence of deletions or mutations in the transcription factor *IKAROS* (*IKZF1*), especially when combined with mutations in *CDKN2A*, *CDKN2B*, *PAX5*, or *PAR1* in the absence of *ERG* deletion (*IKZF1*$^{+}$), also confers a poor prognosis and is often seen in Ph+ and Ph-like ALLs.[252]

Another common translocation seen in adult B-cell ALL is t(4;11)(q21;q23), which is seen in 7% of B-cell ALLs. The translocation involves the *AF4* and *KMT2A* (formerly *MLL*) genes and is associated with a poor prognosis. Similarly, other translocations involving *KMT2A* may have a poor prognosis as well.

Disorders of chromosome copy number also have prognostic significance. Hyperdiploidy (51-65 chromosomes), especially with triploidy of chromosomes 4, 10, or 17, is a favorable risk and is much more common in children than adults. By contrast, hypodiploidy (<44 chromosomes) and near triploidy (56-78 chromosomes) have a poor prognosis and are highly associated with mutations in *TP53*.[253]

Other common cytogenetic changes seen in adult ALL involve del(9p) in 5% to 9% of patients, del(6q) in 5% to 7% of patients, del(13q) in 3% to 5% of patients, and t(1;19)(q23;p13) involving the *TCF3* and *PBX1* genes, which has an improved prognosis with current ALL therapy. T-cell ALLs often have translocations involving chromosome 7 or 14 at T-cell receptor enhancer gene sites.

An increasing number of genes in key signaling pathways (eg, regulation of lymphoid differentiation, tumor suppression and cell cycle, cytokine receptors, lymphoid signaling, epigenetic modification) are recognized to be recurrently mutated in ALL. Some of these are associated with prognosis. For example, alterations in the *IKAROS* gene family members confer a poor prognosis and are found selectively in different subtypes of high-risk ALL, such as Ph+ ALL or Ph-like ALL. *TP53* is commonly mutated in hypodiploid/near-triploid ALL. T-cell ALL is characterized by activating mutations in *NOTCH1* (seen in >50% of patients) and by rearrangement of transcription factors such as *TLX1* (also known as *HOX11*), *TLX3* (*HOX11L2*), *LYL1*, *TAL1*, and *KMT2A*.[254]

PROGNOSTIC FACTORS

Pretreatment Factors

Various pretreatment characteristics have been shown to affect CR rates and survival, including increasing age, elevated WBC counts, CNS involvement, obesity, and particularly cytogenetic and molecular abnormalities (Table 19-13).

Table 19-13 Prognostic Risk Factors in ALL

	Risk Factor
Pretreatment	Age

Based on such factors, investigators have segregated patients who have ALL into standard-risk and high-risk disease groups. Although the exact schemas have inconsistencies, 5-year DFS averages are approximately 55% for patients who have standard-risk and 25% for those who have high-risk disease. With modern therapy, other factors such as immunophenotypic characteristics of leukemic blasts (eg, expression of T-cell or myeloid antigens by ALL blasts), which previously were associated with a worse prognosis, have lost their independent prognostic importance.

Cytogenetic characteristics have important prognostic and therapeutic significance.[249] Between 15% and 20% of all patients who have ALL are Ph+ (5% in childhood and 20% to 30% in adulthood), with an incidence that increases with age and can be seen in 40% to 50% of patients older than 60 years. In studies conducted before the availability of imatinib, the likelihood of complete remission was lower for patients who had Ph+ ALL, and the probability of remaining in complete remission was much lower.

Studies designed to find evidence of *BCR-ABL1* rearrangement by quantitative reverse-transcription PCR or FISH have shown that up to 10% of patients who are Ph− or are inadequately assessed by karyotype analysis will have *BCR-ABL1* rearrangement. The prognosis for these patients is the same as that for patients who are Ph+ by karyotypic analysis. Therefore, FISH and quantitative reverse-transcription PCR for the *BCR-ABL1* fusion should be conducted at diagnosis for all patients who have B-cell ALL. Although Ph+ ALL had a poor prognosis when treated with conventional ALL therapy alone, the use of BCR-ABL1–targeted TKIs,

especially second- (dasatinib, nilotinib) and third-generation (ponatinib) agents, in combination with chemotherapy, immunotherapy, or allo-SCT, has dramatically improved the prognosis for patients who have Ph+ ALL.

The responsiveness of Ph-like ALL to TKIs remains undefined, although in vitro studies suggest a potential benefit to targeting ABL1/2 or the JAK/STAT pathway in this subset of B-cell ALL. Other cytogenetic abnormalities of adult ALL that carry a poor prognosis (in terms of both achieving complete remission and remaining in complete remission) include t(4;11) and other *KMT2A* rearrangements, *IgH* translocations, low hypodiploidy/near triploidy, and complex cytogenetics with five or more abnormalities. By contrast, adults with high hyperdiploidy or del(9p) seem to have a more favorable prognosis. A higher risk of relapse is independently associated with *KMT2A* gene rearrangement, focal *IKZF1* gene deletion, and *TP53* mutations in B-cell ALL and with the absence of *NOTCH1*/*FBXW7* mutation, *NRAS* or *KRAS* mutation, and/or *PTEN* gene alterations in T-cell ALL.[255,256]

Post-Treatment Factors

Depth of early response to chemotherapy is a primary determinant of outcome in ALL. Several studies have shown that rapid clearance of blasts from the peripheral blood and bone marrow and an early complete remission after the first chemotherapy course are associated with improved outcomes. For those experiencing complete remission, the presence or absence of detectable MRD is a powerful prognostic factor. Many studies have demonstrated that the presence of MRD after induction, after consolidation, or before SCT can identify patients at high risk of disease recurrence.[246] These studies have provided the rationale for exploring novel interventions to eliminate persistent MRD and overcome intrinsic chemotherapy resistance to optimize patient outcomes.

TREATMENT

Induction Chemotherapy

Induction therapy for ALL aims to eliminate detectable ALL, restore bone marrow function, reverse any ALL-related organ damage, and begin the process of curing patients by achieving an MRD-negative state. Standard induction therapy for adult ALL most commonly involves combination chemotherapy with a backbone of vincristine, prednisone, or dexamethasone and an anthracycline. L-asparaginase is an important component of pediatric and younger adult ALL therapy. Adult regimens sometimes add cyclophosphamide to induction. With such regimens, 80% to more than 90% of patients achieve CR to induction. There are several variations among regimens, but no prospective randomized trial has identified a clearly superior regimen. Older patients who have ALL have lower rates of CR and tolerate standard chemotherapy regimens poorly, and treatment-related mortality rates are high.[257] Dose reductions with omission of some chemotherapy agents have shown promise in reducing treatment-related mortality and maintaining efficacy, although long-term results are still poor. Investigators have recently exploited preclinical evidence of BCL-2 dependence of lymphoblasts to support the inclusion of the BCL-2 inhibitor venetoclax to dose-reduced multiagent chemotherapy in older patients who have B-cell or T-cell ALL. Results from the recent phase 1b/2 trial in patients who have newly diagnosed ALL and are older than age 60 demonstrated safety and a promising MRD-negative CR rate of 83%.[258] Chemotherapy-free regimens are also being explored for patients who have newly diagnosed ALL; there is a phase 2 trial of the CD22 antibody-drug conjugate inotuzumab induction, followed by CD19/CD3 T-cell engager blinatumomab consolidation that demonstrates a 97% cumulative CR rate after two courses of therapy.[259] A number of investigators have explored the use of hematopoietic growth factors immediately after induction chemotherapy. Similar to the findings for AML, the results of such studies demonstrate accelerated myeloid recovery and a decrease in the incidence of febrile neutropenia. In some trials, the CR rate was improved, but no findings have indicated an improvement in DFS or OS.[260] For younger adults (younger than 60 years) with CD20[1] Ph-negative B-cell ALL, adding the CD20 antibody rituximab to combination chemotherapy improves EFS when it is part of induction and post-remission therapy.[261] For Ph+ disease, the addition of a BCR-ABL1–targeted TKI to first-line therapy improves remission rates and long-term survival with or without allo-SCT.

Post-Remission Therapy

If no additional therapy is administered after complete remission, the duration of remission is invariably short. Post-remission therapy aims to prevent relapse and cure patients who have ALL in first complete remission. Common non–cross-resistant agents used in post-remission therapy include those used in induction as well as methotrexate, cytarabine, and mercaptopurine. Recent randomized data in children and young adults who have T-cell ALL treated with a pediatric regimen showed that the addition of nelarabine improved PFS and CNS relapse rates but did not improve OS.[262] Allo-SCT is considered for eligible patients to maximize the chance of cure and long-term survival for those who have ALL and are at high risk of relapse with chemotherapy alone, such as those with positive MRD or potentially poor-risk genetic findings. Post-remission therapy includes CNS prophylaxis with intrathecal chemotherapy; otherwise, CNS relapse of ALL will develop in at least 35% of adults. Patients who have a high tumor burden at diagnosis, as evidenced by a high WBC count and elevated LDH levels, are at the highest risk. With CNS prophylaxis, the incidence of CNS relapse as an isolated event is approximately 5%. Post-remission regimens differ but generally include several cycles of intensive consolidation therapy administered over several months after achievement of complete remission, delayed intensification using a combination similar to induction therapy in some regimens, and less intensive maintenance therapy

(eg, mercaptopurine, vincristine, methotrexate, prednisone) administered for 2 to 3 years. The phase 3 ECOG1910 study randomly assigned adults who had Ph–B-cell ALL in first MRD-negative complete remission to receive a standard multiagent chemotherapy regimen or the same regimen with the CD19-CD3 bifunctional T-cell engager blinatumomab. MRD-negative patients receiving blinatumomab had superior OS and RFS compared with the control arm, which justifies the addition of blinatumomab to post-remission therapy as an FDA-approved new standard of care.[24]

Some data from randomized pediatric studies indicate that modifying post-remission treatment intensity on the basis of MRD status can optimize treatment outcomes.[263-265] In addition, the use of allo-SCT has been shown to improve outcomes of patients who are MRD positive in first complete remission.[266] No single optimal regimen for CNS prophylaxis, consolidation therapy, and maintenance has been identified. More intensive regimens, such as those used in pediatric ALL, are tolerable and may improve outcomes in adolescent and young adult ALL (patients younger than age 40), although randomized studies have not been conducted. One study suggested that patients aged 55 years or younger can also be considered for an intensive pediatric regimen if they are fit and are treated by experienced physicians; otherwise, the regimen was poorly tolerated with poor short- and long-term outcomes.[267] With current regimens, approximately 40% of adult patients who have ALL will remain alive and disease-free at 5 years after diagnosis. With pediatric-inspired therapies, studies have shown 5-year survival rates of 67% to 78% in adolescents and younger adults. For older patients who have ALL, the use of less-intensive regimens is appropriate to reduce therapy-related morbidity and mortality. Given the poor outcomes in older patients, enrollment in clinical trials of novel therapies is especially appropriate.

Treatment of Persistent or Recurrent Disease

Persistent ALL MRD after induction portends a high risk of relapse that can be overcome by myeloablative allo-SCT. For patients whose MRD does not clear with successive rounds of chemotherapy or recurs, blinatumomab is an FDA-approved agent to treat MRD. In adults who have B-cell ALL who were MRD positive after three or more cycles of chemotherapy, treatment with blinatumomab converted 78% of patients to MRD negativity. Patients who were MRD responders had improved RFS and OS compared with MRD nonresponders.[268]

Patients whose disease does not go into complete remission or subsequently relapses after complete remission have dismal outcomes with long-term survival at 5 years of less than 10%. Therefore, the current strategy is to achieve a second complete remission and then to proceed with allo-SCT. A variety of chemotherapeutic agents have been used in combinations similar to those used during first-line therapy, such as vincristine, corticosteroids, anthracyclines, L-asparaginase, methotrexate, and high-dose cytarabine. Newer purine analog drugs for relapsed/refractory ALL include clofarabine and nelarabine, the latter of which can achieve complete remission rates of 30% or higher in patients who have recurrent T-cell ALL, but it can have significant neurotoxic effects. In addition, dysregulation of BCL-2 family members has been reported in ALL, leading to evidence for the promising preclinical activity of the BCL-2 inhibitor venetoclax in ALL. Venetoclax combined with low-intensity chemotherapy in a phase 2 study of relapsed/refractory Ph– ALL was shown to be well tolerated and yielded a composite complete remission rate of 57%.[269]

Newer targeted therapies have dramatically improved response rates in patients who have relapsed/refractory B-cell ALL and are now considered standard of care for most of them. Blinatumomab, a bispecific T-cell–engaging antibody that targets CD19 and CD3 in a single molecule, targets the patient's T cells to CD19-expressing cells, specifically, the malignant and normal B cells. Blinatumomab has been approved by the FDA as a treatment for relapsed/refractory Ph– B-cell ALL and for MRD eradication for B-cell ALL in first or second complete remission. A randomized phase 3 study reported an improved complete remission rate (44% vs 25%; $P < .001$) and improved median OS (7.7 vs 4.0 months) with blinatumomab compared with standard-of-care chemotherapy in adults who have relapsed/refractory B-cell ALL.[270] Notably, inferior response was seen in patients who have high bone marrow blast percentages at relapse. Unique toxicities of blinatumomab include neurologic events and, uncommonly, cytokine release syndrome.

A randomized phase 3 study of the anti-CD22 antibody-drug conjugate inotuzumab ozogamicin demonstrated higher CR rates (80% vs 30%) and longer PFS and OS compared with standard-of-care chemotherapy in adults who have relapsed/refractory B-cell ALL. Inotuzumab ozogamicin is associated with myelosuppression and hepatic sinusoidal obstruction syndrome (veno-occlusive disease) in approximately 10% of patients, mostly occurring among complete responders who went on to undergo allo-SCT using double-alkylator conditioning regimens.[271]

CR rates of 70% to 90% have been reported with adoptive cellular immunotherapy using autologous T cells that express CARs that recognize CD19 in pediatric and adult patients who have B-cell ALL, even after allo-SCT has failed (Fig. 19-6). Tisagenlecleucel is approved by the FDA as a treatment of B-cell ALL in patients aged 25 years or younger with refractory disease or at least two relapses.[272] Brexucabtagene autoleucel was approved for all adults who have relapsed/refractory B-cell ALL based on the data from a phase 2 study showing a complete remission/complete remission with incomplete recovery rate of 71% and a median duration of response of 12.8 months, which led to FDA approval of the drug in 2021.[25,273] More recently, another CD19-directed CAR T-cell therapy, obecabtagene autoleucel, was approved for adults with relapsed or refractory B-cell precursor ALL.[25] Cytokine release syndrome and neurologic toxicity are two key and common toxicities of cell therapy with T cells that express

CARs, which, at times, can be fatal. Cytokine release syndrome typically is managed successfully with anti–IL-6 antibody therapy (tocilizumab) and sometimes corticosteroids.

Allo-SCT

Allo-SCT is an important post-remission treatment of ALL, but its curative potential must be balanced against transplantation-related morbidity and mortality, late complications, and associated reductions in quality of life. An evidence-based review of available trials led an expert panel to recommend the consideration of myeloablative allo-SCT for adults younger than 35 years with ALL in first complete remission after multiagent chemotherapy for all disease risk groups because of superior outcomes with regard to post-remission chemotherapy.[256] Currently, most ALL experts recommend reserving allo-SCT in first complete remission for those at high risk of relapse, especially those with MRD positivity after intensive induction. Comparative studies have not demonstrated a benefit from allo-SCT in patients achieving an early MRD-negative first complete remission.[266] In addition, allo-SCT has not yet been compared prospectively with pediatric-inspired chemotherapy regimens typically now used in younger adult patients who have ALL. Retrospective analyses find that this chemotherapy approach yields survival outcomes superior to those of allo-SCT because of lower nonrelapse-associated mortality rates and no increased risk of relapse.[274] With increasing age, the survival advantage of allo-SCT diminishes because of increased rates of nonrelapse-associated mortality. In the absence of a suitable HLA-matched related or unrelated donor, a haploidentical or cord blood donor can be considered as a stem cell source.[275] Conditioning that includes total body irradiation has consistently been shown to yield optimal outcomes in ALL.

For patients in second or later complete remission, allo-SCT is recommended versus chemotherapy alone if the patient did not receive a transplant in first remission. Myeloablative total body irradiation–based conditioning is generally preferred; there is limited data suggesting that reduced-intensity conditioning may produce reasonable outcomes in patients unfit for myeloablative regimens. Not surprisingly, the outcomes with SCT depend largely on the disease status of the patient. If allo-SCTs are performed during the first complete remission, long-term survival rates range from approximately 40% to 60%. If such transplantations are performed in patients who have disease resistant to conventional chemotherapy, long-term survival can be obtained in only 15% to 25% of patients.[276]

Efforts have been undertaken to use a risk-adapted approach to allo-SCT to spare patients from transplantation-related toxicities by allocating them to undergo chemotherapy if chemotherapy sensitivity was documented (eg, confirmed MRD-negative status after induction chemotherapy).[266,277] Conversely, MRD persistence after induction and/or consolidation signals a high risk

of relapse. MRD at the time of transplantation also indicates a higher risk of relapse, but outcomes are likely better than with chemotherapy alone. A recent study reported that, for patients who were MRD-positive after chemotherapy, treatment with blinatumomab converted 78% to MRD negativity, and patients who were MRD responders had improved RFS and OS compared with MRD nonresponders.[268] Based on this study, the FDA granted accelerated approval for the use of blinatumomab in late March 2018 to treat adults and children with B-cell precursor ALL who are in remission but still have MRD.

SPECIAL TYPES OF ADULT ALL

Ph+ ALL

As noted, ALL associated with t(9;22) translocations or BCR-ABL1 fusion has a poor prognosis when treated with conventional chemotherapy. However, the disease is sensitive to TKIs, such as imatinib, dasatinib, nilotinib, or ponatinib. When combined with induction chemotherapy or with corticosteroids alone, CR rates are 90% to 100%, and OS seems to be improved, especially with later-generation TKIs. In younger adults, less intensive chemotherapy combined with imatinib over the entire induction period is as effective as and less toxic than a more intensive regimen with imatinib administered only over the first 2 weeks.[278]

The role of allo-SCT, although it is a curative option particularly for younger adults, may be changing because the degree of improvement in outcome over TKI-containing combination chemotherapy is unclear, especially with regimens using ponatinib.[279,280] One retrospective study of patients who have Ph+ ALL in first molecular remission after chemotherapy with a TKI suggests that ASCT, although associated with substantially higher post-transplantation relapse risk, may yield similar survival outcomes for matched-sibling and unrelated-donor allo-SCTs.[281] If an MRD-negative remission is achieved early in Ph+ ALL, chemotherapy combined with a TKI may provide an alternative treatment strategy, particularly if patients are believed to be at high risk of death resulting from SCT.[282] Therapy with dasatinib and prednisone alone results in CRs in more than 90% of older patients who have Ph+ ALL without the need for concomitant chemotherapy, but disease in most patients ultimately relapses with the development of a *T315I* mutation in BCR-ABL1 being a major mechanism of resistance.

An exciting development in the treatment of Ph+ ALL has been the use of a BCR-ABL1–directed TKI in combination with blinatumomab to minimize the use of chemotherapy and minimize or eliminate treatment-related mortality and morbidity. In a phase 2 study of blinatumomab combined with dasatinib in 63 patients, a CR rate of 98% was achieved with a molecular response of 60% and an OS rate of 95% at a median follow-up of 18 months.[283] Recently, long-term follow-up was reported for this trial (D-ALBA trial), and with a median follow-up of 53 months, the OS was 80.7%.[26] Similar results have been reported from the SWOG 1318 phase 1/2 study.[284] In both studies, the *T315I* resistance mutation (which is sensitive to ponatinib) was commonly present at relapse. The single-center study of ponatinib and blinatumomab in adults who have newly diagnosed Ph+ ALL reported an MRD rate of 98% by next-generation clono-sequencing at a median follow-up of 24 months, and a 3-year OS of 91% and 3.[27] A randomized trial of chemotherapy plus dasatinib-ponatinib versus blinatumomab and dasatinib-ponatinib is currently enrolling in the United States (ECOG-ACRIN EA9181 study; NCT 04530565). Recently, based on data from the phase 3 PhALLCON trial of combination chemotherapy with ponatinib versus imatinib that demonstrated a median EFS that was not reached after 20 months of follow-up in the ponatinib arm, ponatinib was approved by the FDA for use in combination with chemotherapy in newly diagnosed Ph+ ALL.[285] Concerns remain about the long-term vascular toxicity associated with ponatinib reported from nonrandomized studies, although this may be ameliorated with planned dosage reductions.[279,280] Dasatinib has been explored in combination with STAMP inhibitor, asciminib, and prednisone in a phase I trial of Ph+ ALL, leading to 100% of patients achieving complete cytogenetic remission. Based on this data, dasatinib plus asciminib is an option for use in relapsed/refractory Ph+ ALL per NCCN guidelines.[286]

KEY POINTS

- Induction therapy for adult ALL generally should include vincristine, prednisone, and an anthracycline with or without L-asparaginase or cyclophosphamide. With such regimens, complete remission can be achieved in 80% to 90% of patients. Consideration of a pediatric-inspired regimen should be given for all patients aged 40 years or younger and possibly in select patients aged 55 years or younger.
- Patients who have CD20+ B-cell ALL should receive rituximab during induction and consolidation.
- Patients who have Ph+ ALL should receive a BCR-ABL1–directed TKI in combination with chemotherapy or blinatumomab.
- Recently, ponatinib was an FDA-approved agent in combination with chemotherapy for newly diagnosed Ph+ ALL.
- Blinatumomab can convert up to 80% of MRD-positive patients who have B-cell ALL and are in remission to an MRD-negative state and also improves outcomes.
- Allo-SCT is an important post-remission treatment except perhaps in patients who have highly chemotherapy-sensitive disease, as indicated by early MRD negativity.
- Salvage treatment options for patients who have relapsed/refractory B-cell ALL include blinatumomab, inotuzumab ozogamicin, and CAR T-cell therapy (tisagenlecleucel, brexucabtagene autoleucel, and obecabtagene autoleucel).
- Given the rarity of ALL and the complexity of its treatment, it is generally recommended that patients who have ALL be treated at high-volume centers (>10 new cases managed per year) with access to clinical trials, cell therapies, and SCT.

CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is the most prevalent adult leukemia in Western countries. The disease is more common in men than women (ratio, 1.7:1) with a steeply climbing age-related incidence beginning after approximately age 40 years and peaking in the decade between ages 65 and 74 years. The incidence is higher in Jewish people of Russian or Eastern European ancestry and is rare in Asian countries. There are no known risk factors for CLL. It is one of the few leukemias that does not seem to be associated with exposure to ionizing radiation, chemicals, or drugs. However, a strong inherited component is well recognized, and genome-wide association studies have identified more than 40 susceptibility loci.[287]

CLINICAL PRESENTATION

Most patients who have CLL are asymptomatic at diagnosis, which is often made incidentally when lymphocytosis is noted during a routine evaluation. The findings on physical examination are normal for 20% to 30% of patients, whereas lymphadenopathy, hepatosplenomegaly, or both are observed in 40% to 50% of patients. However, as the disease progresses, generalized lymphadenopathy and splenomegaly become common features. Involvement of other organs and systemic symptoms such as fever and unexplained weight loss are unusual and should suggest the possibility of transformation (ie, Richter syndrome [see Aggressive Transformation (Richter Syndrome) section]) (Table 19-14).

Table 19-14 Clinical Features and Associations With CLL

Infections
Hypogammaglobulinemia
Reduced levels of complement
Impaired phagocytic killing of nonopsonized bacteria
Functional impairment of T-cell subsets
Autoimmunity
Autoimmune hemolytic anemia
Immune thrombocytopenia
Pure red cell aplasia
Aggressive transformation
Richter transformation
Secondary malignant disease
Skin cancers (including melanomas)
Colon cancers
Lung cancers
Myeloid neoplasms

Infections

Increased susceptibility to infection reflects quantitative and qualitative defects seen within the innate and adaptive immune response (eg, hypogammaglobulinemia, reduced levels of complement, impaired phagocytic killing of nonopsonized bacteria, reduction in or functional impairment of T-cell subsets) that worsen with disease progression.[288] Historically, the most common pathogens have been those that require opsonization to kill bacteria, such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae.* The use of immunosuppressive agents such as fludarabine, cladribine, pentostatin, and alemtuzumab to treat CLL markedly increases the number of infections by opportunistic organisms, such as *Candida* species, *Listeria*, *Pneumocystis jirovecii*, cytomegalovirus, *Aspergillus*, and herpes viruses. The prophylactic use of intravenous immunoglobulins or antimicrobial agents should be reserved for select patients who have documented repeated infections and a reduction in serum IgG levels. The use of prophylaxis for *P. jirovecii* pneumonia (PJP) or antiviral prophylaxis should be considered in patients at risk for these opportunistic infections. Live vaccines should be avoided in patients who have CLL; influenza vaccines, COVID-19 vaccinations, and zoster vaccine recombinant, adjuvanted, for those receiving Bruton tyrosine kinase inhibitors (BTKis) are recommended. It is anticipated that infection risk will diminish as the treatment of CLL continues to move away from adenosine deaminase inhibitors and steroids to more targeted therapies.

Autoimmunity

Autoimmune hemolytic anemia is noted in 10% to 15% of patients who have CLL and has been associated with fludarabine monotherapy.[289] Many additional patients have a positive direct antiglobulin test (direct Coombs) but no clinical evidence of hemolysis. The frequency of immune thrombocytopenia is approximately 2% to 15%. In most cases, antiplatelet antibodies are polyclonal and are not a product of the malignant B cells. Autoimmune anemia or thrombocytopenia generally responds to corticosteroids such as prednisone at 1 mg/kg once per day, which may be tapered after 1 or 2 weeks with evidence of response. Patients who have immune thrombocytopenia who do not experience a response to corticosteroids may respond to high-dose intravenous immunoglobulins. Rituximab and alternative immunosuppressants may also be used for patients who do not respond to steroids. CLL-associated immune thrombocytopenia may respond to thrombopoietin receptor agonists, such as romiplostim and eltrombopag. Splenectomy may be considered when systemic approaches fail. BTKis may also be of benefit when hemolysis is refractory to steroids or recurs after steroid use.

Pure Red Cell Aplasia

Pure red cell aplasia is uncommon in CLL (<1% of patient cases).[289] It is characterized by normochromic and normocytic anemia with an absolute reticulocyte count of <10,000/mL and an absence or near absence of erythroblasts in the marrow. WBC count, WBC differential count, and platelet counts are generally normal. Immunosuppressants, such as corticosteroids, as well as cyclosporine and rituximab, may be effective.

Aggressive Transformation (Richter Syndrome)

Annually, in approximately 0.5% of patients who have CLL, the disease will evolve into a more aggressive lymphoid malignant process termed Richter syndrome that characteristically presents with rapidly increasing lymphadenopathy, hepatosplenomegaly, fever, abdominal pain, weight loss, progressive anemia, and thrombocytopenia, often with an increased serum LDH level.[290]

This transformation is not clearly related to either the nature or extent of previous therapy. The WHO classification recognizes two distinct pathologic variants of Richter syndrome, namely, the diffuse large B-cell lymphoma (DLBCL) variant and the Hodgkin lymphoma (HL) variant. This is now classified under "high-grade transformation of indolent B-cell lymphomas." Molecular lesions in tumor suppression (*TP53*), cell cycle (*CDKN2A*), and cell proliferation (*NOTCH1*, *MYC*) genes are found in approximately 90% of patients who have Richter syndrome tumors. Approximately 80% of the variants (and 40% to 50% of the HL variants) are definitively clonally related to the preceding CLL phase. In the other patients, analyses of immunoglobulin heavy-chain variable domain (*IGHV*)-D-J genes show different rearrangements compared with the underlying CLL, likely indicating de novo lymphoma arising in a patient who has CLL. The prognosis of the DLBCL variant is usually unfavorable but not uniform, with outcomes being better in patients who have clonally unrelated Richter syndrome or in those with unmutated *TP53* who have not required treatment of CLL.[290] Outcomes with the HL variant of Richter syndrome are better than with the DLBCL variant but not as good as with de novo HL.[290,291] CLL may also have prolymphocytic progression, which is associated with progressive anemia and thrombocytopenia with 15% or more prolymphocytes in the peripheral blood and/or bone marrow. Clinical features include lymphadenopathy, hepatosplenomegaly, wasting syndrome, and increased resistance to therapy. This entity is no longer recognized in the WHO classification, 5th edition, because of heterogeneity. When this progression occurs in CLL, cells retain CD5 but do not express *IGH-CCND1* as would be seen in a prolymphocytic mantle cell variant.[2]

Secondary Malignant Diseases

Secondary malignant diseases occur with increased frequency in patients who have CLL, which are related to the immune defects of the disease and to the consequences of therapy. The most frequent tumors are skin cancers (including melanomas), colon cancers, lung cancers, and myeloid neoplasms.

DIAGNOSIS

Morphology

The diagnosis of CLL requires a sustained increase in mature-appearing B lymphocytes in the peripheral blood to more than 5,000/mm^3.[292] The presence of fewer clonal B cells without palpable lymphadenopathy in an asymptomatic individual is called monoclonal B lymphocytosis. In CLL, it is not unusual to find a small percentage of larger atypical cells, cleaved cells, or prolymphocytes. The bone marrow is usually infiltrated by at least 30% lymphocytes. Although a bone marrow aspirate and biopsy specimen are not needed to make the diagnosis, they can be useful in evaluating the etiology of cytopenias. Neither lymph node biopsy nor CT scanning is needed in the initial evaluation and should be performed only if clinically indicated, such as for suspicion of Richter syndrome.

Immunophenotype

The predominant CLL cell population expresses B-cell markers (CD19, CD20, and CD23) and CD5 but not other pan–T-cell markers. The B cells are monoclonal as evidenced by the presence of either κ or λ restricted light chains, and they characteristically express surface immunoglobulin, CD79b, CD22, and CD20 with low density (as opposed to mantle cell lymphoma, which usually

has higher expression of CD20 and surface immunoglobulin). Distinguishing CLL from mantle cell lymphoma is essential because both express CD5. CD23 is often helpful (often negative in mantle cell lymphoma), but the absence of cyclin D1 expression is critical for differentiation of CLL from mantle cell lymphoma.

Cytogenetic and Molecular Abnormalities

Conventional metaphase chromosome banding techniques and FISH detect cytogenetic abnormalities in more than 50% and more than 80% of patients who have CLL, respectively.[293] The most common abnormality, either alone or in combination with other abnormalities, is del(13q), which occurs in 55% of patients. The disease course is more benign for patients who have 13q14 abnormalities, and such patients often have a normal lifespan. The del(11q) abnormality is identified in 15% to 20% of patients and is associated with massive lymphadenopathy, often out of proportion to the increase in the peripheral blood lymphocyte count. Trisomy 12 can be detected in 15% to 20% of patients. Structural abnormalities of chromosome 17 occur in approximately 15% of patients when FISH testing is performed. The del(17p13) abnormality leads to loss of the *TP53* gene and is found more frequently in cases of atypical CLL that are associated with a higher likelihood of Richter transformation, more prolymphocytes, advanced stage, resistance to chemotherapy, and a poor prognosis with conventional chemoimmunotherapy. More than one-third of patients who have *TP53* loss have complex cytogenetic abnormalities (Table 19-15).

Table 19-15 Cytogenetic and Molecular Abnormalities of CLL

Deletion of 13q14
Deletion of 11q
Trisomy 12
Abnormalities of chromosome 17 (del(17p) with *TP53* gene disruption)
BCL2 gene overexpression
IgH variable domain mutations
ZAP70
Recurrent mutations involving *TP53*, *NOTCH1*, *SF3B1*, and *BIRC3*

Abbreviation: CLL, chronic lymphocytic leukemia.

Translocations involving *BCL-2* [t(14;18)(q32;q21)] and *BCL-3* [t(14;19)(q32;q13.1)] have been detected in only 5% to 10% of patients, but overexpression of the *BCL-2* gene is present in more than 70% of patients. The expression ratio of the antiapoptotic gene *BCL-2* to the proapoptotic gene *BAX* is increased in CLL cells, supporting the concept that CLL is more a disorder of prolonged cell survival than a hyperproliferative disease, although both factors probably contribute.

Lymphocytes from approximately half of patients who have CLL are thought to develop from naive B cells and have unmutated *IGHV*; the other half contain mutated *IGHV*, indicating their CLL cells derive from post-germinal-center B cells. *IGHV* mutation status does not change over the course of the disease. These two subtypes are characterized by markedly different clinical outcomes, and survival is significantly shorter for the group with unmutated *IGHV*. Other unfavorable molecular prognostic markers, such as positive ZAP-70, positive CD38 expression, del(17p), and del(11q), are also more commonly found in patients who have unmutated *IGHV* than in those with mutated *IGHV*. Sequencing technologies have identified recurrent mutations in CLL involving *TP53*, *NOTCH1*, *SF3B1*, and *BIRC3z*,[294] and are used for risk prognostication. Among the many mutations identified in CLL, *TP53* mutation is an inferior prognostic and predictive marker, as shown in multiple studies demonstrating inferior PFS and OS in this molecular subgroup after conventional chemoimmunotherapy. Because the presence of a *TP53* mutation influences treatment decisions, testing for *TP53* mutation before treatment, alongside FISH analysis and *IGHV* mutation status, is recommended. Cytogenetic and molecular markers in CLL can change over time, requiring reassessment if the tempo of disease seems to be changing and new treatment interventions are required.

PROGNOSTIC FACTORS

Several characteristics can stratify patients who have CLL into groups according to different clinical outcomes that may require different therapeutic approaches. The five-stage Rai classification[295] is most commonly used in the United States, and the three-stage Binet system[296] is most often applied in Europe (Tables 19-16 and 19-17). The major difference between the two systems is that Rai stages 0 and I are mostly combined into Binet stage A, and Rai stages III and IV are combined into Binet stage C. Numerous cytogenetic and molecular markers have been found to have prognostic value. An internationally applicable prognostic index has been developed that is based on five independent prognostic factors: age, clinical stage, del(17p) and/or *TP53* mutation, unmutated *IGHV*, and β2-microglobulin level. This allows separation of patients into four different prognostic groups with substantially different 5-year OS.[297] More recently, an international prognostic score for patients who have asymptomatic

early-stage CLL was developed to predict time to first treatment. It relied on individual patient data from 11 international cohorts (a total of 4,933 patients) to build and validate the score with three covariates—unmutated *IGHV* gene, absolute lymphocyte count greater than 15 × 10^9/L, and presence of palpable lymph nodes—to robustly define three different risk groups.[298]

Table 19-16 Rai Classification for Clinical Staging of CLL[295]

Risk	Stage	Description	Median Survival (Years)[a]
Low	0	Lymphocytosis in blood or bone marrow	>12.5
Intermediate	I	Lymphadenopathy	8.5
	II	Splenomegaly and/or hepatomegaly with or without lymphadenopathy	6
High	III	Anemia (hemoglobin, <13 g/dL)[b]	1.5
	IV	Thrombocytopenia (platelet count <105/mcL)[b]	1.5

Abbreviation: CLL, chronic lymphocytic leukemia.
[a]Of historical significance because outcomes are changing with newer therapies.
[b]Anemia and thrombocytopenia cannot be immune-mediated.

TREATMENT

With the possible exception of allo-SCT and a small percentage of favorable-prognosis patients treated with fludarabine, cyclophosphamide, and rituximab (FCR), most patients who have CLL are not curable with currently available therapies. Randomized studies have found no improvement in survival with early versus delayed treatment of patients who have early-stage disease (Rai 0-II or Binet A). A recent trial examining ibrutinib in early-stage disease did not show a survival advantage of ibrutinib monotherapy.[299] Therefore, asymptomatic patients should be monitored unless they are enrolled in a clinical trial. Indications to start therapy include evidence of progressive bone marrow failure (eg, anemia or thrombocytopenia not associated with autoimmune hemolytic anemia or immune thrombocytopenic purpura), symptomatic splenomegaly, massive or symptomatic lymphadenopathy, rapid lymphocyte doubling time of less than 6 months, steroid-refractory autoimmune anemia or thrombocytopenia, and constitutional B symptoms that limit activities of daily living (eg, weight loss, night sweats, fevers). Leukapheresis results in only transient reductions in circulating lymphocytes and is not recommended in CLL. Patients who have CLL rarely experience hyperleukocytosis symptoms; therefore, regardless of the number of circulating cells, systemic treatment is usually sufficient.

Initial Therapy

Before the advent of highly active targeted agents, the standard of care for patients who had treatment-naive CLL was chemoimmunotherapy. The addition of an anti-CD20 monoclonal antibody to chemotherapy (chemoimmunotherapy) prolongs survival in CLL compared with chemotherapy alone. Currently, chemotherapy regimens such as FCR are rarely used for first-line therapy except in rare younger patients who are fit have mutated IGHV, and are without del(17p)/*TP53* mutation. A subset of patients who have favorable genetic markers has been shown to achieve durable responses to chemoimmunotherapy lasting more than 10 years.[300]

- Currently, when deciding on first-line therapy in CLL, physicians and their patients must decide between single-agent targeted therapy, two-drug therapy that may be time-limited, or other investigational approaches. All regimens are associated with overall excellent PFS and OS.
- FDA-approved targeted agents for the initial treatment of CLL include ibrutinib, acalabrutinib, zanubrutinib, and venetoclax. BTKis (ibrutinib, acalabrutinib, zanubrutinib) were tested in randomized phase 3 trials and compared with conventional chemoimmunotherapy in treatment-naive CLL. A summary of first-line venetoclax combinations used in more

than 900 patients who have CLL has now been published.[301] The RESONATE-2 trial initially established the efficacy of ibrutinib compared with chlorambucil in older patients who have *TP53* mutations. The ECOG E1912 study compared ibrutinib and rituximab with FCR in younger treatment-naive patients who had CLL (younger than 70 years). The Alliance for Clinical Trials in Oncology study was a three-arm trial comparing bendamustine and rituximab with ibrutinib and rituximab or ibrutinib alone in older treatment-naive patients who had CLL (age 65 or older). Long-term outcome studies have now been published from each of these trials, and all continue to demonstrate superior PFS in the BTKi versus standard chemo(immunotherapy) arms with acceptable long-term toxicity profiles.[302-305] In patients on the ibrutinib arms in the A041201 trial, PFS was not inferior in those with a *TP53* mutation.[304]

- A phase 3 study comparing acalabrutinib with ibrutinib for treatment-naive CLL showed acalabrutinib to be noninferior to ibrutinib for PFS but with reduced rates of atrial fibrillation (9.4% vs 16.0%; $P = .02$).[28]
- The phase 3 SEQUOIA trial randomly assigned adults with treatment-naive CLL without del(17p)/*TP53* mutation to receive zanubrutinib or bendamustine and rituximab. PFS was superior for zanubrutinib (HR, 0.29; one-sided $P = .0001$). For the nonrandomized del(17p)/*TP53*-mutated arm D, 24-month PFS was 92% with zanubrutinib continuously and venetoclax for 24 months.[31,32]
- Venetoclax, a BCL-2 inhibitor, was initially approved for the treatment of relapsed/refractory disease and later received an expanded approval in treatment-naive CLL. The German CLL14 study reported a PFS benefit with venetoclax plus obinutuzumab compared with chlorambucil plus obinutuzumab in treatment-naive patients who had CLL with coexisting conditions.[306] This study has now been updated with a median observation period of 76.4 months, and PFS is 78.2 versus 36.4 months for venetoclax versus chlorambucil.[306] Venetoclax was stopped after 1 year in all patients, but a PFS benefit was still seen 2 years after completion of therapy.[307]

All of these studies demonstrated superior PFS in BTKi arms compared with conventional chemoimmunotherapy. It remains to be determined in which context the combination of an anti-CD20 antibody and a BTKi adds clinical benefit. There was no PFS difference between the two ibrutinib arms with or without rituximab in the Alliance study, whereas an exploratory analysis of ELEVATE-TN, a three-arm study of acalabrutinib plus obinutuzumab, acalabrutinib alone, or chlorambucil plus obinutuzumab did demonstrate improved PFS with the addition of obinutuzumab to acalabrutinib. Eighteen percent of patients receiving ibrutinib developed atrial fibrillation, and 55% had hypertension.[308] In a 6-year follow-up, OS was longer for acalabrutinib-obinutuzumab than for the cholorambucil-obinutuzumab arm (p0.0349).[309] In an update of the Alliance trial (A041202) in older patients, at 48 months, the PFS estimates were 47% for bendamustine and rituximab, 76% for ibrutinib, and 76% for ibrutinib plus rituximab.[302]

With the availability of BTKis and anti-Bcl-2 agents such as venetoclax, almost all patients who have CLL, especially those with del(17p)/*TP53* mutation and with more aggressive disease, are treated with these agents incorporated into first-line therapy. Ibrutinib, acalabrutinib, zanubrutinib, and venetoclax with or without an anti-CD20 monoclonal antibody are preferred first-line therapies.[32,292] In initial studies of BTKis such as ibrutinib and acalabrutinib, they were often continued indefinitely. Fixed-duration regimens have now been studied, and some of the many trials still ongoing are highlighted here:

- In the German CLL14 trial, patients were randomly assigned to receive venetoclax and obinutuzumab for 12 months compared with 6 months of chlorambucil and obinutuzumab. Those who received venetoclax and obinutuzumab had improved PFS (62.6% vs 27% at 5 years), but there was no effect on OS.[310]
- In the CAPTIVATE fixed-duration trial, patients received 3 months of ibrutinib and then ibrutinib plus venetoclax for 12 months. There was a 95% PFS at 2 years.[311]
- In the phase 3 GLOW study, patients were randomly assigned to ibrutinib plus venetoclax versus chlorambucil plus obinutuzumab, with PFS at 30 months of 87% versus 36%, respectively.[312]
- In the AMPLIFY study, the PFS was 76.5% with acalabrutinib-venetoclas, 83.1! With acalabrutinib-venetoclax-obinutuzumab and 66.5% with chemoimmunotherapy.[29] In this study, fourteen 28-day cycles were administered. Longer follow-up is awaited for OS and EFS data.
- A randomized trial of ibrutinib versus fixed-duration venetoclax and obinutuzumab or fixed-duration venetocalx and ibrutinib has now been published as an abstract, and this demonstrated noninferiority of the fixed dose combinations.[30]

MRD detection has been implemented to guide the duration of therapy and to prognosticate the duration of response after various treatment regimens, but the impact it will have on long-term survival potential remains to be seen.[313] MRD can be measured with multiparameter flow cytometry, PCR to the *IGHV* gene, which requires allele-specific oligonucleotides, and NGS. All have been used in CLL and have varying degrees of sensitivity, ranging from detection of 1 in 10^4 to 1 in 10^6 aberrant cells. In continuous treatment regimens with BTKis or venetoclax, this can be examined as an indicator of PFS, but it is often not helpful because PFS is excellent even with positive MRD, given time to relapse, and the multitude of salvage regimens available. In first-line fixed-duration treatment of CLL, MRD can be measured 2 to 3 months after treatment ends, and its role in determining future treatment decisions is evolving.[313] Most relapses can be picked up at a molecular level, and this may make retreatment more effective, but longer

follow-up is desired. The use of venetoclax consolidation after more than 12 months of ibrutinib therapy was found to achieve a high rate of MRD at the 10^{-4} level.[314] It is also possible that using MRD may help define the duration of treatment in a personalized manner, as noted in the FLAIR study, in which MRD was used to direct how long ibrutinib and venetoclax were continued.[315]

Important adverse events associated with BTKis include bleeding, atypical infection (*P. jirovecii*, *Aspergillosis*, progressive multifocal encephalopathy), and atrial fibrillation. BTKis such as acalabrutinib are associated with improved toxicity profiles relative to ibrutinib, particularly in the reduction of the rate of atrial fibrillation to 7% from 13% of patients treated with ibrutinib.[316] Although BTKis are associated with atypical fungal infections, the incidence of these infections is low, and routine prophylaxis for fungal and viral organisms is generally not recommended. Tumor lysis syndrome can occur in patients treated with chemoimmunotherapy or venetoclax, especially those with high WBC counts, bulky lymphadenopathy, or impaired renal function. Tumor lysis syndrome may be fatal and is not consistently preventable with the use of prophylactic allopurinol and/or hydration. Patients at higher risk of developing tumor lysis syndrome should be monitored closely with laboratory testing and hydration during the initial period of venetoclax-based therapy or chemoimmunotherapy. A 5-week dosage ramp-up and inpatient or close outpatient monitoring is often recommended.

Fludarabine may be associated with autoimmune hemolytic anemia and immune thrombocytopenia; if such complications are seen, treatment should be stopped, and the patient should be switched to an alternative treatment. Despite the profound immunosuppression associated with fludarabine, the risk of secondary malignant disease does not seem to be increased with fludarabine alone, but there may be an increased incidence of myelodysplasia when fludarabine is combined with an alkylating agent, such as cyclophosphamide. This will likely be seen less frequently because regimens such as FCR have been replaced with BTKis and BH3-mimetics. Common toxicities of drugs used for first-line treatment of CLL are provided in Table 19-18. Diminished vaccine responses are seen with all targeted agents; in general, live vaccines are not recommended in CLL.

Table 19-18 Common Toxicities of Drugs Used for First-Line CLL Therapy

Drug	Adverse Effect
BTKis	Diarrhea
	Fatigue
	Arthralgias/cramps
	Infections
	Bleeding (with acalabrutinib and ibrutinib; warfarin should be avoided)
	Atrial fibrillation
	Hypertension - Acalabrutinib and zanubrutinib have more favorable toxicity profiles compared with ibrutinib because they are more specific inhibitors[292,316]
	PPIs are discouraged with acalabrutinib
Venetoclax	Tumor lysis syndrome (5-week ramp-up recommended)
	Neutropenia

Abbreviations: BTKi, Bruton tyrosine kinase inhibitor; CLL, chronic lymphocytic leukemia; PPI, proton pump inhibitor.
Diminished vaccine responses are seen with all targeted agents; in general, live vaccines are not recommended in CLL.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

The following summarizes first-line treatment of CLL[317]: There are multiple factors both disease and patient related such as comorbidities which are factored into these choices.

- For patients without del(17p)/*TP53* mutation:
  - BTKis with or without anti-CD20 monoclonal antibody; acalabrutinib or zanubrutinib are now usually recommended compared with ibrutinib on the basis of more favorable toxicity profiles
  - Venetoclax plus obinutuzumab (fixed-duration treatment)
- For patients with del(17p)/*TP53* mutation:
  - BTKis with or without obinutuzumab
  - Venetoclax plus obinutuzumab (fixed-duration treatment)

Treatment of Relapsed/Refractory Disease

The management of relapsed CLL depends on several factors, including age, performance status, presence of del(17p)/*TP53* mutation, previous therapies, response to and duration of last therapy, and time from last therapy. With many potential treatments

available, the best sequence and timing of salvage therapies are being addressed in clinical trials. The current standard of care for relapsed/refractory CLL includes acalabrutinib or zanubrutinib or venetoclax with anti-CD20 monoclonal antibody, ibrutinib, and duvelisib (currently approved as a third-line therapy).[318,319] In a randomized study, zanubrutinib was shown to yield superior PFS compared with ibrutinib in relapsed/refractory CLL.[320] This has now been finalized with a median follow-up of 42.5 months with PFS higher in the zanubrutinb arm and higher overall response rates with zanubrutinib versus ibrutinib (86% vs 75%). Median OS was not reached in either group.[32] Acalabrutinib is also a more selective BTKi and may provide a better safety profile than ibrutinib. Data from a head-to-head comparison trial of acalabrutinib and ibrutinib in previously treated patients showed acalabrutinib to be noninferior to ibrutinib for PFS and OS but with a significantly lower incidence of atrial fibrillation in those treated with acalabrutinib.[28] Acalabrutinib and zanubrutinib are not able to overcome resistance in patients who have ibrutinib-refractory CLL with BTK C481S mutations.[321] Pirtobrutinib can be tried in these situations. Pirtobrutinib is also now approved as second- or third-line therapy in those who are resistant or intolerant to other BTKis and have had two lines of previous therapy, including a BTKi and an anti-BCL-2 inhibitor.[322] This is a noncovalent (reversible) BTKi. In the BRUIN trial, the ORR in those previously treated with a BTKi was 73%, and the median PFS was 19.6 months in a heavily pretreated population.[323] Cytopenias, fatigue, bruising, musculoskeletal pain, and infections were among the most common adverse effects reported. In the BRUIN CLL-321 trial, pirtobrutinib versus idelalisib/rituximab or bendamustine/rituximab resulted in superior PFS and longer time to next treatment or death.[324] Venetoclax can be used as a monotherapy or in combination with an anti-CD20 monoclonal antibody in relapsed/refractory CLL. The MURANO study was a phase 3 trial in relapsed/refractory CLL in which 389 patients were randomly assigned to receive venetoclax for up to 2 years in combination with rituximab for the first 6 months or bendamustine and rituximab for 6 months. The study reported a PFS benefit in favor of venetoclax and rituximab over bendamustine and rituximab in the initial report and an OS benefit in a 5-year follow-up.[325] Clearance of MRD at 9 months was significantly better for venetoclax and rituximab at 62% versus 13% for bendamustine and rituximab, and OS was improved in the venetoclax and rituximab group. The following studies or agents have been examined in relapsed/refractory CLL: at 7 years of follow-up, the OS was 70% versus 51% in favor or pritobrutinib.[326]

- ASCEND—PFS 62% at 42 months with acalabrutinib[327]
- ELEVATE-RR—acalabrutinib noninferior to ibrutinib (PFS); median PFS was 38 months on both arms[28]
- RESONATE—ibrutinib versus ofatumumab; superior PFS with ibrutinib; median PFS was 44 versus 8 months[328]
- MURANO—venetoclax-rituximab versus bendamustine plus rituximab; venetoclax-rituximab was superior; median PFS was 54 months versus 17 months[325]
- ALPINE—zanubrutinib was more effective than ibrutinib with longer PFS; 78.4% versus 65.9% at 24 months[320]

Note that PI3 kinase inhibitors idelalisib and duvelisib met with safety concerns. Idelalisib is available in combination treatments, but duvelisib was withdrawn by the FDA on April 13, 2022, due to possible detriment in OS and safety concerns compared with ofatumumab.

CAR T-Cell Therapy

Encouraging results have also been reported with CD19-targeted autologous T cells expressing CARs. In one phase 1 study, the 6-year duration of response and OS were 26.4% and 31.2%, respectively.[329] Factors associated with durable responses are being examined. In March 2024, the FDA approved lisocabtagene maraleucel (liso-cel) for the treatment of adult patients who have relapsed/refractory CLL and who have received at least two previous lines of therapy, and these must include a BTKi and a BCL-2 inhibitor.[213]

Allo-SCT

Given that CLL is associated with advanced age and increased comorbidities, allo-SCT applies to a minority of patients for whom targeted agents have failed, who have a donor available, and who are relatively fit to undergo intensive therapy. Allo-SCT can provide long-term disease control and cure for a subset of patients. However, the NRM rate remains high in CLL.

Treatment of Richter Transformation

Treatment of Richter transformation is usually approached with regimens used for de novo DLBCL such as rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP), dosage-adjusted etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (EPOCH), or other chemoimmunotherapy combinations.[291] BTKis can be used, and pirtobrutinib, in particular, has been examined in this setting. PD1-PD-L1 inhibitors, BCL-2 inhibitors, and anti-CD20-CD3 bispecifics are also being examined in patients who have Richter transformation to DLBCL. CAR T-cell therapies directed to CD19 may also be effective in these patients. A trial of liso-cel with nivolumab and ibrutinib (NCT05672173) is underway.

FUTURE DIRECTIONS IN CLL THERAPY

Trials with combinations of BTKis and venetoclax are underway. The addition of obinutuzumab to BTKis and venetoclax (triple therapy) is also being investigated. Whether a triplet regimen will be needed to obtain and maintain an undetectable MRD state

is still not understood. In the CLL2-GIVe trial, obinutuzumab, ibrutinib, and venetoclax were combined in patients who had untreated CLL with del(17p) or mutated *TP53*.[330] The 36-month PFS was 79.9%, and the 36-month OS was 92.6%.

Studies such as the ongoing MAJIC (NCT05057494) trial with obinutuzumab and venetoclax versus a fixed duration of acalabrutinib and venetoclax will help answer the question of whether an all-oral regimen might be as effective as a regimen with an anti-CD20 monoclonal antibody infusion.

Novel BH3-mimetics, BTK degraders, and new noncovalent BTKis are being examined in the treatment of CLL.[331] New roles for CAR T cells and bispecifics are also being examined in CLL.[332]

KEY POINTS

- Distinguishing CLL from other diseases, notably hairy cell leukemia or the leukemic presentations of marginal zone lymphoma or mantle cell lymphoma, is based on the morphologic appearance of the cells, the distinct immunophenotype of the malignant cells, and cytogenetic findings.
- Survival for patients who have CLL has improved with the introduction of highly active targeted agents.
- In patients who have treatment-naive CLL, five randomized phase 3 trials showed improved PFS in patients treated with BTKi-based regimens (ibrutinib, acalabrutinib, or zanubrutinib either as monotherapy or in combination with an anti-CD20 monoclonal antibody) compared with those treated with conventional chemoimmunotherapy. Another randomized phase 3 trial showed improved PFS with venetoclax plus obinutuzumab compared with chemoimmunotherapy. These results establish four targeted agents—ibrutinib, acalabrutinib, zanubrutinib, and venetoclax—as effective first-line therapy for CLL, regardless of the patient's age or cytogenetic status.
- In first-line therapy, a single-agent BTKi on a continuous basis is acceptable, especially in patients with *TP53* mutations.
- It is important to review the benefits of continuous versus fixed duration treatment with patients.
- In patients who have relapsed/refractory CLL, consider the type of first-line therapy, duration of response or remission to first-line therapy, and possible acquired resistance to therapy class.
- In the relapsed/refractory CLL setting, with many potential treatments available, the optimal sequence and timing of salvage therapies are being addressed in clinical trials. Current standards of care for relapsed/refractory CLL include ibrutinib, acalabrutinib, zanubrutinib, venetoclax with or without an anti-CD20 monoclonal antibody, or pirtobrutinib in those who have had at least two previous lines of therapy. The use of CAR T-cell therapy is evolving.
- The role that MRD will play in defining type and duration of therapy and whether resistance patterns emerge after time-limited therapies is still being investigated.[315]

PROLYMPHOCYTIC LEUKEMIA

T-cell prolymphocytic leukemia (T-PLL) is a rare lymphoid neoplasm that occurs predominantly in older adults. There is a slight male predominance. At presentation, the primary clinical features include rapidly increasing lymphocyte counts and splenomegaly. Lymphadenopathy, rashes, peripheral edema, and pleuroperitoneal effusions are relatively common in T-PLL.

T-PLL typically expresses CD2, $CD3^{+/-}$, CD5, CD7, and CD52 with variable expression of CD4 and CD8. It does not express DNA nucleotidylexotransferase or CD1a. Common cytogenetic abnormalities include complex karyotypes typically involving chromosome 14q32 or Xq26. T-cell clonality can be demonstrated by PCR, and there should be >5,000/mcL prolymphocytes in the blood or marrow. Patients who have T-PLL have T-cell leukemia 1 (TCL1) or MTCP1 overexpression and ATM loss (11q22.3).[333] T-PLL treatment can include alemtuzumab, pentostatin, or combinations of fludarabine, mitoxantrone, and cyclophosphamide.[334] Therapeutic activity of alemtuzumab and purine analogs tends to be transient. Allo-SCT should be considered for suitable patients in first remission. New therapeutic strategies may include BH3-mimetics, JAK inhibitors such as ruxolitinib, and epigenetic modulation.[334]

In the WHO 5th edition classification of lymphoid neoplasms,[2] B-cell PLL was eliminated as an entity because of its heterogeneity, some being mantle cell variants, some representing progression of chronic lymphocytic leukemia or small lymphocytic leukemia (CLL/SLL), and some being what others called "splenic B-cell lymphoma/leukemia with prominent nucleoli."[2]

HAIRY CELL LEUKEMIA

Approximately 1,000 new cases of hairy cell leukemia occur each year in the United States, primarily in middle-aged individuals, with a 4:1 male predominance.

CLINICAL PRESENTATION AND DIAGNOSIS

Patients typically present with symptoms related to pancytopenia,[335,336] including infections, weakness or fatigue, shortness of breath, bleeding, or left upper quadrant abdominal pain related to splenomegaly. In addition to cytopenias and splenomegaly, the most common sign is the presence of circulating hairy cells. These cells generally have an eccentric spongiform kidney-shaped nucleus with characteristic filamentous cytoplasmic projections.

A bone marrow biopsy specimen is typically required to establish the diagnosis because an aspirate often cannot be obtained. The malignant cells in classic hairy cell leukemia are of B-cell origin; have no (or inconspicuous) nucleoli; and express CD19, CD20, CD123, and CD200 as well as the monocyte antigens CD11c, CD25, and VE1 (a *BRAF* V600E stain). The most specific marker is CD103. The cells stain positively with tartrate-resistant acid phosphatase, but this is rarely used diagnostically, given the availability of flow cytometry discrimination. Monocytopenia is a common feature of the disease. Mutations in *BRAF*, specifically V600E, have been found in virtually all cases of classic hairy cell leukemia. *BRAF* V600E is thought of as a causal genetic event, leading to the constitutive activation of the RAF-MEK-ERK signaling pathway, which represents the key event in the molecular pathogenesis of hairy cell leukemia.[337]

Hairy cell variant leukemia has biology and clinical behaviors that are distinct from those of classic hairy cell leukemia, and patients often present with significant leukocytosis. This entity is now called splenic B-cell lymphoma/leukemia with prominent nucleoli.[2] Cells are characterized by prominent nucleoli and a lack of CD200 expression. They also typically do not express CD25 or CD123, and molecularly, they lack the *BRAF* V600E mutation.

TREATMENT

Treatment is indicated in the setting of massive or progressive splenomegaly, worsening blood cell counts, recurrent infection, more than 20,000 hairy cells/mcL of peripheral blood, or bulky lymphadenopathy.

Classic hairy cell leukemia typically follows an indolent disease course and is now highly controllable. More than 80% of patients will experience a durable response to treatment with purine analogs cladribine or pentostatin with or without an anti-CD20 antibody such as rituximab.[338] The results with cladribine are equivalent to those with pentostatin. Rituximab can be given concurrently or sequentially; concurrent use is associated with a higher probability of achieving an undetectable MRD state.[338] The shorter duration of treatment makes cladribine somewhat more attractive. In patients who have renal impairment, purine analogs should be used with caution. Although IFN-α was the first systemic therapy to demonstrate activity in hairy cell leukemia, its current role is limited because the purine analogs are superior with regard to response duration, safety, and outcome. Likewise, splenectomy is no longer used to treat hairy cell leukemia. Some studies have examined the use of BRAF inhibitors along with obinutuzumab as initial therapy.[339]

Ultimately, approximately 30% to 40% of patients experience relapse after purine analog–based therapy. In many cases, relapse is characterized only by an increase in hairy cells in the bone marrow with no indication for treatment. Patients who develop symptomatic disease or progressive cytopenias as a result of relapse require retreatment. Selection of treatment at relapse is guided by the duration of remission after initial therapy.[340] A second durable response is achieved for most patients. Treatment options at relapse include a purine analog with rituximab for later relapses (>2-year remission). In those with shorter remissions, an alternate purine analog with rituximab or a BRAF inhibitor such as vemurafenib plus rituximab is an option.[36] For patients beyond first relapse, other options include the BTKi ibrutinib or other BRAF or MEK inhibitors, such as dabrafenib and trametinib, respectively.[35,341] The ideal sequence of these regimens is unknown.[342]

Variant hairy cell leukemia has a more aggressive disease course than does classic hairy cell leukemia.[343] Treatment results with purine analog monotherapy are substantially inferior (ORR, <50% vs 75% to 100% for the classic version; CR rate, <10% vs >50% to 70%), but the addition of rituximab or obinutuzumab seems to improve outcomes.[344] In relapsed/refractory disease, ibrutinib seems to have efficacy.[35]

KEY POINTS

- Classic hairy cell leukemia is highly responsive to treatment with purine analogs (eg, cladribine or pentostatin) administered alone or in combination with rituximab.
- Patients who have relapsed/refractory disease who require treatment may respond to retreatment with purine analog–based therapy, especially if they are in late relapse. In addition, anti-CD20 antibodies, a *BRAF* inhibitor, or ibrutinib are options for relapsed disease.

MATURE T-CELL/NK-CELL LEUKEMIAS

In the WHO 5th edition classification of lymphoid neoplasms, the mature T-cell and NK-cell neoplasms include T-PLL, T-large granular lymphocytic leukemia, NK-large granular lymphocytic leukemia, adult T-cell leukemia/lymphoma, Sezary syndrome, and aggressive NK-cell leukemia.[2] These diseases have phenotypic, genotypic, and clinical heterogeneity.[345,346]

Large granular lymphocytoses can be divided into two major subsets: T-cell large granular lymphocytosis ($CD3^+$, representing activated cytotoxic T cells) and NK-cell large granular lymphocytosis ($CD3^-$). T-cell large granular lymphocytosis tends to occur in older individuals, and most patients (60%) are symptomatic at diagnosis. Anemia and recurrent infections associated with neutropenia are common, and thrombocytopenia may also occur. Autoimmune hemolytic anemia and pure red cell aplasia can be associated. Diagnosis generally requires 2,000/mcL large granular lymphocytosis (LGL) cells and persistence for at least

6 months, but some series allow 500/mcL LGL cells for diagnosis with unexplained cytopenias. The immunophenotype includes positivity for CD3, CD8, and CD57. Clonal rearrangement of the T-cell receptor (*TCR*) gene is typically detected. There are also rare patients who have $CD4^+$ T-cell large granular lymphocytic leukemia (T-LGLL). In about 30% of patients, activating *STAT3* mutations are present, and other patients express mutations in *STAT5B* and *CCL22*.[347] The presence of these mutations helps further subclassify these disorders, and *STAT3* mutations can be associated with more severe neutropenia. The NK-cell variety accounts for approximately 15% of LGLs and includes aggressive NK-cell leukemia and a more indolent NK-cell lymphocytosis. The cells are negative for CD3; positive for CD8, CD16, and CD56; and may or may not be positive for CD57. *TCR* gene rearrangements are absent. Aggressive NK-leukemias are often associated with Epstein-Barr infections.

For the indolent forms of T-LGLL, a notable feature is their association with other diseases in up to 40% of patients, including rheumatoid arthritis; other autoimmune diseases, such as systemic lupus erythematosus; and other hematologic disorders, such as CLL, hairy cell leukemia, lymphoma, MDS, and monoclonal gammopathy of undetermined significance. With the indolent forms, treatment regimens vary and are not standardized. Generally, immunosuppressive therapy (eg, methotrexate, cyclophosphamide, cyclosporine) is the mainstay of initial treatment, and these drugs may be combined with corticosteroids in some patients.[348] Salvage therapies may include ruxolitinib or alemtuzumab.[349] G-CSF may be helpful in some cases to mitigate neutropenic complications.

Patients affected by the aggressive form of the disease tend to be younger and do not have rheumatoid arthritis. Infiltration of the gastrointestinal tract and bone marrow is common. Neutropenia is modest compared with the severity of anemia and thrombocytopenia. Patients often die as a result of multiorgan failure with a coagulopathy, generally within a few months of diagnosis, despite aggressive chemotherapy.

Approximately 5% of LGLs are a nonclonal expansion of $CD3^+$ LGL that is generally unaccompanied by lymphadenopathy or hepatosplenomegaly. The features of the cells are positivity for CD3, CD16, and CD56 and negativity for CD4 and CD8. The disease is indolent, rarely requiring intervention unless accompanied by neutropenia. Prednisone and immunosuppressive agents have been used. It is not clear whether this disorder is actually neoplastic.

KEY POINTS

- T- and NK-LGLL are a heterogeneous group of disorders, and it is important to obtain immunophenotyping and *STAT3* and *STAT5B* analysis at diagnosis.
- Some patients do not require treatment, but in those who have symptomatic neutropenia or require treatment of an underlying autoimmune disease, therapy should be started.
- Understanding mutational aberrancies in these disorders may suggest new treatment paradigms for the future, but none have been forthcoming thus far.

ADULT T-CELL LEUKEMIA/LYMPHOMA

Adult T-cell leukemia/lymphoma (ATLL) is endemic in certain geographic areas, including the southeastern United States, islands in southern Japan, the Caribbean basin (including Jamaica and Trinidad), northeast Iran, western Africa, and Peru. The disease is linked to human T-cell lymphotropic virus type 1 infection (HTLV-1). HTLV-1 carriers lose a balance between infected $CD4^+$ T cells and antiviral immunity in about 5% to 10% of patients and develop ATLL.[350]

Four clinical variants of ATLL are acute, chronic, smoldering, and lymphomatous disease. Elevated serum calcium and LDH are prognostic for poor outcomes. Patients who have the acute, lymphomatous, or unfavorable chronic type require multiagent chemotherapy with or without subsequent allo-SCT. The median survival without SCT is 7 to 13 months.[350] The addition of the anti-CC4 antibody mogamulizumab to the multiagent chemotherapy can improve the rate of overall response and PFS.[351] For the chronic or smoldering type, watchful waiting can be considered. Antiviral therapy with zidovudine plus IFN-α has also been examined, but has a controversial role. Retrospective studies demonstrated OS benefits in patients who have acute, chronic, and smoldering types but not the lymphomatous type. Approximately 10% to 25% of patients present with CNS involvement at diagnosis or relapse; therefore, patients who have an acute or aggressive presentation of the disease should be evaluated for CNS involvement and receive intrathecal chemotherapy for prophylaxis. Efforts to prevent mother-to-child or horizontal transmission are the subjects of current research efforts. Lenalidomide and PD-1 inhibitors are being examined in ATLL.

HIGH-YIELD TAKEAWAYS

- ATRA should be given right away when suspicious for APL; ATRA plus arsenic is a highly curable regimen.
- AML management can involve intensive or less intensive treatment regimens based on age, prognostic features, and other patient comorbidities.

- Tyrosine kinase inhibitors are the treatment of choice for chronic phase CML.
- Polycythemia vera and essential thrombocythemia are most often characterized by *the JAK2 V617F* variant.
- Treatment for Ph+ ALL should include TKI with chemotherapy or blinatumomab.

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

LEUKEMIAS AND OTHER MYELOID NEOPLASMS

19

CHAPTER SUMMARY GUIDE

KEY POINTS

- Leukemias, MDSs, and MPNs encompass a diverse group of clonal diseases of the hematopoietic system.
- Familial or genetic predisposition and exposure to certain infectious pathogens, radiation, chemicals, and therapeutic agents have been associated with an increased incidence of these hematopoietic neoplasms.
- In 60% of patients who have AML, at least one clonal abnormality in chromosome number or structure can be found. These cytogenetic abnormalities, in combination with age and performance status, are the most important prognostic factors in AML and are indispensable in making therapeutic decisions.
- Genome-wide sequencing has identified more than 50 genes that are recurrently mutated in AML. Testing for mutations in *FLT3, NPM1, CEBPA, IDH1, IDH2, KMT2A, NPM1,* and *TP53*, among other genes, is important in making treatment decisions for patients who enter first remission.
- On the basis of cytogenetic and molecular markers, AML can be divided into several categories with distinct disease risk.
- Standard induction therapy for those eligible for intensive chemotherapy in AML involves the use of an anthracycline and cytarabine.
- All patients aged 70 to 75 years or younger who achieve complete remission, except those with a favorable-risk cytogenetic or molecular profile who achieve an early first complete remission and have no evidence of MRD after induction, should be considered for allo-SCT, particularly if the SCT comorbidity index score is low and a donor is available. Myeloablative conditioning is preferred for patients up to age 60 to 65 years.
- Patients who are considered unfit to receive chemotherapy because of age or medical comorbidities are treated with venetoclax in combination with an HMA or low-dose cytarabine. Studies of multiple novel combination therapies combining venetoclax with chemotherapy or targeted therapy are ongoing.
- The prognosis is poor for patients who have recurrent AML, and the likelihood of achieving a second remission is predicted by the length of the first remission. Individuals who have remained in remission for more than 1 year can be induced with the same chemotherapy administered for the first complete remission. Because of this poor outcome, transplantation should be considered for most patients who have recurrent AML and who are appropriate candidates.
- Genetic analysis should be repeated at the time of disease progression or relapse, given that multiple targeted therapies are currently approved in this setting. Gilteritinib is approved for relapsed/refractory *FLT3*-ITD–mutated AML, and ivosidenib, olutasidenib, and enasidenib are approved for *IDH1*- and *IDH2*-mutated relapsed/refractory AML. Revumenib is approved for relapsed/refractory AML with KMT2Ar. In addition, both revumenib and ziftomenib are approved for relapsed/refractory *NPM1*-mutated AML.
- The suspicion of APL in a patient who has newly diagnosed acute leukemia should trigger the immediate administration of ATRA to reduce the risk of early death resulting from hemorrhage.
- Patients who have APL should receive ATRA and ATO as part of induction and/or consolidation therapy.
- TKIs such as imatinib, nilotinib, dasatinib, and bosutinib are remarkably effective in newly diagnosed CP-CML, leading to complete hematologic and cytogenetic responses for most patients with OS similar to that of age-matched controls. However, continued therapy and careful follow-up are necessary. Asciminib, an allosteric inhibitor of the myristoyl site of the BCR-ABL1 protein, is now also approved in the newly diagnosed setting.
- Second-generation TKIs (eg, dasatinib, nilotinib, and bosutinib) result in quicker cytogenetic and molecular responses compared with imatinib, with no differences in OS.
- Patients who have *T315I*-mutated CML may respond to ponatinib, although the duration of response is typically short.
- Asciminib is approved by the FDA for patients who have CP-CML with resistance to at least two previous TKIs or CP-CML with a *T315I* mutation.
- Patients who have accelerated or blast-phase CML can respond to TKIs, but responses are generally short, and the disease is relatively resistant to most types of therapy. Allo-SCT is potentially curative for these patients.

- Clonal hematopoiesis is defined by a hematologic neoplasm driver mutation at a VAF greater than 2% in the absence of cytopenia, dysplasia, or increased blasts. Cytopenia is present in both CCUS and ICUS; note that CCUS is associated with a clonal mutation in addition to cytopenia.
- The risk of progression to a myeloid malignancy (MDS or AML) is comparably lower for those with clonal hematopoiesis (approximately 0.5%-1% per year) or ICUS (approximately 1% per year) and higher for those with CCUS (approximately 10%-20% per year). Risk factors have now been validated, and a clonal hematopoiesis risk score can be determined.[13,14]
- The important prognostic factors for patients who have MDS are percentage of marrow blasts, karyotype, number of peripheral blood cytopenias, and molecular mutations.
- The therapeutic strategy for MDS is based primarily on the disease risk, with the main goals of reducing consequences of cytopenias, improving quality of life for patients who have lower risk disease, preventing transformation into AML, and improving survival for patients who have higher risk disease.
- The 5q-minus subtype responds well to therapy with lenalidomide, and administration of lenalidomide early in the disease course can delay the onset of RBC transfusion dependence.
- Luspatercept can be used in low- and intermediate-risk transfusion-dependent patients who have MDS independent of erythropoietin level, either before or after a trial with an ESA. Imetelstat is also now approved for those MDS patients with low to intermediate-1 risk who are transfusion dependent and have not responded to ESAs.
- Allo-SCT is the only curative treatment for MDS.
- The treatment of PV, ET, and primary MF is tailored to the likelihood of the development of venous or arterial thrombosis, bleeding, or evolution to AML, the major life-threatening and limiting complications of these MPNs. In PV and ET, cytoreductive therapy is reserved for the high-risk disease categories.
- In MF, treatment is also based on risk stratification, and multiple prognostic scoring systems are available. By using the risk levels from the MIPSS70 + v2.0 for categorizing patients, those in low-risk categories can enter a period of observation, and for patients in the high-risk categories, allo-SCT is recommended for those who are appropriate candidates. Those in intermediate-risk categories must be individualized but may benefit from JAK inhibitors and treatments to improve anemia. Transplantation is indicated for some of these patients.
- Multiple JAK inhibitors are now available for treatment of MF (ruxolitinib, fedratinib, pacritinib, and momelotinib), and they can be selected on the basis of their adverse effect profiles.
- There is increased awareness of the MPN/MDS overlap syndromes, and classification based on clinical and molecular characteristics continues to evolve, as evidenced by the changes in the 2022 WHO and ICC classifications.
- Induction therapy for adult ALL generally should include vincristine, prednisone, and an anthracycline with or without L-asparaginase or cyclophosphamide. With such regimens, complete remission can be achieved in 80% to 90% of patients. Consideration of a pediatric-inspired regimen should be given for all patients aged 40 years or younger and possibly in select patients aged 55 years or younger.
- Patients who have CD20+ B-cell ALL should receive rituximab during induction and consolidation.
- Patients who have Ph+ ALL should receive a BCR-ABL1–directed TKI in combination with chemotherapy or blinatumomab.
- Recently, ponatinib was an FDA-approved agent in combination with chemotherapy for newly diagnosed Ph+ ALL.
- Blinatumomab can convert up to 80% of MRD-positive patients who have B-cell ALL and are in remission to an MRD-negative state and also improves outcomes.
- Allo-SCT is an important post-remission treatment except perhaps in patients who have highly chemotherapy-sensitive disease, as indicated by early MRD negativity.
- Salvage treatment options for patients who have relapsed/refractory B-cell ALL include blinatumomab, inotuzumab ozogamicin, and CAR T-cell therapy (tisagenlecleucel, brexucabtagene autoleucel, and obecabtagene autoleucel).
- Given the rarity of ALL and the complexity of its treatment, it is generally recommended that patients who have ALL be treated at high-volume centers (>10 new cases managed per year) with access to clinical trials, cell therapies, and SCT.
- Distinguishing CLL from other diseases, notably hairy cell leukemia or the leukemic presentations of marginal zone lymphoma or mantle cell lymphoma, is based on the morphologic appearance of the cells, the distinct immunophenotype of the malignant cells, and cytogenetic findings.
- Survival for patients who have CLL has improved with the introduction of highly active targeted agents.
- In patients who have treatment-naive CLL, five randomized phase 3 trials showed improved PFS in patients treated with BTKi-based regimens (ibrutinib, acalabrutinib, or zanubrutinib either as monotherapy or in combination with an anti-CD20 monoclonal antibody) compared with those treated with conventional chemoimmunotherapy. Another randomized phase 3 trial showed improved PFS with venetoclax plus obinutuzumab compared with chemoimmunotherapy. These results establish four targeted agents—ibrutinib, acalabrutinib, zanubrutinib, and venetoclax—as effective first-line therapy for CLL, regardless of the patient's age or cytogenetic status.
- In first-line therapy, a single-agent BTKi on a continuous basis is acceptable, especially in patients with *TP53* mutations.

- It is important to review the benefits of continuous versus fixed duration treatment with patients.
- In patients who have relapsed/refractory CLL, consider the type of first-line therapy, duration of response or remission to first-line therapy, and possible acquired resistance to therapy class.
- In the relapsed/refractory CLL setting, with many potential treatments available, the optimal sequence and timing of salvage therapies are being addressed in clinical trials. Current standards of care for relapsed/refractory CLL include ibrutinib, acalabrutinib, zanubrutinib, venetoclax with or without an anti-CD20 monoclonal antibody, or pirtobrutinib in those who have had at least two previous lines of therapy. The use of CAR T-cell therapy is evolving.
- The role that MRD will play in defining type and duration of therapy and whether resistance patterns emerge after time-limited therapies is still being investigated.[315]
- Classic hairy cell leukemia is highly responsive to treatment with purine analogs (eg, cladribine or pentostatin) administered alone or in combination with rituximab.
- Patients who have relapsed/refractory disease who require treatment may respond to retreatment with purine analog–based therapy, especially if they are in late relapse. In addition, anti-CD20 antibodies, a *BRAF* inhibitor, or ibrutinib are options for relapsed disease.
- T- and NK-LGLL are a heterogeneous group of disorders, and it is important to obtain immunophenotyping and *STAT3* and *STAT5B* analysis at diagnosis.
- Some patients do not require treatment, but in those who have symptomatic neutropenia or require treatment of an underlying autoimmune disease, therapy should be started.
- Understanding mutational aberrancies in these disorders may suggest new treatment paradigms for the future, but none have been forthcoming thus far.

CHAPTER TABLES AND IMAGES

Table 19-1 **2022 WHO Classification of AML[1,2]**

Type of Leukemia	Classification
AML	
With defining genetic abnormalities	APL with *PML::RARA* fusion
	AML with *RUNX1::RUNX1T1* fusion
	AML with *CBFB::MYH11* fusion
	AML with *DEK::NUP214* fusion
	AML with *RBM15::MRTFA* fusion
	AML with *BCR::ABL1* fusion
	AML with *KMT2A* rearrangement
	AML with *MECOM* rearrangement
	AML with *NUP98* rearrangement
	AML with *NPM1* mutation
	AML with *CEBPA* mutation
	AML, myelodysplasia-related
	AML with other defined genetic alterations
Defined by differentiation	AML with minimal differentiation
	AML without maturation
	AML with maturation
	Acute basophilic leukemia
	Acute myelomonocytic leukemia
	Acute monocytic leukemia
	Acute erythroid leukemia
	Acute megakaryoblastic leukemia
Acute leukemia of ambiguous lineage	
With defining genetic abnormalities	Mixed-phenotype acute leukemia with *BCR::ABL1* fusion
	Mixed-phenotype acute leukemia with *KMT2A* rearrangement
	Acute leukemia of ambiguous lineage with other defined genetic alterations
	• Mixed-phenotype acute leukemia with *ZNF384* rearrangement
	• Acute leukemia of ambiguous lineage with *BCL11B* rearrangement
Immunophenotypically defined	Mixed-phenotype acute leukemia, B/myeloid
	Mixed-phenotype acute leukemia, T/myeloid
	Mixed-phenotype acute leukemia, rare types
	Acute leukemia of ambiguous lineage, NOS
	Acute undifferentiated leukemia
B-lymphoblastic leukemia/lymphoma	
	B-lymphoblastic leukemia/lymphoma, NOS
	B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
	B-lymphoblastic leukemia/lymphoma with t(9;22)(q34.1;q11.2); *BCR-ABL1*
	B-lymphoblastic leukemia/lymphoma with t(v;11q23.3); *KMT2A* rearranged
	B-lymphoblastic leukemia/lymphoma with t(12;21)(p13.2;q22.1); *ETV6-RUNX1*
	B-lymphoblastic leukemia/lymphoma with hyperdiploidy
	B-lymphoblastic leukemia/lymphoma with hypodiploidy
	B-lymphoblastic leukemia/lymphoma with t(5;14)(q31.1;q32.3); *IL3-IGH*

Type of Leukemia	Classification
	B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3); *TCF3-PBX1*
	Provisional entity: B-lymphoblastic leukemia/lymphoma, *BCR-ABL1*-like
	Provisional entity: B-lymphoblastic leukemia/lymphoma with *iAMP21*

Abbreviations: AML, acute myeloid leukemia; APL, acute promyelocyte leukemia; NOS, not otherwise specified; WHO, World Health Organization.

Table 19-2 **Tests and Procedures for Patients With AML**[39]

Test	Procedure
Diagnostic tests	CBC and differential count
	Bone marrow aspirate
	Bone marrow trephine biopsy
	Immunophenotyping, flow cytometry, next-generation sequencing for myeloid mutation panel, and RNA gene re-expression
Genetic analyses	Cytogenetics[a]
	Screening for these gene mutations[b]: *NPM1*, *CEBPA*, *IDH1*, *IDH2*, *FLT3*, *TP53*, *ASXL1*, *BCOR*, *EZH2*, *RUNX1*, *SF3B1*, *SRSF2*, *STAG2*, *U2AF1*, *ZRSR2*, *DDX41*
	Screening for these gene rearrangements: *PML-RARA*, *CBFB-MYH11*, *RUNX1-RUNX1T1*, *BCR-ABL1*, other fusion genes (if available)
Additional tests/procedures at diagnosis	Demographics and medical history[c]
	Detailed family history[d]
	Patient bleeding history[e]
	ECOG performance status
	Analysis of comorbidities
	Biochemistry, coagulation tests, urine analysis[f]
	Serum pregnancy test[g]
	Information on oocyte and sperm cryopreservation[h]
	Eligibility assessment for allo-SCT (including HLA typing)[i]
	Hepatitis A, B, C; HIV-1 testing
	Chest radiograph, 12-lead electrocardiogram, and echocardiography or MUGA (on indication)
	Lumbar puncture[j]
	Biobanking[k]
Sensitive assessment of response to treatment (MRD) by RT-qPCR or MFC[l]	RT-qPCR[m,n] for *NPM1* mutation, *CBFB-MYH11*, *RUNX1-RUNX1T1*, *BCR-ABL1*, other fusion genes (if available)
	MFC[n,o]

Abbreviations: allo-SCT, allogeneic stem cell transplantation; AML, acute myeloid leukemia; CBC, complete blood count; ECOG, Eastern Cooperative Oncology Group; HLA, human leukocyte antigen; MFC, multiparameter flow cytometry; MRD, measurable residual disease; MUGA, multigated acquisition (scan); RT-qPCR, reverse transcription quantitative polymerase chain reaction.

[a]Results from cytogenetics should be obtained preferably within 5 to 7 days. At least 20 bone marrow metaphases are needed to define a normal karyotype and are recommended to describe an abnormal karyotype. Abnormal karyotypes may sometimes be diagnosed from blood specimens.

[b]Results from *NPM1* and *FLT3* mutational screening should be available within 48 to 72 hours (at least in patients eligible for intensive chemotherapy), along with results from additional molecular genetics within the first treatment cycle. Screening for gene mutations is an evolving field of research; screening for single genes is now frequently replaced by gene panel diagnostics.

[c]Including race or ethnicity, previous exposure to toxic agents, previous malignancy, therapy for previous malignancy, and information on smoking.

[d]Thorough family history is needed to identify potential myeloid neoplasms with germline predisposition.

[e]History of bleeding episodes may inform cases of myeloid neoplasms with germline predisposition and preexisting platelet disorders.

[f]Biochemistry: levels of glucose, sodium, potassium, calcium, creatinine, aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, lactate dehydrogenase, bilirubin, urea, total protein, uric acid, total cholesterol, total triglycerides, and creatinine phosphokinase. Coagulation tests: prothrombin time; international normalized ratio, where indicated; activated partial thromboplastin time. Urine analysis: pH, and levels of glucose, erythrocytes, leukocytes, protein, and nitrite.

[g]In women with childbearing potential.

[h]Cryopreservation to be done in accordance with the wishes of the patient.

[i]HLA typing and cytomegalovirus testing should be performed in those patients eligible for allo-SCT.

[j]Required in patients who have clinical symptoms suspected of central nervous system involvement; the patient should be evaluated by an imaging study for intracranial bleeding, leptomeningeal disease, and mass lesion; lumbar puncture is considered optional in other settings (eg, high white blood cell count).

[k]Pretreatment leukemic bone marrow and blood samples for research studies are recommended.

[l]Sensitive assessment of response can be performed at early time points, for example, after induction and consolidation courses to assess remission status and determine kinetics of disease response, and sequentially beyond consolidation to detect impending morphologic relapse. No generally applicable time points can be defined because the kinetics of MRD response differ by treatment given, marker analyzed, and method used.

[m]Monitoring of response by RT-qPCR is recommended in clinical trials and clinical practice.

[n]Sensitivity of response assessment varies by method used and by marker tested; the test used and sensitivity of the assay should always be reported; analyses should be done in experienced laboratories (centralized diagnostics).

[o]Increasing evidence that response assessment by multiparameter flow cytometry qualitatively provides a better remission status than morphologic assessment and is of high prognostic value.

Table 19-3 **2022 ELN Cytogenetic and Molecular Risk Stratification of AML**[39]

Risk Level	Subset
Favorable	t(8;21)(q22;q22.1)/*RUNX1::RUNX1T1*[a,b]
	inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB::MYH11*[a,b]
	Mutated *NPM1*[a,c] without *FLT3*-ITD
	bZIP in-frame mutated *CEBPA*[d]
Intermediate	**Mutated *NPM1*[a,c] with FLT3-ITD**
	Wild-type *NPM1* with *FLT3*-ITD (without adverse-risk genetic lesions)
	t(9;11)(p21.3;q23.3)/*MLLT3::KMT2A*[a,e]
	Cytogenetic and/or molecular abnormalities not classified as favorable or adverse
Adverse	t(6;9)(p23.3;q34.1)/*DEK::NUP214*
	t(v;11q23.3)/*KMT2A*-rearranged[f]
	t(9;22)(q34.1;q11.2)/*BCR::ABL1*
	t(8;16)(p11.2;p13.3)/*KAT6A::CREBBP*
	inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2*, *MECOM* (*EVI1*)
	t(3q26.2;v)/*MECOM* (*EVI1*)-rearranged
	−5 or del(5q); −7; −17/abn(17p)
	Complex karyotype,[g] monosomal karyotype[h]
	Mutated *ASXL1*, ***BCOR***, ***EZH2***, *RUNX1*, ***SF3B1***, ***SRSF2***, ***STAG2***, ***U2AF1***, and/or ***ZRSR2***[i]
	Mutated *TP53*[j]

Abbreviations: AML, acute myeloid leukemia; bZIP, basic leucine zipper; ELN, European LeukemiaNet.
Frequencies, response rates, and outcome measures should be reported by risk category and, if sufficient numbers are available, by specific genetic lesions indicated.
Bold text indicates the latest changes for AML.
[a]Mainly based on results observed in intensively treated patients. Initial risk assignment may change during the treatment course on the basis of the results from analyses of measurable residual disease.
[b]Concurrent *KIT* and/or *FLT3* gene mutation does not alter risk categorization.
[c]AMLs with *NPM1* mutation and adverse-risk cytogenetic abnormalities are categorized as adverse risk.
[d]Only in-frame mutations affecting the bZIP region of *CEBPA*, irrespective of whether they occur as monoallelic or biallelic mutations, have been associated with a favorable outcome.
[e]The presence of t(9;11)(p21.3;q23.3) takes precedence over rare, concurrent adverse-risk gene mutations.
[f]Excluding *KMT2A* partial tandem duplication.
[g]Complex karyotype: ≥3 unrelated chromosome abnormalities in the absence of other class-defining recurring genetic abnormalities; excludes hyperdiploid karyotypes with three or more trisomies (or polysomies) without structural abnormalities.
[h]Monosomal karyotype: presence of two or more distinct monosomies (excluding loss of X or Y), or one single autosomal monosomy in combination with at least one structural chromosome abnormality (excluding core-binding factor AML).
[i]For the time being, these markers should not be used as an adverse prognostic marker if they co-occur with favorable-risk AML subtypes.
[j]*TP53* mutation at a variant allele fraction of at least 10%, irrespective of the *TP53* allelic status (mono- or biallelic mutation); *TP53* mutations are significantly associated with AML with complex and monosomal karyotype.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-4 **NCCN Criteria for Hematologic, Cytogenic, and Molecular Response and Relapse**[127]	
Complete hematologic response	Complete normalization of peripheral blood counts with a leukocyte count $<10 \times 10^9$/L
	Platelet count $<450 \times 10^9$/L
	No immature cells, such as myelocytes, promyelocytes, or blasts, in peripheral blood
	No signs or symptoms of disease with the disappearance of palpable splenomegaly
Cytogenetic response[a]	Complete cytogenetic response: no Ph+ metaphases
	Major cytogenetic response: 0%-35% Ph+ metaphases
	Partial cytogenetic response: 1%-35% Ph+ metaphases
	Minor cytogenetic response: >35%-65% Ph+ metaphases
Molecular response	Early molecular response: *BCR-ABL1* (IS) ≤ 10% at 3 and 6 months
	Major molecular response: *BCR-ABL1* (IS) ≤ 0.1% or a 3-log reduction in *BCR-ABL1* mRNA from the standardized baseline, if qPCR (IS) is not available
	Deep molecular response:
	MR4.0: *BCR-ABL1* (IS) ≤ 0.01% or
	MR4.5: *BCR-ABL1* (IS) ≤ 0.0032%
	Complete molecular response is variably described and is best defined by the assay's level of sensitivity (eg, MR4.5)
Relapse	Any sign of loss of hematologic response or loss of CCyR
	A 1-log increase in *BCR-ABL1* transcript levels with loss of MMR should prompt bone marrow evaluation for loss of CCyR, but is not itself defined as relapse (eg, hematologic or cytogenetic relapse)

Abbreviations: CCyR, complete cytogenic response; IS, International Scale; MMR, major molecular response; MR4.0, molecular response 4.0; mRNA, messenger RNA; NCCN, National Comprehensive Cancer Network; Ph+, Philadelphia chromosome–positive; qPCR, quantitative polymerase chain reaction.
[a]A minimum of 20 metaphases should be examined.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-5 **ELN Definitions of Response to TKIs as First-Line Therapy**[125,128]

Time	Optimal	Warning	Failure
Baseline	NA	High risk or CCA/Ph+	NA
3 Months	*BCR-ABL1* ≤ 10% and/or Ph+ ≤ 35%	*BCR-ABL1* > 10% and/or Ph+ 36%-95%	Non-CHR and/or Ph+ > 95%
6 Months	*BCR-ABL1* < 1% and/or Ph+ 0	*BCR-ABL1* > 1%-10% and/or Ph+ 1%-35%	*BCR-ABL1* > 10% and/or Ph+ > 35%
12 Months	*BCR-ABL1* ≤ 0.1%	*BCR-ABL1* > 0.1%-1%	*BCR-ABL1* > 1% and/or Ph+ > 0
After 12 months	*BCR-ABL1* ≤ 0.1%	Or loss of ≤ 0.1/% (MMR)	Loss of CHR, loss of CCyR, confirmed loss of MMR,[a] new mutations, or CCA/Ph+ changes

Abbreviations: CCA/Ph+, clonal chromosomal abnormalities in Philadelphia chromosome–positive cells; CCyR, complete cytogenetic response; CHR, complete hematologic response; ELN, European LeukemiaNet; MMR, major molecular response; NA, not applicable; TKI, tyrosine kinase inhibitor.
[a]MMR: *BCR-ABL1* ≤ 0.1% or ≥3-log reduction of *BCR-ABL1*.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-6 **NCCN Criteria for TKI Discontinuation**[127]
Outside a clinical trial, all the following criteria should be met:
Age 18 years or older
Reliably taking TKI for ≥3 years
No previous resistance to a second-generation TKI that required switching to another agent
Previous evidence of a quantifiable *BCR-ABL1* transcript
Stable molecular response (ie, MR4; *BCR-ABL1* ≤ 0.01% by the IS) for ≥2 years, as documented by ≥4 separate tests performed ≥3 months apart
Access to a reliable qPCR test capable of detecting at least MR4.5, providing results within 2 weeks
Access to close monitoring: first 6 months, monthly measurement of *BCR-ABL1* by qPCR; next 18 months, measure every 2 months

Abbreviations: IS, International Scale; MR4, molecular response 4; NCCN, National Comprehensive Cancer Network; qPCR, quantitative polymerase chain reaction; TKI, tyrosine kinase inhibitor.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-7 **Myeloid Precursor Conditions**

Characteristic	Myeloid Precursor Subtype			
	CHIP	**ICUS**	**CCUS**	**MDS**
Clonal	Yes	No	Yes	Yes
Dysplasia	No	No	No	Yes
Cytopenias	No	Yes	Yes	Yes

Abbreviations: CCUS, clonal cytopenia of undetermined significance; CHIP, clonal hematopoiesis of indeterminate potential; ICUS, idiopathic cytopenia of undetermined significance; MDS, myelodysplastic syndrome.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-8 **Outcomes Based on IPSS-M Risk Stratification**

Characteristic	Very Low	Low	IPSS-M Risk Category*		High	Very High
			Moderate Low	Moderate High		
Patients—No. (%)	381 (14)	889 (33)	302 (11)	281 (11)	379 (14)	469 (17)
Risk score	≤−1.5	>−1.5 to −0.5	>−0.5 to 0	>0 to 0.5	>0.5 to 1.5	>1.5
Hazard ratio (95% CI)†	0.51 (0.39-0.67)	1.0 (Reference)	1.5 (1.2-1.8)	2.5 (2.1-3.1)	3.7 (3.1-4.4)	7.1 (6.0-8.3)
Median LFS (25%-75% range)—years‡	9.7 (5.0-17.4)	5.9 (2.6-12.0)	4.5 (1.6-6.9)	2.3 (0.91-4.7)	1.5 (0.80-2.8)	0.76 (0.33-1.5)
Median OS (25%-75% range)—years	10.6 (5.1-17.4)	6.0 (3.0-12.8)	4.6 (2.0-7.4)	2.8 (1.2-5.5)	1.7 (1.0-3.4)	1.0 (0.5-1.8)
AML-t—%						
By 1 year	0	1.7	4.9	9.5	14.3	28.2
By 2 years	1.2	3.4	8.8	14	21.2	38.6
By 4 years	2.8	5.1	11.4	18.9	29.2	42.8
Death without AML—%						
By 1 year	2.2	8.5	12	18	19.3	30.6
By 2 years	7	16.2	19.8	31.1	39.8	45.6
By 4 years	15.9	29.5	33.6	51.1	54.2	51.3

Abbreviations: AML, acute myeloid leukemia; AML-t, acute myeloid leukemia transformation; CI, confidence interval; IPSS-M, International Prognostic Scoring System with Molecular; LFS, leukemia-free survival; OS, overall survival.

*Key metrics are presented across clinical endpoints per IPSS-M risk category.

†Hazard ratio is for the risk of leukemic transformation or death. Because the low category had the largest size, it was used as the reference level.

‡The 25% to 75% range represents the central interquartile interval. For example, for a 25% to 75% OS range from A to B years, 50% of patients lived longer than A years and died before B years.

Table 19-9 **2022 WHO Classification of MPNs, Myeloid Neoplasms Associated With Eosinophilia, and MDS/MPNs**

Neoplasm	Classification
MPN	Chronic myeloid leukemia
	Polycythemia vera
	Essential thrombocythemia
	Primary myelofibrosis
	Primary myelofibrosis, prefibrotic or early stage
	Primary myelofibrosis, overt fibrotic stage
	Chronic neutrophilic leukemia
	Chronic eosinophilic leukemia
	Juvenile myelomonocytic leukemia
	MPN, NOS
Mastocytosis	
Myeloid and lymphoid neoplasms associated with eosinophilia and tyrosine kinase gene fusions	*PDGFRA* rearrangement
	PDGFRB rearrangement
	FGFR1 rearrangement
	JAK2 rearrangement
	FLT3 rearrangement
	ETV6::ABL1 fusion
	Other defined tyrosine kinase fusions: *ETV6*::*FGFR2*, *ETV6*::*LYN*, *ETV6*::*NTRK3*, *RANBP2*::*ALK*, *BCR*::*RET*, *FGFR1OP*::*RET*
MDS/MPN	Chronic myelomonocytic leukemia
	MDS/MPN with neutrophilia
	MDS/MPN with *SF3B1* mutation and thrombocytosis
	MDS/MPN, NOS

Abbreviations: MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; NOS, not otherwise specified; WHO, World Health Organization.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-10 **2016 WHO Diagnostic Criteria for PV, ET, and PMF[196]**	
Diagnosis	**Criteria Required for Diagnosis**
PV	Elevated hemoglobin concentration (men, >16.5 g/dL; women, >16.0 g/dL) or increased hematocrit (men, 49%; women, 48%) or increased red cell mass
	BM biopsy showing BM hypercellularity, trilineage hematopoiesis with prominent erythroid, granulocytic, and megakaryocyte proliferation with pleomorphic, mature megakaryocytes
	JAK2 V617F or *JAK2* exon 12 mutation; if such a mutation is absent, diagnosis of PV is still possible if there is a subnormal erythropoietin level
	Minor criterion: subnormal serum erythropoietin level
	Diagnosis of PV requires meeting either all three major criteria, or the first two major criteria and the minor criterion[a]
ET	Persistently elevated platelet count (≥450 × 10^9/L)
	BM with predominant proliferation of enlarged, mature megakaryocytes with hyperlobulated nuclei
	Not meeting diagnostic criteria for classic CML, PV, PMF, MDS, or other myeloid neoplasms
	JAK2 V617, *CALR*, or *MPL* mutation
	Minor criterion: presence of another clonal marker; if no clonal marker is present, there is no evidence of reactive thrombocytosis
	Diagnosis of ET requires meeting all four major criteria or the first three major criteria and the minor criterion
PMF	Megakaryocyte proliferation and atypia. For pre-PMF: no reticulin fibrosis grade >1, BM hypercellularity, granulocytic proliferation, and often decreased erythropoiesis. For overt PMF: grade 2-3 reticulin and/or collagen fibrosis
	Not meeting diagnostic criteria for classic CML, PV, ET, MDS, or other myeloid neoplasms
	JAK2 V617, *CALR*, or *MPL* mutation or other clonal marker; if no clonal marker is present, there is no evidence of minor reactive BM reticulin fibrosis (for pre-PMF) or reactive myelofibrosis (for overt PMF)
	Minor criteria: (1) anemia, (2) leukocytosis ≥11 × 10^9/L, (3) palpable splenomegaly, (4) LDH elevation, or (5), leuko-erythroblastosis (for overt PMF only)
	Diagnosis of overt PMF requires meeting all three major criteria and at least one minor criterion

Abbreviations: BM, bone marrow; CML, chronic myeloid leukemia; ET, essential thrombocythemia; LDH, lactate dehydrogenase; MDS, myelodysplastic syndrome; MF, myelofibrosis; PMF, primary myelofibrosis; PV, polycythemia vera; WHO, World Health Organization.

[a]Criterion number 2 (BM biopsy) may not be required in patients with sustained absolute erythrocytosis: hemoglobin levels >18.5 g/dL in men (hematocrit, 55.5%) or >16.5 g/dL in women (hematocrit, 49.5%) if major criterion 3 and the minor criterion are present. However, initial MF (present in up to 20% of patients) can be detected only by performing a BM biopsy; this finding may predict a more rapid progression to overt MF (post-PV MF).

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-11 **Major Adverse Effects of *JAK* Inhibitors Used in Myelofibrosis**[196]

Drug	Adverse Effect
Ruxolitinib	Anemia and thrombocytopenia
	Herpes simplex and zoster reactivation (give recombinant vaccine before starting if possible)
	Tuberculosis reactivation
	Progressive multifocal leukoencephalopathy (rare)
	Reactivation of hepatitis B
	Nonmelanoma skin cancers
	Lymphoid neoplasms
	Withdrawal syndrome if stopped suddenly
	Hyperlipidemia and weight gain
Fedratinib	Diarrhea
	Liver function changes
	Wernicke encephalopathy (thiamine level should be tested before initiation)
Pacritinib	Anemia
	Thrombocytopenia (but less than with other *JAK2* inhibitors and approved in those with platelets $<50 \times 10^9$/L)
	Diarrhea
	Edema
Momelotinib	Anemia and thrombocytopenia, but less anemia and transfusion dependence with its use
	Abdominal pain
	Headache
	Neuropathy
	Asthenia
	A “first dose” effect with dizziness, hypotension, and flushing has been reported

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-12 **Summary of WHO Classification of Lymphoid Leukemia**[196]	
	B-Lymphoblastic Leukemia/Lymphoma, NOS
B-lymphoblastic leukemia/lymphoma	B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
	B-lymphoblastic leukemia/lymphoma with t(9;22)(q34.1;q11.2); *BCR-ABL1*
	B-lymphoblastic leukemia/lymphoma with t(v;11q23.3); *KMT2A* rearranged
	B-lymphoblastic leukemia/lymphoma with t(12;21)(p13.2;q22.1); *ETV6-RUNX1*
	B-lymphoblastic leukemia/lymphoma with hyperdiploidy
	B-lymphoblastic leukemia/lymphoma with hypodiploidy
	B-lymphoblastic leukemia/lymphoma with t(5;14)(q31.1;q32.3); *IL3-IGH*
	B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3); *TCF3-PBX1*
	Provisional entity: B-lymphoblastic leukemia/lymphoma, *BCR-ABL1*-like
	Provisional entity: B-lymphoblastic leukemia/lymphoma with *iAMP21*
T-lymphoblastic leukemia/lymphoma	Provisional entity: early T-cell precursor lymphoblastic leukemia
	Provisional entity: NK-cell lymphoblastic leukemia/lymphoma

Abbreviations: NK, natural killer (cell); NOS, not otherwise specified; WHO, World Health Organization.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-13 **Prognostic Risk Factors in ALL**	
	Risk Factor
Pretreatment	Age
	Leukocyte count
	CNS involvement
	Cytogenetic abnormalities
	Molecular abnormalities
Post-treatment	Achievement of complete remission
	MRD state

Abbreviations: ALL, acute lymphoblastic leukemia; CNS, central nervous system; MRD, measurable residual disease.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-14 **Clinical Features and Associations With CLL**
Infections
Hypogammaglobulinemia
Reduced levels of complement
Impaired phagocytic killing of nonopsonized bacteria
Functional impairment of T-cell subsets
Autoimmunity
Autoimmune hemolytic anemia
Immune thrombocytopenia
Pure red cell aplasia
Aggressive transformation
Richter transformation
Secondary malignant disease
Skin cancers (including melanomas)
Colon cancers
Lung cancers
Myeloid neoplasms

Abbreviation: CLL, chronic lymphocytic leukemia.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-15 **Cytogenetic and Molecular Abnormalities of CLL**
Deletion of 13q14
Deletion of 11q
Trisomy 12
Abnormalities of chromosome 17 (del(17p) with *TP53* gene disruption)
BCL2 gene overexpression
IgH variable domain mutations
ZAP70
Recurrent mutations involving *TP53*, *NOTCH1*, *SF3B1*, and *BIRC3*

Abbreviation: CLL, chronic lymphocytic leukemia.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-16 **Rai Classification for Clinical Staging of CLL**[295]

Risk	Stage	Description	Median Survival (Years)[a]
Low	0	Lymphocytosis in blood or bone marrow	>12.5
Intermediate	I	Lymphadenopathy	8.5
	II	Splenomegaly and/or hepatomegaly with or without lymphadenopathy	6
High	III	Anemia (hemoglobin, <13 g/dL)[b]	1.5
	IV	Thrombocytopenia (platelet count <105/mcL)[b]	1.5

Abbreviation: CLL, chronic lymphocytic leukemia.
[a]Of historical significance because outcomes are changing with newer therapies.
[b]Anemia and thrombocytopenia cannot be immune-mediated.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-17 **Binet Classification for Clinical Staging of CLL**[296]

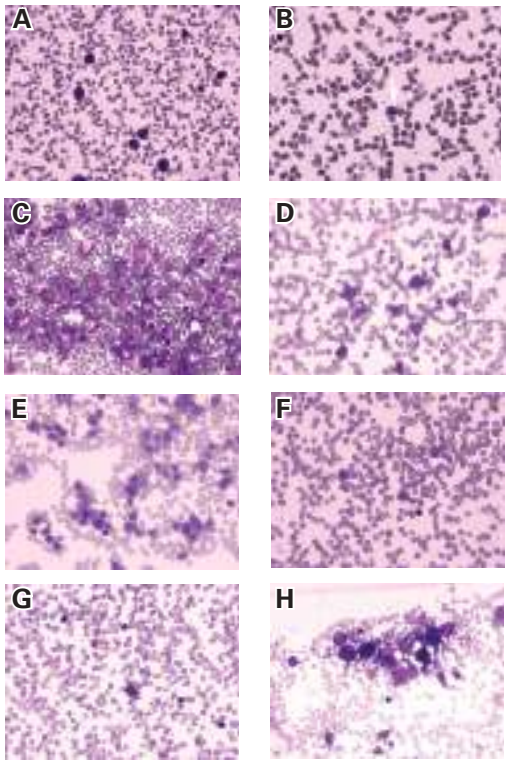
Stage	Description	Median Survival (Years)[a]
A	<2 node-bearing areas[b]	>10
B	>3 node-bearing areas	5
C	Anemia (<10.0 g/dL) and/or thrombocytopenia (platelet count <100,000/mcL)	2

Abbreviation: CLL, chronic lymphocytic leukemia.
[a]Of historical significance because outcomes are changing with newer therapies.
[b]Five node-bearing areas are possible: cervical, axillary, inguinal-femoral, spleen, and liver.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 19-18 **Common Toxicities of Drugs Used for First-Line CLL Therapy**	
Drug	**Adverse Effect**
BTKis	Diarrhea
	Fatigue
	Arthralgias/cramps
	Infections
	Bleeding (with acalabrutinib and ibrutinib; warfarin should be avoided)
	Atrial fibrillation
	Hypertension - Acalabrutinib and zanubrutinib have more favorable toxicity profiles compared with ibrutinib because they are more specific inhibitors[292,316]
	PPIs are discouraged with acalabrutinib
Venetoclax	Tumor lysis syndrome (5-week ramp-up recommended)
	Neutropenia

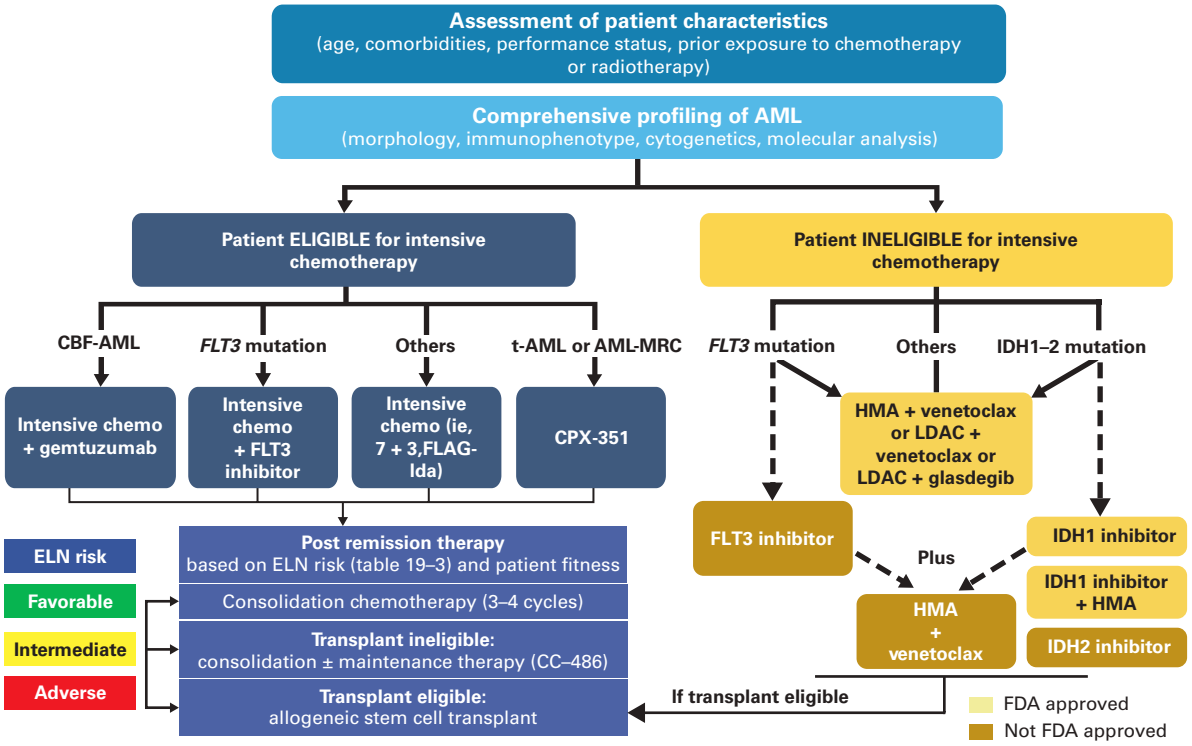
Abbreviations: BTKi, Bruton tyrosine kinase inhibitor; CLL, chronic lymphocytic leukemia; PPI, proton pump inhibitor.
Diminished vaccine responses are seen with all targeted agents; in general, live vaccines are not recommended in CLL.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 19-1 Morphologic Spectrum of AMLs



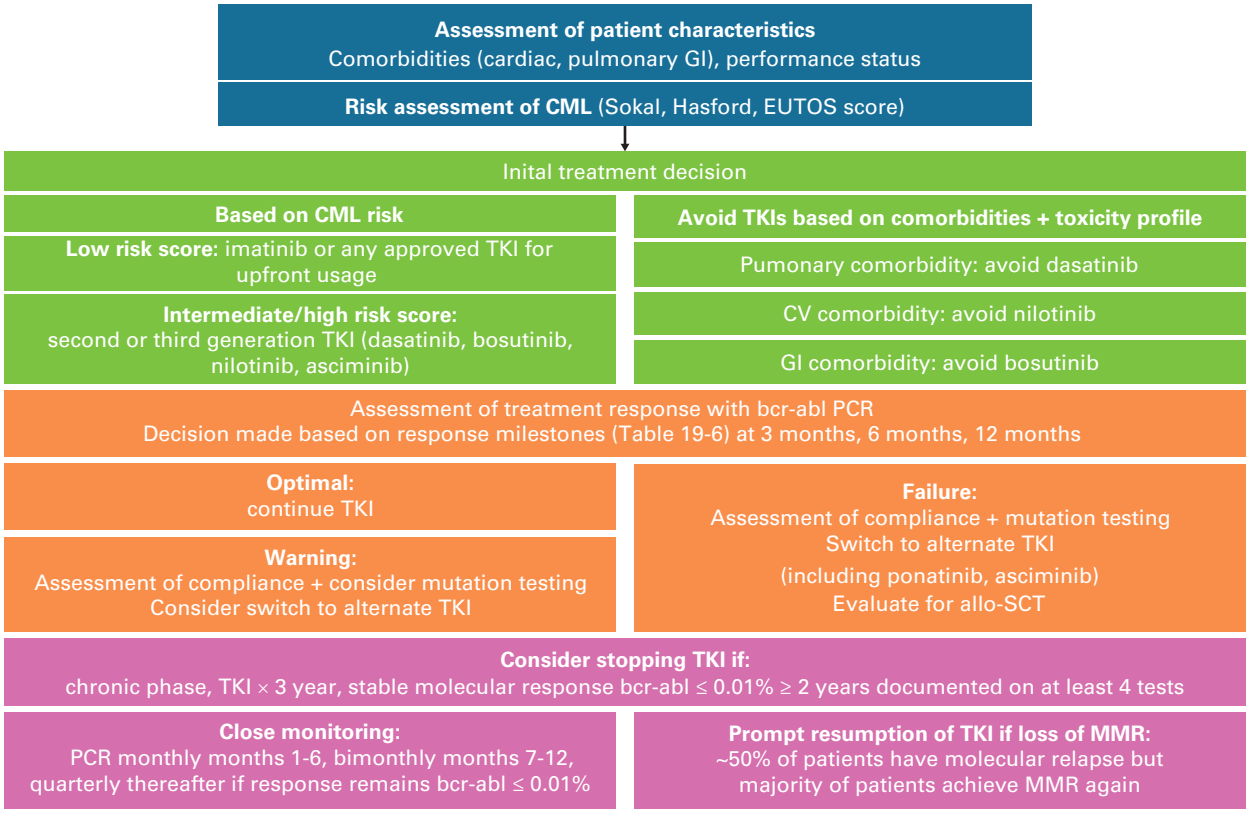
(A) Acute myeloblastic leukemia (AML) with minimal maturation. The cells are myeloblasts with dispersed chromatin and variable amounts of agranular cytoplasm; some display medium-sized, poorly defined nucleoli. (B) AML with maturation. Some of the blasts contain azurophilic granules, and there are promyelocytes. Note the Auer rod (arrow). (C) Acute promyelocyte leukemia. All of these cells are promyelocytes containing coarse cytoplasmic granules that sometimes obscure the nuclei. (D) Acute myelomonocytic leukemia. Promonocytes with indented nuclei are present with myeloblasts; the dense nuclear staining is unusual. (E) Acute monoblastic leukemia. These characteristic monoblasts have round nuclei with delicate chromatin and prominent nucleoli that stain intensely with nonspecific esterase (not shown); cytoplasm is abundant. (F) Acute monocytic leukemia. Most of the cells in this field are promonocytes; monoblasts and an abnormal monocyte are also present. (G) Acute erythroid leukemia. Dysplastic multinucleated erythroid precursors with megaloblastoid nuclei are present. (H) Acute megakaryoblastic leukemia. In this marrow biopsy specimen, there are large and small blasts as well as atypical megakaryocytes. Photographs and permission provided by Dr. Farid Barakat.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 19-2 First-Line Treatment Algorithm for AML



Abbreviations: AML, acute myeloid leukemia; AML-MRC, AML with myelodysplasia-related changes; CBF, core binding factor; CBF-AML, core binding factor AML; CC-486, oral azacitidine; chemo, chemotherapy; CPX-351, liposomal formulation of cytarabine and daunorubicin coencapsulated at a fixed molar ratio (5:1); ELN, European LeukemiaNet; FLAG-Ida, fludarabine, cytarabine, and granulocyte colony-stimulating factor with idarubicin; FL3, fms-like tyrosine kinase 3; HMA, hypomethylating agent; IDH, isocitrate dehydrogenase; LDAC, low-dose Ara-C (cytarabine); t-AML, therapy-related AML.
Dotted lines indicate alternative considerations.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 19-3 Treatment Algorithm for CP-CML Adapted From NCCN and ELN Guidelines[32,36,40]



Abbreviations: allo-SCT, allogeneic stem cell transplantation; CP-CML, chronic phase chronic myeloid leukemia; CV, cardiovascular; ELN, European LeukemiaNet; EUTOS, European Treatment Outcome Study; GI, gastrointestinal (tract); MMR, major molecular response; NCCN, National Comprehensive Cancer Network; PCR, polymerase chain reaction; TKI, tyrosine kinase inhibitor.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 19-4 Treatment Algorithm for Newly Diagnosed MDS

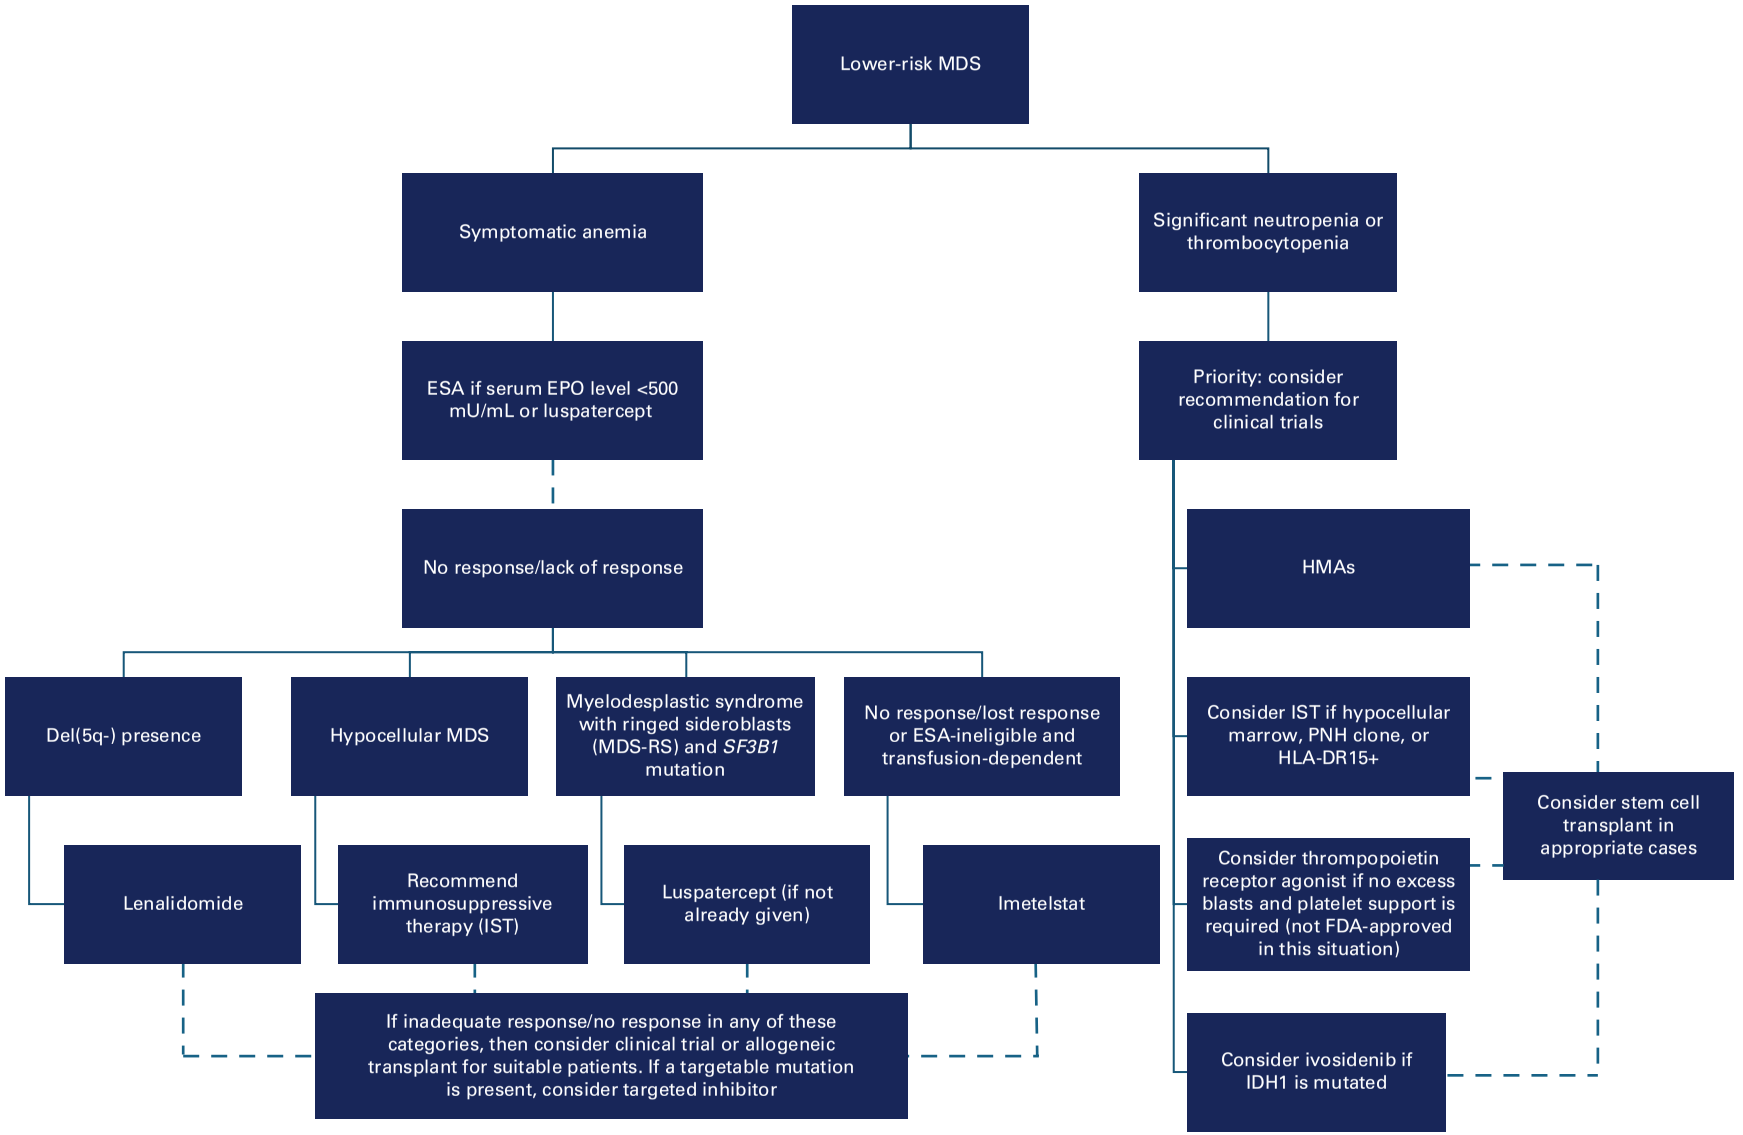


Figure 19-4 Continued

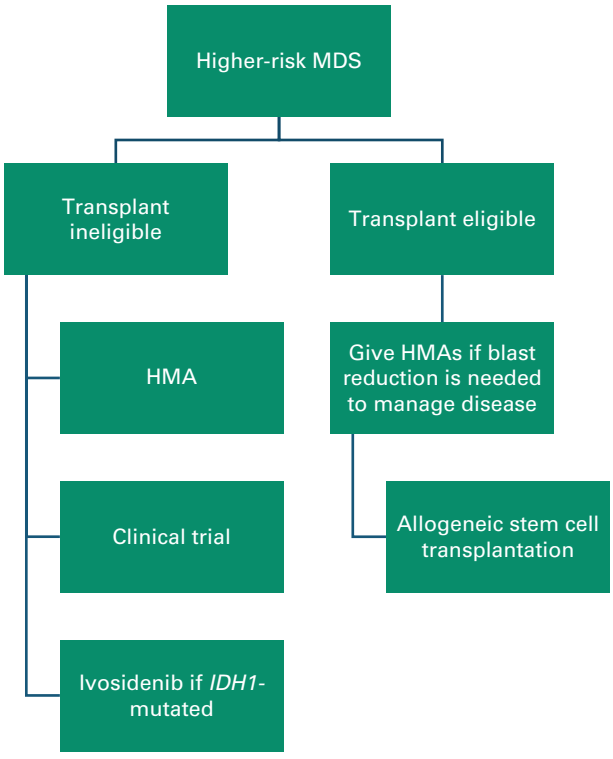

Abbreviations: EPO, erythropoietin; ESA, erythropoiesis-stimulating agents; HMA, hypomethylating agent; IDH, isocitrate dehydrogenase; IST, immunosuppressive therapy; MDS, myelodysplastic syndrome; PNH, paroxysmal nocturnal hemoglobinuria.
Dotted lines indicate alternative considerations.
Lower risk = very low and low by IPSS-R and very low, low, and moderate low by IPSS-M; higher risk = intermediate, high, and very high by IPSS-R and moderate high, high, and very high by IPSS-M.

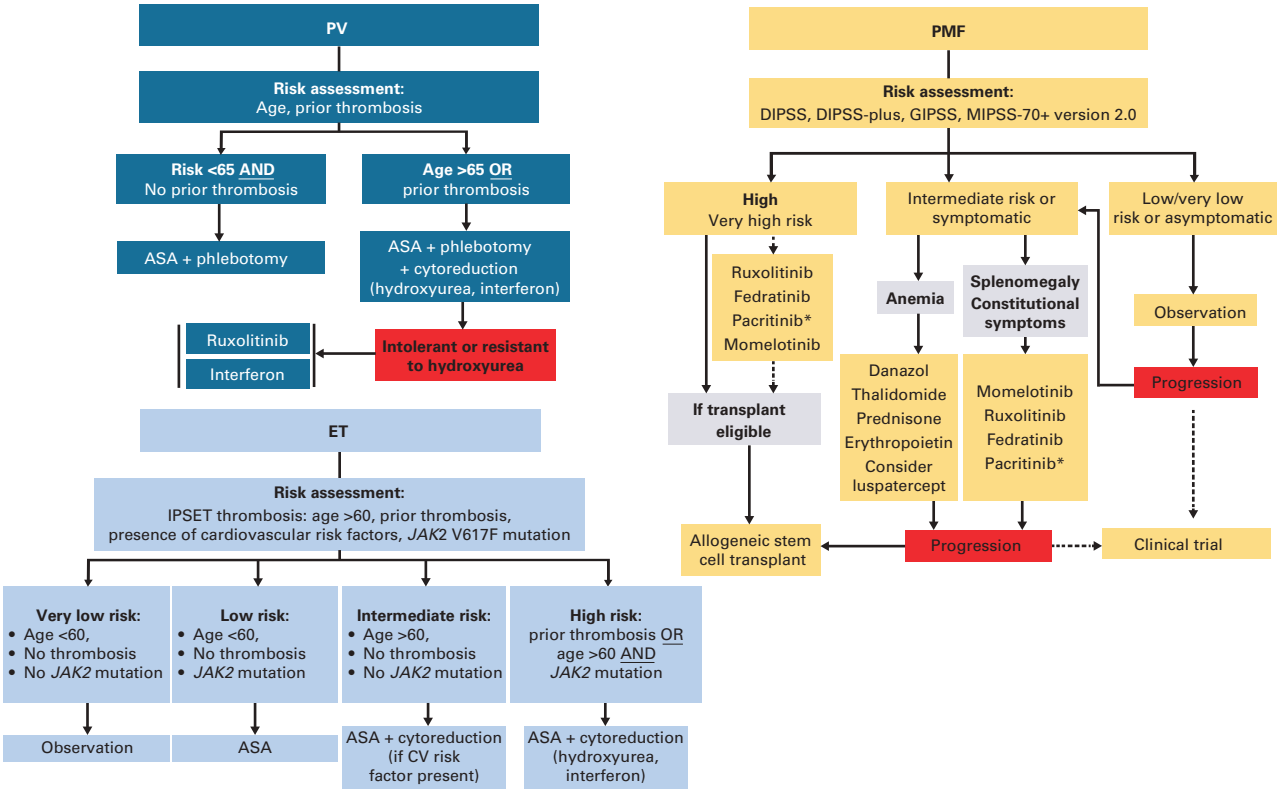
Figure 19-5 Treatment Algorithm for MPNs



Abbreviations: ASA, acetylsalicylic acid; CV, cardiovascular; DIPSS, Dynamic International Prognostic Scoring System; DIPSS Plus is based on clinical and cytogenetic information; ET, essential thrombocythemia; GIPSS, Genetically Inspired Prognostic Scoring System; IPSET, International Prognostic Score (of thrombosis) in Essential Thrombocythemia (IPSET-thrombosis); MIPSS70 + v2.0, mutation-enhanced IPSS plus karyotype is based on clinical, cytogenetic, and mutational information; MPN, myeloproliferative neoplasm; PMF, primary myelofibrosis; PV, polycythemia vera.
*If platelets <50 x 10^9/L
Dotted lines indicate alternative considerations.

LYMPHOMAS 20

Kathryn Lurain, MD, MPH, and Venu Madhav Konala, MD

RECENT UPDATES

- The World Health Organization (WHO) released a new classification for lymphoid neoplasms, altering nomenclature and diagnostic criteria and introducing new subtypes.[1]
- Second-line chimeric antigen receptor T-cell therapies gained approval in diffuse large B-cell lymphoma (DLBCL), including the following:
  - Axicabtagene ciloleucel (axi-cel) and lisocabtagene maraleucel (liso-cel): for patients refractory or relapsing within 12 months of first-line chemoimmunotherapy.[2]
  - Liso-cel for patients who have DLBCL relapsed/refractory to first-line therapy and not eligible for hematopoietic stem cell transplantation (HSCT) because of comorbidities or age.[3]
- Tisagenlecleucel and liso-cel are now approved for treatment of relapsed or refractory follicular lymphoma after two or more lines of systemic therapy, adding to axi-cel previously approved in this setting.
- Novel, bispecific T-cell engagers targeting CD20 and CD3 represent an important new class of therapy with recent approvals for both follicular lymphoma and DLBCL after two or more lines of therapy, and the combination of the Bruton tyrosine kinase (BTK) inhibitor zanubrutinib with obinutuzumab gained accelerated approval for relapsed/refractory follicular lymphoma.[4]
- Epcoritamab-bysp, now FDA approved both as monotherapy and in combination with lenalidomide and rituximab for relapsed or refractory follicular lymphoma, significantly improved progression-free survival and response rates compared with standard R^2 therapy in the EPCORE FL-1 trial.[5]
- The FDA approved the combination of tafasitamab with lenalidomide and rituximab for adults with relapsed or refractory follicular lymphoma, with demonstrated consistent benefit across all prespecified subgroups, including high-risk patients.[6]
- The STARGLO trial demonstrated an overall survival benefit of glofitamab plus gemcitabine and oxaliplatin (GemOx) over R-GemOx alone in patients with relapsed or refractory DLBCL ineligible for autologous stem cell transplant after at least one prior line of therapy.[7]
- An update of the ECHELON-1 trial showed that brentuximab and vedotin and doxorubicin, vinblastine, and dacarbazine (BV-AVD) showed a small but statistically significant overall survival benefit in first-line treatment of advanced-stage classic Hodgkin lymphoma (cHL) compared with standard doxorubicin, bleomycin, vinblastine, and dacarbazine at a cost of an increase in certain acute toxicities.[8]
- SWOG trial 1826 demonstrated a progression-free survival advantage of nivolumab in combination with AVD (N-AVD) over BV-AVD in newly diagnosed advanced-stage cHL, and N-AVD is considered a new standard-of-care option in this patient population.[9-11]
- Randomized trials in first-line treatment of mantle cell lymphoma (MCL) incorporating BTK inhibitors have been reported with a potential effect on the standard of care for transplant-eligible and transplant-ineligible older patients.[12]
- Brexucabtagene autoleucel and liso-cel are approved for relapsed/refractory MCL.
- In March 2026, there was a voluntary manufacturer recall of tazemetostat, previously used to treat follicular lymphoma. This was based on emerging data from the ongoing Phase Ib/III SYMPHONY-1 trial on secondary hematologic malignancies.

OVERVIEW

Lymphomas are a heterogeneous group of malignancies derived from mature B, T, and natural killer (NK) cells that encompass more than 100 distinct biologic entities, according to the latest version of the World Health Organization (WHO) classification.

This chapter covers indolent B-cell lymphomas (BCLs), aggressive BCLs, and T-cell lymphomas (TCLs). In the United States, approximately 85% to 90% of non-Hodgkin lymphomas (NHLs) are of B-cell origin, 10% to 15% are T-cell-derived, and less than 1% are NK-cell malignancies, but there is considerable worldwide variation, including higher rates of T- and NK-cell lymphomas in East Asian populations.

Hodgkin lymphoma, discussed in the final section of this chapter, is considered a mature B-cell malignancy with a deregulated B-cell program. The initial diagnostic approach and staging considerations for non-Hodgkin and Hodgkin lymphomas are similar and are discussed jointly. However, historically, treatment algorithms for these two groups have been distinct; therefore, management of non-Hodgkin and Hodgkin lymphomas is discussed separately. In this chapter, the term "lymphoma" is used whenever discussing issues pertinent to both non-Hodgkin and Hodgkin lymphomas. The WHO lymphoma classification, last published in 2008 and updated in 2022, is the reference standard for defining lymphoma subtypes.[1,13] Clinicians often classify NHL subtypes into indolent (slow growing) or aggressive (fast growing) to facilitate clinical decision-making regarding therapy and to estimate disease prognosis.

NON-HODGKIN LYMPHOMA

EPIDEMIOLOGY AND ETIOPATHOGENESIS

NHL is the seventh most common cause of cancer in men and the sixth most common cause in women. Annually, NHL accounts for approximately 80,000 new cancers and 20,000 deaths.[14] The median age of patients diagnosed with NHL varies by histologic subtype, although the incidence of most subtypes increases with age. In 2020, an estimated 790,000 people were living with lymphoma.[15] Many patients can expect to be cured of lymphoma or to live with it for a prolonged time. This is an important consideration when making management decisions because survivors are at increased risk of late toxicity and organ damage related to treatment.

The etiology of NHL in most patients is unknown beyond inherent genomic instability related to the B- and T-cell gene rearrangement process, but associations exist with chronic viral or bacterial infections, innate or acquired immunodeficiency, autoimmunity, environmental exposures, and rarely familial predisposition. Several viruses have been linked, either directly or indirectly, to specific lymphoma subtypes, including Epstein-Barr virus (EBV), hepatitis C virus, human herpesvirus 8, human

T-lymphotrophic virus 1, and human immunodeficiency virus (HIV), among others. Of note, the incidence of lymphoma subtypes associated with HIV has decreased in the era of antiretroviral therapy (ART). Bacterial infections, such as *Helicobacter pylori*, observed in association with gastric marginal zone lymphomas (MZLs), may result in lymphoma as a result of chronic antigenic stimulation. Autoimmune conditions (eg, Sjogren syndrome, systemic lupus erythematosus) are associated with an increased risk of lymphoma, including MZL and follicular lymphoma (FL). Support for an environmental contribution to lymphoma risk comes from observations that NHL incidence increases in industrialized regions, and several pesticides and chemical substances might contribute to lymphoma development.[16] Genetic predisposition plays a small role in lymphoma and remains an underexplored area. Whereas hereditary forms are rare, familial clustering is observed more frequently, and first-degree relatives of patients with lymphoma are at higher risk of developing a lymphoproliferative disorder.[17]

In terms of pathophysiology, B-cell NHL develops at various points during normal B-cell ontogeny (Fig. 20-1). A majority of BCLs are thought to originate from B cells undergoing the germinal center reaction.[13] After birth in the bone marrow, B cells undergo affinity maturation via exposure to antigenic stimuli, resulting in class-switch recombination and somatic hypermutation in the germinal center. These tremendous pressures and associated rapid proliferation likely increase the retention of adverse mutations and chromosomal errors, leading to malignancy and distinct diagnostic features.

DIAGNOSIS, STAGING, AND INITIAL EVALUATION

Diagnosis

The clinical presentation of NHL is variable. Most patients who have indolent disease present with incidentally noted, asymptomatic adenopathy, organomegaly, or occasionally peripheral blood abnormalities detected during a routine exam. By contrast, patients with aggressive lymphomas often present after noticing a rapidly growing mass or experiencing constitutional symptoms or pain associated with a site of disease. Symptoms may be related to compression of anatomic structures and may include cough, jaundice, ureteral obstruction, and neurologic compromise, among others. Constitutional symptoms may include classic B symptoms (eg, unexplained fevers, recurrent drenching night sweats, and ≥10% unintentional weight loss), which are more common in diffuse large B-cell lymphoma (DLBCL) and Hodgkin lymphoma, or may be asthenia or weakness. Pruritus, a classic paraneoplastic phenomenon associated with Hodgkin lymphoma, may occasionally occur in other B-cell malignancies.

Confirming a lymphoma diagnosis requires adequate tissue and appropriate preparation, permitting pathologic evaluation, which may include immunohistochemistry, flow cytometry, cytogenetic testing, and gene sequencing. An excisional lymph node biopsy yields the most tissue and is the gold standard for lymphoma diagnosis. It allows the hematopathologist to examine the nodal architecture, which is critical to adjudicating lymphoma subtypes. For example, in FL, morphologic analysis typically shows a preserved nodular pattern, whereas mantle cell lymphoma (MCL) or small lymphocytic lymphoma (SLL) is characterized by a diffuse infiltrate, and DLBCL causes a complete effacement of the lymph node architecture. When a lymph node or extranodal lesion is difficult to access, or a surgical biopsy would be unsafe, multiple core biopsies may be performed in lieu of an excision. Fine-needle aspiration (FNA) is rarely sufficient for diagnostic purposes.

Cytogenetic testing is routinely performed at most centers and can aid in ascertaining the lymphoma subtype (Table 20-1). These are especially helpful when the morphologic and immunohistochemical testing is inconclusive. These may also inform prognostication and guide the selection of therapy. For example, the t(11;14) leading to upregulation of cyclin D1 is a diagnostic hallmark of MCL and translocations involving the *MYC* gene (t(8;14)(q24;q32); t(2;8)(p11;q24), or t(8;22)(q24;q11)). On the other hand, the t(14;18) is a less specific marker as it is present in most patients with FL, some cases of DLBCL, and occasionally other subtypes[18] or even healthy individuals.[19] Concurrent rearrangements involving *MYC* and *BCL2* genes in a patient with DLBCL are diagnostic of so-called double-hit lymphoma (DHL) or DLBCL/HGBCL-MYC/BCL2 by the 2022 WHO classification.[1] This subtype is associated with a poor prognosis using standard therapy for DLBCL, warranting strong consideration for clinical trial or intensive treatment regimens.

Staging and Pretreatment Testing

The historical staging system for both Hodgkin and NHL has been the Ann Arbor classification, Cotswolds revision.[4] Typical staging involved CT scans of the chest, abdomen, and pelvis, along with a bone marrow biopsy. With the advent of functional imaging via PET, the Lugano classification was introduced and has several implications for the modern staging of lymphomas.[21] First, a staging bone marrow biopsy is no longer routinely required for the staging of Hodgkin lymphoma or DLBCL if PET/CT imaging has been performed. Second, PET/CT imaging should be used to assess response in consistently fluorodeoxyglucose (FDG)-avid histologies; interpretation of PET scans should be via the five-point scale,[22] also called the Deauville criteria. Third, the suffix notations for the absence (A) and presence (B) of B symptoms are required only for Hodgkin lymphoma, although many practitioners continue to use these as descriptive elements for NHL. For the most up-to-date staging information, please consult the NCCN guidelines.

Stage describes disease location (nodal vs. extranodal) and extent (limited vs. advanced) and may incorporate information on disease bulk. Stage may also have an effect on prognosis and treatment, although, typically, the specific subtype and its associated pathobiologic features have a greater influence on the choice of initial treatment.

Table 20-1 **Key Diagnostic Immunophenotypic and Cytogenetic Features of Non-Hodgkin Lymphomas**

Lymphoma Subtype	CD20	CD10	CD5	CD30	Other	Cytogenetics/ FISH Results	Genes
DLBCL: germinal center subtype	+++	+/−	Rare	Rare	*BCL6*$^+$ and MUM1$^-$	*BCL2* translocations (18q21)	*BCL6* and *EZH2* upregulation
DLBCL: nongerminal center subtype	+++	—	+/−	Rare	*BCL6* negative or *BCL6*$^+$, MUM1$^+$	*BCL6* translocations (3q27)	B-cell receptor signaling/*NFkB* activation
FL	+++	+	—	—		t(14;18)	*BCL2*
CLL/SLL	Dim	—	+	—	CD23$^+$		
MCL	+++	—	+	—	CD23$^-$, Cyclin D1$^+$, SOX11$^+$	t(11;14)	*Cyclin D1*
MZL	+++	—	Rare	—		t(11;18) (ENMZL) trisomy 3, 18 (NMZL) del 7q (SMZL)	*API2-MALT1*
LPL/WM	+++	—	Rare	—			*MYD88, CXCR4*[20]
Burkitt lymphoma	+++	+	—	—	TdT$^-$	t(8;14), t(8;22), t(2;8)	*MYC*
PMBL	+++	+/−	—	Occasional		t(16;X), 9p24.1 gain	*CIITA, PDL1/ JAK2/PDL2*
Hairy cell leukemia	+++	—	—	—	CD11c$^+$, CD25$^+$, CD103$^+$		
ALCL, ALK$^+$	—	—	—	+++		t(2; 5)	*ALK*
ALCL, ALK$^-$	—	—	—	+++		t(6;7)	*DUSP22*
AITL	—	+/−	+/−	—	At least three T_{FH} markers: PD-1, BCL6, CXCL13, ICOS, SAP, CCR5		*TET2, IDH2, DNMT3A, RHOA, ITK-SYK*
PTCL-NOS	—	+/−	+/−	—	Can have the same immunophenotype as AITL, often with dropped CD3 or CD7		

Abbreviations: AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; ALK, anaplastic lymphoma kinase; API2-MALT1, fusion of apoptosis inhibitor 2 and mucosa-associated lymphoid tissue lymphoma translocation 1; BCL2, B-cell CLL/lymphoma 2; BCL6, B-cell lymphoma 6; CCR5, chemokine, CC motif, receptor 5; CIITA, class II major histocompatibility complex transactivator; CLL, chronic lymphocytic leukemia; CXCL13, chemokine, CXC motif, ligand 13; DLBCL, diffuse large B-cell lymphoma; DNMT3A, DNA methyltransferase 3A; DUSP22, dual-specificity phosphatase 22; ENMZL, extranodal marginal zone lymphoma; FISH, fluorescence in situ hybridization; FL, follicular lymphoma; ICOS, inducible T-cell costimulator; IDH, isocitrate dehydrogenase 2; ITK-SYK, fusion of IL2-inducible T-cell kinase and protein-tyrosine kinase SYK; LPL, lymphoplasmacytic lymphoma; MCL, mantle cell lymphoma; MYC, MYC proto-oncogene, bHLH transcription factor; MYD88, MYD88 innate immune signal transduction adaptor; MZL, marginal zone lymphoma; NMZL, nodal marginal zone lymphoma; PD-1, programmed cell death protein 1; PMBL, primary mediastinal B-cell lymphoma; PTCL-NOS, peripheral T-cell lymphoma not otherwise specified; RHOA, RAS homolog gene family, member A; SLL, small lymphocytic lymphoma; SMZL, splenic marginal zone lymphoma; TET2, TET methylcytosine dioxygenase 2; T_{FH}, T-follicular helper cell; WM, Waldenström macroglobulinemia.

In addition to radiographic staging, screening for central nervous system (CNS) involvement, which may include leptomeningeal or parenchymal involvement, should be undertaken in all patients with suspicious neurologic findings, those with Burkitt lymphoma, and select people with high-grade lymphomas (eg, double-hit lymphoma [DHL], DLBCL of the testis, or very high CNS International Prognostic Index [CNS-IPI] risk score).[23] A lumbar puncture with cytologic and, ideally, flow cytometric analysis of cerebrospinal fluid (CSF) and imaging with MRI may identify CNS disease in high-risk patients and guide CNS-directed therapy.

Other tests performed at the time of initial evaluation may include cardiac function assessment (if treatment will include anthracyclines); pulmonary function testing (if treatment will include bleomycin); and laboratory testing including, at a minimum,

a complete blood count (CBC) with differential, comprehensive metabolic profile, serum lactate dehydrogenase (LDH), uric acid, hepatitis B screening, and a pregnancy test in women of childbearing age. Additional tests, including hepatitis C and HIV screening and b-2 microglobulin, may be helpful in selected patients. Testing for hepatitis B is required before the use of rituximab or other CD20-directed therapies because of the risks of viral reactivation and fatal hepatitis. Tests should include those for hepatitis B surface antigen and core antibody for patients who do not have risk factors. Patients who are seropositive for hepatitis B surface antigen or hepatitis core antibody must receive prophylactic therapy against hepatitis B with an antiviral during therapy and at least 12 months after completion.[24-26] Those who are HBV DNA positive may require therapeutic doses of anti–hepatitis B therapy and a hepatology consultation as appropriate. Similarly, hepatitis C treatment may be warranted in cases of lymphoma associated with hepatitis C, such as splenic marginal zone lymphoma.

SURVIVORSHIP AND SURVEILLANCE

Improved diagnostic and staging methods, improved treatments, and supportive care measures have led to an ever-increasing number of people who are either cured of their disease or are living with chronic NHL. Consequently, survivorship care plays an important role in the long-term management of lymphoma patients. The review of late effects of therapy is beyond the scope of this chapter and is offered elsewhere.[27,28]

Most patients who have Hodgkin lymphoma and a majority of those who have DLBCL can expect to be cured of their disease with standard therapy. The risk of recurrence is highest in the first 2 years after initial therapy and then decreases. Relapses are rare beyond 5 years, at which point follow-up with a lymphoma specialist is generally no longer required. The need for routine radiographic surveillance of asymptomatic patients has been questioned based largely on several retrospective analyses. Collectively, these studies found that recurrence was detected in only 2% to 5% of patients who were otherwise clinically and hematologically stable; furthermore, there was no difference in survival if relapse was detected radiographically or after the patient presented with signs or symptoms of disease recurrence.[29,30] Because of the increased exposure to radiation and contrast dye, associated cost and patient inconvenience, and potential test-related anxiety, routine surveillance scans after FDG PET–defined complete remission should be performed no more often than every 6 months for the first 2 years after completion of therapy per National Comprehensive Cancer Network (NCCN) guidelines. However, all patients should be observed clinically for disease monitoring and to address specific toxicities that may emerge later, such as hypothyroidism, infertility, premature menopause, and secondary malignancies. Guidelines for the surveillance of patients with indolent NHL are less defined, and practice varies among physicians.

INDOLENT NON-HODGKIN LYMPHOMA

Indolent lymphomas are characterized by slow growth, sometimes spanning decades, and by a waxing and waning course. With the exception of limited-stage disease treated with radiation therapy (RT), they are incurable with standard approaches. The most common indolent lymphomas include FL, MZL, lymphoplasmacytic lymphoma/Waldenström macroglobulinemia (LPL/WM), and chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL). The lifetime risk of transformation of an indolent NHL to an aggressive B-cell NHL is approximately 30%; the transformation rate is approximately 2% per year but varies somewhat by tumor type.

KEY POINTS

- NHLs comprise a group of heterogeneous diseases that vary widely with respect to clinical presentation, therapy, and prognosis.
- Advances in the diagnosis and classification of these diseases are facilitated by immunophenotyping and by newer molecular and genetic approaches.
- Establishing a correct diagnosis at the time of initial presentation is critical to optimal management of NHL. Therefore, an adequately sized biopsy specimen is mandatory to permit rigorous classification. FNA is virtually never adequate for establishing the initial subtype of non-Hodgkin lymphoma.
- Indolent NHLs usually grow slowly and are also known as low-grade lymphomas. FL, MZL, LPL, and SLL are all indolent lymphomas.
- Transformation to a higher grade occurs at a rate of approximately 2% per year.

FOLLICULAR LYMPHOMA

FL is the second most common type of lymphoma and represents the paradigm for indolent NHL. FL typically presents with painless lymph node enlargement without systemic B-symptoms, though disseminated disease and marrow involvement are common. Symptoms of FL are often associated with high tumor burden and may include nodal enlargement alone, organ compression (eg, hydronephrosis) from nodes or conglomerates, cytopenias, splenomegaly, effusions, and, in a minority of cases, systemic "B" symptoms. Lymph node biopsy shows a mixture of centrocytes and centroblasts forming densely packed follicles (a follicular

growth pattern) in classic FL. Two other FL variants, based on the 2022 WHO classification, are defined by predominant centroblasts (known as follicular large B-cell lymphoma) or a diffuse growth pattern (FL with uncommon features).[1] The characteristic immunophenotype reflects a germinal center origin, including the B-cell markers CD20 and often CD10 without CD5. The protein BCL2 is overexpressed in >85% of patients, generally as a result of a t(14;18)(q32;q21) chromosome translocation, which can be detected by fluorescence in situ hybridization or standard cytogenetics (Table 20-1). Most patients who have FL have an indolent course with a median survival exceeding 10 years. However, not all patients have a long survival, and identifying patients with more aggressive disease relies on clinical prognostic scoring systems.

STAGING AND PROGNOSIS

At diagnosis, the main clinical tool for risk stratification at diagnosis is the Follicular Lymphoma International Prognostic Index (FLIPI), which includes five risk factors: (1) more than four nodal sites, (2) elevated LDH level, (3) age older than 60 years, (4) stage IV disease, and (5) hemoglobin level less than 12 g/dL (Table 20-2).[29] Although initially developed in the pre-rituximab era, the prognostic relevance of the FLIPI has been validated in modern clinical trials.

Table 20-2 Prognostic Indices for Non-Hodgkin Lymphomas

Risk Factors	Risk Group	No. of Factors	Patient Distribution (%)	Endpoint, OS (%)
IPI for patients treated with R-CHOP				
Age >60 years				3-year OS
PS >1	Low	0-1	52	91
Serum LDH > ULN	Low intermediate	2	21	81
1 EN Site	High intermediate	3	17	65
Stage III-IV	High	4-5	10	59
Stage-modified IPI for aggressive lymphoma[31]				
Age >60 Years				5-year OS
PS >1		0-1	71	82
Serum LDH >ULN		2	22	71
Stage II		3	14	48
FLIPI[30]				
Four nodal sites				5-year OS
Serum LDH > ULN	Low	0-1	36	91
Age >60 Years	Intermediate	2	37	78
Stage III-IV	High	3-5	27	36
Hemoglobin <12 g/dL				
MIPI[32]				
Age				5-year OS
Performance status	Low	0-3	44	60
LDH: ULN	Intermediate	4, 5	35	45
WBC count	High	6-11	21	20

Abbreviations: EN, extranodal; FLIPI, Follicular Lymphoma International Prognostic Index; IPI, International Prognostic Index; LDH, lactate dehydrogenase; MIPI, Mantle Cell Lymphoma International Prognostic Index; OS, overall survival; PS, performance status; R-CHOP, rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone; ULN, upper limit of normal; WBC, white blood cell.

A useful mnemonic is NoLASH[29]:

No = number of nodal sites of disease

L = LDH, lactate dehydrogenase

A = age

S = stage

H = hemoglobin

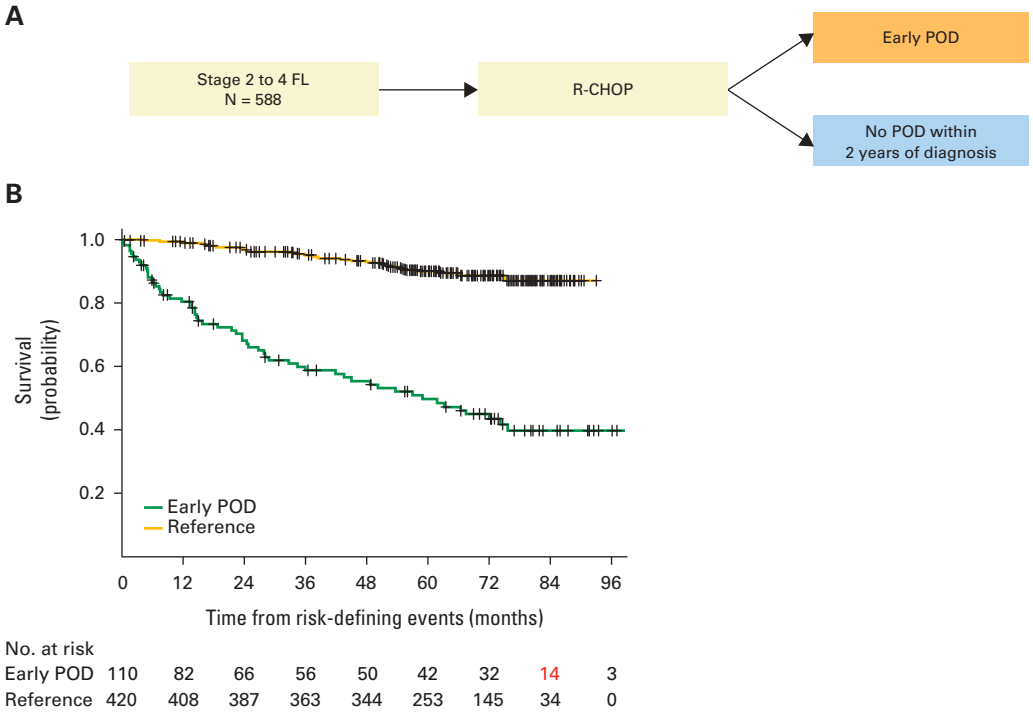
The FLIPI score stratifies patients into three groups with differing 5-year overall survival (OS) rates: (1) low risk (zero to one risk factor; OS, 91%), (2) intermediate risk (two risk factors; OS, 78%), and (3) high risk (three to five risk factors; OS, 53%).[30] Validating and comparing molecular predictive models in FL, which may assess pretreatment mutation status, epigenetic alterations, gene expression, and/or genomic aberrations, remains an active area of research.

FDG PET-CT is an essential study for initial staging and evaluation of FL, a routinely FDG-avid disease.[18] PET staging detects additional nodal and extranodal sites and permits accurate confirmation of localized FL (stage I/II) patients, who may be candidates for RT alone. Whereas early data suggested FDG PET-CT is prognostic in FL and can be used to predict transformation (or direct additional biopsies) based on maximum standardized uptake value, data from the randomized GALLIUM trial showed no such value.[30] Thus, the primary role of PET-CT remains for accurate staging and delineation of disease rather than guiding first-line therapy in FL (as reviewed by Trotman et al).[33]

The decision to initiate therapy for FL requires identifying symptomatic patients or those who have high tumor burden or risk of organ compromise (Fig. 20-2). Criteria used in clinical trials by the Groupe d'Etude des Lymphomes Folliculaires (GELF) can be useful in identifying such patients and include the following[34]:

- Involvement of three or more nodal sites >3 cm
- Any nodal or extranodal tumor mass >7 cm
- Systemic B symptoms
- Splenomegaly
- Cytopenias or leukemic blood involvement
- Pleural effusions or malignant ascites
- Impending organ dysfunction resulting from compression

Figure 20-2 Identification of a High-Risk Subgroup of FL Based on Early Relapse After Initial R-CHOP Chemoimmunotherapy



(A) Patients and methods in the National LymphoCare study. (B) Overall survival from a risk-defining event after diagnosis among patients receiving R-CHOP in the National LymphoCare study, demonstrating poor survival in those with early disease progression.
Abbreviations: FL, follicular lymphoma; POD, progression of disease; R-CHOP, rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone.
Reprinted from Casulo C, Byrtek M, Dawson KL, et al. Early relapse of follicular lymphoma after rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone defines patients at high risk for death: An analysis from the national lymphocare study. *J Clin Oncol.* 2015;33:2516-2522. doi: 10.1111/bjh.15718

Approximately 10% to 15% of patients who have FL present with stage I or nonbulky stage II disease. Involved-field radiation therapy (IFRT) or extended-field RT produces a 10-year failure-free survival (FFS) rate of 50% to 60% and a median OS rate of 60% to 80% and has traditionally been considered the standard of care in this setting. However, given the excellent prognosis of

stage I/II FL, selection of RT requires thorough staging with FDG PET-CT and bone marrow aspirate/biopsy to exclude advanced-stage disease and expert consideration of short-term and late risks (largely related to radiation dose and field).

The remaining 85% to 90% of FL patients have advanced-stage disease (bulky stage II or stage III or IV) at the time of presentation. Numerous randomized trials show no survival benefit with immediate treatment of asymptomatic FL even in advanced-stage disease. Thus, the decision to initiate treatment depends on the patient's symptoms and assessment of tumor burden based on GELF criteria discussed earlier.

KEY POINTS

- FL is the most common indolent lymphoma.
- Most patients with FL live for more than a decade.
- Prognostic scores using clinical risk factors can estimate OS.
- Defined treatment indications based on history, physical, imaging, and laboratory results are key to inform whether patients should receive treatment versus active surveillance without therapy (observation).

FIRST-LINE THERAPY

Patients who have symptomatic, low-tumor-burden FL can be treated with single-agent anti-CD20 monoclonal antibody therapy, primarily rituximab, the subject of the vast majority of clinical trials. When rituximab is used as monotherapy in the initial treatment of patients who have FL or low-grade NHL, the response rate ranges from 50% to 70% with a median duration of response (DoR) of 1.0 to 2.5 years.[35] In low-volume tumor settings, the median time to treatment failure is 3.9 or 4.3 years if maintenance rituximab follows induction.[36] Note that biosimilar CD20 antibodies with toxicity and drug exposure similar to rituximab are now in common use, depending on local insurance or center-specific policies on substitution for rituximab.

Patients who have high tumor burden disease are treated with chemoimmunotherapy, combining a CD20 monoclonal antibody and cytotoxic chemotherapy. The optimal chemoimmunotherapy regimen must be individualized and is informed by randomized trials and key findings related to safety. A randomized trial showed superior progression-free survival (PFS) with rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) compared with nonanthracycline therapy in FL but no OS benefit.[37] The risk of cardiomyopathy with R-CHOP requires consideration, including pretreatment cardiac assessment.

Two subsequent trials compared bendamustine, a unique alkylating agent possessing a purine-like moiety, plus rituximab (BR) to either R-CHOP or the investigator's choice of rituximab, cyclophosphamide, vincristine, prednisone (R-CVP) or R-CHOP.[38,39] These trials found that BR was associated with improved PFS and lower rates of severe neutropenia, alopecia, and peripheral neuropathy. Of note, bendamustine has been associated with hypersensitivity reactions and an increased risk of opportunistic infections and secondary malignancies in the context of prolonged lymphopenia during and after therapy. None of these chemoimmunotherapy regimens has superior OS, although R-CVP) seems inferior, although less toxic in nearly all settings.

Recently, newer and second-generation anti-CD20 monoclonal antibodies have been tested. Obinutuzumab is a glycoengineered monoclonal antibody targeting CD20 with enhanced antibody-dependent, cell-mediated cytotoxicity compared with rituximab. The GALLIUM trial compared obinutuzumab and chemotherapy versus rituximab and chemotherapy in patients with treatment-naive FL and indolent lymphoma.[40] The trial demonstrated a significant PFS but no OS advantage of obinutuzumab and a chemotherapy arm, albeit with increased toxicity, leading to US FDA approval.

To replace first-line chemotherapy in FL, the RELEVANCE trial was designed to show the superiority of rituximab and lenalidomide in comparison with rituximab and chemotherapy in more than 1,000 previously untreated patients; both arms received rituximab maintenance. Three-year PFS was equivalent in both arms (77% and 78%, respectively).[41] Rituximab plus chemotherapy was associated with increased rates of high-grade neutropenia, febrile neutropenia, nausea, and peripheral neuropathy, whereas lenalidomide was associated with increased cutaneous reactions, diarrhea, and tumor flare reactions. Despite its efficacy, lenalidomide with rituximab lacks approval for first-line treatment of FL, in contrast to relapsed follicular and MZL.

MAINTENANCE THERAPY

Maintenance strategies after induction to partial response (PR) or complete response (CR) have been examined in FL to delay or prevent disease relapse. Trials consistently show an improvement in PFS without improvement in OS, and as expected, a substantial increase in rituximab use in the first years of therapy and an increased risk of infections. The largest study of maintenance in first-line therapy for FL (the PRIMA trial) randomly assigned patients who have high-tumor-burden disease treated with non-bendamustine immunochemotherapy to 2 years of maintenance versus placebo.[42] Maintenance improved PFS (75% vs. 58%; $P < .0001$) but did not affect OS, which was >90% in both arms; infections were more common in the maintenance group (39% vs. 24%). Highlighting important context-specific risks of maintenance, the randomized GALLIUM trial showed that patients older than 70 receiving bendamustine and obinutuzumab had the highest risk of fatal events and severe infection.[43] Thus, maintenance therapy with a CD20 antibody remains an option in first-line treatment of FL—to prolong remission—acknowledging risks and lack of survival benefit.

RELAPSED/REFRACTORY FOLLICULAR LYMPHOMA

Although FL and other low-grade lymphomas have an indolent natural history, they are predominantly incurable, and nearly all patients experience relapse. At the time of relapse, a similar approach considering tumor burden and symptoms is applied because not all patients with progression need immediate therapy. Many patients require numerous treatments over a period of many years. Thus, an individualized approach is required for R/R FL with attention to fast-evolving clinical trial data and drug approvals.

There are limited prognostic tools at the time of relapse, but a pivotal study found that the 15% to 20% of FL patients who progress within 24 months of first-line treatment (POD24) experience inferior survival, including a 5-year OS of only 50% (Fig. 20-2).[44] POD24—defined as progression of FL within 24 months of initiating first-line chemoimmunotherapy—identifies a biologically aggressive subset of patients with markedly inferior outcomes. In the pooled analysis by Casulo et al,[45] which included 5,225 patients across 13 randomized trials, POD24 was confirmed as a strong adverse prognostic factor, with affected patients experiencing significantly worse subsequent OS (adjusted hazard ratio [HR] ≈ 3-5) compared with those without early progression.

Group	Events/Total	Median OS, years (95% CI)	3-Year OS % (95% CI)	5-Year OS % (95% CI)
No POD	459/3,328	17.9 (17.5-NE)	93.6 (92.7-94.4)	85.6 (84.0-87.1)
POD within 24 months	422/1,095	11.4 (9.8-NE)	68.6 (64.6-72.5)	55.6 (49.4-61.4)
All patients	881/4,423	17.9 (17.5-NE)	89.5 (89.4-90.1)	87.9 (86.9-88.9)

Data from Casulo C, Dixon JG, Le-Rademacher J, et al. Validation of POD24 as a robust early clinical end point of poor survival in FL from 5225 patients on 13 clinical trials. Blood. 2022;139(11):1684-1693. doi: https://doi.org/10.1182/blood.2020010263

The analysis also identified baseline predictors of POD24, including male sex, poor performance status, elevated β2-microglobulin, and high FLIPI scores. This study firmly established POD24 as a validated early endpoint and clinically meaningful marker for risk stratification in FL. This subgroup is also at high risk of transformation to DLBCL, particularly among patients receiving BR as first-line therapy, emphasizing the need for full evaluation and rebiopsy for early R/R FL.[46,47] In nontransformed, relapsed FL, several factors may influence the selection of therapy:

- Duration of initiation remission (POD24): clinical trials, novel agents, and consideration of cellular therapies may be indicated in patients with POD24.
- Biopsy findings (confirmation of FL and exclusion of histologic transformation in selected patients).
- Composition of prior therapy and depth/DoR.
- Patient comorbidities.
- Patient preference.

The treatment landscape for R/R FL is diverse and includes CD20 monoclonal antibodies, chemotherapy, and novel agents (zanubrutinib and lenalidomide); bispecific T-cell-engaging antibodies; and cellular therapies, including chimeric antigen receptor (CAR)–modified T cells and hematopoietic stem cell transplantation (HSCT).

CD20-DIRECTED MONOCLONAL ANTIBODIES

Rituximab, a chimeric monoclonal antibody targeting CD20, was initially approved for R/R CD20 positive low-grade or follicular NHL in 1997 based on an initial pivotal trial showing responses in 48% of chemotherapy-treated patients and a median time to progression of 13 months.[48,49] In the modern era, given its frequent first-line use, the use of single-agent rituximab for R/R FL is relegated to rituximab-sensitive disease and those unable to tolerate other therapies.

The CD20-antibody obinutuzumab is also approved in combination with bendamustine in patients who have relapsed/refractory FL (R/R FL) after prior rituximab, based on the phase 3 GADOLIN trial.[50] This study compared obinutuzumab and bendamustine versus bendamustine alone in patients who were refractory to rituximab (failure to respond or progress within 6 months of therapy). Although the combined chemoimmunotherapy arm was superior in terms of PFS and OS, the pervasive use of bendamustine in first-line therapy and aspects of the study design (the comparator of bendamustine alone), and a study showing no benefit in PFS with single-agent obinutuzumab over rituximab render the role of obinutuzumab in R/R FL unclear.

BISPECIFIC T-CELL ENGAGERS

The class of agents known as bispecific T-cell engagers, including bispecific antibodies with B- and T-cell specificity, act by redirecting T cells toward malignant B cells, leading to their elimination. A number of agents are in development and represent an important emerging class of lymphoma therapy. Mosunetuzumab, a bispecific antibody targeting CD20 and CD3, was the first to receive accelerated approval (in December 2022) for the treatment of R/R FL after at least two prior therapies. In a phase 1/2 study of 90 patients with R/R FL, an 80% overall response rate (ORR) and CR rate of 60% were observed, and 70% of those

with a CR had continued remission at 18 months.[51] Treatment is administered for up to 17 cycles (given every 21 days), and patients with a CR after eight cycles can discontinue therapy. Cytokine release syndrome (CRS) was observed in 42% of patients, but was generally mild or moderate; only two patients experienced severe CRS. A step-up dosing regimen, premedications, and capability for immediate hospitalization are required to limit and mitigate the risk of CRS. Neurologic toxicity (mainly headache but also dizziness and confusional state), hypophosphatemia, infections, cytopenias, and tumor flare are other known toxicities, and intensive monitoring and recognition/management of toxicities of this novel class is paramount.[52] Subsequently, subcutaneous epcoritamab was approved by the US FDA in June 2024 for the same indication (R/R FL after two or more prior therapies). Epcoritamab, dosed until disease progression or unacceptable toxicity, is also efficacious (ORR 82%, and 63% CRs), but CRS was observed in 65% of patients.[53] The FDA has granted traditional approval to epcoritamab-bysp as monotherapy for relapsed or refractory FL after two or more prior lines of therapy and approved it in combination with lenalidomide and rituximab (R^2) based on the EPCORE FL-1 trial, who had received at least one line of therapy.[5] In this randomized study of 488 patients, epcoritamab-bysp plus R^2 significantly improved PFS and ORR compared with R^2 alone (PFS HR 0.21; ORR 89% vs. 74%). Safety findings included CRS in 24% of patients (serious in 12%), immune effector cell–associated neurotoxicity syndrome (ICANS) in 0.8%, and serious adverse reactions in 51%, predominantly infections.

These bispecific antibodies are, thus, an important therapeutic option but require experience in the prevention and management of unique toxicities such as CRS. Nonetheless, they are likely safer than intensive transplant or chimeric antigen receptor T (CAR-T) cell therapies, suggesting a role before these modalities in the third-line setting and beyond. Larger data sets, including more detail and follow-up, are needed to help inform the optimal choice and sequence of therapy for R/R FL. Bispecific T-cell engagers targeting other antigens, such as CD19, are currently being investigated.

NOVEL TARGETED AGENTS

Although there is a major need for improved, noncytotoxic therapies for FL because of its high prevalence and long natural history, relatively few agents are proven to be both safe and efficacious. Phosphoinositide 3-kinase inhibitors achieved initial approval for R/R FL but have been withdrawn from the US market in light of toxicity, including serious infections. Currently, the approved targeted small-molecule agents available for R/R FL is lenalidomide.[49]

Lenalidomide, which has a complex mechanism of action, including immunomodulatory, proapoptotic, and transcriptome-based antitumor properties, induces a response in approximately one-third of FL patients.[53] When combined with rituximab, the response rate is 76%, and CR is seen in approximately one-third of patients; PFS in the AUGMENT trial was 39 months, superior to PFS with rituximab alone.[54]

Inhibitors of Bruton's tyrosine kinase (BTK) have shown low single-agent efficacy in R/R FL, and biomarkers predicting patients most likely to benefit remain undefined. However, the combination of zanubrutinib and obinutuzumab (Z + O) was compared to obinutuzumab alone in R/R FL patients who have two or more prior treatments, including a response rate of 69% versus 46% and median PFS of 28 months versus 10.4 months.[55] This open-label, randomized study, which also involved long-term zanubrutinib administration (until progression or excess toxicity)—and obinutuzumab maintenance in both arms—showed more thrombocytopenia, pneumonia, zoster infections, and diarrhea in the Z + O arm and comparable OS. Nonetheless, these results led to accelerated approval of Z + O by the US FDA in 2024 for R/R FL after two or more prior lines of therapy.

The FDA recently approved tafasitamab in combination with lenalidomide and rituximab for adults with relapsed and refractory FL. This approval is based on a phase 3 randomized, double-blind, placebo-controlled study involving more than 500 patients with FL. Patients were stratified by POD24 status, refractoriness to prior therapy, and the number of prior lines of treatment. They were randomized to receive tafasitamab in combination with lenalidomide and rituximab for 12 cycles, versus lenalidomide and rituximab plus placebo every 4 weeks for up to 12 cycles. With a median follow-up of 14.1 months, PFS was 22.4 months in the tafasitamab arm, compared to 13.9 months in the placebo arm, corresponding to a 57% reduction in the risk of progression or death. Subgroup analysis demonstrated consistent benefit across all prespecified groups, including high-risk patients. The PET/CT CR rate increased from 40% in the placebo arm to 49% in the tafasitamab arm, and the ORR increased from 72% to 83%. The DoR was also improved, with the median not reached in the tafasitamab arm versus 28 months in the placebo arm. Adverse events were relatively similar between both treatment arms.[9]

HSCT AND CAR-T-CELL THERAPIES

Autologous stem cell transplantation (ASCT) may be useful for selecting patients who have high-risk disease and early relapse, but results are based on historical and nonrandomized trials. The potential efficacy of ASCT in R/R FL must be weighed against several risks, including secondary myelodysplasia and acute myeloid leukemia occurring in approximately 5% of patients. Allogeneic transplantation is associated with greater treatment-related risk but a lower likelihood of late relapse. In a registry study of 440 FL patients relapsing within 2 years of frontline therapy (POD24), ASCT and matched sibling allogeneic transplantation each achieved a 5-year OS of about 70% with nonrelapse mortality rates of 5% and 17%, respectively.[56] However, this study included patients undergoing HSCT from 2002 to 2014 and may have limited relevance in the modern therapeutic era as FL patients have an increasing array of immunotherapy options, including mosunetuzumab and CAR-T-cell therapies.

The first CAR-T-cell therapy approved (2021) was axicabtagene ciloleucel (axi-cel) for patients with R/R FL after at least two prior systemic therapies. The pivotal trial ZUMA-5 tested a single infusion of axictabtagene cilolecel in 148 patients who have R/R FL and MZL.[57] In a subset of 84 patients who have FL considered in the primary activity analysis, the ORR was 94%, including a 79% CR rate, and the 18-month PFS was 65%. The CR rates were similar in subgroups with high-risk baseline features, including those with relapse within 24 months of first-line rituximab-including therapy. However, CRS (7% grade ≥3), cytopenias, infections, and neurologic events (19% grade ≥3) were frequent toxicities in ZUMA-5, and half of the enrolled patients experienced serious adverse events. The 5-year update from the ZUMA-5 trial demonstrated that axi-cel provides durable and potentially curative responses in patients with relapsed or refractory FL. The 5-year PFS rate was approximately 50%, and the 5-year OS rate was 69%. In the FL cohort, the ORR was 94%, with a CR rate of 79%. More than half of the patients remained in remission due to ongoing responses. The median DoR in the FL group was approximately 60 months.[58] Subsequently, in 2022, tisagenlecleucel (tisa-cel) became the second CD19-directed CAR-T approved for FL, also after two or more lines of systemic therapy, based on a phase 2 trial of 94 efficacy-evaluable patients.[59] A single infusion of tisa-cel led to CR in 69% of patients and ORR in 86%; 12-month PFS was 85%, and instances of grade 3 CRS were seen. The 4-year follow-up data from the ELARA trial demonstrated a median PFS of 53.3 months, with a 4-year PFS rate of 50.2% and a 4-year OS rate of 79.3%. High-risk disease characteristics—such as being double refractory, having bulky disease, or experiencing progression within 2 years of prior therapy—did not predict inferior efficacy.[60] Responders also achieved higher rates of minimal residual disease negativity. Most recently, lisocabtagene maraleucel (liso-cel) was also approved in this setting—R/R after two or more lines of therapy—comprising the third CD19-directed CAR-T therapy available for FL.[61] Selection among these options is challenging as each carries significant risks, including CRS, neurologic toxicity, and infection. As a result, these agents are most appropriately considered for patients who have successive relapses of FL in a short time frame and limited comorbidities.

KEY POINTS

- Symptomatic patients who have progressive FL or other low-grade lymphomas have a number of treatment options without any evidence indicating a major survival advantage for any specific approach.
- Chemoimmunotherapy remains a standard for first-line FL treatment with high tumor burden, but the subset of patients relapsing within 2 years faces poor survival rates. In these cases, optimal therapy is unknown, but clinical trials, novel targeted therapies, and cellular therapies (HSCT, bispecific T-cell engagers, CAR-T-cell therapy) may be considered.
- The novel small-molecule therapy currently approved for relapsed FL is lenalidomide.
- Combination therapies currently approved for relapsed FL include Rituximab with lenalidomide, zanubrutinib with obinutuzumab, and tafasitamab in combination with lenalidomide and rituximab.
- Recently FDA-approved immunotherapies include the bispecific T-cell engager mosunetuzumab, epcoritamab, and CAR-T-cell therapies (axi-cel, tisa-cel, and liso-cel), representing an important new class of therapies in R/R FL.

HISTOLOGIC TRANSFORMATION OF FL TO AGGRESSIVE LYMPHOMA

Approximately one-third of patients who have FL undergo documented transformation to a more aggressive histology in their lifetime, typically DLBCL. The annual rate of transformation is 2% to 3%.

Confirming a diagnosis of transformed FL can be difficult. The gold standard is a biopsy specimen of a lymph node showing an aggressive BCL that is clonally related to the FL; biopsy of bulky, rapidly growing, or the most FDG-avid sites should be prioritized when safe. Clinical features associated with histologic transformation include rapid progression of nodal disease, increased LDH level, declining PS, hypercalcemia, new involvement in extranodal sites, and new-onset B symptoms. If a biopsy procedure is not safe or feasible, clinical symptoms and supportive laboratory abnormalities can justify the treatment of transformed disease.

Treatment of transformed FL depends on the extent and type of prior therapy, biologic features (eg, presence of *MYC* and *BCL2* rearrangement), and patient factors. For anthracycline-naive patients, R-CHOP or a similar regimen may be used; otherwise, regimens commonly used for relapsed DLBCL may be used (including platinum-based chemotherapy combinations). For eligible patients who have transformed lymphoma, consolidation with ASCT,[62-64] allogeneic transplantation,[63,65] RT, or CAR-T-cell therapy may be considered, but there are limited prospective, controlled data to support one strategy over another. In case of recurrent transformed lymphoma, therapies for relapsed DLBCL, such as bispecific antibodies, CAR-T-cell therapy[66] or less intensive regimens (tafasitamab and lenalidomide, loncastuximab tesirine, selinexor), can be considered.[67,68]

MARGINAL ZONE LYMPHOMA

MZLs constitute 10% of B-cell NHLs and have an indolent course. The three primary subtypes of MZL have varying incidence, biology, and prognosis (reviewed expertly by Rossi et al).[69]

The clinical presentation of MZL depends on the site of involvement. ENMZL arises from lymphoid tissue associated with epithelial tissues (mucosa-associated lymphoid tissue [MALT]), and most commonly involves the stomach or other gastrointestinal

sites as well as ocular adnexa, thyroid, lung, or skin. Nodal and splenic MZL typically present with node or spleen/peripheral blood/marrow involvement, respectively, but share histologic features with ENMZL; all arise from marginal zone B cells and express CD19/CD20, typically without CD10. Diagnosis of MZL requires adequate biopsy material to distinguish from chronic lymphocytic leukemia, MCL, LPL, and even DLBCL. Expert pathology review and consideration of surface markers, cytogenetic findings, and potentially sequencing-based analysis (*MYD88* mutations are typically absent in MZL but present in LPL).

The concept of lymphoma as an antigen-driven disease is best described for gastric ENMZL, formerly called gastric mucosa-associated lymphoid tissue, in which *H. pylori* consistently irritates the mucosal T and B cells that line the stomach, causing them to proliferate. At some point, the B cells become autoreactive and develop into an *H. pylori*–dependent lymphoma. Other examples of chronic antigenic stimuli associated with MZL include *Chlamydia psittaci* in ocular adnexal MZL; hepatitis C, leading to SMZL (treated successfully with elimination of hepatitis C); and *Borrelia burgdorferi* in cutaneous MZL. Autoimmune conditions associated with MZL include Hashimoto thyroiditis, leading to thyroid MZL, and Sjogren disease, leading to salivary gland MZL.

LOCALIZED GASTRIC ENMZL: FOCUS ON *H. PYLORI* ERADICATION

The most common MZL is gastric ENMZL in association with *H. pylori*. Patients typically present with nausea, abdominal discomfort, or GI bleeding. Patients should be evaluated for *H. pylori* by histopathology, and if negative, a stool antigen test or urea breath test should be performed. If *H. pylori* infection is present, fluorescence in situ hybridization or polymerase chain reaction testing for t(11;18) should also be performed to exclude *MALT1* translocation. The presence of t(11;18) is predictive of a lack of response to *H. pylori* eradication therapy.

H. pylori–positive gastric MZL is treated first with *H. pylori* eradication with either triple therapy (proton-pump inhibitor and two antimicrobials) or quadruple therapy (proton-pump inhibitor, bismuth, tetracycline, and metronidazole) for 14 days, which results in high rates of *H. pylori* eradication and histologic CR in more than half of patients.

Response assessment after *H. pylori* eradication requires repeated endoscopy, but this should not be performed sooner than 3 months after therapy because responses are often delayed. If repeated endoscopy is normal but biopsy specimens show lymphoid aggregates, asymptomatic patients may be kept under observation. Surveillance can stop after two sequential negative endoscopies.

Patients who have *H. pylori*–negative gastric ENMZL or relapse/refractoriness after *H. pylori* eradication are treated with RT or rituximab (if RT is contraindicated). RT offers excellent local control and is associated with high long-term survival rates, and rituximab monotherapy achieves responses in most patients, including those with t(11;18).[70,71]

SYSTEMIC THERAPIES FOR MZL: FIRST LINE AND BEYOND

First-line treatments for MZL prioritize eradication of infectious drivers such as *H. pylori* and hepatitis C and consideration of RT for localized disease because these modalities may result in long-term remission or cure. For advanced-stage disease, symptomatic patients often receive rituximab or chemoimmunotherapy. Single-agent rituximab is particularly effective in splenic MZL and represents a reasonable treatment option for many advanced-stage patients. Those who have bulky or high-risk disease may achieve deeper, longer remissions with combination chemoimmunotherapy (BR, R-CVP) at the cost of increased risk of infection and myelotoxicity. There is no proven role for anthracycline therapy (eg, R-CHOP) in MZL outside of defined histologic transformation. In the relapsed setting, akin to FL, factors including quality and duration of initial response, patient comorbidities, and goals must be considered during selection of therapy. Retreatment with rituximab is often feasible. Importantly, the oral BTK inhibitor zanubrutinib is available for relapsed MZL among patients who received prior anti-CD20–based therapy, based on phase 2 showing a response rate of 68% (35% CR) and PFS exceeding 80% at 15 months.[72] As in other B-NHL, zanubrutinib is dosed continuously until progression, and diarrhea, contusion, neutropenia, and infection are known risks.

NCCN guidelines also include combination with lenalidomide, specifically lenalidomide in combination with CD20 antibody therapy. Although FDA approved and supported by single-agent data, lenalidomide combined with rituximab failed to improve PFS, ORR, or the probability of 2-year OS compared with placebo and rituximab in the subset of patients with MZL of the AUGMENT trial.[54] Given its low incidence, clinical trials specific to MZL are challenging to conduct, but advances in oral targeted therapies and immunotherapies (CAR-T cells and bispecific antibodies are likely to benefit MZL patients and gain integration into standards of care in the relatively near future.

KEY POINTS

- Three types of MZL are EMZL, SMZL, and NMZL.
- MZLs are frequently antigen-driven diseases, and eradication of infection (eg, *H. pylori*) can result in regression of lymphoma without the need for additional therapy.
- RT for localized MZL, including persistence of gastric MZL after *H. pylori* eradication, is effective; systemic therapy for advanced-stage MZL incorporates rituximab and, for selected patients, chemotherapy with rituximab.
- R/R MZL requires individualized consideration of therapy, including additional rituximab, chemoimmunotherapy when appropriate, zanubrutinib, or lenalidomide-based therapy.

LYMPHOPLASMACYTIC LYMPHOMA/WALDENSTRÖM MACROGLOBULINEMIA

LPL is an uncommon and incurable indolent BCL. A vast majority of LPLs produce an IgM paraprotein, designated WM. Because less than 5% of cases produce IgG or IgA or are nonsecretory, most studies of LPL pertain to WM.

LPL/WM is typically diagnosed because of the presence of cytopenias or during the workup of a paraprotein. Less commonly, patients may have adenopathy or organomegaly at the time of diagnosis. Diagnosis requires a bone marrow biopsy specimen that shows infiltration by a spectrum of small lymphocytes, plasmacytoid cells, and plasma cells with associated B-cell and plasma cell markers.[1,73] However, this admixture of cell types renders accurate diagnosis challenging, and LPL/WM requires distinction from lymphoma, including MZL and MCL, among others. It has been found that >90% of WMs harbor a point mutation in the *MYD88* gene (L265P), aiding in diagnosis and differentiation from other lymphomas.

PRINCIPLES OF SYSTEMIC THERAPY FOR WM

As with other indolent lymphomas, treatment of LPL/WM is indicated only if the patient has disease-related symptoms, cytopenias related to marrow infiltration, bulky disease, or IgM-related complications. Elevated IgM may result in hyperviscosity as well as neuropathy, coagulopathies, or cryoglobulinemia syndromes/cold agglutinin disease.[74] Symptomatic hyperviscosity represents an emergent indication for plasmapheresis followed by systemic therapy and may be manifested by visual changes, neurologic symptoms (headache, confusion, or vertigo), or bleeding (retinal hemorrhage, epistaxis). In addition, rituximab can lead to an acute increase in IgM levels, leading to symptomatic hyperviscosity lasting several weeks.[74]

First-line treatment options include rituximab monotherapy, chemoimmunotherapy including bendamustine and rituximab, bortezomib-based treatment, or BTK inhibitors. A randomized trial demonstrated a trend toward improved depth of response and less toxicity with zanubrutinib compared with ibrutinib, leading to regulatory approval of this agent in 2021.[75] However, whereas associated with low risks of cardiac events or severe toxicities, zanubrutinib is administered continuously, and cumulative toxicities, including infection, hypertension, and bleeding, increase over time. Thus, fit patients should also be considered for fixed-duration regimens (such as BR) in first-line therapy. A 2021 French multicenter study of 69 WM patients treated with first-line BR reported an ORR of 97%, with 96% of patients achieving at least a 50% reduction in serum paraprotein.[76] Only six patients had progressed within 23 months of median follow-up.

Notably, in patients at high risk of hyperviscosity—generally, IgM 4,000 mg/dL or higher but with substantial interpatient variation—omission of rituximab from the first one to two cycles of chemoimmunotherapy or prophylactic plasmapheresis and close IgM monitoring should be considered.

KEY POINTS

- Despite its rarity and lack of comparative trials in WM, several key management aspects are evident from available data: An elevated paraprotein level alone is not an indication for therapy in asymptomatic patients.
- First-line therapy may include rituximab, chemoimmunotherapy, or a continuous BTK inhibitor, depending on goals and patient factors (disease burden, age, and comorbidities).
- Rituximab may result in a sudden increase in IgM levels, leading to symptomatic hyperviscosity.
- R/R WM is treated upon symptomatic progression, and selection of therapy depends on depth and DoR to initial therapy, as in other indolent NHL.
- BTK inhibitors, particularly zanubrutinib, are a mainstay of WM therapy.

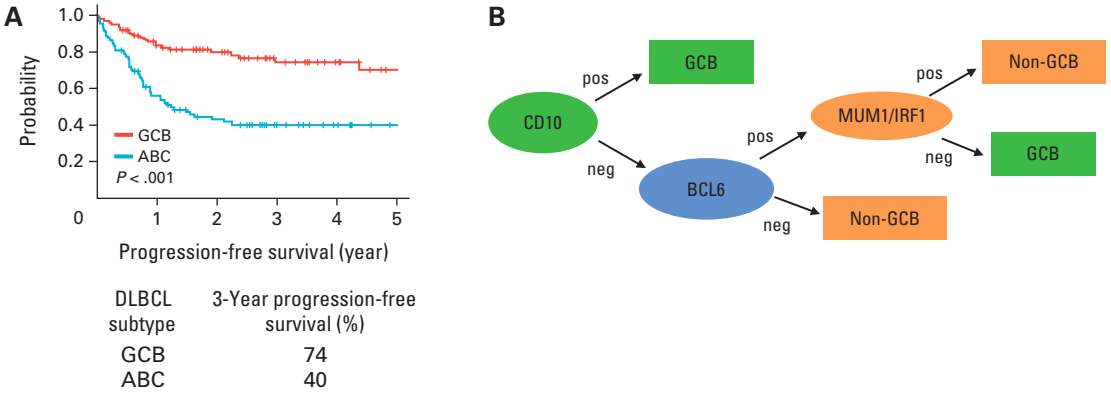
DLBCL AND OTHER AGGRESSIVE B-CELL LYMPHOMAS

Aggressive lymphomas are characterized by a rapid and usually symptomatic growth phase leading to clinical presentation. DLBCL not otherwise specified (NOS; heretofore referred to as DLBCL) is the prototype of aggressive B-cell NHL and constitutes 30% of all NHLs, although nomenclature has evolved as the heterogeneity of this disease has been better defined. Up to 40% of patients initially present with extranodal involvement, most commonly in the GI tract and also with involvement of the CNS, genitourinary or reproductive tract, lung, or other sites. Optimal diagnosis requires a sufficiently large tissue specimen to confirm histology and performance of important prognostic and predictive tests; FNA is never appropriate as the sole means of diagnosis and only serves to differentiate between solid tumors and lymphomas. The classic morphology is diffuse effacement of the normal lymph node architecture by intermediate to large cells expressing CD19, CD20, CD79a, and CD45. However, DLBCL is increasingly understood to be a heterogeneous disease with genetic, biologic, and clinical variants that have an important effect on clinical outcomes.

The International Prognostic Index (IPI) is the most used prognostic score that incorporates five clinical (Table 20-2) features that stratify patients into four risk categories: age >60 years, PS >1, increased LDH level, more than one extranodal site, and stage III to IV disease. The original IPI was developed before the advent of rituximab in DLBCL treatment, and several updates to the IPI have been developed, including the Revised-IPI and the NCCN-IPI[77,78]; however, the original IPI continues to be most widely used in clinical trials.

DLBCL is genetically heterogeneous. One way of classifying DLBCL is by the B cell of origin (COO) through gene-expression profiling (Fig. 20-3).[79] DLBCL specimens genetically resembling germinal center B cells are designated germinal center B-cell-like DLBCL (GCB-DLBCL), whereas those resembling activated B cells are called activated B-cell-like DLBCL (ABC-DLBCL); 10% to 15% of cases are unclassifiable by COO. GCB-DLBCL is characterized by common germinal center B-cell pathways, such as *BCL6* and *EZH2*, and ABC-DLBCL is characterized by chronic B-cell receptor signaling and activation of the NF-κB pathway.[79-81] New taxonomies of DLBCL based on in-depth genomic analyses have been proposed, including the LymphGen classification and DLBCL clusters, but they require further validation.[80,82,83] Testing for COO and performing genomic analysis is difficult in routine clinical practice because gene-expression profiling requires time and frozen material and is not widely available at this time. Several immunohistochemical algorithms are used as surrogates for COO, but there is an error rate of approximately 20%. One of the more common algorithms is the Hans method, which stains for CD10, MUM1, and *BCL6* to determine the COO as GCB versus non-GCB (akin to the ABC subtype and many unclassifiable cases). Despite similar clinical risk features, patients who have ABC-DLBCL have inferior survival compared with those who have GCB-DLBCL treated with CHOP or R-CHOP.[79]

Figure 20-3 Cell Origin Cultures



(A) Survival outcomes by genomic profiling determination of COO in patients treated with R-CHOP. (B) Hans algorithm for immunohistochemical determination of COO.
Abbreviations: ABC, activated B cell; COO, cell of origin; DLBCL, diffuse large B-cell lymphoma; GCB, germinal center B cell; neg, negative; pos, positive; R-CHOP, rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone.

MYC, a proto-oncogene and transcription factor classically rearranged in Burkitt lymphoma, is rearranged in up to 15% of cases of DLBCL and can be detected by fluorescent in situ hybridization (FISH). Because DLBCL is substantially more common than Burkitt lymphoma, many more patients with *MYC* rearrangements have DLBCL rather than Burkitt lymphoma in the United States. Of note, *MYC* rearrangement is diagnostic in Burkitt lymphoma, in which it is associated with upregulation of target genes of the c-myc transcription factor, whereas it is adversely prognostic in DLBCL.[83,84] In 5% to 7% of cases, the majority of which are GCB-DLBCL, *MYC* rearrangement may occur with *BCL2* and/or *BCL6*. These lymphomas are classified as high-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* rearrangements, but are often commonly called DHL or triple-hit lymphoma. This is a clinically aggressive phenotype with poor long-term survival after R-CHOP, and there is considerable debate surrounding optimal management of high-grade BCL.

Both MYC and BCL2 proteins can be overexpressed as measured by immunohistochemical analysis, either with or without the underlying respective chromosomal rearrangements, in up to 30% of patients with DLBCL.[85,86] These are termed double-expressor lymphomas and can occur in either GCB-DLBCL or ABC-DLBCL. When DEL occurs without underlying DHL, outcomes are still poor but not quite as dismal. As discussed later in this chapter, it is unknown precisely how these patients should be treated.

PRESENTING CASE STUDY 1

A previously healthy 60-year-old man presents to his primary care physician with a 1-month history of swollen lymph nodes, night sweats, and unintentional weight loss. Core biopsy of an axillary node reveals sheets of large cells positive by immunohistochemistry for CD20, CD19, MUM1, *BCL2*, and *MYC*; *CD10* is negative. Fluorescent in situ hybridization (FISH) assessment is negative for *MYC*, *BLC2*, and *BCL6* rearrangement. PET/CT identifies diffusely FDG-avid lymphadenopathy

throughout the neck, axillae, chest, and abdomen. Kidney and liver function tests are within the upper reference limit. HIV test is negative. Complete blood count indicates a lactate dehydrogenase (LDH) level of 350 U/L (upper reference limit, 200 U/L). The patient's Eastern Cooperative Oncology Group (ECOG) performance status is 2.

How would this patient's disease presentation inform diagnosis and staging?

This patient's presentation and pathology are consistent with stage IIIB nongerminal center B-cell–like diffuse large B-cell lymphoma (DLBCL) based on the Hans algorithm. His International Prognostic Index (IPI) score is 4 (1 point each for age >60 years, ECOG performance score ≥2, elevated LDH, and stage III/IV disease), indicating high-risk disease with a 5-year overall survival rate around 26%.

If there are no feasible clinical trial options available to this patient, what are the treatment options you should consider?

Standard treatment options for this patient include six cycles of rituximab and cyclophosphamide, vincristine, doxorubicin, and prednisone (R-CHOP) or polatuzumab (a CD79b-directed antibody-drug conjugate) and rituximab in addition to cyclophosphamide, doxorubicin, and prednisone (pola-*R*-CHP). R-CHOP has been the standard of care for untreated DLBCL for several decades. In 2022, the phase 3 POLARIX trial randomized patients with an IPI score of 2 to 5 to receive either R-CHOP or pola-*R*-CHP. Patients in the pola-*R*-CHP arm had improved progression-free survival (PFS) over patients in the R-CHOP arm, with a 2-year PFS of 77% versus 70%, respectively, and pola-*R*-CHP is now FDA approved for untreated DLBCL. Like the patient in this case, study participants who were older than 60 years of age, those with an IPI score of 3 to 5, and those with the activated B-cell–like subtype of DLBCL seemed to benefit most from pola-*R*-CHP.

After discussing with the patient, the decision was made to treat his stage IIIB DLBCL with six cycles of pola-*R*-CHP. PET/CT at the end of treatment shows complete resolution of all previously noted, metabolically active lymph nodes. Three months after completing treatment, he presents for routine follow-up and reports feeling well. He continues to have mild peripheral sensory neuropathy in his fingertips; his ECOG performance status is 0, and he has returned to work. Physical examination demonstrates enlarged lymph nodes in the right axilla. Lymph node biopsy demonstrates relapsed DLBCL with the same immunophenotype as the original biopsy. Laboratory findings reveal a hemoglobin level of 10 g/dL; kidney and liver function tests are within the upper reference limit. The patient would like to be aggressive with the treatment of his lymphoma.

What factors should be taken into consideration when deciding the next treatment for this patient?

This patient has relapsed DLBCL less than 1 year after first-line treatment. He would be considered fit for autologous stem cell transplantation (ASCT) based on his age (<70 years), ECOG performance status, and organ function; before 2022, high-dose chemotherapy followed by ASCT in patients with chemosensitive disease was the standard treatment for relapsed/refractory DLBCL. ASCT is still the standard treatment for patients whose disease relapses more than 1 year after first-line treatment. However, in 2022, two phase 3 clinical trials randomized participants with refractory or relapsed DLBCL within 1 year of first-line treatment to either high-dose chemotherapy followed by ASCT in those with chemosensitive disease or anti-CD19 CAR-T-cell therapy. There was superior event-free survival of both axicabtagene ciloleucel (axi-cel) and lisocabtagene maraleucel (liso-cel) over ASCT as well as an overall survival advantage of axi-cel over ASCT, leading to the FDA approval of axi-cel and liso-cel in patients with early relapsed or refractory DLBCL in the second-line setting. Thus, this patient with early relapsed disease should be treated with either axi-cel or liso-cel.

TREATMENT OF NEWLY DIAGNOSED AGGRESSIVE LYMPHOMAS

Limited-Stage Disease

Approximately 30% of patients with DLBCL have limited-stage disease (stage I or nonbulky stage II) at the time of presentation and have a superior prognosis compared with patients with advanced-stage disease. Before the advent of rituximab, standard treatment of limited-stage DLBCL included three cycles of CHOP followed by IFRT. Because 5-year OS in limited-stage disease is 85% to 95%, prospective trials have focused on reducing toxicity through limiting the number of cycles of CHOP and omitting radiation. The randomized FLYER study enrolled patients younger than 60 years old with low risk by age-adjusted IPI and nonbulky (less than 7.5 cm) stage I and II DLBCL who received either six cycles of R-CHOP or four cycles of R-CHOP with two additional doses of rituximab.[87] The 3-year event-free survival (EFS) and 3-year OS were nearly identical in both treatment

arms. Another trial treated patients with nonbulky (<10 cm) stage I/II DLBCL based on interim PET.[88] All received three cycles of standard R-CHOP therapy followed by an interim PET. Those with a negative interim PET proceeded with one additional cycle of R-CHOP, whereas those with a positive interim PET received IFRT followed by ibritumomab tiuxetan radioimmunotherapy (RIT). The 5-year PFS estimate was 87% (95% CI, 79-92), and the OS estimate was 89% (95% CI, 82-94) with interim PET-positive and -negative patients having similar outcomes. Therefore, the routine use of RT may not be required in limited-stage DLBCL and is definitely not needed in younger patients lacking IPI risk factors. An important caveat to the discussion regarding limited-stage DLBCL is that none of these trials fully evaluated the effect of biology (eg, DHL, DEL, and high-grade morphology) or the specific extranodal site (eg, primary breast). An extension to this latter point is that primary testicular lymphoma, which is often stage I to II, constitutes a distinct clinicopathologic subset of DLBCL and has its own treatment approach, which is reviewed below.

Advanced-Stage Disease

In the early 2000s, rituximab added to CHOP chemotherapy demonstrated an advantage in not only PFS but also OS of approximately 15% in younger and older patients.[89,90] Importantly, most studies show a plateau after 5 years, supporting the curative potential of treatment of DLBCL. However, not all patients are cured, and there are a number of clinical and biologic factors affecting curability (reviewed by Sehn and Salles).[91] The standard of care is six cycles of R-CHOP, and additional cycles have shown no benefit in a randomized trial.[92] Attempts to improve on R-CHOP have taken several approaches, including dose-dense delivery, the addition of etoposide or novel agents to an R-CHOP backbone, the use of consolidative HSCT, maintenance therapy, and delivery of treatment by continuous infusion. Until recently, no major randomized trial had shown a clear benefit over full-course R-CHOP. In 2022, the POLARIX trial randomized 879 patients with an IPI 2 to 5 to receive either R-CHOP or polatuzumab vedotin (a CD79b-directed antibody-drug conjugate [ADC]) substituted for vincristine (pola-*R*-CHP). Patients in the pola-*R*-CHP arm had an improved PFS over patients in the R-CHOP arm, with a 2-year PFS of 77% versus 70%, respectively. Response rates, toxicity, including peripheral neuropathy, and OS were similar between the arms. Although the trial was not powered to evaluate subgroups, participants older than 60 years of age, those with IPI 3 to 5, and those with the activated B-cell–like subtype of DLBCL seemed to benefit most from pola-*R*-CHP. Pola-*R*-CHP is now FDA approved for untreated DLBCL, including high-grade DLBCL with an IPI of ≥2.

Patients who have high-grade B-cell lymphoma, including those with dual rearrangements of *MYC* and *BCL2* DLBCL/HGBCL-MYC/BCL2; high-grade BCL), probably need augmented approaches. Large retrospective series consistently show less than 20% long-term survival in high-grade BCL treated with R-CHOP.[85,93] Several retrospective reviews indicate that more-intensive regimens may have better outcomes, and the largest multicenter analysis showed R-CHOP to be inferior to almost any other regimen with a HR of 0.5.[94,95] Prospective data supporting the use of one regimen over another are limited, but a phase 2 trial showed promising activity of the 5-day infused regimen of dose-adjusted etoposide, doxorubicin, vincristine, and cyclophosphamide plus rituximab although not all patients in this trial had true high-grade BCL with dual translocations of both *MYC* and *BCL2*.[96]

For patients unlikely to tolerate standard R-CHOP, first-line regimens may incorporate attenuated dosing (eg, mini-R-CHOP for older patients[97]) or substitution of doxorubicin (eg, incorporating gemcitabine for patients with poor cardiac function).[98] Maximal supportive care, including growth factor support and attention to risk of neuropathy, infection, and cytopenias are required in these subgroups. Maximal supportive care, including growth factor support and attention to risk of neuropathy, infection, and cytopenias are required in these subgroups.

KEY POINTS

- Most patients with primary mediastinal BCL (PMBL) do well with chemoimmunotherapy (eg, R-CHOP) and RT or approaches that seek to eliminate RT (eg, dose-adjusted etoposide, doxorubicin, vincristine, and cyclophosphamide plus rituximab [DA-EPOCH-R]).
- The role of RT remains a controversial issue, and PET-adapted strategies are under investigation.
- CAR-T-cell therapy, high-dose chemotherapy (HDC) and ASCT, and pembrolizumab can be used in the relapsed setting.

Primary Mediastinal BCL

PMBL is a distinct, aggressive BCL derived from medullary thymic B cells and presents as a large and symptomatic mediastinal mass, often with superior vena cava syndrome and a predilection for extranodal organ involvement. The median age at onset is 30 years with a slight female predominance. Histopathology shows a diffuse infiltrate of large cells with CD20, CD79a, and *PAX5*, usually positive for CD10, BCL6, and CD23.7 CD30 can be expressed as well and is often weaker in intensity compared with that in Hodgkin lymphoma. Of interest, there are significant similarities in gene expression between PMBL and classic Hodgkin lymphoma (cHL) with deregulation of nuclear factor kB, Janus kinase 2, and programmed-death ligand 1 (PD-L1)/PD-L2.[99] Cases with intermediate histopathologic features between PMBL and Hodgkin lymphoma are termed gray-zone lymphomas, and these have a worse prognosis.[10,100]

The treatment of PMBL is not standardized, and prospective data are limited because of the rarity of PMBL. R-CHOP with consideration of radiation to bulky disease sites, borrowing from treatment of more common DLBCL-NOS subtypes, has emerged as a standard approach. However, this approach was associated with induction failure in 21%, and R-CHOP-like regimens achieve long-term disease control in only 60% to 70%.[101,102] On the other hand, a prospective international trial of rituximab plus various chemotherapy backbones followed by RT showed, in a majority of patients, 5-year PFS and OS rates >90% with the end-of-treatment PET being the most important discriminator of outcome.[103]

Investigators at the NCI and Stanford tested DA-EPOCH-R as a means to obviate the need for RT and reported a 5-year EFS rate of 93% with no relapses beyond 1 year.[104] Given the mediastinal location, avoiding RT is an appealing option, and it is omitted as part of planned therapy after DA-EPOCH-R. RT may also be avoided in patients with a negative FDG-PET scan after full-course therapy, although final results from a current randomized trial (International Extranodal Lymphoma Study Group-37[105]) are needed to ascertain whether this approach can be uniformly recommended.

Relapsed PMBL may occur in sites of initial disease bulk or in extranodal sites and generally occurs in the first 2 years.[101-103] Chemotherapy-sensitive, later relapses (more than a year from initial therapy) are treated similarly to DLBCL-NOS with salvage chemotherapy and consideration of ASCT. For R/R PMBL within a year of completing first-line therapy or in chemorefractory disease after second or later relapse, CAR-T-cell therapy is an approved option. Relapsed PMBL after two or more prior lines of therapy have another treatment option using the immune checkpoint inhibitor pembrolizumab.[106] At a median follow-up of 9.7 months, the ORR to single-agent pembrolizumab was 45% with a CR rate of 11% and a PR rate of 34%. The median time to initial objective response was 2.8 months (range, 2.1-8.5 months). The median DoR was not reached (range, <1.1 to <19.2 months).

Primary Testicular Lymphoma

Primary testicular lymphoma is usually an aggressive BCL limited to the testes. It is relatively rare and occurs most commonly in men in the sixth decade of life. Despite being localized (stages I to IIE) in most cases, outcomes are poor compared with those in other early-stage DLBCLs. In particular, there is a high risk of CNS recurrence (up to 25%) and a continuous risk of relapse persisting even 10 years after diagnosis.[107] Treatment should include R-CHOP for six cycles, CNS prophylaxis, and irradiation of the contralateral testis at the end of systemic therapy.[108]

CNS Prophylaxis

Aggressive BCLs can recur in the CNS with an extremely high risk of fatal outcome within 1 year. CNS recurrence typically occurs early, within 6 to 12 months after initial treatment, and is often parenchymal. Fortunately, the overall risk of secondary CNS involvement in the rituximab era is low at approximately 3% and 5% in all patients with DLBCL. Defining patients with a higher risk of recurrence and delivering CNS prophylaxis are essential, but these areas remain incompletely outlined. Extranodal areas confer increased risk of CNS involvement, although not all anatomic areas confer the same risk. Marrow, paranasal sinus, testis, and breast involvement confer a higher risk. One international collaboration evaluated 2,164 patients with aggressive BCLs and proposed a new CNS-IPI comprising kidney and/or adrenal gland involvement, age >60 years, LDH level higher than normal, Eastern Cooperative Oncology Group performance status (ECOG PS) >1, stage III to IV disease, or more than one extranodal site. Patients who had high-risk disease had a 10% to 12% risk of CNS relapse.

Unfortunately, prospective data are lacking to guide the best prophylactic regimen. Historically, CNS prophylaxis has involved four to eight doses of intrathecal methotrexate and/or cytarabine or systemic methotrexate (3-3.5 g/m^2) during or after the course of treatment.[109,110] There remains considerable debate, based on emerging data, surrounding the optimal role and value of CNS prophylaxis in DLBCL, summarized recently by Schmitz and Frontzek.[111]

Relapsed/Refractory Disease

Despite improved cure rates with chemoimmunotherapy, approximately 30% to 40% of patients who have DLBCL will have either primary refractory disease or experience relapse after a prior response. The treatment of R/R DLBCL is evolving with many recent and likely upcoming changes to the standard of care (Fig. 20-4). HDC and ASCT were the long-standing standard therapies for chemosensitive disease based on the randomized Parma trial conducted >20 years ago.[112] This trial randomly assigned 109 patients who were younger than 60 years and had relapsed aggressive BCL to either dexamethasone and cytarabine/platinum agent (DHAP) chemotherapy or ASCT, and ASCT was associated with superior EFS and OS rates of 46% versus 12% (P = .001) and 53% versus 32% (P = .038), respectively. Platinum chemotherapy is the backbone of common regimens. The CORAL trial randomly assigned patients with R/R DLBCL after either CHOP or R-CHOP to one of two salvage regimens (rituximab plus ifosfamide, carboplatin, and etoposide [ICE] or rituximab plus DHAP) before ASCT. Among 398 patients, the 3-year PFS rate was 37% overall, but it was 53% for those who had chemotherapy-sensitive disease who successfully underwent transplantation.[113] Patients with relapse within 12 months and having received prior R-CHOP therapy had worse outcomes with a 3-year PFS of 23%. Registry data suggest chemosensitivity remains an important predictor of ASCT outcomes with a 40% to 50% rate of durable remission among patients able to proceed to ASCT.[114]

However, chemotherapy and ASCT fail to cure at least half of patients with R/R DLBCL. CAR-T-cell therapy has emerged as a major treatment modality, first approved after two prior lines (or after ASCT) and more recently for primary refractory DLBCL or relapse within 1 year after first-line therapy. Initially, three CAR T-cell constructs targeting the B-cell receptor antigen CD19 were approved for patients receiving two prior lines of treatment. axi-cel demonstrated an ORR of 82% and a CR rate of 54%.[115] At 5 years, the OS was 42.6%, and with a median follow-up of 63 months, 31% of responses were ongoing.[116] Tisa-cel was the second CAR T-cell product approved after demonstration of an ORR of 54% and a CR rate of 32%. The median DoR was not reached in patients with CR.[117] A third construct, liso-cel, was approved in late 2020. It differs from the other two products in that the cell product contains a defined population of $CD4^+$ and $CD8^+$ T-cells. The ORR was 73% with a CR rate of 53%, similar to those of the first two constructs (46.8%-59.4%). After 2 years of follow-up, the estimated DoR, PFS, and OS rates of liso-cel were 49.5%, 40.6%, and 50.5%, respectively. The most common grade ≥3 adverse events were neutropenia in 161 patients (60%), anemia in 101 (37%), and thrombocytopenia in 72 (27%).[118] The long-term follow-up of these three agents demonstrates the curative potential of CAR T-cell therapy in a subset of patients.

Subsequently, in 2022, two randomized trials compared CAR-T therapy to ASCT in second-line therapy for patients with primary refractory disease to first-line therapy (R-CHOP) or relapse within a year, showing improved outcomes with CAR-T. In the Zuma-7 trial, patients were randomly assigned to axi-cel (N = 5,180) or standard care defined as two to three cycles of salvage chemotherapy then ASCT for those with chemosensitive disease (N = 5,179).[119] This study showed a superior CR rate with axi-cel versus standard care (65% vs. 32%) and superior EFS in accordance with the primary endpoint (2-year EFS 41% with axi-cel vs. 16% with standard care). Notably, 2-year OS was 61% with axi-cel versus 52% for standard care, even though 56% of patients in the standard care group subsequently received CAR T-cell therapy. The estimated OS benefit of axi-cel over standard care at 4 years was still significant.[120] A second randomized trial, TRANSFORM, included a similar patient population: 184 patients with primary refractory DLBCL or relapse within 12 months of first-line therapy randomized to either liso-cel or standard care (three cycles of salvage then ASCT in chemotherapy-sensitive disease).[121] Similar to Zuma-7, an improved EFS was observed with CAR-T therapy (10.1 months with liso-cel vs. 2.3 months after standard care), and at 3 years of follow-up, the median PFS was not reached for liso-cel and was 6.2 months for standard care.[122] Based on these data, CAR-T-cell therapy using axi-cel and liso-cel has gained approval for second-line use in refractory/early relapsing DLBCL, and it has emerged as an important option.

An additional second-line approval for CAR-T followed the PILOT trial, testing liso-cel specifically in patients who have DLBCL who were ineligible for ASCT based on prespecified criteria, including age 70 or older, ECOG 2, or impaired organ function.[123] This phase 2 study treated 61 patients with liso-cel, noting an 80% ORR (54% CR), median DoR 12 months, and only one case of grade 3 CRS with no treatment-related deaths. With a median follow-up of 18 months, the PFS and OS rates were 43% and 59%, respectively.[124] Thus, for patients ineligible for ASCT after second-line therapy who are eligible for CAR-T therapy, liso-cel is an effective treatment option.

Based on this rapidly evolving data, CAR-T therapy has become an important treatment option for relapsed DLBCL-NOS as well as DLBCL arising from FL, grade 3b FL, and PMBL. High-grade B-cell lymphomas (including DLBCL/HGBCL-MYC/BCL2) appear to achieve similar benefit from CAR-T therapies, though representing off-label use. Comparative studies between CAR-T-cell therapies are lacking, and critical questions remain related to their cost-effectiveness, efficacy in less common aggressive B-cell NHL subtypes (Richter transformation, secondary CNS lymphoma), the best measurement of tumor CD19 expression, and its relationship to CAR-T efficacy, and the best choice of bridging therapy to achieve disease control during cell manufacturing while avoiding T-cell depletion and excess myelotoxicity. Toxicities of CAR-T are significant and include CRS, neurologic toxicity (ICANS), cytopenias, infections, and potentially secondary malignancies; these require careful patient selection, monitoring, and prompt intervention based on defined algorithms at qualified centers.

The newest and most promising class of active agents in DLBCL is the bispecific antibodies (reviewed by Falchi et al.).[125] There are two bispecific CD20-directed CD3 T-cell engagers approved by the FDA in DLBCL, epcoritamab and glofitamab. These agents, as well as additional agents, are in development and represent an important emerging class of lymphoma therapy. The major toxicity of these agents is CRS, which occurs in 40% to 70% of patients, and various strategies have been used to decrease the risk of severe CRS with these agents. Corticosteroids, acetaminophen, and antihistamines should be administered before the agents during the first cycle of treatment, and the drugs are given in step-up dosages to reduce the risk of CRS. In addition, a dose of the anti-CD20 monoclonal antibody obinutuzumab is given before glofitamab to deplete circulating B cells and reduce the risk of severe CRS. Epcortamab and glofitamab were both granted accelerated approval by the FDA in 2023 for the treatment of DLBCL after two or more lines of prior therapy based on single-arm phase 2 studies.[126,127] These two agents have the same targets (CD20 and CD3) but differ in their dosing strategy and delivery. Epcoritamab is given subcutaneously until disease progression or unacceptable toxicity, whereas glofitamab is given as an intravenous infusion for a fixed duration of up to 12 cycles. In the phase 2 study, epcoritamab was given to 157 patients with an ORR of 63% with a CR rate of 39% and DoR of 12 months and a CRS rate of 50%. Quite similarly, glofitamab was given to 154 patients with an ORR of 56% and a CR rate of 43% with a median DoR of 18.4 months and a CRS rate of 63%.

Given the clear activity of bispecific antibodies in DLBCL, these agents are currently being tested alone and in combination with other agents in all lines of lymphoma therapy. The most important outcome so far has been the results of the randomized phase 3 STARGLO trial of glofitamab plus gemcitabine and oxaliplatin (GemOx) versus R-Gem-Ox in patients with relapsed or

refractory DLBCL after at least one prior therapy who were not eligible for ASCT.[7] This study randomized 274 patients from Asia, Australia, Europe, and North America in a 2:1 fashion of glofitamab-GemOX for eight cycles plus four additional cycles of glofitamab monotherapy versus R-GemOx for eight cycles. The patients in the glofitamab-GemOx arm had a significantly better median OS of 25.5 months versus patients in the R-GemOx arm with a median OS of 12.9 months (HR = 0.62). Although not FDA approved in the United States, this regimen is a new option for patients with relapsed or refractory DLBCL who are ineligible for ASCT after at least one prior therapy. For patients with R/R DLBCL ineligible to receive intensive therapies, including ASCT and CAR T cells, there have been additional drug approvals in recent years. In June 2019, the FDA approved polatuzumab vedotin-piiq (pola) for the treatment of R/R DLBCL in combination with BR after at least two prior therapies. In a randomized comparison, pola and BR afforded an end-of-treatment ORR of 45% and a CR rate of 40%, superior to the control arm of BR (ORR, 17.5%).[128] After a median follow-up of 22.3 months, median PFS and median OS were also improved by the addition of pola compared with BR alone (9.5 and 12.4 months vs. 3.7 and 4.7 months, respectively). Infectious prophylaxis and growth factor support must be considered in patients treated with pola and BR. The combination of pola plus mosunetuzumab (mosun), a CD20-directed CD3 T-cell engager, was evaluated against R-GemOx in a randomized phase 3 trial in patients with relapsed DLBCL who were ineligible for autoHSCT, and pola-mosun demonstrated a significantly longer PFS of 11.5 months versus 3.8 months with R-GemOx. There were infrequent CRS events in the pola-mosun group along with fewer chemotherapy-associated toxicities.[129] Pola-mosun is now another option available for patients with relapsed disease who are ineligible for autoHSCT.

In July 2020, the FDA approved tafasitamab-cxix, a CD19-directed cytolytic antibody, indicated in combination with lenalidomide for adults who have R/R DLBCL-NOS, including DLBCL arising from low-grade lymphoma, who are not eligible for ASCT. Half of the patients had received only one prior line of therapy. The L-MIND study coadministered intravenous tafasitamab (12 mg/kg) and oral lenalidomide (25 mg/day) for up to 12 cycles (28 days each), followed by tafasitamab monotherapy (in patients with stable disease or better) until disease progression.[130] The ORR in 71 patients was 55% with CR and PR rates of 37% and 18%, respectively. Although the PR remission duration was short, 93% of CR patients sustained the remission at 18 months of follow-up.

In April 2021, the FDA approved the CD19-based ADC loncastuximab tesirine for relapsed DLBCL and high-grade BCL in which at least two prior therapies have failed, based on the LOTIS-2 trial.[131] This trial administered loncastuximab tesirine-lpyl, a novel ADC incorporating a pyrrolobenzodiazepine cytotoxic payload, every 3 weeks until progressive disease or unacceptable toxicity. The ORR was 48% with a CR rate of 24%; the trial included patients with refractory, transformed, or high-grade B-cell lymphoma. Loncastuximab tesirine-lpyl represents another option for treating R/R DLBCL and variants ineligible for cellular therapies (eg, CAR-T cells and ASCT) or when these therapies have failed. In the absence of comparative trials or definitive assays predicting response, careful consideration of toxicity profiles, disease features, prior therapies, patient preferences, medical comorbidities, and logistics is required when selecting among these options.

Whereas the oral exportin-1 inhibitor selinexor is approved for R/R DLBCL-NOS, its modest activity and toxicity may lead to a minimal clinical role alongside other options.[132]

KEY POINTS

- DLBCL is the most common and prototypical aggressive lymphoma.
- IPI is the most commonly used prognostic tool.
- Molecular classifications, including the most commonly used COO, currently provide prognostic information and may inform treatment strategies in the future.
- *MYC* rearrangement with or without *BCL2* is a poor prognostic feature in DLBCL.
- Early-stage DLBCL is increasingly treated with immunochemotherapy alone without RT, using PET scanning to tailor therapy.
- Patients with nonbulky disease and lacking IPI risk factors or with a negative PET/CT after three cycles of R-CHOP can be treated with four cycles of R-CHOP alone.
- Aggressive NHLs are potentially curable and require prompt initiation of therapy soon after the diagnosis to ameliorate symptoms, avert rapid progression of the disease, and optimize survival.
- Calculation of the IPI for a patient at the time of diagnosis with DLBCL permits estimation of projected survival on the basis of individual clinical characteristics.
- DLBCL is the most common aggressive NHL, and it is a heterogeneous disease with clinical and genomic variants. With a combination of anthracycline-containing chemoimmunotherapy, it has a cure rate of approximately 60% to 70%.[133,134] Current first-line options are R-CHOP or the newer combination of pola-*R*-CHP.
- The presence of dual *MYC* and *BCL2* rearrangements defines DLBCL/HGBCL-MYC/BCL2, a unique entity with poor prognosis when treated with standard R-CHOP treatment.
- CD-19-directed CAR-T-cell therapy is the treatment of choice for patients who have primary refractory or early relapsed DLBCL. If the patient is not transplant or CAR-T eligible, tafasitamab-cxix with lenalidomide (tafa-len) is a reasonable option.

- Patients who have relapsed more than 1 year following first-line treatment with chemosensitive disease are candidates for high-dose chemoimmunotherapy plus ASCT with curative intent, or if patients are not transplant-ineligible DLBCL, consider CD-19-directed CAR-T-cell therapy.
- Epcoritamab and glofitamab are bispecific CD20-directed CD3 T-cell engagers FDA approved for R/R DLBCL after two or more lines of prior therapy.
- Glofitamab plus gemcitabine and oxaliplatin and polatuzumab vedotin plus mosunetuzumab are new options for patients with relapsed or refractory DLBCL who are ineligible for ASCT, although not approved by the US FDA.
- Other FDA-approved regimens for R/R disease include polatuzumab vedotin (pola), tafa-len, loncastuximab tesirine, and selinexor; all have unique mechanisms of action and toxicity profiles but do not produce long-term disease control for most patients with R/R DLBCL.

MANTLE CELL LYMPHOMA

INTRODUCTION AND BACKGROUND

MCL is an uncommon NHL subtype that occurs in approximately 3,000 to 5,000 patients per year in the United States. For unclear reasons, there is a strong predilection for male sex at a ratio of three to one. The median age at onset is 70 years. The malignant cells characteristically express CD20 and CD5, features shared with CLL. However, MCL does not express CD23 (a feature of CLL) or CD10 (found in most cases of FL). Diagnosis is confirmed by the presence of mature $CD20^+$ $CD5^+$ B cells with cyclin D1 overexpression, most commonly resulting from t(11;14)(q13;q32).

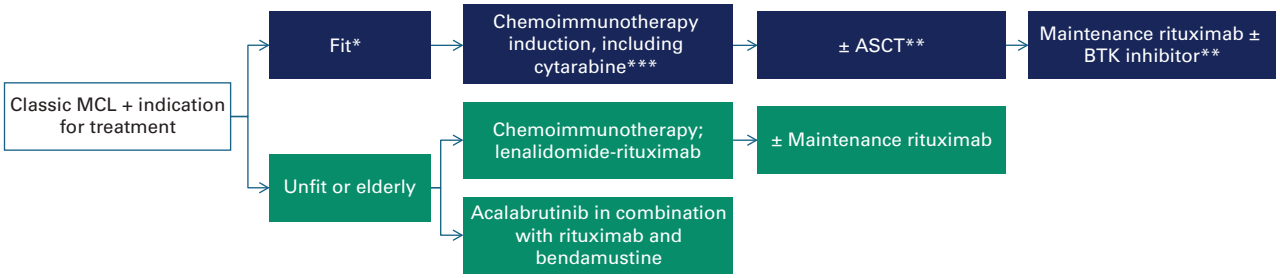
Three main clinicopathologic MCL variants have been described, including classic MCL, blastoid MCL, and indolent MCL. SOX11 is positive in classic and blastoid MCL but is frequently absent in indolent MCL, which presents with splenomegaly and lymphocytosis and has a better initial prognosis. Blastoid MCL presents with large and variable cell size and a high proliferation index, typically accompanied by complex cytogenetic abnormalities and abnormalities of *TP53* and an aggressive clinical course. Classic MCL is most common and presents with both adenopathy and extranodal involvement of the GI tract (lymphomatous polyposis) or with peripheral blood lymphocytosis. A vast majority of patients have bone marrow involvement at diagnosis.

Prognosis in MCL is affected by clinical and biologic features. The Mantle Cell Lymphoma International Prognostic Index (MIPI) stratifies patients into low-, intermediate-, and high-risk groups based on a calculation that involves age, PS, LDH level, and leukocyte count; the MIPI-c further incorporates a proliferation index based on Ki67 immunohistochemical staining, with ≥30% associated with poor prognosis.[135] Mutation of the *TP53* gene, although present in a minority of cases of newly diagnosed MCL, is associated with chemoresistance and poor outcomes even with intensive therapy, including ASCT, and genetic sequencing is now regarded as essential testing at the time of initial diagnosis.

FIRST-LINE SYSTEMIC THERAPY FOR MCL

Although MCL is highly heterogeneous, the majority of patients present with advanced-stage disease and symptoms related to lymphadenopathy, effusions, or extranodal disease. Patients who do not have any symptoms or the indolent MCL variant may safely undergo expectant management (observation) instead of receiving immediate therapy. Goals of first-line therapy in MCL include alleviation of symptoms and organ dysfunction and attainment of long-lasting remission, although even with highly effective therapy, relapses are inevitable for most patients. The MIPI prognostic index, although useful in discriminating high-risk

Figure 20-5 Treatment Algorithm for MCL



Abbreviations: ASCT, autologous stem cell transplantation; BR, bendamustine and rituximab; BTK, Bruton tyrosine kinase; MCL, mantle cell lymphoma; R-CHOP, rituximab and cyclophosphamide, doxorubicin, vincristine, and prednisone; VR-CAP, bortezomib, rituximab, cyclophosphamide, doxorubicin, prednisone.
Chemoimmunotherapy includes BR; R-CHOP; and VR-CAP.
*"Fit" patients are generally aged 65 or younger, without comorbidities precluding myelotoxic chemoimmunotherapy and potential ASCT.
**Regimens are varied; see published treatment guidelines.
***Cytarabine chemotherapy with a BTK inhibitor for 2 years (and no ASCT) is supported by the randomized TRIANGLE study.[140]

patients who may benefit from clinical trials or novel approaches, has not been validated in the context of first-line treatment selection (Fig. 20-5).

The standard approach to first-line therapy for classic MCL (without *TP53* mutation) depends on age and eligibility for intensive, myelotoxic therapy. Specific regimens are varied and best considered in the context of treatment guidelines[136] and/or tertiary lymphoma center consultation. The general strategies, with merits/disadvantages, are as follows:

1. Younger (generally age 65 or under) patients, fit/eligible for intensive therapy: cytarabine-containing chemoimmunotherapy, then consolidation ASCT, and 3 years of rituximab maintenance.
    a. Merits: High probability of CR; prolonged remissions often exceeding 5+ years depending on MIPI.
    b. Disadvantages: No conclusive long-term survival benefit from randomized trials. High-dose cytarabine is associated with severe myelotoxicity with risk of infection and potential transfusion requirements. Consolidation ASCT carries unique, additional risks of severe myelo- and organ toxicity, treatment-related MDS/AML, and treatment-related mortality.
2. Older patients >65 or ineligible for intensive therapy: lower intensity chemoimmunotherapy, consideration of rituximab maintenance.
    a. Merits: Lower risk of severe myelotoxicity/neutropenia and acute infections and treatment-related mortality.
    b. Disadvantages: Shorter remissions (median PFS about 5 years or less), risk of late infections after bendamustine and in the setting of rituximab maintenance.

Randomized clinical trial data on the selection of first-line treatment is scarce, but some key examples have demonstrated the following:

- Cytarabine-containing therapy improves depth of response and EFS over R-CHOP induction therapy in younger patients receiving ASCT, but at a cost of greater toxicity.[31]
- Three years of rituximab maintenance after ASCT improves both PFS (83% vs. 64%; $P < .001$) and OS (89% vs. 80%; $P = .04$).[137]
- In patients 65 or older with MCL, the SHINE trial demonstrated a PFS benefit with the addition of long-term ibrutinib therapy to BR induction (over BR alone). However, there was no survival benefit because of excess non-lymphoma deaths in the experimental arm, a finding that influenced the withdrawal of ibrutinib's indication for treatment of MCL in the United States.[138]
- On January 16, 2025, the FDA approved acalabrutinib combined with bendamustine and rituximab for adults with previously untreated MCL who are ineligible for autologous HSCT. This decision was based on the ECHO trial, which randomized ~600 patients aged 65 or older to receive either acalabrutinib + BR or BR + placebo. Adding acalabrutinib in this transplant-ineligible, older population significantly prolonged progression-free survival by approximately 16 to 17 months compared to BR alone, with slightly increased side effects that were generally manageable.[139]

This paradigm, in particular the role of ASCT for consolidation of response, is rapidly evolving as data from randomized trials testing first-line BTK inhibitors and novel, response-adapted strategies become available. In particular, although preliminary, the TRIANGLE trial tested the role of ibrutinib induction and the additive value of consolidative ASCT in a three-arm, randomized trial including 870 younger, fit MCL patients.[140] The three arms included cytarabine-containing chemoimmunotherapy then ASCT for patients with a response (arm A, the current standard of care); the same treatment and ibrutinib for 2 years (A + I); and chemoimmunotherapy and ibrutinib without ASCT (arm I). At 31 months of follow-up, the standard arm A was no better than arm I; in fact, it had numerically worse FFS than the ibrutinib-containing, nontransplant arm. The best 3-year FFS rate was achieved in the combination arm A + I (88%) compared with 72% in arm A ($P < .05$). Whereas arm A + I was also the most toxic during the maintenance phase, the authors conclude that BTK inhibition may benefit young, eligible patients with MCL as part of first-line therapy and call into question the universal application of ASCT. Further key details (outcomes based on induction response) and more follow-up are needed to better inform clinical decision-making using these results.

RELAPSED/REFRACTORY MCL

Patients who have MCL face a continual risk of relapse even after long-term remissions. Treatment options for R/R MCL range from chemoimmunotherapy to novel agents, including bortezomib, lenalidomide, and BTK inhibitors, to transplant or CAR-T cellular therapies. The BTK inhibitors acalabrutinib and zanubrutinib, administered on a continuous oral basis, represent the mainstay of second-line MCL therapy. Phase 2 trials with these agents demonstrate an ORR of approximately 80%, although a minority achieve CR, and median PFS is under 2 years.[141,142] Contusion/hemorrhage, infection, and neutropenia are well-described

risks. Notably, ibrutinib was withdrawn from the market due to its less favorable toxicity profile and data from the SHINE trial. Bortezomib and lenalidomide ± rituximab provide responses in a minority of R/R MCL patients and tend to be of shorter duration (PFS <1 year).

A noncovalent and highly specific BTK inhibitor, pirtobrutinib, was approved in January 2023 for relapsed or refractory MCL after at least two lines of systemic therapy, including a BTK inhibitor. Approval was based on demonstration of an ORR of 58% in a phase 1/2 trial of 90 patients with R/R MCL, the vast majority of whom had received another BTK agent with low rates of severe adverse events.[143]

Despite the efficacy of this class, most patients who have MCL ultimately experience disease progression and require additional therapy, and rapid progression has been reported on cessation of BTK inhibitors. CAR-T-cell therapy in MCL with brexucabtagene autoleucel, which targets CD19, resulted in an objective response rate of 87%, including a 62% CR rate, in 68 patients reported from the single-arm ZUMA-2 study.[144] Patients in this trial had a median age of 65 and three prior lines of therapy, and all had received treatment with a BTK inhibitor; toxicities included severe (grade 3 or higher) CRS and neurologic events in 15% and 31% of patients, respectively. After a median follow-up of 3 years, the objective response rate was 91%, including 61% CRs. The median DoR, progression-free survival, and OS were 28.2, 25.8, and 46.6 months, respectively.[145] In cohort 3 of ZUMA-2, which included patients with R/R MCL who were naive to BTK inhibitors, the efficacy was similar to that in cohort 1 of ZUMA-2 (which consisted of BTK-exposed patients).[146] High efficacy was also observed with liso-cel, including CR in 72% of patients and PFS of 15.3 months with lower observed rates of grade 3 or higher CRS and neurologic events (1% and 9%, respectively).[147] These CAR-T-cell therapies represent intensive but important options for patients with MCL, particularly with multiply relapsed disease, short remissions, and/or failure of BTK inhibitor-based therapy. Similarly, allogeneic HSCT remains an option for the highest risk, fit patients, including those with *TP53*-mutated, refractory MCL, but would generally be considered after CAR-T therapy, given the risk of complications and treatment-related mortality.

KEY POINTS

- MCL is a heterogeneous disease. Those with an indolent variant can often forgo initial therapy, although most will need treatment eventually.
- *TP53* sequencing is regarded as a standard component of biopsy evaluation in the workup of newly diagnosed MCL.
- Induction chemotherapy for classic MCL includes high-dose cytarabine and ASCT, followed by rituximab maintenance for young and eligible patients, but the advancement of BTK inhibitors into first-line therapy may soon change this paradigm.
- Older and ineligible patients have several first-line treatment options, including BR. If rituximab maintenance is used, attention to toxicity and particularly infections is required, particularly after bendamustine induction.
- Acalabrutinib in combination with rituximab and bendamustine is an option for transplant-ineligible older population with significant improvement in progression-free survival.
- R/R MCL is generally treated with a covalent BTK inhibitor with subsequent options, including the new noncovalent pirtobrutinib and CAR-T therapy.

LYMPHOBLASTIC LYMPHOMA

Lymphoblastic lymphoma is an aggressive neoplasm that typically presents in young men (median age, 16 years) with mediastinal masses. The tumor exhibits an immature T-cell immunophenotype with expression of CD7, cytoplasmic CD3, and TdT. Rearrangements of the T-cell receptor genes are virtually always present, and activating *NOTCH* mutations are present in a majority of cases. The clinical distinction between lymphoblastic lymphoma and T-cell acute lymphoblastic leukemia (ALL) is based on an arbitrary definition that assigns diagnosis as T-cell ALL if the bone marrow contains >25% lymphoblasts and lymphoblastic lymphoma if it contains less than 25%. The presence of an elevated serum LDH level and bone marrow or CNS involvement confers an unfavorable prognosis. The treatment of lymphoblastic lymphoma mirrors that of ALL; please refer to Chapter 19: Leukemias.

KEY POINT

- Lymphoblastic lymphoma is an aggressive lymphoma that expresses immature markers (ie, TdT) and is treated similarly to ALL.

BURKITT LYMPHOMA

Burkitt lymphoma is a highly aggressive tumor characterized by an exceptionally high proliferation rate (Ki67 score, approximately 100%), mature B-cell immunophenotype (monoclonal surface IgM and CD10, CD19, CD20, CD22, BCL6, CD38, and CD43 expression), and histologic appearance demonstrating diffuse infiltration with a starry sky pattern of macrophages phagocytosing apoptotic tumor cells. All cases of Burkitt lymphoma possess a translocation of the *MYC* oncogene at band 8q24, most commonly associated with a t(8;14) translocation, although t(2;8) and t(8;22) translocations involving k and l loci, respectively, also

occur. The three forms are endemic, sporadic, and HIV-associated. The endemic version occurs in certain parts of sub-Saharan Africa, typically presenting as jaw tumors in children, and is almost always associated with EBV. Sporadic cases occur elsewhere in the world, often presenting with ileocecal masses, and are associated with EBV in less than 30% of cases. Burkitt lymphoma is approximately 10 times more common in people who have HIV and occurs in patients who have long-term HIV viremia and relatively well-preserved $CD4^+$ T-cell counts. Despite its aggressive nature, more than 90% of children and 75% to 80% of adults are cured with highly dosage-intensive chemotherapy. Adult patients can be stratified into risk categories based upon the Burkitt Lymphoma International Prognostic Index (BL-IPI),[148] with patients given one point each for each factor:

- CNS involvement
- LDH is more than three times the institutional upper limit of normal
- ECOG PS score ≥2
- Age ≥40 years

According to the BL-IPI, patients who have no risk factors have low-risk disease, patients who have one risk factor have intermediate-risk disease, and patients who have two or more risk factors have high-risk disease.

Burkitt lymphomas are characterized by a rapid growth rate, and treatment may be associated with potentially fatal tumor lysis syndrome and renal failure. Biochemical abnormalities should be corrected, and patients should receive vigorous hydration as well as prophylactic rasburicase (in patients with LDH more than two times the upper limit of normal or bulky disease) or xanthine oxidase inhibitors (allopurinol) before treatment. Rasburicase is contraindicated in patients with G6PD deficiency. All variants of Burkitt lymphoma are treated with the same approach involving intensive chemotherapy regimens. The choice of treatment regimen may be based on risk category and the presence of CNS disease (reviewed in Roschewski et al).[149] The addition of rituximab to chemotherapy improved 3-year EFS in one randomized trial of adults with Burkitt lymphoma, and it is standard to include rituximab in the treatment of all patients with Burkitt lymphoma.[149] *R*-CODOX-M/IVAC, which is a highly intensive regimen with alternating courses of cyclophosphamide, vincristine, doxorubicin, and methotrexate (CODOX-M) and courses of mesna and ifosfamide, etoposide, and cytarabine (IVAC) and intrathecal methotrexate and cytarabine, is a well-studied, highly intensive regimen in adults, including people who have HIV. *R*-CODOX-M/IVAC is associated with a 2-year 65% to 80% EFS in various series, depending on patient selection factors.[150-152] DA-EPOCH-R was studied in a prospective, multicenter trial in Burkitt lymphoma using a risk-adapted approach with a 4-year EFS survival rate of 85% regardless of age or HIV status.[153] In this study, patients who had low-risk disease received three cycles of DA-EPOCH-R without CNS prophylaxis, and patients who had high-risk disease received six cycles of treatment with intrathecal prophylaxis or active treatment. DA-EPOCH-R is not appropriate for patients who have parenchymal CNS disease. A randomized trial compared DA-EPOCH-R and *R*-CODOX-M/IVAC in patients with high-risk Burkitt lymphoma without CNS involvement. Although the study was closed prematurely because of slow accrual, there was no significant difference in 2-year PFS between the two regimens, but *R*-CODOX-M/IVAC was associated with more severe toxicity.[154]

Nearly all cases of relapsed or refractory Burkitt lymphoma are fatal. R/R disease is generally treated with aggressive second-line chemotherapy regimens followed by consideration of either autologous or allogeneic HSCT, but consideration for clinical trials is the best option.

KEY POINTS

- Burkitt lymphoma is an aggressive lymphoma characterized by *MYC* rearrangement, lack of *BCL2* expression, and extremely high proliferation index.
- Treatment consists of intensive chemotherapy regimens in combination with rituximab in a risk-adapted approach.
- Cure rates are high overall with intensive, multi-agent regimens, although regimens are associated with significant toxicity.
- Patients with relapsed or primary refractory disease have few treatment options and are rarely cured.

PRIMARY CNS LYMPHOMA

Primary CNS lymphomas (PCNSLs) are uncommon de novo lymphomas limited to brain structures, including brain parenchyma, leptomeninges, eyes, and spinal cord. Intraocular involvement is seen in 10% to 20% of cases. These are usually aggressive BCLs, with DLBCL being the most common. PCNSL can occur in both immunocompromised (eg, people who have HIV with very low CD4 T-cell counts, associated with EBV infection) and immunocompetent patients. Among immunocompetent patients, the median age is 60 years.

Patients typically present with symptoms related to mass effect or infiltration with neurologic compromise and symptoms. The diagnosis generally requires a tissue diagnosis, usually via a stereotactic biopsy or CSF analysis, although compatible magnetic resonance imaging findings in conjunction with expert consultation may support initiation of therapy for PCNSL without

histologic confirmation in some cases. If possible, it is important to avoid steroids, which are lympholytic, before planned biopsy because of the risk of a false-negative result/nondiagnostic biopsy with necrosis. If there is concern for irreversible neurologic compromise or impending herniation, avoiding steroids may not be possible. Histopathology shows a dense diffuse infiltrate of large B cells that are positive for CD20, CD19, and *PAX5* and often of a nongerminal center phenotype with MUM1 positivity.[10] Diagnostic and staging evaluation should also include a lumbar puncture (if safe to perform); slit-lamp eye examination; CT scan of the chest, abdomen, and pelvis; bone marrow biopsy; and an HIV test. For men aged >60 years, testicular examination and ultrasonography should also be performed.

The most frequently used regimens to treat PCNSL include high-dose methotrexate. High-dose methotrexate (minimum dose, 3 g/m^2) with or without high-dose cytarabine produces superior results compared with RT alone, with a median survival of 51 months.[155-157] In the setting of HIV-associated PCNSL, high-dose methotrexate along with ART can be used with curative intent, often without consolidation therapies, particularly if ART results in immune reconstitution.[158] Given the significant morbidity and long-term side effects of whole-brain radiation (WBRT), it is generally used only in the salvage setting.[159]

Radiation-sparing approaches include chemotherapy induction, high-dose methotrexate induction followed by either HDC or ASCT[160-162] and/or induction followed by chemotherapy consolidation.[163] Common induction regimens include methotrexate with temozolomide or rituximab with methotrexate, vincristine, and procarbazine. ASCT consolidation has impressive results with long-term PFS over 50%, similar to WBRT, but with less impairment in cognitive function as demonstrated by the randomized IELSG32 and PRECIS trials.[160,163] The addition of intravenous administration of rituximab may also improve outcomes and is standard in first-line therapy for PCNSL.[164]

The management options for R/R PCNSL are limited overall, but several exciting agents and approaches are in development. If patients have not undergone prior HDC and ASCT, this may be an option if salvage regimens can be safely delivered and if there is chemotherapy-sensitive disease.[165] WBRT is also used either with or without preceding salvage chemotherapy. Temozolomide, ibrutinib, lenalidomide, CAR-T-cell therapy, and intraventricular rituximab have also demonstrated activity in salvage settings.[166]

KEY POINTS

- PCNSL is a clinical variant of DLBCL that occurs exclusively in CNS structures, which may include the brain parenchyma, eyes, leptomeninges, and spinal cord.
- Treatment requires CNS-penetrating agents, usually high-dose methotrexate in the upfront setting.
- In the setting of HIV-associated PCNSL, high-dose methotrexate along with ART can be used with curative intent.

LYMPHOMAS ASSOCIATED WITH IMMUNODEFICIENCY

Acquired and iatrogenic immune suppression increases the risk of many types of lymphomas. Among people who have HIV, DLBCL, Burkitt lymphoma, plasmablastic, primary effusion lymphoma, primary CNS lymphoma, and cHL are the most common subtypes, but TCLs also occur at higher rates. Compared with the general population, people who have HIV typically present with more advanced-stage disease, including extranodal and leptomeningeal disease. In the era of effective ART, the incidence of lymphomas associated with profound immune suppression and low CD4$^+$ T-cell counts has significantly decreased, and the overall prognosis of HIV-associated lymphomas has substantially improved. Patients who have HIV-associated Hodgkin lymphoma, GCB-DLBCL, and Burkitt lymphoma tend to have higher CD4 counts compared with those with other subtypes; in particular, patients who have HIV-associated PCNSL have the lowest CD4 counts at diagnosis, and HIV-associated PCNSL is rare when ART is readily available.[167] There is a higher incidence of virus-associated lymphomas among people with HIV, including primary effusion lymphoma, which is caused by HHV8, and an increased association with EBV among HIV-associated plasmablastic, Hodgkin lymphoma, DLBCL, and Burkitt lymphoma compared with those without HIV.[168]

Treatment of HIV-associated lymphomas generally follows treatment of lymphoma in the general population, although DLBCL is typically treated with EPOCH-R based on the results of phase 2 trials[169] and metanalyses.[170] HIV-associated Burkitt lymphoma outcomes are similar to those of non-HIV-associated Burkitt lymphoma with a modified version of *R*-CODOX-M-IVAC or DA-EPOCH-R.[153,171] Despite initial concern over increased infectious toxicity with the use of rituximab, a meta-analysis and subsequent prospective trials conducted by the AIDS Malignancy Consortium have shown improved outcomes, and rituximab should be used as part of the treatment regimen for HIV-associated CD20$^+$ lymphomas.[170] Prophylaxis for neutropenic and opportunistic infections is standard, and attention to comorbid conditions (hepatitis B or C) is important. HIV-associated Hodgkin lymphoma can be managed with nivolumab in combination with doxorubicin, vinblastine, and dacarbazine (*N*-AVD) or brentuximab vedotin and AVD (BV-AVD).[172,173] Treatment of HIV-associated lymphomas should be delivered concurrently with ART with the assistance of an HIV specialist to avoid drug-drug interactions. Patients who have R/R disease are treated similarly to their HIV-negative counterparts based on a number of phase 2 trials demonstrating the feasibility of autologous and allogeneic transplantation.

Iatrogenic immunosuppression after solid organ transplantation or HSCT is associated with an increased risk of subsequent lymphomas, termed post-transplantation lymphoproliferative disorders (PTLDs). Iatrogenic T-cell suppression facilitates

EBV-driven B-cell proliferation and consequent PTLD, particularly in cases diagnosed within the first year after transplantation. Therefore, a vast majority of PTLDs are of B-cell origin, although other lymphomas can also occur. Risk factors for PTLD include recipient EBV-seronegative status and duration and intensity of immunosuppressive agents (reviewed by Dharnidharka et al.).[174] Early PTLDs (less than 1-2 years after transplantation) are usually EBV positive and may respond to reduced immunosuppression, whereas later PTLDs are more likely EBV negative and less amenable to reduced immunosuppression.

Confirming a diagnosis of PTLD requires a biopsy specimen. Histopathology can show early lesions (ie, plasmacytic hyperplasia and infectious mononucleosis-like lesions), polymorphic PTLD, monomorphic PTLD (which includes DLBCL and Burkitt lymphoma), or cHL-like PTLD.[10] A rising EBV titer and abrupt-onset adenopathy with constitutional symptoms increase the suspicion for PTLD. The general treatment approach to early-lesion PTLD is prompt reduction of immunosuppression followed by rituximab monotherapy. Phase 2 trials of rituximab monotherapy showed response rates of 40% to 60%.[175,176] The sequential addition of CHOP chemotherapy if there is an inadequate response to rituximab monotherapy improved the response rate to 90%; however, treatment-related mortality was increased by approximately 10%.[177] For patients who have advanced monomorphic PTLD, is it generally treated with standard chemotherapy for the specific subtype (eg, R-CHOP for DLBCL), similar to what is given in the immunocompetent setting. Another potential strategy to treat PTLD is to target EBV. Tabelecleucel is an off-the-shelf, allogeneic, EBV-specific T-cell immunotherapy that was studied in a phase 3 clinical trial in patients with EBV-positive relapsed or refractory PTLD after either HSCT or solid organ transplant, with an objective response rate of ~50%. Tabelecleucel is not currently FDA-approved.[178]

Finally, autoimmune diseases (eg, rheumatoid arthritis, Sjogren disease, and systemic lupus erythematosus) and treatment of autoimmune conditions with immunosuppressive agents are associated with an increased risk of lymphoma.[179,180] Both the specific risk and NHL subtype are variable, and the incidence may be up to sixfold higher compared with populations without autoimmune conditions. Methotrexate is the most common offending agent. Cessation of immunosuppression is the first step in treatment and can lead to regression of lymphoma without the requirement for additional treatment in a large proportion of patients.[181]

KEY POINTS

- Immune suppression (acquired, iatrogenic, or related to underlying autoimmunity) is associated with an increased risk of lymphoma.
- If possible, removing the cause of immune suppression can lead to lymphoma regression, particularly in early PTLD, leading to a stepwise approach. However, late PTLDs act like aggressive lymphomas.
- HIV-associated lymphomas should generally be treated in the same way as lymphoma in the general population, with the addition of ART. Oncologists should work with HIV specialists to help manage potential infectious complications and avoid drug-drug interactions between ART and cancer treatment.

T- AND NK-CELL LYMPHOMAS

OVERVIEW

Lymphomas arising from mature NK and T cells represent 10% to 15% of NHLs in the United States and nearly 30% of NHLs in Asian countries. The term peripheral TCL (PTCL) refers to a diverse group of post-thymic T-cell malignancies that have a mature T-cell phenotype. NK/TCLs are diverse and individually relatively rare entities with nearly 30 defined subtypes. In adult patients, the WHO classification identifies the following TCL groups: mature T/NK leukemias (covered in Chapter 19), primary cutaneous TCLs, intestinal T/NK lymphomas, hepatosplenic TCL, anaplastic large-cell lymphoma (ALCL), nodal T-follicular helper (T_{FH}) cell lymphoma, other PTCL (or PTCL-NOS), and EBV + NK/T lymphomas.[10] Compared with their B-cell counterparts, PTCLs are more often associated with higher risk features, including systemic symptoms and advanced-stage disease. In addition, patients who have PTCL generally have lower response rates to chemotherapy and a higher risk of relapse and death when treated with multi-agent chemotherapy regimens such as CHOP. A prognostic index specific for PTCL (known as the PIT) includes patient age, LDH level, PS, and presence of bone marrow involvement.[182] Poor prognosis is also associated with *p53* expression[183]; high Ki67 proliferation index (>25%); certain chemokine expression profiles (CXCR3 positive/CCR4 negative); and expression of CD56, *BCL2*, or *BCLXL*. A full exposition of the details of this diverse group of disorders is beyond the scope of this chapter and available elsewhere.[184] Given its rarity and clinical/biologic diversity, few trials have been dedicated to NK/TCL, and most treatment paradigms are extrapolated from treatment of aggressive BCLs. Brief descriptions of the most common entities and general treatment principles follow.

PERIPHERAL T-CELL LYMPHOMA NOT OTHERWISE SPECIFIED

PTCL-NOS is a provisional group encompassing mature aggressive TCLs not included in the other groups, and it is the most common PTCL (25%-30%). By nature, this category is subject to continuous revision as genetic and/or molecular markers allow

reclassification into known or newer entities. TCL usually presents with paracortical or diffuse nodal infiltration of malignant lymphoid cells expressing T-cell markers, including CD2, CD3, T-cell receptor, and usually CD4. Proving clonality can be difficult because oligoclonal or small clonal T-cell receptor populations can occur in nonmalignant tissue; however, loss or downregulation of T-cell lineage markers, such as CD5 or CD7, is characteristic of these neoplasms.[185] The median age of patients who have PTCL-NOS is 60 years, with a male-to-female ratio of 9:1. Clinically, it is characterized by frequent B symptoms, extranodal involvement, and advanced-stage presentation (69%).

ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA

Angioimmunoblastic T-cell lymphoma (AITL) accounts for 18% of TCLs worldwide and typically presents with generalized lymphadenopathy with or without fever, weight loss, and rash with autoimmune phenomena, including hypergammaglobulinemia and a positive Coombs test.[186] The disease is derived from T_{FH} cells with malignant cells typically expressing CD10, *BCL6*, programmed cell death protein 1 (PD-1), and CXCL13 in addition to typical T-cell markers (ie, CD2, CD3, CD5, and CD4). The disease course is frequently complicated by serious, potentially life-threatening infections. AITL is frequently associated with EBV, which plays a pathogenetic role in a proportion of cases. EBV-associated BCL derived from EBV-infected B-cell blasts present in the tumor may also develop during the course of treatment. AITL exhibits frequent mutations in *RHOA* (70%) as well as epigenetic regulators such as *TET2* (82%), *IDH2* (30%), and *DNMT3A* (26%).[187,188]

ANAPLASTIC LARGE CELL LYMPHOMA

ALCL is a malignancy of large pleomorphic mature T lymphocytes that express T-cell surface markers such as CD2, CD4, and CD5, and almost invariably the CD30 antigen (Ki-1). Curiously, the pan T-cell antigen CD3 is negative in >75% of cases. There are two subtypes of ALCL based on the presence or absence of nucleophosmin-ALK t(2;5) translocation: ALK positive and ALK negative.[189] Patients who have ALK-positive ALCL are younger, with a median age at onset of 30 years, and the disease often occurs in pediatric patients. ALK-negative ALCL has a median age at onset of 55 years. ALCL is more common in men and often presents at an advanced stage with frequent extranodal involvement. ALK-positive ALCL has a more favorable prognosis with 5-year survival rates in the 70% to 90% range compared with 40% to 60% for ALK-negative ALCL after anthracycline-containing therapy. A subset of patients with ALK-negative ALCL harboring a *DUSP22* translocation may have outcomes similar to those in ALK-positive ALCL.[32]

GENERAL APPROACH TO NEWLY DIAGNOSED PTCL

Treatment of PTCL is challenging as CHOP is associated with ORRs of 60% to 70%, but long-term disease control of only 25% to 30%[190] and most of the benefit is in IPI low-risk groups. In a retrospective analysis of patients enrolled in sequential German trials, the addition of etoposide to CHOP (CHOEP) improved EFS in patients younger than 60 years, primarily those with ALK-positive ALCL (a subtype of PTCL associated with a more favorable prognosis). On the contrary, this regimen resulted in excessive toxicity in older patients, and ultimately, in neither cohort was an OS difference observed.[191] Despite the limitation of that analysis, CHOEP is sometimes used in younger, fit patients with newly diagnosed PTCL in clinical practice. Over the years, other clinical trials have explored the addition of novel agents (eg, romidepsin, alemtuzumab, lenalidomide)[192-194] to a CHOP-like backbone, largely without success. More recently, the ECHELON-2 randomized phase 3 trial compared CHOP with BV-CHP, in which vincristine in CHOP was replaced with the ADC brentuximab vedotin (BV-CHP).[195] In this 452-patient study, BV-CHP yielded a PFS of 48 months compared with 21 months with CHOP alone. OS and ORR were also significantly improved in the experimental arm. Although several subsets of PTCL were eligible for this trial and minimal CD30 positivity (the target of brentuximab vedotin) was required, 70% of the patients had ALCL (a subtype for which CD30 positivity is a diagnostic hallmark). The results of the ECHELON-2 trial led to US FDA approval of BV-CHP for all newly diagnosed $CD30^+$ PTCLs in November 2018.

Results of nonrandomized trials suggest an advantage to consolidative HDC and autologous stem cell support (HDT-ASCS) in patients who have newly diagnosed PTCL achieving CR to induction chemotherapy with a 60% PFS rate. Registry studies also suggest an advantage with this approach, with a 5-year OS of 48% versus 26% in favor of patients undergoing consolidative HDT-ASCS versus those who did not.[196,197] Similar benefits were seen in the ECHELON-2 study, with the caveat that only 16% of patients underwent HDT-ASCS, and this treatment was not randomly allocated.[198] It is important to note that achieving a CR to chemotherapy is the prerequisite for considering HDT-ASCS consolidation. Therefore, studies suggesting a benefit of this procedure generally carry a selection bias in that they only include chemosensitive patients (who inherently have a better prognosis than those with chemorefractory disease). In sum, although often considered in clinical practice, HDT-ASCS consolidation for patients with PTCL in first remission after induction chemotherapy is not supported by randomized controlled studies, and its clinical benefit remains uncertain.[198]

RELAPSED/REFRACTORY PTCL

Treatment options for patients who have R/R PTCL are limited, and the inability to offer effective salvage treatment to patients precludes opportunities for an allogeneic stem cell transplantation (alloSCT, the only curative therapy) in the majority of patients.

Historical population-based data show a median OS of less than 6 months for patients with relapsed PTCL,[199] though this notion may be changing in the era of new agents. Three agents are approved for use in relapsed PTCL based on the results of large phase 2 trials: pralatrexate, brentuximab vedotin (for CD30$^+$ disease), and belinostat. Pralatrexate is a competitive inhibitor of dihydrofolate reductase and inhibits polyglutamylation via the folylpolyglutamyl synthetase enzyme. A CR rate of 11% and a PR rate of 18% with a 10.1-month response duration were reported.[200] Belinostat is a histone deacetylase (HDAC) inhibitor and indicated response rates of 25% to 40%; despite a modest response rate, remissions can be durable. Brentuximab vedotin, an ADC against CD30, is highly active with single-agent response rates of 85% (CR >50%) in R/R ALCL and other CD30$^+$ TCLs, but it is less useful in the R/R setting if administered first line.[201] Romidepsin is another HDAC inhibitor with previous approval in R/R PTCL,[202] now only available through a restricted access program[203] because of failure to confirm efficacy in a randomized controlled trial.[192] Clinical trial enrollment should be prioritized for patients with R/R PTCL and HDT-ASCS (if not performed after first-line therapy), or alloSCT should be considered whenever feasible in patients who achieve a second or subsequent remission. Duvelisib is a dual PI3K-δ,γ inhibitor and was evaluated in a phase 2, open-label, multicenter, parallel cohort PRIMO trial in R/R PTCL.[204] The initial results of the dose-optimization phase (N = 33) demonstrated a 54% ORR in the 75 mg twice daily (N = 13) and 35% in the 25 mg twice daily (N = 20) cohorts.

Patients who have relapsed ALK + ALCL may be treated effectively with ALK inhibitors such as crizotinib or ceritinib (the latter is not FDA approved). In a small phase 2 study in 14 patients with ALK-positive lymphomas, crizotinib led to an objective response rate of 60%.[205] Recent long-term follow-up data support the preferential use of next-generation ALK inhibitors in relapsed or refractory ALK-positive lymphomas. In a 5-year, phase 2, single-center, open-label study, lorlatinib demonstrated rapid and strong anti-lymphoma activity in patients previously treated with chemotherapy, immunotherapy, and earlier-generation ALK inhibitors, including crizotinib. All participants responded within 1 month, with four of seven achieving CRs, two of which have been sustained for up to 56 months. Responses were especially durable in those achieving early complete remission, and lorlatinib was generally well tolerated, with mostly mild to moderate adverse events, highlighting its value as a salvage therapy and potential bridge to alloSCT.[206] Likewise, alectinib was evaluated in a phase 2, single-arm, open-label, multicenter trial in Japan in patients with relapsed or refractory ALK-positive ALCL. Given at standard oral doses, alectinib achieved a high ORR, with a significant proportion of patients attaining durable CRs. The therapy was well tolerated and formed the basis for its regulatory approval in Japan for this patient population.[207]

PRIMARY EXTRANODAL NK/TCL

Enteropathy-Associated TCL

Enteropathy-associated TCL (EATL) accounts for approximately 5% of TCLs and is more common in geographical areas with a higher incidence of celiac disease, including North America and Europe. Patients typically present with pain, weight loss, and bowel perforation.[208] Cases associated with celiac disease typically exhibit a pleomorphic histology and express CD3 and CD7, but not CD56, whereas patients who do not have celiac disease often display a monomorphic histology and express CD56. Up to 70% of cases of EATL contain gains at chromosome 9q33-q34.[209] Conventional therapy consists of CHOP with a median OS of only 10 months in one international series of 62 patients and a median FFS of only 6 months.[208] The presence of clinical sprue and an adverse PIT score both predicted poor survival independently. One study suggested that outcomes with EATL may be improved by inducing remission with a novel regimen of ifosfamide and etoposide and epirubicin alternating with intermediate-dose methotrexate followed by consolidation with ASCT.[210] This approach yielded a 5-year PFS rate of 52% and an OS rate of 60% among 26 patients who underwent transplantation. Monomorphic epitheliotropic intestinal TCL, formerly considered a variant of EATL, is now recognized as a distinct subtype of intestinal TCL[211] for which optimal treatment has not yet been identified.

Hepatosplenic Gamma-Delta TCL

Hepatosplenic gd TCL is a rare disease, predominantly affecting young men, derived from immature or nonactivated gd T cells. Recurrent genetic abnormalities include isochromosome 7q, trisomy 8, activating mutations of the JAK/STAT pathway (ie, STAT5B, STAT3), and chromatin-modifying genes (ie, *SETD2*, *INO80*, *ARID1B*).[212] This lymphoma typically infiltrates the liver, spleen, and marrow sinusoids with minimal adenopathy.[209] Patients often present with fever, chills, and other systemic symptoms. Cytopenias, especially thrombocytopenia, are typical and often accompanied by hemophagocytic syndrome. Outcome is generally poor, and the recommended induction regimen comprises aggressive multi-agent chemotherapy, such as ICE, followed by allogeneic HSCT in first remission.[213]

Cutaneous TCL

Cutaneous TCLs (CTCLs) are a heterogeneous group of lymphomas characterized by infiltration of the skin and other organs by malignant mature T cells. In the WHO classification, these disorders are considered indolent T-cell malignancies. The most common type of CTCL is mycosis fungoides (MF)/Sézary syndrome (SS), but other subtypes include primary cutaneous ALCL (not to be confused with systemic ALCL), subcutaneous panniculitis-like TCL, and many others.[10]

In most cases of MF, the diagnosis is made after a prolonged period of ill-defined skin disease or parapsoriasis. Subsequently, patches or plaques characteristic of MF develop. At the time of diagnosis, fewer than half of patients have limited plaques,

one-third have extensive plaques, and 10% to 15% have generalized erythroderma. The spleen, liver, and lymph nodes may also be involved, especially in patients with advanced skin disease and circulating malignant cells. Staging is performed using the T (skin) N (nodes) M (viscera) B (blood) system.[214] When the peripheral blood becomes extensively involved with the malignant T cells and erythroderma develops, the condition is called SS.

The treatment approach for MF/SS involves skin-directed therapy for skin-only disease, but may eventually require systemic agents.[215] Most patients who have CTCLs are initially treated with topical corticosteroids, photochemotherapy, and oral methoxypsoralen therapy followed by ultraviolet (UV) light, topical mechlorethamine, bexarotene, or electron-beam RT (either localized or total skin). Systemic therapy is required when these approaches fail or when major organ involvement, diffuse lymphadenopathy, or transformation to large-cell NHL develops. Treatment options for advanced CTCL include extracorporeal photopheresis, interferon-α, bexarotene, denileukin diftitox, liposomal doxorubicin, nucleoside analogs (eg, gemcitabine), alemtuzumab, mogamulizumab, and combination chemotherapy.[216] Mogamulizumab is an antibody against CCR4, a G protein-coupled receptor for CC chemokines that are involved in the trafficking of lymphocytes to various organs, and it showed improved ORR (28% vs. 5%) and DoR (13.0 months vs. 9 months) in a randomized trial leading to FDA approval.[217] Histone deacetylate inhibitors, such as vorinostat and romidepsin, have shown major activity in this condition, as has pralatrexate, and these drugs are being used increasingly earlier in the disease course. Brentuximab vedotin is highly active if there is CD30 expression.[218] Patients who have CTCL often die of infections, and as such, good skin care and oral antibiotics are important adjuncts to therapy. The only known curative therapy for MF is allogeneic HSCT, although a minority of patients are candidate to this approach.[219] The EBMT (European Society for Blood and Marrow Transplantation) guidelines recommend allogeneic hematopoietic cell transplantation as a potentially curative approach for patients with relapsed, refractory, or high-risk peripheral T-cell lymphoma. Patient selection should be individualized based on disease subtype, prior treatments, and overall fitness. Reduced-intensity conditioning is generally preferred to reduce toxicity, although myeloablative regimens may be considered for younger or fitter patients. Donor selection prioritizes matched siblings, followed by matched unrelated donors, with haploidentical or mismatched donors as alternatives. Routine post-transplant interventions, such as prophylactic donor lymphocyte infusions or measurable residual disease monitoring, are not strongly supported by current evidence, emphasizing the need for tailored clinical decisions and further research to optimize outcomes.[220]

Extranodal NK/TCL

Extranodal NK/TCL is an angioinvasive necrotizing lymphoma derived from cytotoxic NK or T cells that is almost invariably associated with EBV infection and typically presents in the nasal cavity, nasopharynx, or paranasal sinuses. It is divided into nasal and extranasal types and can affect skin, the GI tract, or testes. Nasal obstruction, bleeding, and ulceration are typical. The malignant lymphoid cells of nasal NK/TCL typically express CD2, CD56, and cytoplasmic CD3 Im (but not surface CD3) as well as cytotoxic molecules such as T-cell-restricted intracellular antigen, granzyme B, and perforin. The disease often presents at an early stage; RT is a critical therapeutic component of limited-stage disease, either concurrent or variably sequenced with chemotherapy.[221] The disease is relatively resistant to CHOP-type chemotherapy, but it is sensitive to asparaginase-containing regimens, such as SMILE, which contains dexamethasone, methotrexate, ifosfamide, *l*-asparaginase, etoposide, and DDGP (dexamethasone, cisplatin, gemcitabine, and pegaspargase).[133] Relapsed, chemorefractory disease remains a challenge. PD-1 blockers have shown promise in this setting.[222] Allogeneic HSCT should be considered when feasible, and clinical trials should be prioritized with attention to sequence and risk of overlapping toxicities.

KEY POINTS

- PTCL treatment is evolving; younger patients are typically treated with CHOP/CHOEP induction chemotherapy, and response is frequently consolidated with HDT-ASCS, largely based on the results of phase 2 and registry studies.
- Replacing vincristine in CHOP with the ADC brentuximab vedotin demonstrated dramatic improvement in PFS and improvement in OS in the ECHELON-2 randomized phase 3 trial of CD30 + PTCL, although the results are more clearly applicable to $CD30^+$ ALCL.
- Multiple agents are available as second line and beyond, with no clear advantage of one over the other; brentuximab vedotin should be used in patients with R/R $CD30^+$ PTCL if not previously used.
- TCLs are rare, heterogeneous, and aggressive diseases that are frequently chemotherapy resistant.
- Initial treatment of PTCLs without CD30 expression consists of multi-agent chemotherapy with CHOP or CHOEP for younger patients.
- The benefit of HDT-ASCS in first remission is frequently considered, but randomized controlled trials to support this approach are lacking.
- The ECHELON-2 trial showed a dramatic advantage of brentuximab vedotin substitution for vincristine in CHOP over CHOP alone.
- Patients who have R/R PTCL have limited treatment options, and their prognosis is poor, with only allogeneic HSCT representing a curative option in patients who achieve a response to therapy.

- Treatment options for less common TCL subtypes are not well defined, and outcomes are heterogeneous.
- MF is the most common type of CTCL and is an indolent disease in the majority of patients. Treatment is initially skin-directed.
- All patients with localized NK/TCL should have RT as part of their treatment.

HODGKIN LYMPHOMA

CLASSIFICATION

The WHO classification of lymphomas distinguishes two major types of Hodgkin lymphoma: cHL, which includes nodular sclerosis, mixed cellularity, lymphocyte-rich and lymphocyte-depleted subtypes, and nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL).[10] These two major categories of Hodgkin lymphoma, cHL and NLP, present differently and require different treatment paradigms.

EPIDEMIOLOGY AND ETIOLOGY

Hodgkin lymphoma is a mature B-lymphoid neoplasm that annually is diagnosed in approximately 9,050 individuals in the United States and causes approximately 1,150 deaths. cHL has a bimodal incidence distribution with respect to age at diagnosis, with an incidence peak in young adulthood and a second peak in older people, and NLPHL typically presents in middle-aged men. The etiology of Hodgkin lymphoma is not known, although a history of clinical EBV disease (mononucleosis) increases the likelihood of cHL threefold. cHL nodes show evidence of EBV DNA in the genome of the Reed–Sternberg cell in 30% to 80% of cases. HIV and allogeneic bone marrow transplantation increase the risk of cHL in people who have HIV, and cHL is almost always associated with EBV and tends to exhibit high-risk clinical features, such as advanced stage, extranodal involvement, and constitutional symptoms, although the outcomes with standard cHL therapy are similar to those in the general population.

CLASSIC HODGKIN LYMPHOMA

cHL typically presents with painless lymphadenopathy with or without splenomegaly, fever, drenching night sweats, weight loss, and pruritus or pain in a lymph node–bearing area that is associated with alcohol consumption. cHL represents 95% of all cases of Hodgkin lymphoma and is characterized pathologically by the presence of bizarre monoclonal lymphoid cells that may be either mononuclear (Hodgkin cells) or multinucleated (Reed–Sternberg cells). The diagnosis is best established by examination of an excisional lymph node biopsy specimen demonstrating large, atypical lymphocytes surrounded by a heterogeneous infiltrate of non-neoplastic inflammatory and accessory cells. The malignant Hodgkin and Reed–Sternberg (HRS) cells of cHL express CD15 and CD30 surface antigens but usually not typical B-cell markers, such as surface immunoglobulin, CD20, CD79a, or the common leukocyte antigen CD45.[15] The B-cell origin of HRS cells is nevertheless demonstrable by the expression of the B-cell-specific activator protein derived from the *PAX5* gene in 90% of cases.[10] The malignant (HRS) cells are typically surrounded by a heterogeneous infiltrate of reactive T and B lymphocytes, eosinophils, macrophages, fibroblasts, and variable amounts of collagen deposition (sclerosis). Chromosome 9p24.1 is frequently amplified in cHL, increasing the expression of PD-L1 and PD-L2 and promoting their induction through JAK-signal transducer and activator of transcription signaling.[223]

Four discrete histologic subtypes of cHL are recognized by the WHO classification based on the relative proportions of infiltrating small lymphocytes and HRS cells and the amount of collagen (sclerosis) in the biopsy specimen:

- Nodular sclerosis
- Mixed cellularity
- Lymphocyte-rich
- Lymphocyte-depleted

All four subtypes of cHL are evaluated and treated similarly, but the subtype may have an effect on prognosis, with mixed cellularity and lymphocyte-deplete subtypes having a worse prognosis. Figure 20-6 summarizes key points about the differences.

NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA

NLPHL is an indolent B-cell neoplasm that is distinguished from cHL by histologic and immunophenotypic features, including the presence of large neoplastic cells known as popcorn or lymphocytic and histiocytic cells (ie, L and H cells) residing in a large nodular meshwork of follicular dendritic cell processes filled with non-neoplastic lymphocytes. In marked contrast to the HRS cells of cHL, the malignant L and H cells of NLPHL express typical B-cell surface antigens, including CD20 and CD79a, as well as the common leukocyte antigen CD45, but do not express CD15 or CD30.[224] Fifty percent of NLPHL harbor *BCL6* rearrangements in contrast to cHL, in which this is a rare occurrence.[225] NLPHL is responsible for approximately 5% of all cases of Hodgkin

lymphoma, which typically affects men between the ages of 30 and 50 years, usually presents with localized lymphadenopathy (stages I to II), progresses slowly, and is associated with prolonged survival despite frequent relapses. There is a spectrum of associated pathologic entities (reviewed in Savage et al.).[226] Up to 15% of patients who have NLPHL can have a transformation to aggressive B-cell NHLs, frequently T-cell-rich DLBCL, and require aggressive treatment.

STAGING AND INITIAL EVALUATION

Recommended diagnostic tests include history, physical examination, excisional lymph node or core biopsy with specimen evaluation for histology and immunophenotype, CBC count with differential, chemistry panel including liver function test and albumin and LDH levels, erythrocyte sedimentation rate (ESR), HIV testing, chest radiography, FDG PET/CT, and fertility counseling. Other tests useful in selected cases include pulmonary function tests (before bleomycin therapy) and determination of the cardiac ejection fraction (before anthracycline therapy). Bone marrow biopsies are no longer routinely recommended for staging of cHL, provided FDG PET imaging is performed, as patients with early-stage disease rarely have bone marrow involvement in the absence of PET abnormalities, and bone marrow findings do not change treatment in patients with advanced-stage disease.[18] After completion of the diagnostic workup, the extent of involvement with Hodgkin lymphoma is designated using the Lugano staging system.

The clinical approach to Hodgkin lymphoma is based on the subtype (cHL or NLPHL) and initial stage and prognostic factors: early stage (stage I or IIA with favorable or unfavorable features) or advanced stage (stage IIB, III, or IV or bulky disease). Adverse prognostic factors for early-stage cHL include a large mediastinal mass, elevated sedimentation rate, involvement of three or more nodal sites, extranodal disease, age >50 years, or massive splenic disease.[227] Adverse prognostic factors for advanced-stage cHL include age >45 years, stage IV disease, male sex, leukocytosis (white blood cell count ≥15,000/mL), lymphopenia (absolute lymphocyte count <600/mL), low albumin level, or anemia (hemoglobin <10.5 g/dL).[228] As discussed, metabolic response reflected by FDG PET has emerged as one of the most important prognostic factors for survival, and it forms the rationale for response-adapted therapy.

TREATMENT OF HODGKIN LYMPHOMA

Early-Stage CHL

Patients with stage I and II cHL, also known as early-stage or limited-stage disease, have an excellent prognosis with long-term survival exceeding 90% to 95%. Early-stage disease is further split into two groups: favorable and unfavorable. Risk factors for

unfavorable disease are based upon age, bulky tumors (≥10 cm in size), presence of B symptoms, elevation in ESR, and the number of nodal sites, although cooperative groups vary in how they combine these prognostic factors, making it difficult to compare results across clinical trials. In the era of PET imaging, the interim and end-of-treatment PET results are the most important prognostic factors in cHL. Generally, early-stage cHL is treated with two to four cycles of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) followed by IFRT, with the number of cycles of ABVD and the dose of radiation determined by interim PET results. Clinical trials focus on decreasing the amount of radiation and the number of cycles of chemotherapy required to decrease acute and late toxicities of treatment.

The German HD10 trial randomly assigned 1,370 patients with favorable prognostic factors to between two and four cycles of ABVD chemotherapy and IFRT at 20 and 30 Gy in an effort to reduce both chemotherapy cycles and total radiation dose.[229] Response, PFS, and OS were equivalent among the four arms, and two cycles of ABVD and IFRT at 20 Gy is now the recommended treatment of patients who have favorable early-stage disease, as it limits both chemotherapy and RT. Other studies have tested chemotherapy-only regimens. In general, omission of RT in nonbulky, early-stage cHL is associated with inferior disease control (EFS, PFS, and local relapse) on the order of 3% to 7% (reviewed in Engert et al.)[229]; however, long-term follow-up showed a 12-year OS rate of 94% among those receiving ABVD alone with fewer late toxicities.[230] Importantly, each of these trials was conducted before the incorporation of PET and response-adapted approaches. Two randomized trials in favorable-risk (UK RAPID and EORTC H10F) and one in unfavorable risk (EORTC H10U) disease[231,232] tested the omission of RT on the basis of a negative interim PET-CT, usually defined as a Deauville score less than or equal to two after two cycles of chemotherapy. EORTC H10F favored a combined-modality approach with respect to EFS; however, the 5-year OS rates were 96.7% versus 98.3% for the ABVD plus IFRT and ABVD-only arms, respectively.[231] Similar results were seen in the RAPID trial, which enrolled >600 patients who had stage IA to IIA Hodgkin lymphoma. Patients who had a negative PET scan after three cycles of ABVD (n = 426 patients, 74.6%) were randomly assigned to consolidative RT versus no additional therapy.[232] The 3-year PFS was 94.6% versus 90.8%, favoring RT, but with no difference in 3-year OS rates (97.1% vs. 99%; *P* = .27). Given the excellent outcomes, the RAPID approach without RT is now integrated into NCCN guidelines. Regimens incorporating brentuximab vedotin and PD-1 immune checkpoint inhibitors are under active study for initial treatment of early-stage Hodgkin lymphoma and are likely to further reduce dependence on cytotoxic chemotherapy and radiation.

Advanced-Stage CHL

Advanced-stage cHL is highly curable with combination chemotherapy. Clinical trials have refined the optimal systemic therapy (excellent and detailed reviews by Johnson and McKenzie[233] and Lynch and Advani[234]) with important questions revolving around early and late toxicity, role of intensification, role of RT, and response-adapted treatment. Today, the approach is based on several principles and observations.

ABVD was previously the treatment of choice in North America based on 7- or 10-year FFS rates of 70% to 75%, coupled with an excellent toxicity profile.[235-237] The risk of secondary malignancies is extremely low, and fertility is preserved in most patients. More intense regimens, such as the escalated bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) regimen developed in Germany, offer improved disease control but are associated with increased treatment-related mortality and significant infertility. An Italian intergroup study randomly assigned 331 patients who had advanced-stage Hodgkin lymphoma to ABVD or BEACOPP, and patients who had residual or progressive disease were treated with a uniform salvage program.[237] There was more progression in the ABVD arm (45 patients vs. 20 patients), but the 7-year freedom from second progression and OS results were similar in the two groups. Brentuximab vedotin, etoposide, cyclophosphamide, doxorubicin, dacarbazine, and dexamethasone (BrECADD) is an effective, targeted, and better-tolerated frontline regimen for advanced classical Hodgkin lymphoma, representing an evolution beyond escalated BEACOPP by maintaining efficacy while reducing toxicity. Second, response-adapted therapy is an important component of advanced-stage cHL treatment. The two approaches to integrate interim PET into the management of Hodgkin lymphoma are the following:

1. Treatment intensification based on positive interim PET (eg, escalation from ABVD to BrECADD).
2. Treatment de-escalation based on negative interim PET (eg, de-escalation from BEACOPP to ABVD).[234]

The RATHL study used the latter concept to reduce bleomycin from ABVD, a known pulmonary toxin and a cause of pneumonitis and death, particularly in older individuals.[238] The RATHL study enrolled 1,214 patients who had stage II bulky and advanced-stage cHL; 84% had a negative interim PET (Deauville score 1-3) after two cycles of ABVD. These patients were randomly assigned to continue ABVD or to de-escalate therapy to AVD for four additional cycles. With a median follow-up of 41 months, the 3-year PFS was 85.7% versus 84.4%, and the 3-year OS rate was 97% in both arms. Thus, bleomycin can be safely omitted from cycles three to six (ie, only administer bleomycin in the first two cycles) in patients with a negative interim PET.

When treating with ABVD, it is imperative to deliver treatment on time and without dose reduction to maximize efficacy. Although ABVD is associated with neutropenia, febrile neutropenia is uncommon in this generally young and healthy population.[233] The use of routine growth factors is not recommended because of concerns about an increase in bleomycin-induced lung injury, particularly in older patients, with growth factor support.[239,240]

Brentuximab vedotin is an ADC targeting CD30 with a toxic payload of monomethyl auristatin E. It was first shown to be effective in R/R cHL. In an attempt to improve outcomes and avoid the toxicity associated with bleomycin in the first-line setting, brentuximab vedotin was studied in combination with AVD (BV + AVD) and compared with standard ABVD in the randomized phase 3 ECHELON-1 study. In this study, six cycles of BV + AVD showed a PFS and OS benefit over six cycles of ABVD (6-year OS 93.9% vs. 89.4%, respectively) in untreated advanced-stage cHL, albeit BV + AVD was associated with increased neutropenia and peripheral neuropathy and requires the use of hematopoietic growth factor support.[8] BV + AVD was approved for the first-line treatment of advanced-stage cHL by the FDA based upon the ECHELON-1 study.

The German Hodgkin Study Group has also incorporated brentuximab vedotin into first-line treatment with the development of brentuximab vedotin, etoposide, cyclophosphamide, doxorubicin, dacarbazine, and dexamethasone (BrECADD). HD21 was a randomized, open-label phase 3 trial of 1,482 patients with stage IIB to IV untreated cHL who received either eBEACOPP or BrECADD guided by interim PET after two cycles, demonstrating similar 4-year PFS and OS rates between the two regimens but a significantly lower treatment-related morbidity rate of 42% with BrECADD versus 59% with eBEACOPP. These results have led to the adoption of BrECADD as the first-line treatment of advanced cHL in countries where eBEACOPP has previously been the standard treatment.[241]

More recently, monoclonal antibodies targeting PD-1 have been incorporated into first-line cHL treatment after showing excellent activity in the relapsed and refractory setting. SWOG trial 1826 was a phase 3 study in newly diagnosed advanced-stage cHL that randomized patients to receive either six cycles of the anti-PD-1 agent *N*-AVD or BV + AVD.[11] With a median follow-up of 2.1 years, the 2-year PFS was 92% in the *N*-AVD arm versus 83% in the BV-AVD arm. N-AVD was associated with less treatment discontinuation, and there were infrequent immune-related adverse events related to nivolumab. All adverse events were more common in the BV-AVD arm compared with the N-AVD arm, except for neutropenia and arthralgia. Neutropenia occurred in 56% of participants in the N-AVD arm versus 34% in the BV-AVD arm; however, growth factor support was required to be administered to participants in the BV-AVD arm and was optional in the N-AVD arm. Given the improvement in PFS, N-AVD is considered a new standard of care for advanced-stage cHL.

Bulky Hodgkin Lymphoma

Up to 25% of patients who have cHL will have bulky disease, which is a known negative prognostic factor. Bulky disease is defined as a mass 10 cm or larger on a CT scan or a mediastinal mass greater than 0.33 of the chest diameter on a chest radiograph at T5 to T6. Bulky disease may cause cough or chest pain, but more acute symptoms, such as superior vena cava syndrome, are more likely to be from aggressive lymphomas involving the mediastinum, such as PMBL. Bulky disease is described by its size (eg, 12 cm mediastinal mass), and the previous designation of "X" in the Lugano staging system for bulky disease is no longer used. The literature regarding bulky Hodgkin lymphoma is confounded by the general inclusion of bulky disease in early-stage trials in Europe versus inclusion in advanced-stage trials in North America.

Treatment of bulky cHL has traditionally been combined-modality therapy, but overall there is a strong move away from radiation for bulky mediastinal disease, particularly among patients with a CR by PET imaging and/or with historical risk factors (eg, young age and female sex) for late RT complications. Given the primarily mediastinal location of bulky cHL, RT is associated with secondary malignancies (especially medial breast cancer in young women), cardiovascular disease (which may be aggravated by concurrent use of anthracyclines), and pulmonary toxicity. After six cycles of ABVD, consolidative RT at 36 Gy is associated with a 5-year FFS rate of >80% in bulky Hodgkin lymphoma.[242] A German trial (HD15) used PET-directed RT in patients treated with escalated BEACOPP, and the researchers were able to reduce the use of RT to only 11% of patients.[243] The RATHL trial mentioned in the previous section did not administer RT to the small subset of patients with stage II bulky disease. A randomized trial of nearly 300 patients with advanced-stage Hodgkin lymphoma showed that consolidative RT could be omitted if interim and end-of-treatment PETs showed CR.[244] Overall, there is a strong move away from radiation for bulky mediastinal disease, particularly among patients with a CR by PET imaging and/or with historical risk factors (eg, young age and female sex) for late RT complications. Although retrospective data support the omission of RT in patients who have a negative PET scan, early results from prospective trials are more complex and controversial. A German trial (HD15) used PET-directed RT in patients treated with escalated BEACOPP, and the researchers were able to reduce the use of RT to only 11% of patients[243]; extrapolation to ABVD is controversial. The RATHL trial mentioned in the previous section did not administer RT to the small subset of patients with stage II bulky disease. A randomized trial of nearly 300 patients with advanced-stage Hodgkin lymphoma showed that consolidative RT could be omitted if interim and end-of-treatment PETs showed CR.[244] Overall, there is a strong move away from radiation for bulky mediastinal disease particularly among patients with a CR by PET imaging and/or with historical risk factors (eg, young age and female sex) for late RT complications.[173] A randomized trial of nearly 300 patients with advanced-stage Hodgkin lymphoma showed that consolidative RT could be omitted if interim and end-of-treatment PETs showed CR.[244] In addition, less than 1% of patients received radiation in the S1826 study of *N*-AVD versus BV-AVD in advanced cHL.

Relapsed CHL

Although most patients who have cHL are cured with initial treatment, approximately 10% to 20% have disease recurrence. The treatment approach at relapse is influenced by the time to relapse and the nature of the initial treatment, but generally

consists of a multistep process of second-line chemotherapy, hematopoietic stem cell mobilization, HDC with autologous stem cell rescue (ASCT), and consideration of consolidative brentuximab vedotin. In support of ASCT, two randomized trials showed superiority of ASCT over conventional chemotherapy. The historic British National Lymphoma Investigation randomly assigned 20 patients apiece with nonresponding or relapsed disease to either carmustine, etoposide, cytarabine, and melphalan (BEAM) alone or BEAM (augmented doses of the same agents) followed by ASCT. The 3-year EFS was 53% versus 10% in favor of the transplantation group.[245] A second trial, the German HD-R1 trial, randomly assigned 161 patients to either dexamethasone plus BEAM alone or BEAM followed by ASCT and showed an improved freedom from treatment failure for HDC (55% vs. 34%; $P = .019$).[246] Of interest, neither of these trials was powered to determine a survival advantage for transplantation, but a meta-analysis confirmed the benefit of transplantation with mature follow-up, and ASCT is now the standard of care.[247] The most important factors predicting outcome with ASCT are time to relapse and chemosensitivity. Trials show that there is little benefit from ASCT when relapse occurs early within 12 months of first-line chemotherapy, and patients do best when they have a negative PET before ASCT.[248,249] Second-line therapy for R/R cHL thus aims to achieve PET-negative CR to consider ASCT. In 2021, a phase 2 trial in PD-1 naive patients with R/R cHL reported pembrolizumab in combination with gemcitabine, vinorelbine, and liposomal doxorubicin (pembro-GVD), achieving CRs in 95% (36/38) of patients.[134] This outpatient regimen has emerged as an important treatment option for relapsed cHL. Although ASCT is an active and appropriate treatment for relapsed cHL, the long-term disease control rate is only 50% to 60% in randomized trials and registry analyses, with relapses occurring mainly in the first 3 years after ASCT. The AETHERA trial randomly assigned 329 BV-naive patients with high-risk R/R cHL to BV consolidation therapy or observation.[250] High risk was defined as primary refractory disease, relapse within 12 months after first-line treatment, or extranodal disease. Brentuximab vedotin consolidation was associated with improved PFS (42.9 months vs. 24.1 months; HR, 0.57; $P = .0013$), but to date, there is no difference in OS. Brentuximab vedotin is FDA approved for consolidation after ASCT.

Not all patients with relapsed Hodgkin lymphoma need ASCT, and controversy exists regarding the best approach for patients with limited relapse or those with minimal therapy in the first-line setting, particularly in the era of novel targeted agents. In addition, research is ongoing regarding nontransplantation options using newer agents.

The treatment options for multiply relapsed Hodgkin lymphoma, either after ASCT or in patients who are ineligible for ASCT, have greatly expanded in the past several years. Brentuximab vedotin has single-agent ORR and CR rates of 75% and 34%, respectively, with half of patients who have a CR remaining disease-free at 5 years.[251]

Brentuximab vedotin is administered at 1.8 mg/kg every 3 weeks and is well tolerated overall. The most common toxicity is sensory peripheral neuropathy, which occurs to some degree in most patients; >80% of patients in the pivotal trial reported eventual resolution of symptoms. Clearly, brentuximab vedotin would be of limited value if already administered in first-line treatment. A second new option is PD-1 blockade. Amplification of 9p24 in cHL leads to PD-L1 overexpression and activation of the JAK-signal transducer and activator of the transcription pathway, supporting the use of PD1/PD-L1 axis blockade and likely contributing to the highest response rate to PD-1 blockade among all tumor types when these agents are used. Nivolumab and pembrolizumab are FDA approved in the following settings:

- Nivolumab: relapsed or progressed after ASCT and brentuximab vedotin or after three lines of prior therapy including ASCT.[252]
- Pembrolizumab: refractory/relapsed after any prior therapy. This indication is based on a randomized trial of pembrolizumab versus brentuximab vedotin after at least one prior therapy. PFS was statistically significantly longer in the pembrolizumab arm. The median PFS was 13.2 months (95% CI, 10.9-19.4) in the pembrolizumab arm and 8.3 months (95% CI, 5.7-8.8) in the brentuximab vedotin arm with an HR of 0.65 (95% CI, 0.48-0.88; $P = .0027$).[253]

Allogeneic HSCT, usually with a reduced-intensity conditioning regimen, remains an option for eligible patients after failure of BV and/or PD-1 blockade.

Therapy for NLPHL

NLPHL treatment has followed a similar paradigm to cHL, as many clinical trials of cHL have included patients who have NLPHL despite the fact that NLPHL behaves as an indolent lymphoma. However, unlike cHL, rituximab may be added to treatment in NLPHL because of the expression of CD20. Early-stage NLPHL without risk factors (bulky disease, extranodal disease, elevated ESR, or ≥nodal areas) may be treated with excision, ISRT, or rituximab alone. In some cases, patients who have asymptomatic stage IA disease may undergo observation alone. Patients who have early-stage disease and risk factors can receive two to four cycles of ABVD, CHOP, or CVP with rituximab plus RT. Survival after early-stage disease is excellent and is approximately 90% with at least 10 years of follow-up. Patients with advanced-stage disease can be treated with six cycles of rituximab with ABVD, CHOP, or CVP (reviewed in Eichenauer and Engert).[254] Relapse is common in those with advanced-stage disease, although 10-year survival in one retrospective study of patients who had advanced-stage NLPHL who received ABVD or ABVD-like treatments was 83.5%. Suspected relapse should be investigated for transformation to an aggressive lymphoma with a biopsy. Patients who have a transformation to an aggressive B-cell lymphoma are treated with R-CHOP if not previously received or HDC with ASCT.

KEY POINTS

- cHL consists of four subtypes, but clinically is treated as one entity.
- NLPHL is an indolent B-cell neoplasm that progresses slowly and is associated with prolonged survival despite frequent relapses.
- The clinical approach to Hodgkin lymphoma is based on the initial stage and prognostic factors.
- Hodgkin lymphoma comprises cHL (nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted subtypes) and NLPHL, each of which has a distinctive clinical presentation, treatment paradigm, and prognosis.
- cHL of any stage is curable in most patients.
- In general, treatment with combined-modality therapy in early-stage cHL provides better PFS and fresh frozen plasma (FFP) but no difference in OS.
- Combination chemotherapy with ABVD or BV + AVD is the standard option for the treatment of advanced-stage cHL in North America, but Nivo-AVD was found to be superior to BV + AVD and represents a new first-line treatment option. The number of courses of chemotherapy varies with the stage of the disease.
- Low-dose IFRT is commonly administered after a short course of chemotherapy for the management of early-stage cHL, although the role of RT is undergoing reevaluation, and patients at higher risk of late RT complications may reasonably be treated with chemotherapy alone.
- PET-adapted therapy is now incorporated into treatment when ABVD is used.
- cHL expresses CD30, which can be targeted by the ADC brentuximab vedotin.
- Amplification of 9p24 is common in cHL and leads to overexpression of PD-L1, which is the basis for the use of PD-1 blockade.
- Patients with R/R cHL can be treated with a variety of therapies with the goal of PET negativity before consolidative autologous transplantation in eligible patients.
- NLPHL behaves similarly to indolent NHLs and expresses CD20. There is a risk of transformation to DLBCL, usually a T-cell-rich variant of DLBCL, which should be evaluated and confirmed via biopsy and treated as transformed aggressive BCL.

PRESENTING CASE STUDY 2

A 29-year-old man presented with a left-sided neck mass associated with significant unintentional weight loss of 40 pounds over 4 months and night sweats for the preceding 2 months. Initial laboratory evaluation revealed anemia and leukocytosis on complete blood count. His hemoglobin level was 9 g/dL, albumin was 3.5 g/dL, white blood cell count exceeded 15,000 cells/μL, and lymphocyte count was 1,500 cells/μL. His lactate dehydrogenase level was elevated at 400 U/L. Past medical history was notable only for lumbar radiculopathy following a motor vehicle accident.

An excisional biopsy of the cervical lymph node demonstrated lymphadenitis with sclerosing fibrosis.

Combined CT and PET/CT imaging revealed diffuse metabolically active lymphadenopathy throughout the neck, chest, abdomen, and pelvis; splenomegaly with numerous low-density, FDG-avid splenic lesions; and extensive FDG-avid osseous involvement of the axial and appendicular skeleton, including a dominant 5 × 4.5 cm lytic lesion in the left sacrum and posterior iliac bone. Metabolically active subcutaneous nodules were also noted. The patient's Deauville score was 5.

A CT-guided biopsy of the osseous lesion showed large, atypical cells with hyperchromatic nuclei in a background of small lymphocytes, eosinophils, plasma cells, and histiocytes.

Immunohistochemical staining demonstrated that the tumor cells were positive for CD15, CD30, *PAX5*, and MUM1. EBER1 was negative. Additional stains were negative for pancytokeratin, CD3, CD20, CD68, ALK1, and CD45.

This case highlights the importance of integrating clinical, pathologic, and imaging findings to diagnose and stage advanced Hodgkin lymphoma accurately. It underscores the need to tailor frontline therapy to individual patient factors, balancing efficacy and toxicity, as demonstrated by the use of nivolumab plus doxorubicin, vinblastine, and dacarbazine (AVD) in a patient at risk for neuropathy. Finally, the case emphasizes the value of PET-adapted response assessment to confirm remission and guide ongoing management.

How does this patient's presentation influence your determination of their risk level and choice of frontline treatment?

According to the International Prognostic Score, a score of 5 indicates high-risk advanced Hodgkin lymphoma, and the patient's presentation, pathology, and imaging findings were consistent with stage IVB classical Hodgkin lymphoma. Frontline treatment options for advanced disease include PET-adapted ABVD, which consists of two cycles of ABVD followed by interim PET and de-escalation to AVD for four additional cycles; this regimen is well studied but carries a risk of bleomycin-induced pulmonary toxicity. Another option is BV-AVD, which has been shown in the ECHELON-1 trial to improve progression-free survival (PFS) compared with ABVD, but is associated with an increased risk of peripheral neuropathy and febrile neutropenia. Nivolumab plus AVD (N-AVD) has demonstrated superior PFS and a more favorable toxicity profile compared with BV-AVD in the SWOG S1826 trial. Given the patient's pre-existing lumbar radiculopathy and the risk of neuropathy with BV-AVD, N-AVD was selected.

The SWOG S1826 trial, a phase 3 randomized multicenter study of 970 patients with stage III to IV classical Hodgkin lymphoma, compared N-AVD with BV-AVD. After a median follow-up of 2.1 years, N-AVD achieved a 2-year PFS of 92% versus 83% with BV-AVD. Treatment discontinuation due to toxicity (7.6% vs. 12%) and on-treatment mortality (0.6% vs. 1.7%) were also lower with N-AVD, and overall, it was better tolerated, including among older adults. These results established N-AVD as a more effective and safer frontline regimen, now recognized as an NCCN Category 1 preferred option, while BV-AVD remains useful for patients with contraindications to checkpoint inhibitors.

The patient completed six cycles of N-AVD without significant toxicity. End-of-treatment PET demonstrated a complete metabolic response according to Lugano criteria. Although sclerosis persisted in the dominant iliac bone lesion, there was no metabolic activity, and the repeat biopsy was negative for lymphoma.

Given this patient's pre-existing lumbar radiculopathy, nivolumab + AVD is the best option to maximize PFS and minimize the risk of worsening neuropathy.

The phase 3, randomized, multicenter SWOG S1826 trial enrolled 970 adolescents and adults with stage III or IV classical Hodgkin lymphoma. Patients received (BV-AVD). The primary endpoint was PFS, with secondary endpoints including OS, event-free survival, and toxicity. After a median follow-up of 2.1 years, the N-AVD group demonstrated superior outcomes, with a 2-year PFS of 92% compared to 83% in the BV-AVD group, reflecting a significantly lower risk of progression or death. Treatment discontinuation due to toxicity was also lower in the N-AVD arm (7.6% vs. 12%), as was mortality during treatment (0.6% vs. 1.7%). In addition, N-AVD was generally better tolerated, with fewer side effects overall, particularly among patients aged 60 years and older, who experienced reduced toxicity compared to those receiving BV-AVD. These findings establish N-AVD as a more effective and safer frontline treatment option for advanced-stage classical Hodgkin lymphoma, which is more effective and safer than BV-AVD. Recently, the NCCN updated the N-AVD regimen to a preferred Category 1 status due to its superior efficacy and reduced toxicity. In addition, BV-AVD is considered useful in certain circumstances for patients with contraindications to checkpoint inhibitors.

The patient above received N-AVD for six cycles and tolerated it well without any significant toxicities. The end-of-treatment PET demonstrated a complete metabolic response by the Lugano criteria. Although sclerosis was identified in the largest bone lesion in the ileum, there was no metabolic activity, and a repeat biopsy was negative for lymphoma.

HIGH-YIELD TAKEAWAYS

Diffuse large B-cell lymphoma

- The classic morphology of DLBCL is intermediate-to-large cells expressing CD19, CD20, CD79a, and CD45.
- Use the International Prognostic Index (IPI), presence of *MYC* rearrangements with or without *BCL2* rearrangements, and cell of origin to determine prognosis.
- Early-stage DLBCL with low-risk IPI and nonbulky disease is treated in the first line with four cycles of R-CHOP.
- Advanced-stage DLBCL is treated in the first line with six cycles of R-CHOP or pola-*R*-CHP.

- Refractory or early relapsed DLBCL (<1 year after first-line treatment) is treated with anti-CD19 CAR-T-cell therapy (axi-cel or liso-cel).
- Late-relapsed DLBCL (>1 year after first-line treatment) is treated with ASCT in patients who are fit for transplant.

Classical Hodgkin lymphoma

- CHL is characterized by large, multinucleated lymphocytes (Reed–Sternberg cells) that are CD15- and CD30-positive and negative for other typical B-cell markers, surrounded by reactive lymphocytes, macrophages, eosinophils, and collagen deposits (sclerosis).
- There are four subtypes: nodular sclerosis, mixed cellularity (worse prognosis), lymphocyte-rich, and lymphocyte-depleted (worse prognosis).
- Adverse prognostic factors for early-stage CHL include a large mediastinal mass, elevated sedimentation rate, involvement of three or more nodal sites, extranodal disease, age >50 years, or massive splenic disease.
- Adverse prognostic factors for advanced-stage cHL include age >45 years, stage IV disease, male sex, leukocytosis (white blood cell count ≥15,000/mL), lymphopenia (absolute lymphocyte count <600/mL), low albumin level, or anemia (hemoglobin <10.5 g/dL).
- Early-stage disease is treated with PET-adapted ABVD with or without IFRT.
- Advanced-stage CHL is treated with PET-adapted ABVD, six cycles of BV-AVD, or six cycles *N*-AVD.

Essential pathology workup of MCL

- Diagnosis of MCL involves immunohistochemistry (IHC), flow cytometry, potentially FISH testing, and molecular sequencing for *TP53* mutation.
- Cyclin D1 and/or translocation 11;14 are standard diagnostic findings; SOX11 by IHC can assist in uncertain cases. Ki67 index by IHC is prognostic.
- *TP53* mutation is unique from deletion 17p, and is associated with elevated p53 protein expression (>50%) and poor outcomes with standard chemotherapy.

Acknowledgments

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

LYMPHOMAS 20

CHAPTER SUMMARY GUIDE

KEY POINTS

- NHLs comprise a group of heterogeneous diseases that vary widely with respect to clinical presentation, therapy, and prognosis.
- Advances in the diagnosis and classification of these diseases are facilitated by immunophenotyping and by newer molecular and genetic approaches.
- Establishing a correct diagnosis at the time of initial presentation is critical to optimal management of NHL. Therefore, an adequately sized biopsy specimen is mandatory to permit rigorous classification. FNA is virtually never adequate for establishing the initial subtype of non-Hodgkin lymphoma.
- Indolent NHLs usually grow slowly and are also known as low-grade lymphomas. FL, MZL, LPL, and SLL are all indolent lymphomas.
- Transformation to a higher grade occurs at a rate of approximately 2% per year.
- FL is the most common indolent lymphoma.
- Most patients with FL live for more than a decade.
- Prognostic scores using clinical risk factors can estimate OS.
- Defined treatment indications based on history, physical, imaging, and laboratory results are key to inform whether patients should receive treatment versus active surveillance without therapy (observation).
- Symptomatic patients who have progressive FL or other low-grade lymphomas have a number of treatment options without any evidence indicating a major survival advantage for any specific approach.
- Chemoimmunotherapy remains a standard for first-line FL treatment with high tumor burden, but the subset of patients relapsing within 2 years faces poor survival rates. In these cases, optimal therapy is unknown, but clinical trials, novel targeted therapies, and cellular therapies (HSCT, bispecific T-cell engagers, CAR-T-cell therapy) may be considered.
- The novel small-molecule therapy currently approved for relapsed FL is lenalidomide.
- Combination therapies currently approved for relapsed FL include Rituximab with lenalidomide, zanubrutinib with obinutuzumab, and tafasitamab in combination with lenalidomide and rituximab.
- Recently FDA-approved immunotherapies include the bispecific T-cell engager mosunetuzumab, epcoritamab, and CAR-T-cell therapies (axi-cel, tisa-cel, and liso-cel), representing an important new class of therapies in R/R FL.
- Three types of MZL are EMZL, SMZL, and NMZL.
- MZLs are frequently antigen-driven diseases, and eradication of infection (eg, *H. pylori*) can result in regression of lymphoma without the need for additional therapy.
- RT for localized MZL, including persistence of gastric MZL after *H. pylori* eradication, is effective; systemic therapy for advanced-stage MZL incorporates rituximab and, for selected patients, chemotherapy with rituximab.
- R/R MZL requires individualized consideration of therapy, including additional rituximab, chemoimmunotherapy when appropriate, zanubrutinib, or lenalidomide-based therapy.
- Despite its rarity and lack of comparative trials in WM, several key management aspects are evident from available data: An elevated paraprotein level alone is not an indication for therapy in asymptomatic patients.
- First-line therapy may include rituximab, chemoimmunotherapy, or a continuous BTK inhibitor, depending on goals and patient factors (disease burden, age, and comorbidities).
- Rituximab may result in a sudden increase in IgM levels, leading to symptomatic hyperviscosity.
- R/R WM is treated upon symptomatic progression, and selection of therapy depends on depth and DoR to initial therapy, as in other indolent NHL.
- BTK inhibitors, particularly zanubrutinib, are a mainstay of WM therapy.
- Most patients with primary mediastinal BCL (PMBL) do well with chemoimmunotherapy (eg, R-CHOP) and RT or approaches that seek to eliminate RT (eg, dose-adjusted etoposide, doxorubicin, vincristine, and cyclophosphamide plus rituximab [DA-EPOCH-R]).
- The role of RT remains a controversial issue, and PET-adapted strategies are under investigation.
- CAR-T-cell therapy, high-dose chemotherapy (HDC) and ASCT, and pembrolizumab can be used in the relapsed setting.

- DLBCL is the most common and prototypical aggressive lymphoma.
- IPI is the most commonly used prognostic tool.
- Molecular classifications, including the most commonly used COO, currently provide prognostic information and may inform treatment strategies in the future.
- *MYC* rearrangement with or without *BCL2* is a poor prognostic feature in DLBCL.
- Early-stage DLBCL is increasingly treated with immunochemotherapy alone without RT, using PET scanning to tailor therapy.
- Patients with nonbulky disease and lacking IPI risk factors or with a negative PET/CT after three cycles of R-CHOP can be treated with four cycles of R-CHOP alone.
- Aggressive NHLs are potentially curable and require prompt initiation of therapy soon after the diagnosis to ameliorate symptoms, avert rapid progression of the disease, and optimize survival.
- Calculation of the IPI for a patient at the time of diagnosis with DLBCL permits estimation of projected survival on the basis of individual clinical characteristics.
- DLBCL is the most common aggressive NHL, and it is a heterogeneous disease with clinical and genomic variants. With a combination of anthracycline-containing chemoimmunotherapy, it has a cure rate of approximately 60% to 70%.[133,134] Current first-line options are R-CHOP or the newer combination of pola-*R*-CHP.
- The presence of dual *MYC* and *BCL2* rearrangements defines DLBCL/HGBCL-MYC/BCL2, a unique entity with poor prognosis when treated with standard R-CHOP treatment.
- CD-19-directed CAR-T-cell therapy is the treatment of choice for patients who have primary refractory or early relapsed DLBCL. If the patient is not transplant or CAR-T eligible, tafasitamab-cxix with lenalidomide (tafa-len) is a reasonable option.
- Patients who have relapsed more than 1 year following first-line treatment with chemosensitive disease are candidates for high-dose chemoimmunotherapy plus ASCT with curative intent, or if patients are not transplant-ineligible DLBCL, consider CD-19-directed CAR-T-cell therapy.
- Epcoritamab and glofitamab are bispecific CD20-directed CD3 T-cell engagers FDA approved for R/R DLBCL after two or more lines of prior therapy.
- Glofitamab plus gemcitabine and oxaliplatin and polatuzumab vedotin plus mosunetuzumab are new options for patients with relapsed or refractory DLBCL who are ineligible for ASCT, although not approved by the US FDA.
- Other FDA-approved regimens for R/R disease include polatuzumab vedotin (pola), tafa-len, loncastuximab tesirine, and selinexor; all have unique mechanisms of action and toxicity profiles but do not produce long-term disease control for most patients with R/R DLBCL.
- MCL is a heterogeneous disease. Those with an indolent variant can often forgo initial therapy, although most will need treatment eventually.
- *TP53* sequencing is regarded as a standard component of biopsy evaluation in the workup of newly diagnosed MCL.
- Induction chemotherapy for classic MCL includes high-dose cytarabine and ASCT, followed by rituximab maintenance for young and eligible patients, but the advancement of BTK inhibitors into first-line therapy may soon change this paradigm.
- Older and ineligible patients have several first-line treatment options, including BR. If rituximab maintenance is used, attention to toxicity and particularly infections is required, particularly after bendamustine induction.
- Acalabrutinib in combination with rituximab and bendamustine is an option for transplant-ineligible older population with significant improvement in progression-free survival.
- R/R MCL is generally treated with a covalent BTK inhibitor with subsequent options, including the new noncovalent pirtobrutinib and CAR-T therapy.
- Lymphoblastic lymphoma is an aggressive lymphoma that expresses immature markers (ie, TdT) and is treated similarly to ALL.
- Burkitt lymphoma is an aggressive lymphoma characterized by *MYC* rearrangement, lack of *BCL2* expression, and extremely high proliferation index.
- Treatment consists of intensive chemotherapy regimens in combination with rituximab in a risk-adapted approach.
- Cure rates are high overall with intensive, multi-agent regimens, although regimens are associated with significant toxicity.
- Patients with relapsed or primary refractory disease have few treatment options and are rarely cured.
- PCNSL is a clinical variant of DLBCL that occurs exclusively in CNS structures, which may include the brain parenchyma, eyes, leptomeninges, and spinal cord.
- Treatment requires CNS-penetrating agents, usually high-dose methotrexate in the upfront setting.
- In the setting of HIV-associated PCNSL, high-dose methotrexate along with ART can be used with curative intent.
- Immune suppression (acquired, iatrogenic, or related to underlying autoimmunity) is associated with an increased risk of lymphoma.

- If possible, removing the cause of immune suppression can lead to lymphoma regression, particularly in early PTLD, leading to a stepwise approach. However, late PTLDs act like aggressive lymphomas.
- HIV-associated lymphomas should generally be treated in the same way as lymphoma in the general population, with the addition of ART. Oncologists should work with HIV specialists to help manage potential infectious complications and avoid drug-drug interactions between ART and cancer treatment.
- PTCL treatment is evolving; younger patients are typically treated with CHOP/CHOEP induction chemotherapy, and response is frequently consolidated with HDT-ASCS, largely based on the results of phase 2 and registry studies.
- Replacing vincristine in CHOP with the ADC brentuximab vedotin demonstrated dramatic improvement in PFS and improvement in OS in the ECHELON-2 randomized phase 3 trial of CD30 + PTCL, although the results are more clearly applicable to $CD30^+$ ALCL.
- Multiple agents are available as second line and beyond, with no clear advantage of one over the other; brentuximab vedotin should be used in patients with R/R $CD30^+$ PTCL if not previously used.
- TCLs are rare, heterogeneous, and aggressive diseases that are frequently chemotherapy resistant.
- Initial treatment of PTCLs without CD30 expression consists of multi-agent chemotherapy with CHOP or CHOEP for younger patients.
- The benefit of HDT-ASCS in first remission is frequently considered, but randomized controlled trials to support this approach are lacking.
- The ECHELON-2 trial showed a dramatic advantage of brentuximab vedotin substitution for vincristine in CHOP over CHOP alone.
- Patients who have R/R PTCL have limited treatment options, and their prognosis is poor, with only allogeneic HSCT representing a curative option in patients who achieve a response to therapy.
- Treatment options for less common TCL subtypes are not well defined, and outcomes are heterogeneous.
- MF is the most common type of CTCL and is an indolent disease in the majority of patients. Treatment is initially skin-directed.
- All patients with localized NK/TCL should have RT as part of their treatment.
- cHL consists of four subtypes, but clinically is treated as one entity.
- NLPHL is an indolent B-cell neoplasm that progresses slowly and is associated with prolonged survival despite frequent relapses.
- The clinical approach to Hodgkin lymphoma is based on the initial stage and prognostic factors.
- Hodgkin lymphoma comprises cHL (nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted subtypes) and NLPHL, each of which has a distinctive clinical presentation, treatment paradigm, and prognosis.
- cHL of any stage is curable in most patients.
- In general, treatment with combined-modality therapy in early-stage cHL provides better PFS and fresh frozen plasma (FFP) but no difference in OS.
- Combination chemotherapy with ABVD or BV + AVD is the standard option for the treatment of advanced-stage cHL in North America, but Nivo-AVD was found to be superior to BV + AVD and represents a new first-line treatment option. The number of courses of chemotherapy varies with the stage of the disease.
- Low-dose IFRT is commonly administered after a short course of chemotherapy for the management of early-stage cHL, although the role of RT is undergoing reevaluation, and patients at higher risk of late RT complications may reasonably be treated with chemotherapy alone.
- PET-adapted therapy is now incorporated into treatment when ABVD is used.
- cHL expresses CD30, which can be targeted by the ADC brentuximab vedotin.
- Amplification of 9p24 is common in cHL and leads to overexpression of PD-L1, which is the basis for the use of PD-1 blockade.
- Patients with R/R cHL can be treated with a variety of therapies with the goal of PET negativity before consolidative autologous transplantation in eligible patients.
- NLPHL behaves similarly to indolent NHLs and expresses CD20. There is a risk of transformation to DLBCL, usually a T-cell-rich variant of DLBCL, which should be evaluated and confirmed via biopsy and treated as transformed aggressive BCL.

CHAPTER TABLES AND IMAGES

Table 20-1 Key Diagnostic Immunophenotypic and Cytogenetic Features of Non-Hodgkin Lymphomas

Lymphoma Subtype	CD20	CD10	CD5	CD30	Other	Cytogenetics/ FISH Results	Genes
DLBCL: germinal center subtype	+++	+/−	Rare	Rare	*BCL6*$^{+}$ and MUM1^{-}	*BCL2* translocations (18q21)	*BCL6* and *EZH2* upregulation
DLBCL: nongerminal center subtype	+++	—	+/−	Rare	*BCL6* negative or *BCL6*$^{+}$, MUM1^{+}	*BCL6* translocations (3q27)	B-cell receptor signaling/*NFkB* activation
FL	+++	+	—	—		t(14;18)	*BCL2*
CLL/SLL	Dim	—	+	—	CD23^{+}		
MCL	+++	—	+	—	CD23^{-}, Cyclin D1^{+}, SOX11^{+}	t(11;14)	*Cyclin D1*
MZL	+++	—	Rare	—		t(11;18) (ENMZL) trisomy 3, 18 (NMZL) del 7q (SMZL)	*API2-MALT1*
LPL/WM	+++	—	Rare	—			*MYD88, CXCR4*[20]
Burkitt lymphoma	+++	+	—	—	TdT^{-}	t(8;14), t(8;22), t(2;8)	*MYC*
PMBL	+++	+/−	—	Occasional		t(16;X), 9p24.1 gain	*CIITA, PDL1/ JAK2/PDL2*
Hairy cell leukemia	+++	—	—	—	CD11c^{+}, CD25^{+}, CD103^{+}		
ALCL, ALK^{+}	—	—	—	+++		t(2; 5)	*ALK*
ALCL, ALK^{-}	—	—	—	+++		t(6;7)	*DUSP22*
AITL	—	+/−	+/−	—	At least three T_{FH} markers: PD-1, BCL6, CXCL13, ICOS, SAP, CCR5		*TET2, IDH2, DNMT3A, RHOA, ITK-SYK*
PTCL-NOS	—	+/−	+/−	—	Can have the same immunophenotype as AITL, often with dropped CD3 or CD7		

Abbreviations: AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; ALK, anaplastic lymphoma kinase; API2-MALT1, fusion of apoptosis inhibitor 2 and mucosa-associated lymphoid tissue lymphoma translocation 1; BCL2, B-cell CLL/lymphoma 2; BCL6, B-cell lymphoma 6; CCR5, chemokine, CC motif, receptor 5; CIITA, class II major histocompatibility complex transactivator; CLL, chronic lymphocytic leukemia; CXCL13, chemokine, CXC motif, ligand 13; DLBCL, diffuse large B-cell lymphoma; DNMT3A, DNA methyltransferase 3A; DUSP22, dual-specificity phosphatase 22; ENMZL, extranodal marginal zone lymphoma; FISH, fluorescence in situ hybridization; FL, follicular lymphoma; ICOS, inducible T-cell costimulator; IDH, isocitrate dehydrogenase 2; ITK-SYK, fusion of IL2-inducible T-cell kinase and protein-tyrosine kinase SYK; LPL, lymphoplasmacytic lymphoma; MCL, mantle cell lymphoma; MYC, MYC proto-oncogene, bHLH transcription factor; MYD88, MYD88 innate immune signal transduction adaptor; MZL, marginal zone lymphoma; NMZL, nodal marginal zone lymphoma; PD-1, programmed cell death protein 1; PMBL, primary mediastinal B-cell lymphoma; PTCL-NOS, peripheral T-cell lymphoma not otherwise specified; RHOA, RAS homolog gene family, member A; SLL, small lymphocytic lymphoma; SMZL, splenic marginal zone lymphoma; TET2, TET methylcytosine dioxygenase 2; T_{FH}, T-follicular helper cell; WM, Waldenström macroglobulinemia.

MULTIPLE MYELOMA 21

Aimaz Afrough, MD, and Morie Gertz, MD

RECENT UPDATES

- The International Myeloma Working Group definition of high-risk multiple myeloma, integrating cytogenetic and molecular markers, has been updated.[1]
- Several phase 3 randomized controlled trials (RCTs) are reaffirming the quadruplet induction regimens as a standard-of-care approach in newly diagnosed multiple myeloma (NDMM) patients. The GMMG-HD7 trial randomly assigned patients to bortezomib, lenalidomide, and dexamethasone (VRd) with or without isatuximab. The primary endpoint was minimal residual disease (MRD) negativity by next-generation flow cytometry to the 10^{-5} level. The addition of isatuximab improved MRD negativity (50% vs. 36%; $P < .001$).[2]
- The PERSEUS trial examined daratumumab, bortezomib, lenalidomide, and dexamethasone (DVRd) induction and consolidation with daratumumab and lenalidomide maintenance versus VRd induction and consolidation, followed by maintenance with lenalidomide alone. After a median follow-up of 48 months, the DVRd group demonstrated a longer progression-free survival as well as response depth, which showed consistent benefits across various subgroups.[3]
- The IsKia trial was the first RCT to compare carfilzomib, lenalidomide, and dexamethasone (KRd)–based triplet therapy with isatuximab KRd quadruplet therapy in patients with transplant-eligible (TE) NDMM. The trial demonstrated the superiority of isatuximab and KRd in achieving a rate of MRD negativity less than 10^{-5} by next-generation sequencing (NGS) after consolidation in the intention-to-treat population.[4] Benefit was maintained with improvement consistent across all participant subgroups, including patients in high-risk categories.[5]
- The registrational IMROZ trial, an international, open-label, phase 3 trial, randomly assigned (in a 3:2 randomization) transplant-ineligible (TIE) NDMM patients to receive either isatuximab plus VRd or VRd alone. At a median follow-up of 59.7 months, PFS at the 60-month mark favored isatuximab plus VRd at 63.2% compared with 45.2% for VRd alone.[6]
- The registrational CEPHEUS study compared eight cycles of induction with dara-VRd (daratumumab and VRd) to VRd. Induction was followed by maintenance without bortezomib in both arms. Approximately 28% of patients had stage III, and 13% had high-risk cytogenetics. The primary endpoint of MRD negativity at 10^{-5} rate by NGS was met in favor of the quadruplet regimen with an OR of 2.37.[7]
- With the same endpoint, a non-registrational BENEFIT trial compared the isatuximab-Rd with and without bortezomib. Isa-bortezomib, lenalidomide, and dexamethasone improved the MRD-negativity rates and achieved higher rates of complete response (CR) or better, although survival data remain immature.[8]
- The GMMG-CONCEPT trials investigated Isa-KRd in TE and TIE patients with high-risk NDMM. Patients received this regimen in induction, consolidation, and maintenance therapy. However, maintenance therapy was given without dexamethasone. The trial met its primary endpoint with MRD-negativity rates of 67.7% after consolidation for TE patients and 54.2% after consolidation for TIE patients. Sustained MRD negativity for 1 year or longer was achieved in 62.6% of the patients.[9]
- For TE NDMM patients receiving proteasome inhibitor/immunomodulatory drug–based triplet induction, the phase 3 DETERMINATION trial—with a median follow-up of 76 months—demonstrated that incorporating autologous stem cell transplantation (ASCT) into first-line therapy conferred a statistically significant PFS benefit of 21.4 months compared with continued induction without transplant. After a median follow-up of 6.3 years, the median overall survival (OS) has not been reached in either arm of the study, necessitating additional follow-up (the study was not powered for OS).[10]

- The KarMMa-3 study was a phase 3 trial comparing idecabtagene vicleucel with one of five standard regimens in patients with relapsed and/or refractory multiple myeloma (RRMM) who had received two to four previous lines of therapy. After a median follow-up of 18.6 months, the idecabtagene vicleucel arm had superior mPFS and CR rate and overall response rates (ORRs). The toxicity profile in the idecabtagene vicleucel cohort reported no new toxicity concerns.[11]
- The CARTITUDE-4 trial was a phase 3, randomized, open-label trial that compared ciltacabtagene autoleucel with a physician's choice of standard care (pomalidomide, bortezomib, and dexamethasone [PVd] or daratumumab, pomalidomide, and dexamethasone [DPd]). After a median follow-up of 15.9 months, the mPFS was superior in the ciltacabtagene autoleucel arm.[12]
- A recent update of CARTITUDE-1 reported that 32/97 patients are alive and progression-free over 5 years after infusion.[13,14]
- Combination regimens employing belantamab mafodotin, an anti-B-cell maturation antigen (BCMA) antibody-drug conjugate, have demonstrated promising efficacy in RRMM. DREAMM-7 was a phase 3, open-label, randomized trial that evaluated belantamab mafodotin, bortezomib, and dexamethasone (BVd) to daratumumab, bortezomib, and dexamethasone (DVd), in patients after at least one line of therapy. The primary endpoint was PFS. At a median follow-up of 39.4 months, PFS was not reached in BVd versus 33.4 months in DVd.[15,16]
- DREAMM-8 was a phase 3, randomized, open-label trial that compared belantamab mafodotin, pomalidomide, and dexamethasone (BPd) with PVd in relapsed myeloma after the exposure of lenalidomide. The primary endpoint was PFS.[17] At a median follow-up of 28 months, mPFS was 32.6 months versus 12.5 months, favoring BPd. The estimated 18-month PFS rate was 63% compared with 41%. This benefit was maintained across key subgroups. Ocular events occurred in 89% of the BPd arm, grade 3 or 4 in 43%, and 30% in PVd, grade 3 or 4 in 2%. Belantamab mafodotin dose modification helped manage the increase in ocular events.[18] This drug was approved by the FDA on October 23, 2025.[19,20]
- Linvoseltamab-gcpt was approved on July 2, 2025, for patients after at least four prior lines of therapy, including a proteasome inhibitor, an immunomodulatory agent, and an anti-CD38 monoclonal antibody. Linker-MM1 treated 117 patients with five median prior lines of therapy. The ORR was 71%, PFS was 70% at 12 months, and the median OS was 31.4 months.[21,22]
- The combination of teclistamab and talquetamab is being investigated as a novel dual–BsAb approach for relapsed or refractory multiple myeloma, aiming to enhance depth and durability of response through simultaneous targeting of BCMA and GPRC5D.[23,24]
- Anitocel (anitocaptagene autoleucel), a BCMA-directed CAR T therapy, demonstrated an ORR of 97% at a median follow-up of 12.6 months. The 12-month PFS and OS were 79% and 95%, respectively, with 93% achieved MRD negativity. Cytokine-release syndrome was seen in 15% neurotoxicity in 8%. Phase 3 trials are underway (presented at EHA 2025).[25]
- Although CAR T-cell and BsAb therapies have shown unprecedented efficacy in heavily pretreated patients who have RRMM, their use is associated with a significant risk of severe infections.[26] The combined expertise of hematologists and infectious disease specialists is required for proper management of the disease in patients who are recipients of T-cell–redirecting therapy and who have suspected infection.[27] Venous thromboembolism (VTE) at the time of diagnosis is associated with inferior survival in patients who have NDMM; therefore, risk-adapted strategies for prevention of VTE need to be used from the start to mitigate this preventable risk.[28]

OVERVIEW

Multiple myeloma (MM) is a plasma cell malignancy characterized by osteolytic bone lesions, anemia, hypercalcemia, and renal failure.[29,30] The disease is generally considered incurable, and the clinical course is characterized by remissions and relapses. The survival of patients with MM has improved with the advent and incorporation of therapies such as bortezomib, lenalidomide, carfilzomib, and pomalidomide, along with monoclonal antibodies (mAbs),[31,32] and most recently, T-cell–redirecting immunotherapies, into the overall treatment strategy. The use of autologous stem cell transplantation (ASCT) in selected patients remains an important modality in MM.

DISEASE DEFINITION

The definition of MM was last updated by the International Myeloma Working Group (IMWG) in 2014.[33] The revised definition incorporates specific biomarkers associated with a high risk of progression to symptomatic disease and signs revealed by advanced imaging

methods that help diagnose MM in patients who do not have standard features of end-organ damage. The new defining classification of MM results in patients with a higher risk of developing symptomatic disease being treated earlier. MM is currently determined by:

- Multiple myeloma: Diagnosis requires clonal bone marrow plasma cells (≥10% or plasmacytoma) plus either evidence of related end-organ damage (hypercalcemia, renal impairment, anemia, bone lesions) or specific biomarkers of malignancy (≥60% clonal plasma cells, involved: uninvolved free light chain (FLC) ratio ≥100, or >1 focal MRI lesion).
- Smoldering multiple myeloma: Diagnosis requires specific levels of serum or urine monoclonal protein and/or 10% to 59% clonal bone marrow plasma cells, without the presence of myeloma-defining events or amyloidosis.

Patients with MM must be differentiated from those with monoclonal gammopathy of undetermined significance (MGUS), smoldering MM (SMM), and other related plasma cell disorders.[33]

MGUS is an asymptomatic, premalignant phase of MM.[34] The risk of progression of MGUS to myeloma or a related disorder is fixed at approximately 1% per year. SMM is a more advanced, intermediate stage, defined by the presence of a serum monoclonal protein (M-protein) concentration greater than 3 g/dL or 10% to 59% clonal plasma cells in the marrow but without myeloma-defining events or light chain (AL) amyloidosis. SMM is a clonal expansion of plasma cells not associated with clinical manifestations and is at variable risk for progression on the basis of defined prognostic criteria.[35] In a study of 276 patients with SMM, the risk of progression to MM in the first 5 years after diagnosis[36] was 10% per year, 3% per year over the next 5 years, and 1% per year thereafter.[37] This trial was done before the advent of routine PET or MRI imaging and without the immunoglobulin FLC assay. Using modern staging techniques, one would anticipate the risk of progression to be lower. In another IMWG retrospective study evaluating 1,996 patients, incorporating cytogenetic abnormalities to the 2/20/20 model (M-protein >2 g/dL, free light-chain ratio >20, and marrow plasma cells >20%), the patients divided into four groups (low risk with 0, low intermediate risk with 1, intermediate risk with 2, and high risk with ≥3 risk factors) with 6%, 23%, 46%, and 63% risk of progression in 2 years, respectively.[36] Using genomic data from 374 patients, the cohort was divided into genomic MM and genomic MGUS. The genomic profile of the SMM group at biologic features is indistinguishable from MM, showing a high risk of progression. By contrast, 60% of MGUS patients showed genomic MGUS with no progression during follow-up. Integration of these features significantly improved the predictive value of the IMWG criteria for SMM.[38] Diagnosis of MM requires that myeloma-defining effects be attributable to the plasma cell neoplasm and not simply coexistent with MGUS or SMM, which is common and may occur in patients with renal insufficiency, anemia, hypercalcemia, or osteolytic lesions from other medical conditions. Care should be taken when considering alternative causes of myeloma-defining effects, particularly in patients with a low burden of neoplastic plasma cells.

KEY POINTS

- The diagnosis of MM requires evidence of one or more myeloma-defining effects: hypercalcemia, renal insufficiency, anemia, or bone lesions that can be attributed to the plasma cell proliferative disorder; clonal bone marrow plasma cells 60% or more; serum FLC ratio of involved to uninvolved at 100 or more, provided the involved FLC level is 100 mg/L or more; or more than one focal lesion on MRI scan.
- MGUS and SMM are asymptomatic plasma cell proliferative disorders that need to be distinguished from MM.

EPIDEMIOLOGY AND RISK FACTORS

MM accounts for 1.8% of all malignant diseases, and slightly greater than 10% of all hematologic malignancies. In 2024, it is estimated that there will be 36,110 new cases of myeloma, and an estimated 12,030 people will die of this disease.[39,40] There is a male-to-female predominance.[41] MGUS is about 1.6 times more common, and MM is twice as common in the Black population as in the White population.[42,43] The median age of patients at diagnosis is approximately 69 years. There is no known etiology. Exposure to radiation, benzene, other organic solvents, herbicides, or insecticides may play a role.[44-47] The Veterans Administration recognizes Agent Orange (dioxin) exposure in Vietnam Era veterans as a risk factor. If MM develops, it is considered a service-connected disability. There is a statistically significant risk for MM among firefighters, hairdressers, and employees exposed to engine exhaust.[48] The mortality is higher in firefighters and after low-level exposure to ionizing radiation in nuclear workers.[49,50]

There is an increased risk of MGUS in first-degree relatives.[51,52]

HEALTH DISPARITIES IN MM

Black patients are diagnosed with MM at a median age of 65, which is 5 years younger than the median age at diagnosis for White patients.[53] This difference may be partly due to population-specific variations in genomic makeup. There are also fundamental differences in the genetic and molecular signatures of the tumor itself. For example, there is a lower incidence of translocations such as t(11;14), t(4;14), and fewer monosomy 13/del13q and monosomy 17/del17p among Black patients in comparison with White patients.[54] Another study showed a significant difference in mutation frequency of TP53 and IRF4, with frequencies lower among

Black patients.[55] Notably, findings regarding t(11;14) have been inconsistent, with some smaller studies suggesting a higher incidence among Black patients, highlighting the heterogeneity of available data.[56] This higher incidence suggests that Black patients should do just as well as those of other races after anti-plasma cell therapy, but this has not been observed. The gains in survival among Black patients have not been as sizable compared with those of White patients, even with the advent of novel agents. Factors that account for this lag in survival may include socioeconomic determinants, such as access to cancer centers, structural racism, lack of private health insurance, mistrust of the medical community because of a history of previous injustices, and a shortage of Black healthcare workers who can help bridge the gap. Black patients are 50% less likely than White patients to undergo stem cell transplantation (SCT) and are less likely to receive first-line triplet induction therapy with a proteasome inhibitor and immunomodulatory agent.[57] Given the higher incidence of MM in the Black population, Black patients would especially benefit from participating in clinical trials, but currently, this group of patients accounts for only 4.5% of all trial participants.[58,59] The poor representation of Black patients in clinical trials only exacerbates outcome disparity by not considering the unique biology of this patient population when building treatment algorithms for patients with MM in the real world. Several studies have demonstrated that when Black patients are treated with appropriate and timely therapy, outcomes are at least similar and, in some studies, even superior to those of other races.[60]

Taken together, there is ample evidence to suggest that significant disparities still exist and are negatively affecting disease outcomes among Black people. The oncology community is addressing this issue of health inequality by implementing early screening initiatives, expanding the proportion of biospecimens from minority groups in established repositories, and developing study protocols that aim to increase participation by Black patients in clinical trials. These efforts will require a multistakeholder and community approach to overcome this unacceptable disparity.

PREVENTION

Prevention of MM is hampered by the low likelihood of progression in patients with the premalignant MGUS stage. Attempts to reduce the risk of transformation are being studied with ongoing trials of plant-based and ketogenic diets.[61] Investigations looking at potential modifications of the microbiology to prevent progression are also underway.[62]

The risk of MGUS progressing to MM increases by approximately 1% each year. In SMM, the highest risk of progression is in the first 5 years, with 2-, 5-, and 10-year risk of progression of 22%, 42%, and 64%, respectively.[36]

Recent screening efforts of note include the Iceland Screens, Treats, or Prevents Multiple Myeloma (iStopMM) trial, which was a population-based screening study for MGUS and a randomized controlled trial (RCT) of follow-up strategies. In this study, more than 50% of the population (n = 80,759) provided informed consent, and 93.4% (n = 75,422) of enrolled individuals provided serum samples for the study.[63] Of the 75,422 screened individuals, 4.94% were found to have MGUS by diagnostic definitions, which is more common than previously reported (most cases were low- or low-intermediate risk in terms of progression). With 3 years of follow-up, iStopMM has identified a higher-than-expected number of individuals with SMM and MM. Although multiple meaningful and important findings were already reported by the iStopMM study, they represent population-based findings from one Nordic country.[64,65] Notably, the iStopMM study improved on the previously published Mayo Clinic criteria for risk of MGUS progression to MM. The Mayo Clinic model classifies MGUS into four risk groups based on the total score of laboratory values: IgG MGUS, M-protein concentration below 15 g/L, and FLC ratio between 0.26 and 1.65.[66] The new prediction model incorporates MGUS isotype, M-protein level, FLC ratio, and total concentrations of IgG, IgA, and IgM as predictors. Last, as FLCs are primarily cleared by the kidneys, the real prevalence of light chain MGUS is unknown in individuals with chronic kidney disease. Hence, iStopMM helped answer yet another significant question regarding defining new reference intervals for the FLC ratio based on kidney function. Abnormal FLC ratios were defined based on renal function: 0.46 to 2.62 for estimated glomerular filtration rate (eGFR) 45-50, 0.48 to 3.38 for eGFR 45-59, and 0.54 to 3.30 for eGFR less than 30 mL/min/1.73 m^2.[67] This suggests that published normal ranges for kappa FLC do not have the correct upper limit and isolated increases of kappa above published "ULN" should be approached cautiously.

The PROMISE study (NCT03689595) looked at the prevalence of monoclonal gammopathies and clinical outcomes in individuals aged ≥30 years within the high-risk US population, including those who self-identify as Black or with a family history of hematologic malignancy screened by mass spectrometry through a multicenter cohort study. This study detected a high prevalence of monoclonal gammopathies. By using the conventional serum protein electrophoresis/immunofixation (SPEP/IFX) method, the analysis revealed significantly higher rates of MGUS in high-risk individuals older than age 50 years (6%) than has been previously reported (3%); by using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry, the detection rate was even higher (13% in individuals at high risk of disease), including rates of 17% among Black people and 13% among non-Black people with a family history of a close relative with a hematologic malignancy in comparison with 10% of non-Black people without such family history (the control group).[68]

Risk-stratification schemes have been developed to predict the risk of progression to active MM among patients who have SMM and to identify high-risk subsets of patients who might be suitable for earlier intervention. These schemes have included factors such as serum FLC ratio, immune paresis (defined by suppression of normal immunoglobulin levels or elimination of normal plasma cell populations), genetic or cytogenetic features, and other laboratory parameters. It was important to re-evaluate prognostic models after the 2014 revisions to the diagnostic criteria for active MM (discussed above), which reclassified the highest-risk patients with SMM as having active MM. The most useful scheme to be evaluated since then is the 2/20/20 rule developed by the

Mayo Clinic. M-protein greater than 2 g/dL, bone marrow plasmacytosis of greater than 20%, and FLC ratio greater than 20 can stratify patients into three groups with respect to risk of progression: (1) low risk (no factors), (2) intermediate risk (one factor), and (3) high risk (two or more factors). The median times to progression to active MM for low-, intermediate-, and high-risk groups were 110, 68, and 29 months, respectively.[35] The IMWG also added to the 2/20/20 rule by incorporating the presence of chromosomal abnormalities as an additional factor and allowed separation into four risk categories: low, low-intermediate, intermediate, and high. The risk of progression in 2 years for the high-risk group is 63%.[36] This risk of progression, however, has not been confirmed by other groups and may be significantly lower.[69]

Preventive strategies for MM have focused on preventing or delaying progression in high-risk patients with newly diagnosed SMM. A randomized trial conducted by the Spanish Myeloma Group in patients who had high-risk SMM found improved progression-free survival (PFS) and overall survival (OS) with early use of lenalidomide plus dexamethasone versus observation; however, participants in the observation arm may have been undertreated upon progression to active MM (only 11% of such participants received lenalidomide-based induction, which reflects its limited availability at the time); this possible undertreatment leaves uncertainty about whether the observed OS difference was due to early intervention per se.[70] In the long-term follow-up, the treatment arm continued to show a benefit on time to progression compared with the observation arm. Survival in patients who had received subsequent therapy at the time of progression did not differ between groups. The Eastern Cooperative Oncology Group (ECOG) E3A06 study found improved PFS when lenalidomide was used to prevent progression to symptomatic MM compared with observation among patients who had intermediate- to high-risk SMM. Subgroup analysis indicated that the benefit was restricted to the high-risk subset, according to the 2/20/20 rule; no OS difference has been reported.[71]

The AQUILA study randomized patients diagnosed with high-risk SMM to receive either 39 cycles of daratumumab or to undergo observation. With a median follow-up period of 65.2 months, results indicated that the risk of disease progression or death was reduced by 51% with daratumumab when compared with active monitoring (hazard ratio [HR], 0.49; 95% CI, 0.36-0.67; $P < .001$). PFS at 5 years was found to be 63.1% for the daratumumab group, in contrast to 40.8% for those undergoing active monitoring. Daratumumab demonstrated a low-grade safety profile among patients with SMM. A fixed duration of treatment provides patients with intervals free from daratumumab exposure, which may help prevent or delay the emergence of anti-CD38-refractory disease, thereby allowing for the subsequent use of anti-CD38-based quadruplet therapies following the progression to active MM.[72] Unfortunately, the observation group had limited access to daratumumab upon progression, with only 14% receiving this agent. This potential bias results in the comparison of patients receiving the drug to those patients not receiving the drug and may account for the survival difference.

On November 8, 2025, the FDA approved daratumumab for high-risk SMM. Patients with high-risk SMM should be monitored closely and considered for enrollment in clinical trials. With the recent FDA approval, daratumumab monotherapy represents an option to prevent or delay progression, following counseling on potential risks and uncertainties. Treatment with lenalidomide remains controversial because of uncertain OS implications, cost and toxicity concerns, and uncertain effects on outcomes with standard MM therapy in the event of disease progression. Ongoing trials are evaluating the effectiveness and safety of various regimens for treating high-risk SMM, ranging from doublet therapies to quadruplet therapies that incorporate ASCT.

KEY POINTS

- MM accounts for 1% of all cancers and approximately 10% of all hematologic cancers.
- Myeloma is twice as common in the Black population as in the White population.
- Early intervention with lenalidomide or daratumumab[72] prolongs time to progression to active MM and is now considered a possible treatment option for patients with high-risk SMM (participation in clinical trials is preferred).

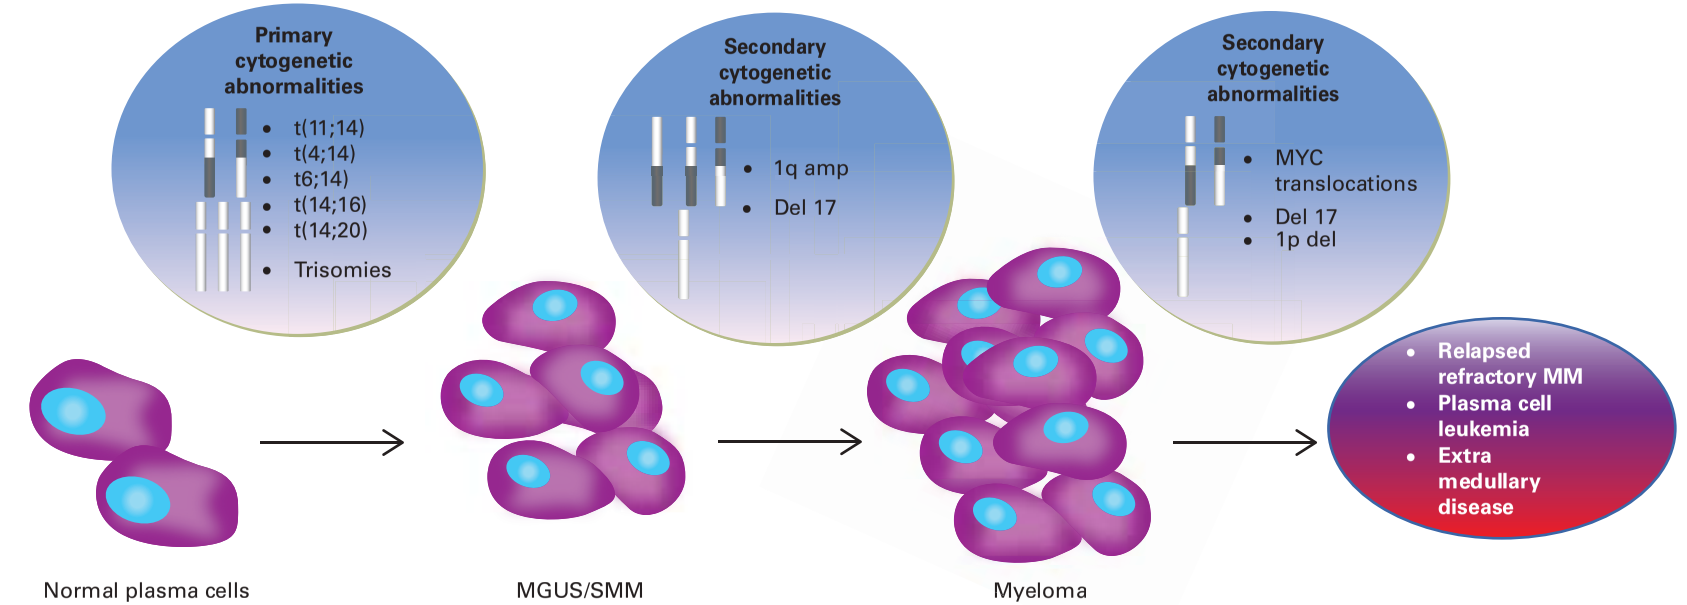
PATHOGENESIS

MM is almost always preceded by a premalignant phase referred to as MGUS. However, because MGUS is asymptomatic and can be detected only through specific laboratory testing, most patients diagnosed with MM do not have a history of MGUS. The pathogenesis of MM involves two initial steps.

The first step is the evolution of a normal plasma cell to an MGUS clone and is likely triggered by an abnormal response to antigenic stimulation. This results in the development of primary cytogenetic abnormalities in the affected plasma cells. In approximately 40% to 50% of patients who have MGUS, the primary cytogenetic abnormality is a reciprocal translocation involving the immunoglobulin heavy chain (IgH) locus on chromosome 14q32 (IgH-translocated MGUS) and one of five recurrent partner chromosome loci: 11q13 (cyclin D1 gene [*CCND1*]), 4p16.3 (*FGFR3* and *MMSET*), 6p21 (cyclin D3 gene [*CCND3*]), 16q23 (*c-Maf*), and 20q11 (*MAFB*). For more information on primary and secondary genetic events that can be identified by fluorescence in situ hybridization (FISH) data, see the IMWG report here.

In most of the remaining patients with MGUS, the primary abnormality is the development of trisomies of one or more of the odd-numbered chromosomes, often resulting in hyperdiploidy (referred to as hyperdiploid MGUS or IgH-nontranslocated MGUS). In a small proportion of cases, neither trisomies nor IgH translocations are found, and in some patients, both types of abnormalities are found in the same clone (Figs. 21-1 and 21-2).

Figure 21-1 Cytogenetic Abnormalities in Multiple Myeloma



Primary cytogenetic abnormalities occur early when the normal plasma cell transitions to a clonal, premalignant stage. Most secondary cytogenetic abnormalities occur later in the disease course with malignant transformation or during progression of the malignancy. The effect of primary and secondary cytogenetic abnormalities on prognosis depends on the disease.

The second step is progression to MM, which occurs once an MGUS clone is established. Progression is often accompanied by additional genetic and transcriptional alterations, including abnormalities involving the *MYC* family of oncogenes; *RAS* mutations, *p16* methylation, and *p53* deletion or mutation; clonal diversification; perturbations of antimyeloma immunity; and permissive changes in the bone marrow microenvironment.

KEY POINTS

- MM is preceded by a premalignant phase that is clinically referred to as MGUS.
- The two principal pathogenetic steps are (1) transition from normal plasma cell to MGUS and (2) transition from MGUS to MM.
- The onset of MGUS is associated with IgH translocations (chromosome 14) in approximately 50% of cases and hyperdiploidy in the remaining 50%.

CLINICAL PRESENTATION AND DIAGNOSIS

Osteolytic bone lesions and/or compression fractures are hallmarks of the disease and can be detected on routine radiography, MRI scans, or CT scans in approximately 70% of patients. Anemia occurs in 70% of patients at diagnosis and is the primary cause of weakness and fatigue. Hypercalcemia is found in 15% of patients. Other symptoms may result from acute renal failure, radiculopathy, or recurrent infections.

When MM is suspected, patients should be tested for the presence of M-proteins by serum protein electrophoresis, serum immunofixation, urine protein electrophoresis, urine immunofixation, and serum FLC assay. The serum FLC assay and urine protein electrophoresis studies help identify the subset of patients with MM who lack M-protein heavy chain expression (ie, light chain MM). Only 82% of patients with MM have an M-protein that is detectable on serum protein electrophoresis, whereas serum immunofixation will identify an M-protein in 93% of patients. Combining serum studies with either urine studies or the serum FLC assay will reveal an M-protein in 97% to 98% of patients who have MM. Patients with serum M-protein concentration of less than 1 g/dL and urine M-protein of less than 200 mg/d are considered to have oligosecretory myeloma. In addition, approximately 2% to 3% of patients with MM have non-secretory disease with no evidence of an M-protein on serum immunofixation or urine immunofixation; a subset of these patients who also have a normal serum FLC ratio are considered to have true non-secretory myeloma.

Other tests considered essential for determining the presence of MM are complete blood cell count and serum creatinine, calcium, β_2 microglobulin, albumin, and lactate dehydrogenase levels. A unilateral bone marrow aspiration and biopsy are needed for the diagnosis. The monotypic nature of marrow plasma cells must be established by an abnormal κ:λ ratio found on immunohistochemistry or flow cytometry. Myeloma cells typically stain positive for CD38, CD56, and CD138. Bone marrow plasma

cells should also be studied with FISH and/or karyotyping to enable risk stratification (see the "Staging and Risk Stratification" section). FISH studies do not require dividing cells; hence, they are considerably more informative in MM than conventional karyotyping, which requires the presence of metaphases; however, conventional karyotyping can identify complex or unexpected abnormalities not detected by commonly used FISH probes.

Examination of all bones using whole-body, low-dose CT scans, whole-body MRI scans, or PET scans is required to detect lytic bone lesions[73] and can help differentiate SMM and solitary plasmacytoma from MM. PET/CT scans are especially useful in assessing extramedullary disease (EMD), whereas MRI scans can be used to visualize soft tissue and bones exceptionally well. Skeletal survey using plain radiography alone is considered inadequate, given that more sensitive testing is now available.

DIFFERENTIAL DIAGNOSIS

MM should be differentiated from some of the other plasmacytic or lymphoplasmacytic disorders, including but not limited to:

- MGUS
- SMM
- Solitary plasmacytoma (osseous or soft tissue)
- Waldenström macroglobulinemia
- Light chain or heavy chain deposition disease
- Systemic light chain (AL) amyloidosis
- Polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes (POEMS) syndrome

MONITORING

Once MM is diagnosed, patients require periodic measurements of complete blood cell counts, serum creatinine, serum calcium, and M-protein levels by serum protein electrophoresis, serum FLC assay, and urine protein electrophoresis to assess treatment response and to monitor for relapse. In patients with oligosecretory myeloma (serum M-protein <1 g/dL and urine M-protein <200 mg/24 h) and in some patients with non-secretory myeloma, the serum FLC assay can be used to monitor response to therapy, provided that the FLC ratio is abnormal and the baseline level of the involved FLC is 100 mg/L or more.[74] In patients with oligosecretory myeloma who have lower levels of FLC and in patients with true non-secretory myeloma, monitoring is more difficult and requires periodic imaging studies and bone marrow examinations. Serum and urine tests for monitoring are done once per month during active therapy and once every 3 to 4 months thereafter. The widespread availability of the serum-FLC assay has reduced the need for frequent measurements of urinary light chain excretion. Bone marrow studies may be repeated to confirm a stringent complete response (CR), which is associated with a favorable prognosis, or when clinically indicated to assess relapse. In patients who experience CR, estimation of minimal residual disease (MRD) using next-generation flow cytometry or NGS with a sensitivity of 10^{-5} to 10^{-6} provides important prognostic information and may be a surrogate for PFS and OS. However, there is no data yet on the use of MRD results or CR status to guide therapy. Studies that assess MRD conversion from negative to positive have been found to be leading indicators of relapse by conventional M protein criteria, with 50% achieving traditional biochemical relapse criteria within 6 months.[75,76] Ongoing studies are using MRD for risk-adapted therapeutic decision-making. MRD can be checked annually through bone marrow studies, because MRD-negative sustainability is prognostic and is being explored as an endpoint to discontinue maintenance therapy. Response to therapy is assessed using the revised IMWG uniform response criteria.[77] For more information about the criteria for response and MRD assessment in MM, see the report here.

STAGING AND RISK STRATIFICATION

The two traditional methods of staging MM were the Durie-Salmon stage and the International Staging System (ISS). However, these staging systems have many limitations, and they do not account for the considerable variation in outcome that is dictated by the underlying cytogenetics of the disease. Previously, patients with del (17p13); translocations t(14;16), t(14;20), and t(4;14); and gain (three copies)/amplification (> 3 copies) (1q) are considered to have high-risk MM. Patients who do not have any of these abnormalities, typically those with trisomies, monosomy 13, or translocations t(11;14) and t(6;14), are considered to have standard risk.[78] The presence of concomitant trisomies may ameliorate the adverse prognosis associated with intermediate- and high-risk MM. This has been updated according to the latest modified version of the 2025 International Myeloma Society (IMS)/IMWG consensus criteria,[79] which require the presence of at least one of the following abnormalities: (1) del(17p), with a cutoff of >20% clonal fraction, and/or TP53 mutation; (2) an IgH translocation including t(4;14), t(14;16), or t(14;20) along with 1q+ and/or del(1p32); and (3) monoallelic del(1p32) along with 1q+ or biallelic del(1p32).

The revised ISS, introduced in 2015, is the current recommended staging system for MM, and it incorporates important markers of disease biology, including standard ISS, FISH for high-risk features (defined as presence of del(17p) and/or translocation t(4;14) and/or translocation t(14;16), and lactate dehydrogenase, a marker of increased proliferation), to provide a more accurate estimation of prognosis than previous staging systems did[80] (Table 21-1).

Table 21-1 **Revised International Staging System for Multiple Myeloma**

Publication Year	Stage	Criteria	Frequency (% of Patients)	Median Survival or 5-Year Survival Rate (%)
ISS stage	1	Serum albumin >3.5 g/dL, serum β2-microglobulin <3.5 mg/L	29	62 months
	2	Neither ISS stage I nor III	37.5	44 months
	3	Serum β2-microglobulin >5.5 mg/L	33.6	28 months
R-ISS stage	1	ISS-I	28	82%
		No high-risk cytogenetics		
		Normal LDH		
	2	Neither ISS stage I nor III	62	62%
	3	High-risk cytogenetics [t(4;14), t(14;16), or del17p13] or elevated LDH level	10	40%
R2-ISS stage*	1	0 points	19.2	Not reached
	2	0.5-1 points	30.8	109.2 months
	3	1.5-2.5 points	41.2	68.5 months
	4	3-5 points	8.8	37.9 months

Abbreviations: ISS, International Staging System; LDH, lactate dehydrogenase; R-ISS, revised ISS.
*ISS-III, 1.5 points; ISS-II, del17p13, high lactate dehydrogenase, or t(4;14), 1 point; and 1q1 0.5 points.
Reprinted from Palumbo A, Avet-Loiseau H, Oliva S, et al. Revised International Staging System for multiple myeloma: a report from International Myeloma Working Group. *J Clin Oncol*. 2015;33(26):2863-2869. doi:10.1200/JCO.2015.61.2267

In a most recent study, the second revision of ISS (R2-ISS) investigated the prognostic value of adding 1q1 as a risk factor by collecting data from 10,843 newly diagnosed patients enrolled in 16 clinical trials. Using a training set (n = 7,072) and a validation set (n = 3,771), a value was assigned to each of the risk factors that had the highest impact on PFS and OS (ISS-III, 1.5; ISS II, 1; del17p13, 1; high lactate dehydrogenase, 1; t(4;14), 1; and 1q1, 0.5 points). Four independent risk groups were identified according to the total additive score: low risk (R-ISS I; 0 points), low-intermediate (R-ISS II; 0.5-1 point), intermediate-high (R-ISS-III, 1.5-2.5 points), and high (R-ISS IV, 3-5 points). Median OS was not reached versus 109.2, 68.5, and 37.9 months, respectively. Median PFS (mPFS) was 68, 45.5, 30.2, and 19.9 months, respectively.[81]

The Mayo Additive Staging System is another staging system that has been developed and validated; it incorporates additional FISH abnormalities not included in the R-ISS (eg, 1q gain/amplification) and reflects the additive effects of co-occurring high-risk disease features.[82]

KEY POINTS

- The most common presenting symptoms of MM are fatigue and bone pain; other presenting features are hypercalcemia, infection, and renal failure.
- When MM is suspected, patients should be tested for the presence of M-proteins by serum and urine protein electrophoresis, serum and urine immunofixation, and serum FLC assay.
- Full-body skeletal imaging studies and a bone marrow biopsy are required if MM is suspected.
- Patients are staged using the variations of ISS (R-ISS or R2-ISS).
- Patients are considered to have high-risk MM if at least one of the following abnormalities is present: (1) del(17p), with a cutoff of >20% clonal fraction, and/or TP53 mutation; (2) an IgH translocation including t(4;14), t(14;16), or t(14;20) along with 1q+ and/or del(1p32); (3) monoallelic del(1p32) along with 1q+ or biallelic del(1p32); or (4) β2 microglobulin ≥5.5 mg/L with normal creatinine (<1.2 mg/dL). Patients with trisomies or translocations t(11;14) and t(6;14) are considered to have standard-risk MM.

THERAPEUTIC MANAGEMENT

INITIAL THERAPY

Choice of initial induction therapy for MM should take into account the baseline comorbidity profile of a patient, specifically including the presence of peripheral neuropathy or cardiovascular comorbidities that may direct the choice of first-line induction regimen, as well as a patient's eligibility and preference for ASCT (Fig. 21-3). In general, eligibility for SCT is determined by performance status and comorbidities, although patients who are more fit and those of advanced age can still be considered. Age alone is not used in determining transplant eligibility. Patients who are not candidates for ASCT or those who choose not to pursue ASCT as first-line therapy are typically treated with an induction regimen for 6 to 12 months, followed by consideration of maintenance therapy, or they may simply continue triplet-based induction until disease progression, toxicity, or intolerance. Patients who are considered potential candidates for ASCT are first treated with three to four cycles of a quadruplet regimen (more recently considered a new standard) followed by stem cell collection. After stem cell harvest, many patients proceed to ASCT (the early ASCT approach), although some may choose to continue the initial treatment regimen if they have achieved a deep response and delay ASCT until relapse (the delayed ASCT approach). After initial treatment of patients who choose transplantation and those who choose not to receive transplantation, the standard treatment is risk-associated consolidation followed by indefinite maintenance until disease progression, unacceptable toxicity, or tolerance. Recent comparative meta-analysis of triplet versus quadruplet induction regimens in newly diagnosed, treatment-naive MM have all demonstrated four-drug induction regimens that include an anti-CD38 antibody improve anti-MM efficacy, although with higher rates of grade 3 or more infections and thrombocytopenia.[83]

TREATMENT OF PATIENTS WHO ARE NOT CANDIDATES FOR ASCT

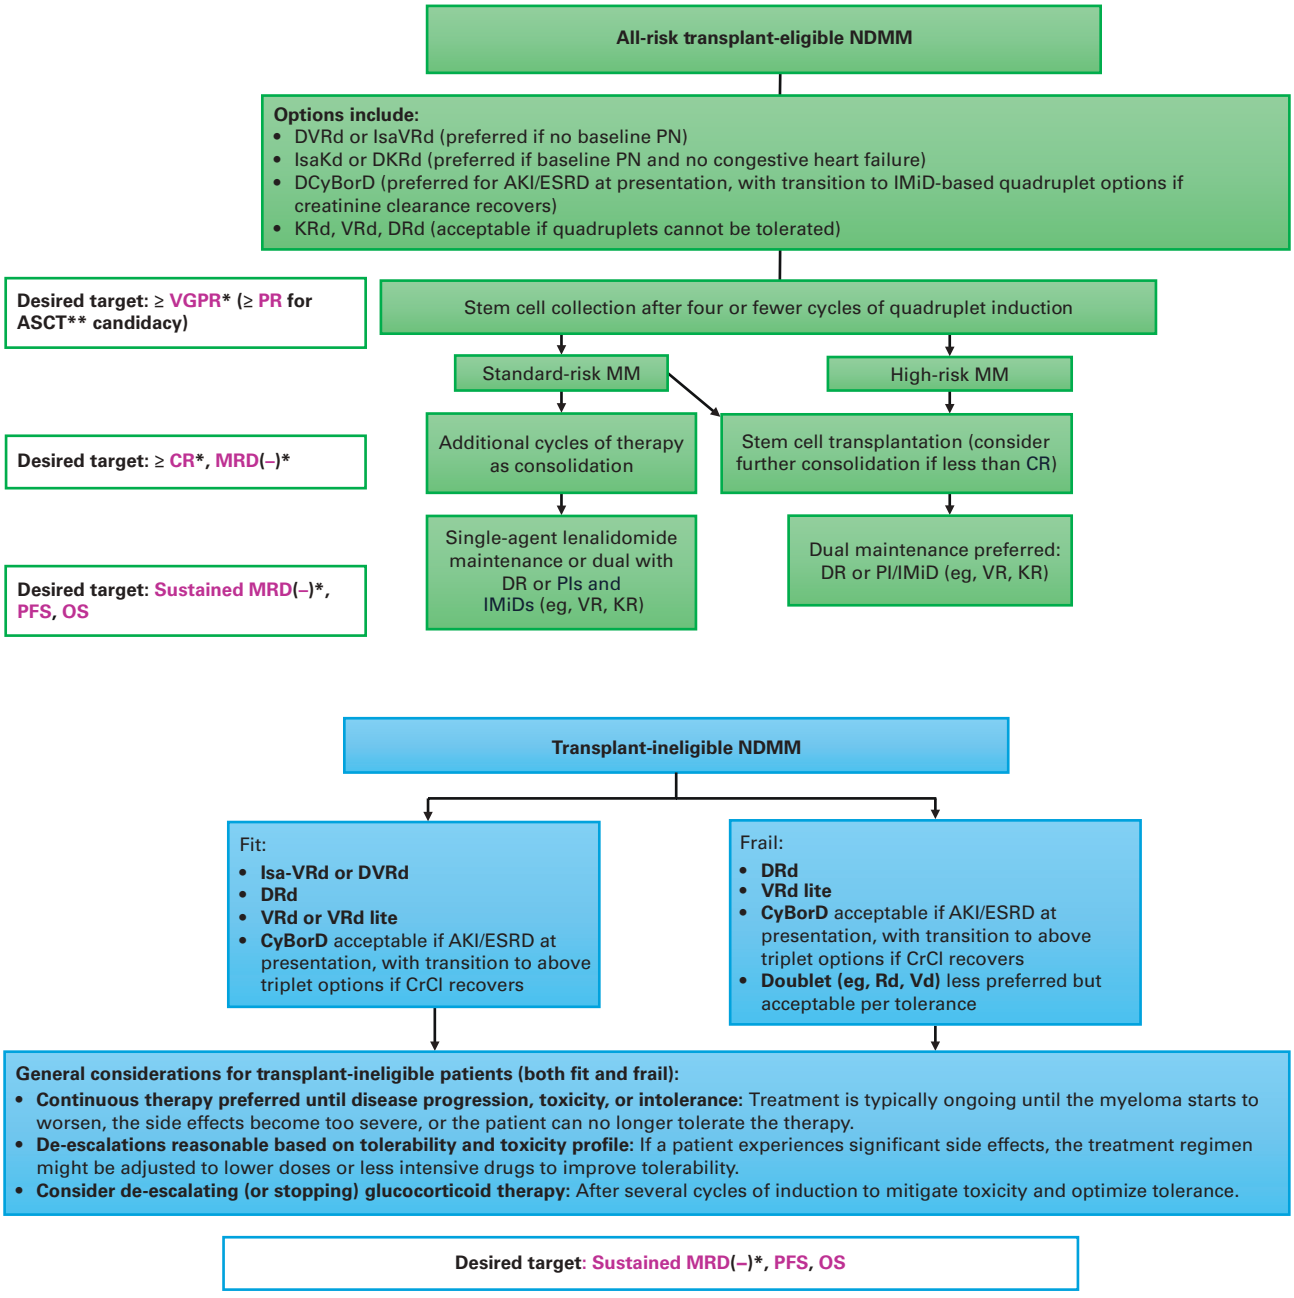
For patients with transplant-ineligible (TIE) newly diagnosed multiple myeloma (NDMM), melphalan-based regimens and doublet therapy are no longer preferred as first-line therapy. Even quadruplet therapies that do not incorporate immunomodulatory drug (IMiD) into the induction backbone, such as that commonly used in Europe based on the ALCYONE[84] data, are not common in the North American practice patterns. Until recently, the standard of care has been first-line therapy with either VRd or DRd triplets. The VRd data are based on superior PFS and OS compared with data for lenalidomide and dexamethasone (Rd) in the SWOG S0777 trial. The mPFS was 43 months versus 30 months (P = .0018); median OS was 75 months versus 64 months (P = .025). Although this study did not include SCT, the median age of the patients was only 63 years, with most intending to receive a transplant. A subgroup analysis suggested that VRd was not as beneficial in patients older than 65 years, and the VRd regimen as studied in this trial used doses and schedules that would be toxic in many older, frail patients. Conversely, the MAIA trial data with DRd were more representative of the TIE patients who had a median age of 73 years.[31] DRd was compared with Rd alone. The regimen was well tolerated, with improvement in deep responses and MRD-negativity rates. The PFS was superior for DRd compared with Rd. At 5 years, DRd reduced the risk of death by 32%, and the risk of progression or death was reduced by 47%. DRd is approved by the FDA for this indication.

Although quadruplet therapies based on triple backbone combinations with IMiDs and PIs added to anti-CD 38 monoclonal antibodies had previously been reserved for patients with transplant-eligible (TE) NDMM, several, recent, phase 3 RCTs and a recent FDA approval now support the use of similar quadruplet combinations in the frontline treatment of TIE, or transplant deferred, NDMM, ushering a new era of quadruplet therapies for all newly diagnosed patients regardless of transplant eligibility. Notable phase 3 RCTs in this space include the IMROZ, BENEFIT, and CEPHEUS trials.[6-8]

IMROZ was an international, open-label, phase 3 trial, which randomly assigned, in a 3:2 ratio, patients 18 to 80 years of age with TE NDMM to receive either isatuximab plus VRd or VRd alone. The median ages in the frail group were 75 and 76, respectively. The median age in the non-frail group was 71 years in both arms. The primary efficacy endpoint was PFS. At a median follow-up of 59.7 months, the estimated PFS at 60 months was 63.2% in the isatuximab-VRd group in comparison with 45.2% in the VRd group (HR for disease progression or death, 0.60; 98.5% confidence interval [CI], 0.41-0.88; P < .001). The percentage of patients with a CR or better was significantly higher in the isatuximab-VRd group than in the VRd group (74.7% vs. 64.1%, P = .01), as was the percentage of patients with MRD-negative status and a CR (55.5% vs. 40.9%, P = .003).[6] On September 20, 2024, the FDA approved isa-bortezomib, lenalidomide, and dexamethasone (Isa-VRd) for adults with NDMM who are not eligible for ASCT, making it the first anti-CD38 therapy available in this patient population plus VRd.[85]

BENEFIT was an Intergroupe Francophone of Myeloma phase 3 study (not a registrational study) that randomized 270 patients with TIE NDMM age 65 to 79 years, to IsaRd versus Isa-VRd. The median age in the two groups was 73.6 and 73.2 years, respectively. The primary endpoint was a MRD-negativity rate at 10^{-5} by NGS at 18 months from randomization. The 18-month MRD-negativity rates at 10^{-5} were reported in 35 patients (26%; 95% CI, 19-34) in IsaRd versus 71 (53%; 95% CI, 44-61) in Isa-VRd (odds ratio [OR] for MRD negativity 3.16; 95% CI, 1.89-5.28, P < .0001). The MRD benefit was consistent across subgroups at 10^{-5} and 10^{-6} and was observed at month 12. The proportion of patients with CR or better at 18 months was higher with Isa-VRd (58% vs. 33%; P < .0001), as was the proportion of MRD negativity and CR or better (37% vs. 17%; P = .0003). At a median follow-up of 23.5 months, no difference was observed for survival times (immature data).[8]

Figure 21-3 Treatment Approaches for Transplant-Eligible and Transplant-Ineligible Newly Diagnosed Multiple Myeloma



The primary goal of treatment for TE and TIE NDMM is to achieve a rapid, deep, and durable response. This aims to provide long-term disease control and ultimately improve patient prognosis.

Abbreviations: AKI, acute kidney injury; ASCT, autologous stem cell transplantation; CR, complete response; CrCl, creatinine clearance; CyBorD, cyclophosphamide, bortezomib, and dexamethasone; DCyBorD, daratumumab, daratumumab, cyclophosphamide, bortezomib, and dexamethasone; DKRd, daratumumab, carfilzomib, lenalidomide, and dexamethasone; DR, daratumumab and lenalidomide; DRd, daratumumab, lenalidomide, and dexamethasone; DVCd, daratumumab, bortezomib, cyclophosphamide, and dexamethasone; DVRd, daratumumab, bortezomib, lenalidomide, and dexamethasone; ESRD, end-stage renal disease; IMiD, immunomodulator (ie, lenalidomide or pomalidomide) drug; Isa-VRd, isatuximab, bortezomib, lenalidomide, and dexamethasone; Isa-KD, isatuximab, carfilzomib; and dexamethasone; KR, carfilzomib and lenalidomide; KRd, carfilzomib, lenalidomide, and dexamethasone; MM, multiple myeloma; MRD, minimal residual disease; NDMM, newly diagnosed multiple myeloma; OS, overall survival; PFS, progression-free survival; PI, proteasome inhibitor (ie, bortezomib, ixazomib, carfilzomib); PN, peripheral neuropathy; PR, partial response; Rd, lenalidomide and dexamethasone; Vd, bortezomib and dexamethasone; VGPR, very good partial responses; VR; bortezomib and lenalidomide; VRd, bortezomib, lenalidomide, and dexamethasone.

*Target indicates the desired level of response, and not a failure of treatment if not achieved.

**For ASCT step: minimum PR and ideally VGPR. Standard risk includes all cytogenetics that are not considered high risk; high risk includes any patient with one high-risk cytogenetic mutation such as del(17p), t(14;16), t(14;20), t(4;14), del(1p), amp(1q) or gain(1q); ultra-high risk includes any patient with more than one high-risk cytogenetic mutation.

Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

The CEPHEUS trial[7] is a phase 3 study that compared the rates of MRD negativity at 10^{-5}, as determined by next-generation sequencing (NGS), following induction with the combination of VRd with or without daratumumab in myeloma patients who are either TE or have deferred transplantation. The trial also assessed response depth and OS as secondary endpoints. The median age of both arms was 70 years. Following eight cycles of induction, patients continued with maintenance therapy excluding bortezomib. A total of 395 patients were randomly assigned to the study. At baseline, approximately 28% of participants presented with high-risk cytogenetics, and 28% had ISS stage III myeloma. After a median follow-up of 58.7 months, 60.9% of patients in the daratumumab-VRd (DVRd) arm achieved MRD negativity, compared with 39.4% in the VRd arm, resulting in an OR of 2.37 (95% CI, 1.58-3.55); $P < .0001$. CR rates were significantly higher in the DVRd cohort at 81.2%, compared with 61.6% in the VRd group, yielding an OR of 2.73 (95% CI, 1.71-4.34); $P < .0001$. In addition, sustained MRD-negativity rates for 12 months or more were higher in the DVRd group at 48.7%, versus 26.3% for the VRd arm, with an OR of 2.63 (95% CI, 1.73-4.00; $P < .0001$). The 54-month PFS in the DVRd group was 68.1% compared with 49.5% in the VRd group, with an HR of 0.57; 95% CI, 0.41 to 0.79; $P = .0005$. No new safety concerns were reported with the addition of daratumumab to the VRd regimen.[7]

Other daratumumab regimens have been studied in combination with standard regimens in TIE candidates. The combination of daratumumab, bortezomib, melphalan, and prednisone was compared with bortezomib, melphalan, and prednisone alone in the ALCYONE trial. After the initial induction therapy, patients in the daratumumab arm continued to receive daratumumab as a single agent. In this study, the daratumumab arm was associated with a significant improvement in PFS in the entire population, and the OS was also superior in that arm.[86] In the subset of high-risk patients, there was no difference in PFS.[87] For extremely frail patients (ie, those who have multiple comorbidities and poor performance status), treatment with a doublet therapy or monotherapy daratumumab may be a consideration to add an agent based on tolerability. Frailty assessments and consultations with geriatric oncologists can be invaluable in the assessment of such a patient.

TREATMENT OF CANDIDATES FOR ASCT

Although three-drug combinations such as VRd and carfilzomib, lenalidomide, and dexamethasone (KRd; cyclophosphamide, bortezomib, and dexamethasone [CyBorD] in select patients who present with acute renal injury with light chain cast nephropathy) represented the previous standard of care, the availability of long-term follow-up data from the GRIFFIN trial and reports from phase 3 randomized trials, including GMMG-HD7, PERSEUS, and IsKia, have ushered in the new era of quadruplet-based induction for TE patients who have newly diagnosed MM.

Quadruplet therapy with DVRd in the randomized phase 2 GRIFFIN study was given in three weekly cycles (bortezomib on days 1, 4, 8, 11, and lenalidomide 14/21 days) and showed superior CR or greater (82% vs. 60%) and MRD-negativity rates (64.4% vs. 30.1%) in comparison with VRd alone in patients who received transplants. The median age for the DRVd arm was 59 years, and in the VRd arm, 61 years. mPFS (although it was not the primary endpoint of the trial) was ultimately improved at 50 months of median follow-up (4-year PFS was 87.2% for DVRd vs. 70.0% for VRd; HR, 0.45; $P = .032$).[88] The PERSEUS trial was a phase 3 counterpart of the GRIFFIN trial which delivered therapy in 28-day cycles (bortezomib on days 1, 4, 8, 11, and lenalidomide 21/28 days). Patients in the DVRd group also received subcutaneous daratumumab. The PERSEUS trial did not have a second randomization to maintenance therapy, allowing for a more precise interpretation of the benefit of adding daratumumab across the entire treatment regimen, compared with VRd induction therapy and lenalidomide maintenance therapy. Therefore, patients in the DVRd arm received at least 24 months of daratumumab before discontinuation if they achieved at least a CR and sustained MRD. After a median follow-up of 48 months, the DVRd group demonstrated a longer PFS than the VRd group (84.3% vs. 67.7%, respectively; HR, 0.42; $P < .001$). Prespecified subgroup analyses suggested a consistent benefit for PFS in the DVRd group compared with the VRd group across clinically relevant subgroups, including patients with ISS stage III disease and those with high cytogenetic risk [defined in this study as del (17p) and/or t(4;14), and/or t (14;16)].[3]

Several isatuximab-based phase 3 trials were also conducted that examined the quadruplet-versus-triplet question. The GMMG-HD7 was one such trial that randomly assigned patients to VRd with or without isatuximab. Median age in the isatuximab arm was 59 and 60 years in the control group. The primary endpoint was MRD negativity by next-generation flow cytometry to the 10^{-5} level. The addition of isatuximab improved MRD negativity (50% vs. 36%; $P < .001$).[2] More recently, the IsKia trial became the first RCT to compare a KRd-based triplet therapy with anti-CD38 antibody–containing KRd quadruplet therapy (isatuximab). The median age of both arms was 72 years. It demonstrated the superiority of isatuximab and KRd (Isa-KRd) in achieving a rate of MRD negativity less than 10^{-5} by NGS after consolidation in intention-to-treat patients (77% vs. 67%; OR, 1.67; $P = .049$). Benefit was maintained, and improvement was consistent across all participant subgroups, including high-risk categories [del(17p) and/or t(4;14) and/or t(14;16)].[5] Updated data[89] reported MRD negativity at 10^{-6} after full-dose consolidation was 67% versus 48% with Isa-KRd versus KRd (OR 2.29; $P < .001$), and 1-year sustained MRD at 10^{-6} after light consolidation was 52% versus 38% (OR 1.82; $P = .012$).

Anti-CD38 antibody quadruplets have become a preferred regimen for TE patients who have NDMM; it remains uncertain whether first-line daratumumab confers an OS benefit compared with its use in later lines of therapy because follow-up data are still premature.[90] As previously mentioned, CyBorD is an adequate alternative if it is used in the setting of acute renal failure with

light chain cast nephropathy (because lenalidomide is renally cleared). The metabolism of cyclophosphamide does not depend on adequate renal function.

Using lenalidomide for more than six cycles can impair the collection of peripheral blood stem cells in some patients when granulocyte colony-stimulating factor alone is used for stem cell mobilization. Stem cell mobilization in these patients is usually successful with a chemotherapy-containing mobilization regimen such as cyclophosphamide and granulocyte colony-stimulating factor, or by using plerixafor, a CXCR4 inhibitor. The influence of daratumumab on stem cell collection is a topic of ongoing debate, with several reports indicating a reduced yield in stem cell collection. Despite the impact of daratumumab on stem cell collection, patients are ultimately able to collect enough stem cells to proceed to transplantation.[91]

Anti-SLAMF7 antibody–containing induction regimens have also been attempted. Preliminary activity of elotuzumab in the frontline setting was suggested in a phase 2 trial[92] of Elo-KRd using an MRD-adapted design, which demonstrated MRD negativity rates (10^{-5} by NGS) of up to 70% and an estimated 3-year PFS of 72% overall (92% among patients achieving MRD negativity). However, in the GMMG-HD6 trial, elotuzumab-VRd was compared with VRd in TE patients who had NDMM, but the treatment arm that used quadruple therapy failed to show PFS or OS benefit.[2,93] Similarly, elotuzumab also failed to provide a PFS benefit when it was used in the same combination in the SWOG-1211 trial[94] in patients who had high-risk newly diagnosed MM. Overall, it seems that elotuzumab in combination with an immunomodulator performs better in the relapsed/refractory setting, in which an OS benefit was reported.[95,96]

HIGH-RISK PATIENTS

The 2025 IMS/IMWG consensus redefined high-risk MM criteria. The prior 2016 consensus had identified t(4;14), del(17/17p), t(14;16), t(14;20), nonhyperdiploidy, and gain(1q) as poor prognostic factors.[97] High-risk MM is now defined by the presence of at least one of the following: (1) del(17p) with a cutoff of 20% clonal fraction or TP53 mutation; (2) an IgH translocation, including t(4;14), t(4;16) OR t(14;20) along with 1q+ and/or del(1p32); (3) monoallelic del (1p32) along with 1q+ or bialellic del(1p32), or (4) beta 2 microglolobulin ≥5.5 mg/L with creatinine ≤1.2 mg/dL.[1] For patients with high-risk myeloma, a combination of an immunomodulator and a proteasome inhibitor should be incorporated into first-line therapy for TE patients, and quadruplet therapy is preferred for delivery, if possible. Considering the high rate of deep responses observed on the GRIFFIN trial, DVRd is an acceptable option for high-risk patients. Some experts recommend a backbone of carfilzomib and an IMiD as initial therapy for high-risk patients based on high response rates observed with carfilzomib in several triplet and quadruplet studies. Of note, KRd has not been prospectively compared with VRd in high-risk patients, but no difference was seen in the ENDURANCE trial, which only included patients with standard-risk cytogenetics. However, a retrospective study in high-risk patients [defined as 1q+, t(4;14), t(14;16), t(14;20), and del(17p)] demonstrated a mPFS of 70.9 months with KRd, compared with 41 months with VRd, highlighting the potential benefit of KRd in this population. The open-label, phase 2 FORTE trial investigated carfilzomib-based induction and consolidation approaches (KRd × 12 cycles vs KRd plus ASCT vs carfilzomib, cyclophosphamide, and dexamethasone [KCd] plus ASCT). KRd plus ASCT showed superior response rates and MRD-negativity rates and significantly prolonged PFS, including among high-risk (defined as presence of one of the del(17p), t(4;14), t(14;16), del(1p), gain(1q), or amp(1q)), and ultra-high-risk (more than one high-risk mutation) groups. In the first published trial of high-risk MM, the addition of elotuzumab to VRd induction and maintenance did not improve patient outcomes. PFS in both study groups exceeded the original assumption, suggesting continuous two-drug maintenance therapy with a PI and IMiDs would be beneficial.[94] In the OPTIMUM/MUKnine OPTIMUM) trial, genetic screening was used to identify patients with high-risk MM. Patients were treated with daratumumab, bortezomib, lenalidomide, cyclophosphamide, and dexamethasone followed by ASCT. There was no control arm. Consolidation consisted of dara-VRd and a second consolidation with VRd and dara-R maintenance therapy. PFS estimates at 36, 48, and 60 months were 75%, 70%, and 61%, respectively. OS estimates at 60 months were 71%. This suggests that a clean triplet induction extended consolidation with the dara-VR group would be beneficial for this ultra-high risk.[98-100]

In the multicenter, single-arm, phase 2 MASTER trial, patients received four cycles of daratumumab, carfilzomib, lenalidomide, and dexamethasone (DKRd) as induction, ASCT, and zero, four, or eight cycles of DKRd consolidation according to MRD status. There was a planned enrichment for patients with high-risk cytogenetics (defined by the presence of del(17p), t(4;14), and/or t(14;16)). The primary endpoint was achievement of MRD negativity. Patients continued to receive therapy until they achieved two consecutive MRD-negative tests at a level less than 10^{-5}, and then they entered a treatment-free observation period with regular MRD testing. Although the odds of achieving two consecutive MRD-negative tests were similar across risk groups, patients with standard-risk or one high-risk mutation had excellent PFS and OS in the absence of maintenance therapy. Alternatively, the risk of progression was higher among patients with ultra-high-risk MM (two or more high-risk mutations); 2-year PFS from treatment cessation was 54% in this latter group. The results of the MASTER trial suggest that for many patients, an MRD-adapted treatment algorithm can provide durable disease control even off therapy, but for the ultra-high-risk patient, continued maintenance is still important regardless of MRD status.[101]

In another phase 2 trial (IFM 2018-04) using DKRd in high-risk disease (defined by the presence of del(17p), t(4;14), and/or t(14;16)), 50 previously untreated patients were treated with DKRd induction, followed by first ASCT, and DKRd consolidation,

followed by second ASCT followed by maintenance with daratumumab and lenalidomide. The overall response rate (ORR) was 96% (92% with a very good partial response [PR] or better) with an MRD-negativity rate by NGS at 64% at 10^{-5} and 62% at 10^{-6} before maintenance.[102] The 30-month PFS and OS rates were 80% and 91%, respectively.[99] This trial is ongoing, and long-term follow-up will be vital in determining whether this aggressive approach can be regarded as safe and efficacious over time.

By using a similar structure, the GMMG-CONCEPT trial investigated the efficacy of combining isatuximab, carfilzomib, lenalidomide, and dexamethasone in patients with high-risk myeloma, defined as ISS stage II to III along with del17p13, t(4;14), t(14;16), or more than three 1q21 copies (amplification 1q21). This category included primary plasma cell leukemia (PCL; oligosecretory or non-secretory disease), provided it was measurable by bone lesions. The trial enrolled patients irrespective of their transplant eligibility. The primary endpoint was achieving MRD negativity at a 10^{-5} level through next-generation flow cytometry. The treatment plan involved six cycles of the quadruplet induction (with stem cell collection after the third cycle), followed by an ASCT if the patient was TE or by two extra cycles otherwise. Consolidation included four cycles of the quadruplet chemotherapy, and maintenance comprised 26 cycles of the quadruplet therapy without dexamethasone. The GMMG-CONCEPT trial strategically integrated two beneficial approaches: quadruplet treatments and ongoing maintenance and treatment. Del17p13 emerged as the most prevalent high-risk cytogenetic feature. With a median age of 58 years, the trial met its primary endpoint with MRD negativity. After consolidation, MRD-negativity rates were 67.7% for TE patients and 54.2% for TIE patients. Significantly, MRD negativity sustained for at least 1 year was observed in 62.6% and 46.2% of TE and TIE patients, respectively.[100]

Other ongoing trial, that focused primarily on ultra-high-risk disease (defined as the presence of ≥2 genetic risk markers t(4;14)/t(14;16)/t(14;20), del(1p), gain(1q), and del(17p), and/or SKY92 gene expression risk signature) or PCL (defined by >20% circulating plasmablasts), include the UK-based OPTIMUM trial, a study using D-CVRd consolidation for 18 cycles after ASCT, followed by maintenance with daratumumab and lenalidomide. Patients with PCL were included in this study. The ORR after induction was 95.3%. The 30-month PFS of 77% compared favorably with that in the MASTER trial.[103]

The bone marrow transplant clinical trials network has not accruing trial for using T-cell–redirecting therapy in high-risk myeloma patients, which includes B-cell maturation antigen (BCMA) chimeric antigen receptor (CAR) T and G protein–coupled receptor, class C, group 5, member D (GPRC5D) consolidation. The results of this trial have not been reported (NCT 05032820).

In patients with clinically aggressive disease (ie, PCL, extensive EMD), combination chemotherapy such as VTd plus cisplatin, doxorubicin, cyclophosphamide, and etoposide (PACE) can be used as initial therapy to achieve rapid disease control, although it is acceptable to treat these patients with potent triplet and quadruplet modern regimens, which may yield similar response rates.

KEY POINTS

- For TE patients, preferred regimens for initial MM treatment include PI, IMiD, and anti-CD38 antibody–containing quadruplet regimens such as DVRd, DKRd, Isa-VRd, Isa-KRd, and daratumumab, bortezomib, cyclophosphamide, and dexamethasone (DCybBorD; in case of inability to dose IMiDs optimally).
- CyBorD and VTd (less so) are alternatives, and may be preferred in the setting of acute renal failure with light chain cast nephropathy.
- For the TIE patients, recent FDA approval of Isa-VRd quadruplet with a category 1 recommendation, and availability of RCT phase 3 data with DVRd regimens adds these quadruplet combinations to the list of available, powerful induction combinations in this space. The triple combinations with either VRd or DRd remain category 1 options for those who are deemed unfit for frontline quadruplet therapy.

AUTOLOGOUS STEM CELL TRANSPLANTATION

Although ASCT is not curative for MM, it prolongs mPFS compared with conventional chemotherapy. The treatment-related mortality rate is low (1%-2%), and 40% to 50% of ASCTs can be performed entirely on an outpatient basis. Melphalan (at a dose of 200 mg/m^2) is used as the standard conditioning regimen, and trials are underway that are trying to improve its efficacy. ASCT can be performed immediately after initial therapy, or it can be delayed until the first relapse. In either case, stem cells must be collected early in the treatment course. Since the initial randomized studies of ASCT were performed, more recent studies have evaluated ASCT in the context of modern first-line and maintenance therapy. In the pivotal DETERMINATION trial, patients who had newly diagnosed MM received three cycles of VRd and underwent stem cell mobilization followed either by five additional VRd cycles (the VRd-alone group) or by ASCT followed by two additional VRd cycles (the ASCT group). Both groups received lenalidomide maintenance therapy until disease progression. After a median follow-up of 76 months, PFS was superior in the ASCT arm (median, 67.5 vs. 46.2 months; $P < .001$); OS was similar between the two arms, although median OS has not been reached, and the trial was not powered to detect differences in OS. Notably, only 22% of the VRd-alone group underwent ASCT at first relapse.[10] Other studies have highlighted the benefits of ASCT as first-line therapy. In the FORTE trial, KRd followed by ASCT provided higher PFS and MRD-negativity rates over KRd without transplantation.[102] In the EMN02 trial, which examined CyBorD induction followed by ASCT versus melphalan, bortezomib, and prednisone, ASCT reduced the risk of

disease progression by 27% and offered an OS advantage over no transplantation. In general, based on superior PFS, early ASCT is preferred. However, patient and physician preferences play an important role in deciding the timing of ASCT, especially in patients with standard risk. Although some earlier randomized trials showed a benefit with two ASCTs performed back-to-back (tandem ASCT), one randomized trial conducted in the United States (STAMINA trial) found no benefit with tandem ASCT in the context of modern therapy, with lenalidomide maintenance.[104] As such, there is no role for tandem ASCT in modern treatment paradigms for TE NDMM.[105]

The Midas trial randomized TE patients into post-induction (Isa-KRd) MRD+ or MRD− groups (MRD at 10^{-5}). MRD− groups post-induction randomized to consolidation versus ASCT, and no improvement of MRD negative at the more stringent 10^{-6} threshold was seen with ASCT. MRD+ patients randomized to single or tandem transplants and no increase in MRD− was seen.[106]

ALLOGENEIC STEM CELL TRANSPLANTATION

Allogeneic stem cell transplantation (allo-SCT) offers the potential benefit of a graft-versus-myeloma effect. However, conventional myeloablative allo-SCT has a limited role in MM because of high treatment-related mortality rates. One study found a significant OS advantage with allo-SCT followed by nonmyeloablative allo-SCT compared with allo-SCT alone. However, other trials have not shown such a benefit. Allo-SCT is safer, but nonmyeloablative allo-SCT is associated with a greater risk of relapse and has not shown a consistent benefit compared with allo-SCT alone. Currently, allo-SCT is generally not recommended for the treatment of MM outside of clinical trials.[107]

MAINTENANCE THERAPY

Myeloma maintenance after ASCT in patients who have newly diagnosed MM is considered standard treatment. Three randomized studies have shown superior PFS with lenalidomide maintenance after ASCT. All maintenance studies had PFS as the primary endpoint, and none were powered for assessment of their impact on OS. A meta-analysis of more than 1,200 patients from RCTs that assessed lenalidomide maintenance versus placebo or observation after ASCT demonstrated significant OS benefit and reaffirmed the PFS benefit with lenalidomide maintenance after ASCT.[108]

An increased risk of second cancers was seen in two randomized trials with lenalidomide maintenance (approximately 7% in the lenalidomide group vs. 3% in the placebo group; $P < .01$); this situation needs to be discussed with the patient and monitored during follow-up. Lenalidomide maintenance is recommended for patients with standard-risk MM after ASCT. In high-risk patients, the benefit of lenalidomide maintenance was shown in the Myeloma XI trial. Patients with high-risk disease benefited from lenalidomide maintenance compared with no maintenance, but the magnitude of that benefit was less.[109] Bortezomib maintenance (administered twice per month) after ASCT has also shown benefit and can be added to lenalidomide for patients with high- or intermediate-risk cytogenetics. Ixazomib, an oral proteasome inhibitor, has been shown to improve PFS compared with placebo as maintenance therapy for patients who have MM after induction therapy that included ASCT (TOURMALINE MM3) or excluded ASCT (TOURMALINE MM4). The PFS was improved from 21.3 months in the placebo group to 26.5 months in the ixazomib-after-transplantation group; however, the OS did not differ between the ixazomib versus placebo group. In the group of patients who did not receive a transplantation, there was a trend toward an inferior survival with ixazomib maintenance; however, the interim OS results may be skewed by early events in patients who did not benefit from maintenance, therefore, the final intention-to-treat outcomes remain uncertain.[110] The updated result showed ixazomib prolonged PFS in patients who were MRD+ before maintenance and at a 14-month landmark analysis.[111]

A combination of ixazomib and lenalidomide has demonstrated a PFS benefit in high-risk patients over lenalidomide alone in TE patients,[112] but in a post-transplant setting, ixazomib did not provide additional benefit to lenalidomide maintenance.[113] Ixazomib as a single-agent maintenance therapy is not FDA approved, and its specific role as maintenance remains unclear.

With the incorporation of daratumumab into first-line therapy, the safety and efficacy of an anti-CD38 mAb–lenalidomide maintenance strategy were evaluated. In the GRIFFIN trial, daratumumab and lenalidomide maintenance led to a doubling of the MRD-negativity rate after 2 years when compared with lenalidomide alone.[88]

The incorporation of anti-CD38 in conjunction with lenalidomide maintenance therapy yielded positive outcomes in the AURIGA trial. This trial is a phase 3 study that assesses the efficacy of daratumumab in combination with lenalidomide (D-R) compared with lenalidomide monotherapy (R) as maintenance treatment of NDMM patients who have attained a very good PR, exhibit positive MRD at a threshold of 10^{-5}, and are anti-CD38 naive following transplantation. The study successfully achieved its primary endpoint concerning MRD-negative (10^{-5}) conversion rates at the 12-month mark from the initiation of maintenance treatment. The addition of daratumumab significantly enhanced MRD-negativity rates (50.5% vs. 18.8%; OR, 4.51; 95% CI, 2.37-8.57; $P < .0001$). Furthermore, the rate of CRs or better rate improved (75.8% vs. 61.4%; OR, 2.00; 95% CI, 1.08-3.69; $P = .0255$) in comparison with maintenance with lenalidomide alone. The 30-month PFS rates were recorded at 82.7% for the D-R cohort and 66.4% for the R cohort.[114] The upcoming results from the SWOG S1803 trial (NCT04071457) are eagerly awaited to evaluate the advantages of implementing daratumumab with lenalidomide maintenance following prior exposure to daratumumab and to embrace an MRD-adapted strategy.

CASSIOPEIA is a two-part, open-label, randomized, phase 3 trial. In part 1 randomization, the trial demonstrated superiority in depth of response after adding daratumumab to VTd for induction and consolidation in patients who had newly diagnosed myeloma. In part 2, patients were randomly assigned to daratumumab once every 8 weeks or to observation-only for up to 2 years. At a median follow-up of 35.4 months from the second randomization, the mPFS was not reached with daratumumab compared with 46.7 months with observation only.[115] Furthermore, the PFS advantage with daratumumab maintenance was more pronounced in patients who did not receive daratumumab before ASCT. Interestingly, PFS was similar among all three arms that contained daratumumab, suggesting that exposure to daratumumab in either the induction or maintenance setting alone was adequate to confer benefit. More recently, an updated analysis showed that daratumumab-based maintenance improved MRD negativity both in patients who received daratumumab-containing induction and those who did not.[116] Daratumumab-VTd followed by daratumumab maintenance consistently produced the highest sustained MRD-negativity rates both at 10^{-5} and 10^{-6} at 77.3% and 60.7%, respectively.

The Atlas phase 3 trial was a randomized study of patients who had newly diagnosed myeloma after ASCT. Participants were assigned to either receive lenalidomide as standard care or to undergo a 36-cycle treatment with KRd, followed by lenalidomide maintenance. Carfilzomib was given at a dose of 20 mg/m^2 in cycle 1 on days 1 and 2 and then at 36 mg/m^2 on days 1, 2, 8, 9, 15, and 16 in cycles 1 to 4 and then at 36 mg/m^2 on days 1, 2, 15, and 16 from cycle 5 up to 36 cycles; lenalidomide was given at a dose of 25 mg on days 1 to 21; and dexamethasone was given at a dose of 20 mg on days 1, 8, 15, and 22 in 28-day cycles. Patients with standard-risk cytogenetics who achieved MRD negativity after six cycles were transitioned to standard lenalidomide maintenance. In the interim analysis, after a median follow-up of 33.8 months, the KRd group exhibited a mPFS of 59.1 months compared with 41.4 months in the lenalidomide group (P = .012).[117]

A comparable regimen was used in the previously mentioned FORTE trial, in which carfilzomib plus lenalidomide maintenance was compared with lenalidomide alone in patients who had newly diagnosed myeloma. In a preplanned analysis conducted after a median follow-up of 37 months, the 3-year PFS from the maintenance randomization was 80% in patients without high-risk cytogenetics, 68% in patients with one high-risk cytogenetic feature, and 53% in patients with two or more high-risk cytogenetic features.[118] It is important to note that the trial is still ongoing.

KEY POINTS

- Patients considered potential candidates for ASCT are typically treated with three to four cycles of quadruplet-based therapy (DVRd, DKRd, Isa-RVd, Isa-KRd, and DCyBorD), followed by a stem cell harvest. After stem cell harvest, patients with standard-risk disease can either proceed to early ASCT or continue the initial treatment regimen and delay ASCT until relapse.
- For patients with high-risk disease, ASCT should be pursued in the frontline setting and not deferred.
- After ASCT, patients can receive risk-adapted consolidation followed by maintenance therapy with lenalidomide; the addition of a proteasome inhibitor or anti-CD38 mAb is normally considered for high-risk patients.
- Even though it was incorporated in the post-induction approaches for TE NDMM, the role of the addition of anti-CD38 mAb to lenalidomide for maintenance after ASCT appears to be beneficial but requires confirmation from currently enrolling studies in daratumumab-exposed patients.

TREATMENT OF RELAPSED DISEASE

Almost all patients with MM eventually experience relapse. In general, patients can be retreated with regimens that have been effective in the past if the duration of the initial remission was more than 6 months. Alternatively, regimens that contain active drugs that the patient has not previously received can also be utilized.

In recent randomized trials, triplet combinations improved response rates and prolonged PFS compared with doublet backbone regimens. However, the newer triplet regimens have not been compared head-to-head in randomized trials, so the choice of a specific regimen at the time of relapse is based on many factors, such as response to previous therapy, aggressiveness of the relapse, patient characteristics, ease of use, and access to treatment.

Based on the effect size seen in randomized trials, reasonable options for the treatment of first relapse are anti-CD38 mAb with either pomalidomide and dexamethasone-based regimens[119] or with carfilzomib and dexamethasone-based regimens for patients whose disease is refractory to lenalidomide.[120] Carfilzomib once per week was compared with twice-per-week dosing in patients with relapsed disease. The mPFS was improved with the once-per-week dosing at 11.2 months compared with 7.6 months for the twice-per-week dosing.[121] Toxicity was similar between the two arms. Regimens combining carfilzomib with isatuximab have been approved by the FDA for use in the relapsed/refractory multiple myeloma (RRMM) setting. In an analogous fashion, the IKEMA trial tested isatuximab with carfilzomib and dexamethasone (Isa-Kd) versus Kd in previously treated patients who had MM and demonstrated excellent PFS benefit in early RRMM: mPFS was 35.7 months versus 19.2 months, respectively. PFS benefit was observed with Isa-Kd across subgroups, including patients with high-risk disease and poor prognosis.[122]

Combining mAbs (elotuzumab, isatuximab, and daratumumab) with immunomodulators has demonstrated impressive results. In the ICARIA trial, the combination of isatuximab with pomalidomide and dexamethasone compared with pomalidomide and dexamethasone alone in patients who had relapsed/refractory MM significantly improved PFS, with a manageable safety profile and a strong trend in OS benefit (24.6 months vs. 17.7 months).[123,124] Similarly, daratumumab combined with pomalidomide and dexamethasone significantly prolonged PFS compared with pomalidomide and dexamethasone alone in the APOLLO study.[119]

Daratumumab and isatuximab are similar CD38-directed mAbs. Although they have not been tested head-to-head, they seem to have similar efficacy and toxicity. Their differences are primarily in the route of administration, the length of infusions, and the degree of complement activation. It also seems that one agent does not overcome resistance to the other based on a study that used isatuximab after daratumumab resistance.[125] It is generally not recommended to sequence these agents immediately after each other. Resistance to CD38-targeted therapies is being investigated in depth.

CAR T-cell therapy is a novel treatment approach that is approved for patients who have MM and who have relapsed after two or more lines of therapy (idecabtagene vicleucel) or for those who have lenalidomide-refractory myeloma (ciltacabtagene autoleucel). This cellular therapy can be associated with substantial toxicity, and the manufacturing process can be time-consuming and laborious. CAR T-cells are made up of genetically engineered T cells that have been leukapheresed from the patient (ie, autologous T cells) and expanded ex vivo. The T cells are transfected with a gene that encodes for a receptor that recognizes an epitope on the myeloma cells and directs the engineered T cells to attack. The majority of existing myeloma CAR T-cell products target BCMA, a protein that is widely expressed on myeloma cells (Table 21-2). Patients receive lymphodepletion chemotherapy, usually with cyclophosphamide and fludarabine, before the infusion of CAR T-cells. The most common nonhematologic toxicity associated with CAR T-cells is cytokine-release syndrome (CRS), an acute systemic inflammatory syndrome that can be categorized by fever, hypoxia, hypotension, and multiorgan dysfunction. CRS typically arises within 1 to 2 weeks after CAR-T infusion and resolves within a few days to 2 to 3 weeks, depending on T-cell activation kinetics.[126] Although CRS is potentially life-threatening, it usually responds to tocilizumab, an interleukin-6 receptor antagonist, steroids, and aggressive supportive care (eg, intravenous fluids or vasopressors). Neurotoxicity represents another common adverse event. Neurotoxicity involving the central nervous system in a non-focal manner is called immune effector–associated neurotoxicity syndrome (ICANS), which can range from mild headaches to more severe presentations, such as encephalopathy, language deficits, hallucinations, tremors, seizures, and even cerebral edema with coma. ICANS typically develops within 1 to 3 weeks of infusion, often overlapping with CRS but sometimes occurring independently. Other neurotoxicities with more variable and wide-ranging symptoms, such as Parkinsonism, cranial nerve palsy, sensory loss, ataxia, peripheral motor or sensory neuropathy, altered mental status, and nystagmus, are often termed atypical neurotoxicity or "non-ICANS neurotoxicity."[127] The rate of Parkinsonism is overall low.[128]

Recipients have a higher incidence of second cancers; however, the real rate needs a longer follow-up. Patients can develop immune cell–associated hematotoxicity, hypogammaglobulinemia, infection, and immune effector cell–associated hemophagocytic lymphohistiocytosis-like syndrome. The rare case series of immune effector cell–associated entrocolitis[129] that can lead to intractable diarrhea. Non-relapsed mortality associated with this therapy ranges from 6% to 10%.[126,130]

Table 21-2 **T-Cell–Redirecting Therapies for Myeloma**

Modality	Target	Mechanism	Comments
Belantamab	BCMA	ADCC	DREAMM-7 Median PFS (BVd): 36.6 months
Teclistimab	BCMA	Bispecific CD3	MajesTEC-1 Median PFS: 11.3 months
Elranatamab	BCMA	Bispecific CD3	MagnetisMM-3 PFS at 15 months: 89%
Linvostelamab	BCMA	Bispecific CD3	LINKER-MM1 PFS at 12 months: 70%
Talquetamab	GPRC5D	Bispecific CD3	MonumenTAL-1 Median VGPR: 57%
Ide-cel	BCMA	CAR-T	KarMMa-3 Median PFS: 11.3 months
Cilta-Cel	BCMA	CAR-T	CARTITUDE-1 PFS at 60 months: 31% sCr: 82.5%

Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; BCMA, B-cell maturation antigen; BVd, belantamab mafodotin, bortezomib, dexamethasone; CAR-T, chimeric antigen receptor T cell; GPRC5D, G protein–coupled receptor class C group 5 member D; PFS, progression-free survival; sCr, serum creatinine; VGPR, very good partial responses.

The two most widely studied CAR T-cell products are idecabtagene vicleucel and ciltacabtagene autoleucel, both of which have received initial FDA approvals for use in patients with four or more previous lines of therapy, with subsequent approvals expanding their use to earlier lines. Common efficacy aspects of these two BCMA-targeting autologous CAR T products are outlined in Table 21-3, whereas their relevant toxicity and safety profiles are specified in Table 21-4. The KarMMa trial evaluated idecabtagene vicleucel in relapsed/refractory MM and reported that the ORRs and CR rates were 73% and 33%, respectively. CRS occurred in 84% of patients, but only 5% was high grade.[131] Neurotoxicity developed in 18% of patients, but only 3% were grade 3 or 4. Hematologic toxicity was also common after T-cell infusion. The mPFS was estimated to be 8.8 months.[131] Ciltacabtagene autoleucel, a second anti-BCMA CAR T-cell therapy, differs from idecabtagene vicleucel in that it comprises two BCMA-binding single-chain variable fragment domains. In the CARTITUDE-1 study, the ORR was 97% with a stringent CR rate of 65%, which is unprecedented in such a relapsed/refractory population (median of six previous lines of therapy) with responses deepening over time. The PFS at 12 months was 77%. At 60 months, PFS was 31%.[14,132]

CAR T-cells, idecabtagene vicleucel, and ciltacabtagene autoleucel were tested in an early relapse setting. KarMMa-3 was a phase 3 trial in which patients who had previously received two to four regimens were randomly assigned in a 2:1 ratio to receive either idecabtagene vicleucel or one of five standard regimens per physician discretion (daratumumab, pomalidomide, and dexamethasone [DPd], DVd, IRd, Kd, Elo-Pd). The disease was refractory to the last treatment before enrollment. At a median follow-up of 18.6 months, the mPFS was 13.3 months in the idecabtagene vicleucel group compared with 4.4 months in the standard regimen group ($P < .001$). All-grade infection rates were similar between groups. However, infections that were grade 3 or above were higher in the CAR T-cell arm (24% vs. 18%).[11] Similarly, the CARTITUDE-4 trial was a phase 3, randomized, open-label trial in which patients who had MM refractory to lenalidomide received ciltacabtagene autoleucel or standard-of-care therapy per the physician's choice (DPd, pomalidomide, bortezomib, and dexamethasone [PVd]). PFS at 12 months was better in the group that received ciltacabtagene autoleucel compared with those who received standard-of-care therapy (75.9% vs. 48.6%).[12] In addition, the CARTITUDE-4 trial demonstrated a substantial enhancement in OS following a median follow-up period of 34 months. The OS rate at 30 months was recorded at 76.4%, in comparison with 63.8%, yielding a HR of 0.55; 95% CI, 0.39-0.79; $P = .0009$. In addition, the 30-month PFS rate of 68.4% indicates that the utilization of cilta-cel in earlier treatment lines exhibited numerically superior overall and PFS rates.[13] It is noteworthy that ciltacabtagene autoleucel increased low-grade movement and neurocognitive symptoms in one patient, cranial nerve palsy in 9%, and CAR T-cell–related peripheral neuropathy in 2.8% of patients.

Research is ongoing to understand the occurrence of second primary malignancies after CAR T-cell therapy, especially in patients who have MM and who have received several previous treatments. Studies indicate that survivors have an increased risk of developing acute myeloid leukemia/myelodysplastic syndrome (AML/MDS). For instance, the CARTITUDE-1 trial reported six cases of MDS and three cases of AML out of 97 patients enrolled after a median follow-up of approximately 28 months.[133] Similarly, idecabtagene vicleucel was associated with MDS in two patients out of 62 enrolled in the CRB-401 trial after 18 months of follow-up. It is worth noting that both patients had previously received alkylating agents and had cytogenetic abnormalities (5q and 7q deletions) known to be associated with MDS after alkylating-agent chemotherapy.[143]

Given the success of CAR T-cell therapy in the relapsed setting, ongoing clinical trials (CARTITUDE-2, NCT04133636 and KarMMa-2, NCT03601078) are evaluating the role of CAR T cells earlier in the treatment paradigm when T-cell fitness may be superior. CARTITUDE-6 is a head-to-head comparison of quadruplet induction therapy followed by cilta-cel compared to quadruplet induction therapy followed by ASCT. The primary goal is to determine whether CAR-T therapy could replace ASCT.[144] Other myeloma targets are also being investigated, including GPRC5D and FcRH5. Natural killer CAR T cells are currently being developed as a strategy to mitigate CRS (ClinicalTrials.gov identifiers: NCT05008536 and NCT03940833).

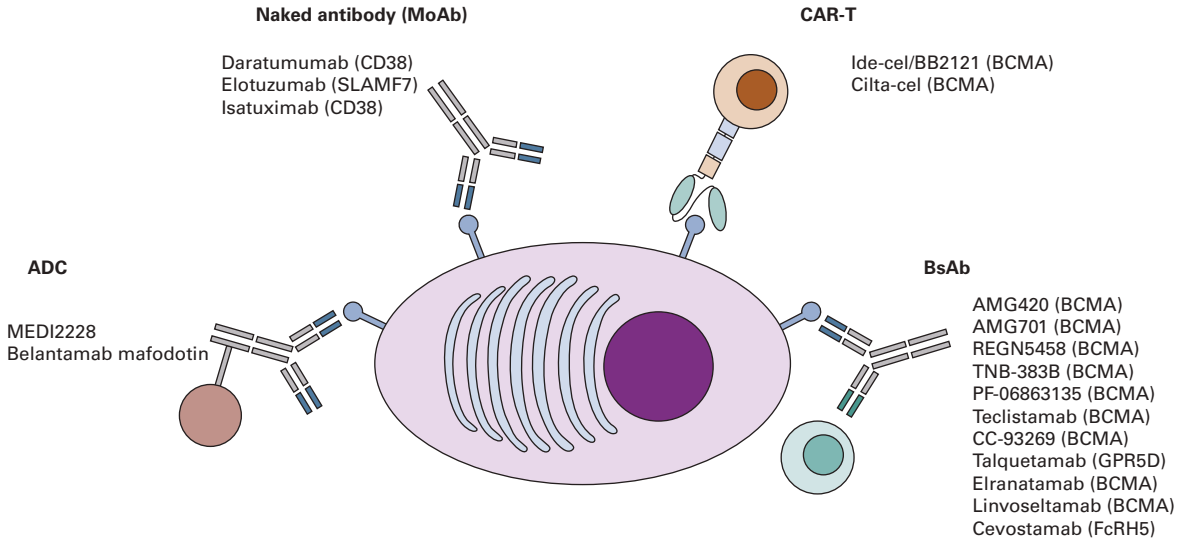
New targets for CAR T therapy are underway. Arlocabtagene autoleucel (BMS-986393) is an autologous CAR T-cell construct targeting GPRC5D that has been granted an FDA Regenerative Medicine Advanced Therapy designation for RRMM. A recent efficacy and safety update of a phase 1 study in patients with heavily pretreated RRMM after 15.1 months of median follow-up demonstrated high ORR (87%), CR (53%), mPFS of 18.3 months, and 1-year OS of 90% (ORR and/or PFS were not impacted by refractory status or exposure to previous BCMA-targeted therapy). Safety signals suggest skin, nail, and oral on-target/off-tumor adverse effects (AEs) as well as weight loss, though they appear to be of low frequency (19%-30%), low severity (all G1-2), and mostly self-resolving (70%-88%). There were no reports of cranial nerve palsy or Parkinsonism and a low incidence of high-grade infections (19% G3/4).[24]

Bispecific antibody (BsAb) represents another novel form of immunotherapy in relapsed/refractory MM. BsAb lacks an Fc region and contains only one variable domain. They can simultaneously bind to two different epitopes: CD3 present on T cells and a specific antigen on myeloma cells.

The function of the BsAb is to bring the patient's own T cells into proximity with the myeloma cells to allow for T-cell activation and destruction of the target cells. The advantage of BsAb therapy over CAR T-cell therapy is the distinct advantage of an off-the-shelf option because leukapheresis and gene modification are not required. Unlike CAR T-cell therapy, BsAb is currently given continuously. Of note, CRS and ICANS are also associated with BsAb therapy. Currently, there are four FDA-approved BsAb: teclistamab, elranatamab, and linvostelamab, which target BCMA, and talquetamab, which targets GPRC5D. Common efficacy aspects of these BsAb are outlined in Table 21-3, and their relevant toxicity and safety profiles are specified in Table 21-4. Teclistamab, an anti-BCMA-targeting BsAb, was granted accelerated FDA approval in October 2022 for patients who have RRMM and who have received at least four previous lines of therapy, including a proteasome inhibitor, an immunomodulatory agent, and an anti-CD38 mAb. This approval was based on the pivotal MajesTEC-1 phase 1/2 study. Patients received once-per-week subcutaneous injection of teclistamab after receiving two step-up doses to mitigate CRS and neurotoxicity. After a median follow-up of 14.1 months, the ORR was 63.0%, with a CR rate of more than 39.4%. The mPFS was 11.3 months (95% CI, 8.8-17.1). Most patients (72.1%) developed CRS, and most cases were low grade. In terms of toxicity, there was a high rate of grade 3 or 4 neutropenia (64%). Not surprisingly, infections were frequent (all-grade, 76.4%; grade 3 or 4, 44.8%), along with severe hypogammaglobulinemia and occasional opportunistic infections such as *Pneumocystis jirovecii* pneumonia and progressive multifocal leukoencephalopathy. Proactive use of intravenous immune globulin and prophylactic antibiotics against *P. jirovecii* pneumonia should be considered. Neurotoxic events occurred in 14.5% of the patients.[10]

Likewise, elranatamab secured accelerated approval in August 2023 as the second anti-BCMA BsAb for patients who have undergone a minimum of four previous lines of therapy, including a proteasome inhibitor, an immunomodulatory agent, and an anti-CD38 mAb. This approval was based on the results from the MagnetisMM-3 study, a multicenter, open-label, single-arm, phase 2 investigation into the efficacy and safety of elranatamab in relapsed/refractory MM. 32% of the enrolled patients reported the presence of EMD. Patients received two step-up priming doses of 12 and 32 mg subcutaneously on days 1 and 4 of cycle 1. Elranatamab was subsequently administered at 76 mg once per week in 28-day cycles. After six cycles, individuals with a PR or better that lasted at least 2 months transitioned to a dosing interval of once every 2 weeks. After a median follow-up of 14.7 months, the ORR was 61.0%; notably, CR or better was achieved in 35.0% of patients. As expected, the most common AEs leading to dose interruptions were infections (50.4%). Most patients received antiviral prophylaxis, and approximately half received anti-*P. jirovecii* prophylaxis. Six patients developed *P. jirovecii* pneumonia, but only one was receiving prophylaxis. Motor dysfunction and sensory neuropathy were observed in 17.1% and 13.8% of patients, respectively. Only grade 1 or 2 CRS was reported in 56.3% of patients (Fig. 21-4).[20]

Figure 21-4 Recent Immunotherapeutic Approaches to the Treatment of Myeloma



Abbreviations: ADC, antibody-drug conjugate; BCMA, B-cell maturation antigen; BsAb, bispecific antibody; CAR-T, chimeric antigen receptor T-cell; Cilta-cel, ciltacabtagene autoleucel; Ide-cel, idecabtagene vicleucel; MoAb, monoclonal antibody.

Linvostelamab was approved based on the results of the Linker-MM1 trial. Step-up dosing was on days 1 and 8, followed by weekly dosing of 200 mg through weeks 13, every other week dosing through week 23, and then dosing every 4 weeks in those achieving a very good PR or better. The median age of patients was 70 years. EMD was reported in 14.5%. The ORR was 70.9% with an 18 month PFS of 68.8%. Eighteen-month OS is 69.8%.[136]

Talquetamab, a BsAb targeting GPRC5D, has also yielded impressive results. The phase 1 MonumenTAL-1 study evaluated talquetamab at various doses and frequencies by using subcutaneous or intravenous administration in patients who had heavily pretreated myeloma. After a median follow-up of 11.7 months for the 405-mcg dose and 4.2 months for the 800-mcg dose, the ORRs were 70% and 64%, respectively. The median duration of response was 10.2 and 7.8 months, respectively. Talquetamab has a unique toxicity profile; many patients experienced grade 1 or 2 oral AEs such as dysgeusia, dry mouth, and dysphagia, resulting in significant weight loss as well as nail changes.

Venetoclax is an oral BCL-2 inhibitor that is currently approved as a single agent or in combination with other medications for various leukemias and lymphomas. Venetoclax has demonstrated increased activity in patients whose MM harbors the t(11;14) mutation. The BELLINI phase 3 trial evaluated the combination of venetoclax, bortezomib, and dexamethasone compared with placebo, bortezomib, and dexamethasone in RRMM. The trial was stopped prematurely because of increased mortality in the venetoclax arm, mostly related to fatal infections. However, a subgroup analysis noted significantly improved PFS without a decrease in OS among patients with t(11;14).[145] Given these findings, venetoclax can be considered in patients who have RRMM with t(11;14) and have limited treatment options. These patients should be started on antibacterial and *P. jirovecii* pneumonia prophylaxis. Venetoclax and other BCL-2–targeted approaches are actively under investigation for relapsed/refractory MM.

Another therapy with a novel target that is approved for use in relapsed/refractory MM is XPO-1 inhibition. Selinexor (an XPO-1 inhibitor) was initially studied in penta-refractory MM and approved at an 80 mg twice weekly schedule, which carried significant toxicities.[146] Since then, it has also been approved with dexamethasone and once-per-week bortezomib and dexamethasone in the BOSTON study, which randomly assigned patients who had RRMM to once-per-week selinexor and bortezomib plus dexamethasone (Vd) (the selinexor dose was 100 mg weekly in 35-day cycles) versus Vd (bortezomib was given twice per week in 21-day cycles). The mPFS between selinexor-Vd versus Vd arms was 13.93 and 9.46 months, respectively.[147] Studies of selinexor combined with other novel agents such as daratumumab, carfilzomib, and pomalidomide have promising results.[148,149]

Selinexor has significant toxicity, including thrombocytopenia, neutropenia, nausea, vomiting, diarrhea, anorexia, and fatigue; however, these are milder and more easily managed when selinexor is given once per week at lower doses (40-100 mg). Prophylactic antinausea medications with two agents and careful monitoring, especially in the first month, are critical.

Belantamab mafodotin, an antibody-drug conjugate targeting BCMA, was withdrawn from the US market after the results of the DREAMM-3 trial (NCT04162210) were published. This phase 3 study assessed belantamab mafodotin versus pomalidomide plus low-dose dexamethasone to treat RRMM, but it did not meet its primary endpoint of PFS. This drug also had poorer outcomes in patients with EMD, and the high rates of keratopathy led to frequent treatment interruptions.[150] However, two new randomized clinical trials reported positive efficacy results of belantamab mafodotin. The DREAMM-7 trial was a phase 3, open-label, randomized study designed to evaluate the efficacy of belantamab mafodotin, bortezomib, and dexamethasone (BVd) versus daratumumab, bortezomib, and dexamethasone (DVd) following at least one line of therapy.[15] The study's primary endpoint was PFS, whereas secondary endpoints included OS and depth of response. At a median follow-up duration of 28.2 months, the mPFS was recorded at 36.6 months for the BVd cohort, compared with 13.4 months in the DVd cohort (PFS HR, 0.41; 95% CI, 0.31-0.53; $P < .001$). The percentage of patients achieving a ≥ CR was 84% for the BVd group and 42% for the DVd group. Notably, subgroup analyses revealed that BVd demonstrated superior outcomes over DVd among patients with high-risk cytogenetics, showing an HR of 0.36 (95% CI, 0.22-0.58). The OS rate at 18 months was 84% in the BVd group, in contrast to 73% in the DVd group. Furthermore, MRD-negative CR status was observed in 25% of patients in the BVd group compared with 10% in the DVd group. Higher incidences of grade 3 or above adverse events were reported in the BVd arm (95% versus 78% in the DVd group). In addition, ocular events were more prevalent in the BVd group (79% vs. 29%). Among patients with normal best-corrected visual acuity (BCVA: 20/25 or better in at least one eye) at baseline, a decline in BCVA to 20/50 or worse in both eyes was evidenced in 34% of cases, whereas a reduction to 20/200 in both eyes occurred in 2%. The median duration until BCVA deterioration was 73 days, with a median interval of 22 days to improvement. Such adverse events were managed through dose modifications, and declining visual acuity incidents proved reversible. The predominant reason for the discontinuation of belantamab mafodotin treatment was the progression of the disease.[15]

The DREAMM-8 trial constituted a phase 3, randomized, open-label study that assessed the efficacy of belantamab mafodotin, pomalidomide, and dexamethasone (BPd) in comparison with PVd for the treatment of relapsed or refractory myeloma in patients who had been previously exposed to lenalidomide.[17] At a median follow-up duration of 21.8 months, the 12-month PFS rates demonstrated an advantage for the BPd treatment group at 71%, in comparison with 51% in the PVd cohort (HR for PFS, 0.52; 95% CI, 0.37-0.73; $P < .001$). Furthermore, a subgroup analysis indicated that BPd exhibited superior efficacy with an HR of 0.57 and a 95% CI of 0.34-0.95. The percentage of patients with PR or above was 77% for the BPd group and 72% for the PVd group, and CR or better was noted in 40% of patients receiving BPd, in contrast with 16% of those receiving PVd. Notably, instances of grade 3 and above AEs were more prevalent in the BPd group, reported at 94%, compared with 76% in the PVd group. Ocular events were more frequently encountered in the BPd cohort, occurring at a rate of 89% (with grade 3 or 4 events noted in 43% of cases) versus 30% in the PVd group (with grade 3 or 4 events reported in 2%). The median duration until BCVA deterioration was 112 days, with a median interval of 29 days to resolution. Deterioration of BCVA to 20/200 or worse occurred at a median of 351 days. Ocular events within the BPd group were addressed through modifications to the dosing of belantamab mafodotin. Furthermore, ocular events necessitated treatment discontinuation in 9% of patients within the BPd group.[17] On October 23, 2025 FDA approved belantamab with bortezomib and dexamethasone for RRMM patients who have received at least two prior lines of therapy, including a proteasome inhibitor and IMiDs for use in the United States.[151] Cereblon E3 ligase modulators (CELMoDs) are a novel class of oral agents that recently entered the MM armamentarium, demonstrating enhanced tumoricidal and immune-stimulatory effects compared with IMiDs. In a multicohort, open-label, phase 1/2 trial in patients who had heavily pretreated IMiD RRMM, the combination of iberdomide and dexamethasone was found to be generally safe, with meaningful clinical activity (ORR, 26%). The most common toxicity profile included myelosuppression with grade 3 and above AEs that included neutropenia (45%), anemia (28%), infection (27%), and thrombocytopenia (22%).[152] Another recently tested CELMoD is mezigdomide, which was similarly tested as part of a dexamethasone doublet in a phase 1/2 trial in patients who had previously treated RRMM. After a median follow-up of 7.5 months, the ORR was 41%, and the mPFS was 4.4 months. The most common AEs included neutropenia (77% of the patients) and infections (65%; grade 3, 29%; grade 4, 6%). Currently, the combination of teclistimab and iberdomide is being tested in NCT 06465316.[153]

In patients with extramedullary plasmacytomas or PCL, multidrug regimens such as VTd and PACE for 1 to 2 months may be used to gain better disease control, but they are associated with greater toxicity.[154]

Other infusional chemotherapy regimens may be equally effective. These combinations are best used as a bridge to more definitive treatment that may be safely used for a longer period or may have a more durable response, such as a promising clinical trial or a second ASCT. A second ASCT is feasible, although remission durations are approximately 50% of what was achieved with the first ASCT. Because there have been no randomized trials, a second ASCT is used in patients who have had a reasonable duration of remission with the first ASCT. Thus, patients who obtain a remission duration of more than 36 months with maintenance therapy (or more than 18 months without maintenance therapy) after the first ASCT are potential candidates for a second ASCT as salvage therapy.[155] Novel immunotherapeutic approaches, such as BsAbs, are now being explored to improve outcomes in this high-risk population. In the phase 1b RedirecTT-1 trial, teclistamab plus talquetamab showed ORRs of 61% in EMD patients versus 92% in those without, with estimated 18-month PFS of 53% and 70%, respectively, highlighting its potential in these high-risk patients.[23]

Many currently used therapies, including bispecific T-cell engagers, CAR-T cells, and others, directly or indirectly depend on the anti-MM activity of T and other effector cells. Reduced T-cell fitness not only diminishes immune defenses, increasing patient susceptibility to opportunistic infections, but can also impact the effectiveness of anti-MM therapies.[156] Various studies have identified several factors that may compromise clinical outcomes following T-cell–redirecting therapies, such as age, performance status, cytogenetic abnormalities, the presence of EMD, prior treatments, and immunologic function, among others. Coupled with the rapid advancement of CAR T-cell and BsAb therapies into the earlier lines of treatment, the field is directing its focus on sequencing strategies that could modulate T-cell fitness and potentially optimize overall benefit and long-term clinical outcomes.[157,158]

KEY POINTS

- Daratumumab and isatuximab (targeting CD38) and elotuzumab (targeting SLAMF7) are the first mAbs approved for the treatment of RRMM.
- Typical first-relapse therapies involve using a CD38 antibody (in anti-CD38 mAb-naive or -sensitive patients) with the addition of an IMiD or a PI with dexamethasone.
- CAR T-cell and BsAb therapies are novel forms of immunotherapy that rely on T-cell–dependent destruction of MM cells through gene modification or the formation of a link between T cells and MM cells, respectively. Both technologies are associated with CRS and immune effector–associated neurotoxicity syndrome, which, in turn, must be carefully monitored for and urgently treated.
- Venetoclax is an oral BCL-2 inhibitor that is particularly effective in patients who have MM and harbor a t(11;14).
- Selinexor with either dexamethasone alone or bortezomib and dexamethasone is approved for patients with RRMM. Weekly dosing, where applicable and appropriate, is critical to toxicity mitigation.
- CELMoDs, including iberdomide and mezigdomide, represent a promising group of oral agents that are being investigated in all phases of MM treatment. Although CELMoDs are designed for superiority in terms of efficacy compared with IMiDs, their toxicity profile resembles the IMiD class with predominant myelosuppression signals.
- Considerations for sequencing and bridging therapies (particularly relating to CAR T and BsAb use) should incorporate strategies for the preservation of T-cell health and the avoidance of factors leading to T-cell exhaustion to maximize long-term outcomes.[159]

TREATMENT OF COMPLICATIONS AND PALLIATIVE CARE

TREATMENT OF DISEASE COMPLICATIONS

Patients who have MM should receive bone-modifying agents such as pamidronate, zoledronic acid, or denosumab to lower the risk of skeletal events. Typical treatment with pamidronate or zoledronic acid has been once per month for 1 to 2 years. In a randomized trial, OS was improved in MM with the use of zoledronic acid as prophylactic therapy. Results of a more recent randomized trial suggested that a reduced frequency of administration (once every 3 months) may be as effective as monthly administration.[160] A large, blinded, randomized study demonstrated that denosumab was noninferior to zoledronic acid for the prevention of skeletal-related effects. AEs were similar, except there was more renal toxicity with zoledronic acid and more hypocalcemia with denosumab. Rates of osteonecrosis of the jaw were similar.[160] Calcium supplementation and daily vitamin D supplementation are needed for patients receiving bisphosphonates. Surgical fixation of fractures or impending fractures of long bones can be performed as needed. Palliative local radiation should be limited to patients who have disabling pain that has not responded to analgesics and systemic therapy, or to treat tumors that threaten other organs by their location, that are not expected to regress quickly with systemic therapy. Radiation to vertebral compression fractures without MRI evidence of plasmacytomas compressing neural structures is not required, unless it is needed for palliative treatment for pain management. Vertebroplasty and kyphoplasty may be useful to decrease pain. Severe hypercalcemia can develop in some patients with MM. This is a medical emergency and requires treatment with hydration, corticosteroids, calcitonin, and either pamidronate (60-90 mg intravenously over 2-4 hours), zoledronic acid (4 mg intravenously over 15 minutes), or denosumab. Denosumab can be prioritized in patients with poor renal function, given its lack of renal toxicity.

Renal failure is common in MM and can be multifactorial. Volume depletion, nonsteroidal anti-inflammatory agents, infection, hypercalcemia, and radiographic contrast media may also contribute to renal failure. The most common cause of acute renal failure is light chain cast nephropathy, which requires prompt therapy to lower serum light chain levels. The role of plasmapheresis is controversial, but it may be incorporated in conjunction with CyBorD to treat patients who have MM and who also have proven or suspected acute light chain cast nephropathy with a goal of reducing the involved FLC level to less than 500 mg/L.[161]

Other disease-related complications include anemia, infections, and hyperviscosity syndrome. Anemia usually improves with treatment of the underlying MM, but some patients may require transfusions or erythropoietin. Recently, the TEAMM study has shown that the use of prophylactic levofloxacin for the first 12 weeks of treatment is associated with a lower risk of febrile infection and/or death.[162] Intravenous gamma globulin has generally been reserved for patients who have recurrent serious infections associated with severe hypogammaglobulinemia; intravenous gamma globulin should be considered even in the absence of infections in patients who have severe hypogammaglobulinemia after potent anti-BCMA immunotherapies, including BsAb, given the high risk of infection with these agents.[27] Hyperviscosity syndrome manifests with symptoms such as epistaxis, mucosal bleeding, headache, and blurred vision. Hyperviscosity syndrome requires emergent plasmapheresis.

Risk of venous thromboembolism (VTE) remains underrecognized in MM, yet it is one of the critically important and preventable causes of morbidity and mortality. It is ninefold higher in patients who have MM compared with the general population, likely driven by factors relating to malignancy, treatment agents, and other patient-related factors. Deep vein thrombosis in the first year after a new diagnosis of MM triples the risk of mortality compared with patients who have MM without VTE. Inferior OS associated with VTE has also been demonstrated in the context of modern induction triplet and quadruplet regimens commonly used in today's practice.[163,164] We currently lack data driven by RCTs in terms of the optimal prophylaxis strategies, and official recommendations for VTE prophylaxis in MM that are part of various national guidelines or multidisciplinary society panels are largely based on expert opinions.[28] Previous understanding of the risk timeline suggested that nearly all events usually occur within 6 months of treatment initiation, regardless of treatment regimen.[165] Most recent insights from analyses of VTE events in the GRIFFIN and MAIA trials suggest that median time to onset can be much longer than that (approximately 305 days for DVRd); events that occur during continuous DRd therapy have been recorded beyond 2 years of continuous therapy.[166,167] Until the gaps in RCT data are filled, simplified expert-based approaches to VTE prophylaxis at various stages of MM treated with various contemporary MM regimens can be considered.[28,168]

MANAGEMENT OF DRUG TOXICITY

The major AEs of thalidomide are sedation, constipation, and peripheral neuropathy. By contrast, the major AEs of lenalidomide are anemia, neutropenia, and thrombocytopenia. Both drugs cause fatigue. Because of the risk of teratogenicity, the use of any of the immunomodulatory agents (ie, thalidomide, lenalidomide, or pomalidomide) in pregnant patients is absolutely contraindicated. Furthermore, to prevent teratogenicity, there are strict requirements that must be met before these drugs can be prescribed. Patients who are receiving thalidomide, lenalidomide, or pomalidomide are also at significant risk of venous and arterial thrombotic events and require thromboprophylaxis with aspirin, low-molecular-weight heparin, a direct oral anticoagulant (DOAC), or warfarin.[169,170] Lenalidomide and pomalidomide can cause a skin rash that can be serious in a small proportion of patients. Medications such as sulfonamides and allopurinol may increase the risk and severity of skin toxicity and should be avoided if possible. Treatment with lenalidomide and pomalidomide can lead to thyroiditis and subsequent hypothyroidism. Thyroid function tests should be performed at baseline and every 3 to 4 months thereafter while a patient is receiving this therapy. Severe diarrhea can develop in approximately 10% to 15% of patients who receive lenalidomide treatment. The treatment is standard antimotility agents, and a bile acid sequestrant such as colestipol.

The major AEs of bortezomib are gastrointestinal toxicity, thrombocytopenia, and neuropathy. The best way to reduce the risk of neuropathy is to use bortezomib in a once-per-week schedule instead of a twice-per-week schedule[171] and administer the medication subcutaneously instead of intravenously. Neuropathy can be treated with drugs such as gabapentin or pregabalin, or antidepressants such as duloxetine. Scrambler therapy has been reported to benefit patients with chemotherapy-induced peripheral neuropathy. Patients who are being treated with bortezomib (and other proteasome inhibitors) are at high risk for reactivation of herpes zoster, and routine prophylaxis with acyclovir is recommended. Neuropathy is less of a risk with ixazomib and carfilzomib compared with bortezomib. The main AEs of ixazomib are nausea and diarrhea. Major AEs of carfilzomib include fatigue, nausea, cytopenias, and shortness of breath. Carfilzomib can also cause significant cardiac dysfunction in approximately 5% of patients; this effect must be considered carefully in the treatment of older patients.[172]

The main AEs of daratumumab, isatuximab, and elotuzumab are infusion-related reactions, which are mostly seen with the first dose. With intravenous daratumumab, approximately 50% of patients may have a grade 3 or above infusion reaction with the first dose, but this decreases to less than 5% with subsequent doses. Montelukast should be given before the first dose of daratumumab to reduce infusion reactions. Daratumumab, as a subcutaneous injection, was evaluated in a phase 3 study and found to be noninferior in terms of efficacy compared with the intravenous formulation. Subcutaneous administration also provided an improved safety profile with significantly fewer infusion-related reactions and was considered more convenient as a

treatment method.[173] Because steroids play a major role in the treatment of MM, patients often have major steroid-related AEs. These are best prevented by using the lowest possible dose of steroids. During the first few months of therapy, dexamethasone at 40 mg once per week is sufficient.[174] Some patients require a lower dose, even at the onset. After the first few months, an attempt should be made to rapidly reduce the dose of steroids. The ongoing IFM2017-03 Phase 3 trial[175] in frail patients with newly diagnosed MM compared a dexamethasone-sparing regimen of daratumumab plus lenalidomide (with dexamethasone only during the first two cycles) versus Rd, showing a 49% reduction in the risk of progression or death, along with a favorable safety profile and improved quality of life in the dexamethasone-sparing group.

We typically recommend ongoing prophylaxis for *P. jirovecii* pneumonia for patients receiving long-term steroid treatment.

Bisphosphonate therapy is associated with a risk of osteonecrosis of the jaw, and dental conditions should be assessed before initiation of bisphosphonate therapy. Other drug-induced complications include myelodysplastic syndrome and a risk of second primary malignancies.

KEY POINTS

- Patients with MM should receive bone-modifying agents prophylactically to prevent skeletal-related events.
- Severe hypercalcemia is a medical emergency and requires treatment with hydration, corticosteroids, and intravenous administration of bisphosphonates.
- The most common cause of acute renal failure is light chain cast nephropathy, which requires prompt therapy to lower SFLCs.
- Patients receiving IMiDs (thalidomide, lenalidomide, or pomalidomide) are at significant risk for venous and arterial thrombotic events and require routine thromboprophylaxis.
- When appropriate, modifications to reduce bortezomib-related neuropathy include a once-per-week schedule instead of a twice-per-week schedule; subcutaneous administration is always preferred to intravenous.
- The standard dose of steroids to be used in MM therapy usually should not exceed dexamethasone 40 mg once per week (or equivalent), unless there is an emergent need.

RELATED DISORDERS

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

MGUS is a premalignant precursor of MM.[34] It is defined by a serum M-protein concentration less than 3 g/dL, less than 10% clonal plasma cells in the bone marrow, and the absence of lytic bone lesions, anemia, hypercalcemia, and renal insufficiency that can be attributed to a plasma cell disorder. The three subtypes of MGUS are nonimmunoglobulin M (non-IgM) MGUS, IgM MGUS, and light chain MGUS. MGUS is present in more than 3% to 4% of the population older than age 50.[34] The risk of MGUS is significantly higher in the Black population compared with the White population.[176,177] The risk of MGUS is also higher in first-degree relatives of patients with MGUS or MM[51] and in those exposed to certain pesticides.[177]

MGUS provides a lifelong risk of transformation to MM or related malignancy at a rate of 1% per year.[34] The size and type of the M-protein at diagnosis of MGUS and an abnormal serum FLC ratio are prognostic factors for progression. A bone marrow evaluation can be deferred in patients with low-risk MGUS and patients with IgM MGUS who have a normal FLC ratio and no anemia, lymphadenopathy, or organomegaly. It is generally indicated for patients with M protein ≥1.5 g/dL (15 g/L), all IgA MGUS cases, and most patients with an abnormal serum FLC ratio. Similarly, bone imaging at diagnosis can be deferred in patients with low-risk MGUS or IgM MGUS if there are no clinical concerns for MM or a related disorder.

No treatment is needed for MGUS. Patients with low-risk MGUS should be observed at 6 months, and subsequently when symptoms occur that may indicate progression. All other patients with MGUS should be observed at 6 months and, if they are stable, annually thereafter.

MONOCLONAL GAMMOPATHY OF CLINICAL SIGNIFICANCE

MGUS is asymptomatic, but in a small subset of patients, there may be complications directly related to the toxicity of the monoclonal immunoglobulin or to other mechanisms. In these cases, the diagnosis changes to monoclonal gammopathy of clinical significance (MGCS). This entity is poorly recognized and undertreated. Early suspicion and rapid intervention to preserve involved organ function are crucial.[178] Examples of organs affected by MGCS are the nervous system (cryoglobulinemia type I and II, IgM-related peripheral neuropathy, POEMS syndrome), skin (eg, scleredema, scleromyxedema, acquired cutis laxa, Schnitzler syndrome), kidneys (eg, amyloid nephropathy, light chain deposition disease, acquired Fanconi syndrome, immunotactoid glomerulopathy, C3 proliferative glomerulonephritis associated with monoclonal immune deposits), and various other target organs. When the kidneys are involved, the condition is called monoclonal gammopathy of renal significance[178] (Table 21-5). For more information on the pathophysiological classification of the main MGCS-related disorders, see the report here.

Table 21-5 **Current Classifications of the Main MGCS-Related Disorders by Mechanism**

Disorder	Mechanism	Main Characteristics of Monoclonal Gammopathy	Organs and Symptoms Involved
Autoantibody activity			
Type II mixed cryoglobulinemia[a]	Immune complex	IgM	Immune complex-mediated vasculitis; skin +++, kidney, peripheral nerve; may be systemic
C1 inhibitor deficiency	C1 inhibitor		Angioedema
von Willebrand disease	vW factor		Bleeding
Bullous skin disease	Dermoepidermal junction (collagen VII)		Skin
Xanthomatosis	Various lipoproteins	Usually IgG	Cholesterol accumulation in macrophages, skin and tendons, other localizations (necrobiotic xanthogranulomatous)
Cold agglutinin disease	Red blood cell (Ii)	IgM	Cold-induced skin manifestations + intravascular hemolysis
IgM-associated peripheral neuropathy	MAG +++	IgM	Peripheral nerve; ataxic polyneuropathy (anti-MAG)
	Gangliosides	IgM	CANOMAD
CAP[a] activation			
C3 glomerulonephritis atypical hemolytic-uremic syndrome	Mechanism to be determined; autoantibody activity against CAP regulator protein (factor H) in some cases	IgG	Kidney only; systemic
Cytokine mediated			
POEMS syndrome	VEGF	λ LC (~100%), IgA 50% Vλ1 (~100%); osteosclerotic bone lesions	Peripheral nerve (100%) and various other manifestations
Unknown mechanism			
Systemic capillary leak syndrome		IgG, IgA (rare)	Systemic
TEMPI syndrome		IgG	Systemic
Neutrophilic dermatosis[b]		IgA >80% (except Sweet syndrome)	Skin +++; different types and different associated manifestations
Acquired cutis laxa		Usually IgG; association with γ HCDD	Skin +++; other manifestations (lung, digestive tract)
Scleromyxedema		IgG with slow electrophoretic mobility	Skin +++; other localizations
Scleredema		IgG	Skin only
Schnitzler syndrome	Acquired autoinflammatory syndrome by IL-1 deregulation?	IgM	Skin +++; systemic symptoms; osteosclerotic bone lesions
Sporadic late-onset nemaline myopathy			Exclusively muscles (skeletal and possibly cardiac)

Abbreviations: +++, significant involvement; CANOMAD, chronic ataxic neuropathy, ophthalmoplegia, IgM paraprotein, cold agglutinins, and disialosyl antibodies; CAP, complement alternative pathway; HCDD, heavy chain deposition disease; IgM, immunoglobulin M; IL-1, interleukin 1; MAG, myelin-associated glycoprotein; MGCS, monoclonal gammopathy of clinical significance; POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes; TEMPI, telangiectasias, elevated erythropoietin level and erythrocytosis, monoclonal gammopathy, perinephric fluid collection, and intrapulmonary shunting; VEGF, vascular endothelial growth factor; vW, von Willebrand (disease).

[a]Type II mixed cryoglobulinemia was observed in 10% of patients with chronic virus C infection.

[b]Including pyoderma gangrenosum, Sweet syndrome, subcorneal pustular dermatosis, and erythema elevatum diutinum.

Some of the above paraprotein-mediated diseases can occur concomitantly with MM or in the presence of SMM. Note that patients with MGUS or SMM may have symptoms or manifestations of unrelated conditions that need to be excluded (eg, kidney damage from diabetes or hypertension). The spectrum of diagnoses that are associated with MGCS is rare and heterogeneous; some patients may benefit from therapy directed at the underlying plasma cell clone using regimens adapted from the MM literature.

MONOCLONAL GAMMOPATHY OF RENAL SIGNIFICANCE

Monoclonal gammopathy of renal significance can apply to a group of patients who harbor an M-protein produced by a B-cell or plasma cell clone that causes kidney injury. The underlying diagnosis may not meet the criteria for overt lymphoma or symptomatic myeloma, although myeloma or lymphoma may occur concomitantly. In fact, the clinical parameters (ie, M-spike size, serum light chain levels, extent of bone marrow involvement) may be identical to those of MGUS.[178] Monoclonal gammopathy of renal significance includes a wide array of pathologies, including light chain deposition disease, amyloid nephropathy, and C3 glomerulopathy with monoclonal gammopathy.[179] Light chain cast nephropathy is not a form of monoclonal gammopathy of renal significance but is rather a consequence of intratubular injury from the overproduction of light chains that have exceeded the resorptive capacity of the kidney and define active MM. Consequently, in monoclonal gammopathy of renal significance, the toxicity of the M-protein rather than the burden of disease is the defining feature. Patients with monoclonal gammopathy of renal significance often present with high-grade albuminuria or nephrotic syndrome rather than acute loss of glomerular filtration rate, which is more typical of light chain cast nephropathy. Monoclonal gammopathy of renal significance requires a renal biopsy to confirm the presence of monoclonal deposits in the kidney. Without treatment, patients may progress to end-stage renal disease. Treatment includes chemotherapeutic agents used to target plasma cell or B-cell neoplasms, depending on the type of clone present. Early recognition is critical, and thus clinicians must consider monoclonal gammopathy of renal significance in any patient with an M-protein who has unexplained and progressive renal failure or high-grade albuminuria.

MONOCLONAL GAMMOPATHY OF NEUROLOGIC SIGNIFICANCE

Peripheral neuropathy (PN) mediated by an M-protein in the serum and urine without any evidence of MM or Waldenström macroglobulinemia (WM) is defined as monoclonal gammopathy of neurologic significance (MGNS). We currently lack any definitive diagnostic methods that can reliably and causatively associate monoclonal paraproteinemia with the presence of PN, which is why the diagnosis of MGNS remains a diagnosis of exclusion.[180] One should consider whether MGNS is at play when PN occurs in the context of IgM-related paraprotein and the following clinical findings: it is sensory predominant, length dependent, slowly progressing (over months or years), bilateral and symmetrical, with MAG antibodies present, and demyelination confirmed by nerve conduction studies.[180] Essential aspects are excluding more common causes of PN, such as diabetes, chronic alcohol intake, cobalamin deficiency, autoimmune conditions, and infections such as HIV. Nerve conduction studies will typically reveal a hallmark feature in demyelination pattern of injury, whereas features commonly not associated with MGNS include purely axonal PN, short time to onset, and peak of symptoms (<6 months), whether PN is relapsing and remitting, if cranial nerve involvement is seen, if there is a nonsymmetrical distribution, or if there is a history of a viral infection 2 to 4 weeks before the onset of symptoms.[180] Pain and carpal tunnel syndrome are typically absent. Autonomic involvement is not seen in the absence of amyloidosis. Once identified, treatment of MGNS should follow the treatment guidelines for WM, with attention to avoiding neurotoxic therapies such as bortezomib or vincristine.

MONOCLONAL GAMMOPATHY OF THROMBOTIC SIGNIFICANCE

Monoclonal gammopathy of thrombotic significance is a newly recognized entity for which diagnostic and treatment criteria have not been established yet. This highly prothrombotic disorder is generally characterized by platelet-activating monoclonal antiplatelet factor 4 (PF4) antibodies, with or without associated persistent concurrent thrombocytopenia and a history of recurrent venous or arterial, micro- or macro-circulation thrombotic events.[181,182] Additional findings may also include reduced levels of natural anticoagulants and the presence of antiphospholipid antibody or cryoprotein activity.[183-185] It is usually accompanied by positive "heparin-induced thrombocytopenia-like" antibody assays such as the PF4/polyanion enzyme-linked immunosorbent assay (ELISA) and serotonin release assay (SRA), though presentations with ELISA/SRA-negative testing in the context of transient thrombocytopenia coincident with recurrent thrombotic episodes have also been described (cases with ELISA/SRA-negative testing require PF4-enhanced platelet-based testing for confirmation).[181,186] Presentations may be severe, despite anticoagulation therapy, suggesting that anticoagulant therapy alone is inadequate to control the underlying clotting.[187] Plasma cell-directed therapy aimed at reducing circulating monoclonal protein, with concurrent antithrombotic therapy is effective in mitigating long-term thrombotic risks.[181] Agents associated with increased thrombotic potential (ie, IMiDs) should be avoided in the context of any planned anti-plasma cell therapy.

SOLITARY PLASMACYTOMA

Solitary plasmacytoma is a localized plasma cell malignancy. It is defined by the presence of a single biopsy-proven plasmacytoma (bony or extramedullary) and a normal bone marrow examination. An M-protein may be present in serum or urine at

diagnosis. Treatment consists of radiation therapy (40-50 Gy) to the involved site. Patients with an apparent solitary plasmacytoma who have limited (<10%) clonal marrow involvement are considered to have solitary plasmacytoma with minimal marrow involvement; these patients are also treated similarly to patients with solitary plasmacytoma. The risk of recurrence or progression to MM within 3 years is approximately 10% in patients with solitary plasmacytoma versus 20% to 60% in patients with solitary plasmacytoma and minimal marrow involvement. Retrospective data demonstrate that patients with high-risk cytogenetic abnormalities by FISH—defined in this study as del(17p), t(14;16), t(4;14), or +1q (gain/amplification)—experience a shorter time to progression to multiple myeloma (8 months [95% CI, 6.3-26] vs. 42 months [95% CI, 25 to not reached]; $P < .001$).[188]

PLASMA CELL LEUKEMIA

PCL is a rare, highly aggressive variant of MM distinguished by the presence of ≥5% clonal plasma cells circulating in the peripheral blood, according to the revised IMWG criteria.[189] This threshold was lowered from the previous ≥20% based on evidence that patients with 5-20% circulating plasma cells have similar poor outcomes as those with higher levels.[190,191] PCL occurs as either primary (pPCL), arising de novo with no evidence of previous MM, or secondary (sPCL), emerging as leukemic transformation in RRMM. Secondary PCL carries a far worse prognosis, with recent cohorts showing median OS of only 3.2 to 3.5 months compared with 13 to 36.6 months in pPCL. Biologically, PCL is distinct from MM, characterized by frequent high-risk cytogenetics (del(17p), 1q gain, t(11;14), MAF translocations), elevated LDH, and EMD.[192-196] The t(11;14) is particularly common in pPCL and may confer a relatively better prognosis than other cytogenetic patterns.[195] Clinically, patients often present with cytopenias, high tumor burden, and rapidly progressive disease. Vigilant monitoring for clinical indications of central nervous system myeloma is crucial in patients diagnosed with PCL. Outcomes remain poor despite modern therapies. A reasonable strategy for initial treatment includes anti-CD38 plus VRd, anti-CD38 plus KRd, or a multidrug regimen such as VTd and PACE for two to three cycles followed by ASCT and subsequent maintenance therapy.[197-199] In the era of T-cell–directed therapy, the multicenter retrospective study[200] of 34 PCL patients treated with BCMA-directed CAR-T (19 ide-cel, 15 cilta-cel) showed mPFS of 9.0 months, and median OS of 13.0 months, with cilta-cel showing longer outcomes (mPFS 19.0 months vs. 6.0 months, median OS >23 months vs. 9.0 months), exceeding historical standards.

In this multicenter study of 122 PCL patients[201] treated with BsAbs, overall outcomes were poor (mPFS 3.2 months), but talquetamab showed superior activity compared with BCMA-directed BsAbs. Among the 60 patients with active PCL, prognosis was markedly worse, yet talquetamab (n = 29) achieved a mPFS of 6.9 months and OS of 12.2 months, substantially outperforming BCMA BsAbs (mPFS 0.7 months, mOS 1.4 months). Despite the relative benefit of T-cell–based therapies, prognosis remains dismal, underscoring the urgent need for dedicated prospective trials and novel therapeutic approaches for this high-risk population.

IMMUNOGLOBULIN LIGHT CHAIN (AL) AMYLOIDOSIS

Amyloid is a proteinaceous substance that consists of rigid, linear, nonbranching fibrils 7.5 to 10 nm in width, aggregated in a β-pleated sheet conformation.[202] It is detected on staining with Congo red and classic apple-green birefringence. Several types of amyloidosis are classified based on the major protein component of the amyloid. In systemic light chain amyloidosis (AL), the fibrils consist of the variable portion of a monoclonal light chain. All patients with a monoclonal gammopathy should be screened by using standard laboratory evaluation, careful history, and physical examination for evidence of amyloidosis if they have proteinuria, diastolic heart dysfunction, autonomic dysfunction, sensory-motor PN, hepatomegaly with elevated transaminases or alkaline phosphatase, or findings of macroglossia, periorbital purpura, or bleeding diathesis.

AL can affect numerous organs, including the tongue (macroglossia), heart, liver, kidneys, peripheral nerves, and lungs. To obtain an accurate diagnosis, four separate criteria must be satisfied: (1) the presence of an amyloid-related systemic syndrome (eg, renal, liver, heart, gastrointestinal tract, or peripheral nerve involvement), (2) positive amyloid staining by Congo red in any tissue (eg, fat aspirate, bone marrow, or organ biopsy), (3) evidence that amyloid is light chain–related established by direct examination of the amyloid using mass spectrometry–based proteomic analysis or immuno-electron microscopy, and (4) evidence of a monoclonal plasma cell proliferative disorder (serum or urine monoclonal protein, abnormal FLC ratio, or clonal plasma cells in the bone marrow).[32] The primary aim in the management of systemic AL is the rapid achievement of deep hematologic response and ultimate reversal of any organ dysfunction caused by the deposition of amyloidogenic light chains.[203] The standard treatment has historically involved bortezomib-based therapy; however, patients who present with significant PN should avoid bortezomib-containing regimens because of the risk of further treatment-related exacerbation and toxicity.[204] The new standard in the management of systemic AL and the ability to achieve deep responses was established with the first FDA approval for the use of daratumumab in combination with CyBorD for newly diagnosed patients. In the pivotal ANDROMEDA study, which randomly assigned patients with newly diagnosed AL amyloidosis to receive six cycles of CyBorD either alone (control group) or with subcutaneous daratumumab followed by single-agent daratumumab once every 4 weeks for up to 24 cycles (daratumumab group); hematologic CR was significantly higher in the quadruplet compared with the triplet arm: 53.3% versus 18.1%, respectively.[205] After a median follow-up of 25.8 months, this response superiority deepened even further (60% vs. 19%, respectively).[206] Even though the ANDROMEDA trial had only two patients with Mayo 2004 stage IIIb disease on the quadruplet

arm, the International Society of Amyloidosis still recommends dose-modified (attenuated) DCyBorD for treating these patients who have the most advanced cardiac involvement.[204] Although patients who have systemic AL can also be considered for ASCT when appropriate, our ability to achieve an unprecedented level of responses with modern quadruplet regimens raises the question of whether ASCT consolidation can be obviated for patients achieving a deep hematologic response.[207]

When possible, patients who have systemic AL should be treated in the context of amyloidosis multidisciplinary programs that can ensure patients receive the full spectrum of multidisciplinary disease-directed and supportive care; this care focuses on symptoms of amyloid organ involvement, the AEs of the treatment directed at clonal plasma cells, and the psychosocial problems related to the treatment or disease. Two trials of fibril-directed therapy using anti-amyloid antibodies have failed to meet their primary endpoint.[203]

It should also be noted that amyloidosis can sometimes present in a localized, organ-specific fashion (eg, tracheobronchial tree, urinary tract, or skin) without evidence of systemic spread. In localized amyloidosis, the deposits are derived from monoclonal light chains, not because of an underlying systemic clonal plasma cell disorder, but sometimes from more than one light chain–variable family, and they may not be clonal in nature.[208] The clinical course is usually benign, and the most common recommendation is long-term follow-up. Surgical excision may be appropriate for patients with bladder, ureteral, or laryngeal deposits).[209]

WALDENSTRÖM MACROGLOBULINEMIA

WM is a lymphoplasmacytic lymphoma arising from post–germinal center B cells that have undergone somatic hypermutation but not immunoglobulin class-switch recombination, accounting for the persistent IgM paraprotein. The neoplastic cells secrete monoclonal IgM and display a lymphoplasmacytic morphology, with features intermediate between small lymphocytes and plasma cells.

The disease definition requires the presence of an IgM M-protein greater than or equal to 10% bone marrow involvement and a typical immunophenotype (eg, surface IgM-positive, CD10-negative, CD19-positive, CD20-positive, CD23-negative) that would exclude other lymphoproliferative disorders. Most patients with WM have a recurrent mutation of the *MYD88* gene (*MYD88* L265P). The main symptoms are weakness, fatigue, and hyperviscosity. Unlike in MM, lytic bone lesions are not seen in WM. Indications for therapy include symptomatic anemia, hyperviscosity, organomegaly, or other cytopenias. Initial treatment is typically with ibrutinib[210] with or without rituximab (eg, the iNNOVATE trial) or zanubrutinib (eg, the ASPEN trial)[211,212] or bendamustine plus rituximab or with bortezomib, dexamethasone, and rituximab. In selected patients with limited disease, single-agent rituximab may be an option but produces response rates under 50%, and there is a risk of a tumor flare if single-agent rituximab is used, resulting in a rapid rise in IgM levels. Therefore, combination therapy is preferred for patients with high IgM M-protein levels. Other active regimens for the treatment of WM are given with or without rituximab, including venetoclax,[213] rarely cladribine, or fludarabine, has been used as has the combination of lenalidomide and dexamethasone.

POEMS SYNDROME

The characteristics of POEMS are captured in its name: polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes (POEMS).[214,215] Patients who have POEMS syndrome usually have osteosclerotic bone lesions or coexisting Castleman disease (a rare polyclonal lymphoproliferative disorder). The major clinical problem in POEMS syndrome is a severe, chronic, inflammatory-demyelinating polyneuropathy with predominantly motor features. If the osteosclerotic lesions are in a limited area, radiation therapy is the treatment of choice. If there are widespread osteosclerotic lesions or bone marrow involvement by a clonal plasma cell population, systemic therapy is pursued using anti-plasma cell agents already approved in MM. Most patients have an elevated vascular endothelial growth factor (VEGF), which can support the diagnosis. SCT is commonly used.

PRESENTING CASE STUDY

A 69-year-old man with a medical history significant for well-controlled diabetes and hypertension is found to have renal insufficiency (creatinine, 1.5 g/dL) during a routine primary care clinic check-up. Workup reveals 160 mg/day of proteinuria and an M spike of 0.4 g/dL. Serum immunofixation was positive for IgG kappa. The hematology team was consulted, and the initial workup identified hemoglobin level within the reference range, no hypercalcemia, and no other clinical complaints or concerns. Serum-free kappa light chain is 30 mg/L, and lambda light chain is 19 mg/L (K/L ratio, 1.57).

In an asymptomatic patient with low-level paraprotein and no CRAB features, what factors guide the decision to pursue advanced testing such as bone marrow biopsy or whole-body imaging?

Given the absence of risk factors for progression, advanced imaging and bone marrow evaluation were deferred. The patient was diagnosed with low-risk monoclonal gammopathy of undetermined significance (MGUS), with an estimated

5% chance of progression at 20 years. After confirmation of stable findings on 6-month follow-up, annual observation was recommended. The degree of proteinuria and kappa light chain burden was not sufficient to explain his mild renal impairment, which was attributed instead to comorbid conditions.

The patient, now 72 years old, presents to the emergency department with generalized fatigue and severe back pain. Lumbar spine MRI reveals multiple lytic lesions with an L4 compression fracture without cord compression or soft tissue mass. Other laboratory values are as follows: hemoglobin, 8.5 g/dL; calcium, 9.5 mg/dL; and creatinine, 3 g/dL (6 months prior, creatinine was 1.4 mg/dL). After consulting with the hematology team, the patient undergoes serum protein electrophoresis, which indicates an M spike of 1.5 g/dL. Serum-free kappa light chain level is now 1,100 mg/L, and lambda light chain is 5 mg/L (K/L ratio, 220). Follow-up whole-body PET/CT shows multiple focal bone lesions without extramedullary disease. Bone marrow biopsy confirms the presence of clonal kappa-restricted CD138 plasma cells, constituting about 70% of the total cellularity of the marrow (30% cellular). Fluorescence in situ hybridization (FISH) reveals del(17p13) with 1q amplification and 1 p deletion and no IgH translocations. The patient's Eastern Cooperative Oncology Group (ECOG) performance status is 3, owing mainly to his back pain and overall coexisting morbidities.

What are the key changes between this patient's original MGUS diagnosis and his current presentation that signal progression to active multiple myeloma? How do his high-risk cytogenetics influence treatment planning?

The patient was diagnosed with high-risk multiple myeloma. Because of acute renal failure, multiple lytic lesions, anemia (meeting several CRAB/SLiM criteria), and poor performance status, inpatient cytoreductive therapy with cyclophosphamide, bortezomib, and dexamethasone (CyBorD) was initiated.

After a few days, his pain is better controlled with oxycodone, and he is cleared by physical therapy and discharged. Due to his poor performance status, he is regarded as a newly diagnosed, high-risk, autologous stem cell transplant (ASCT)-ineligible patient. After one cycle of CyBorD, he achieves a partial response; his M spike reduces to 0.7 g/dL, and serum creatinine level improves to near the reference range (creatinine clearance, 55 mL/min/1.73 m^2). Chemotherapy is switched to anti-CD38, carfilzomib, lenalidomide, and dexamethasone (anti-CD38-KRd), accompanied by the bone-modifying agent zoledronic acid, zoster prophylaxis with acyclovir, and adequate deep vein thrombosis prophylaxis with half-dose direct-acting oral anticoagulant. After an additional two cycles of anti-CD38-KRd therapy, he achieves a very good partial response with an unmeasurable M spike and only positive immunofixation electrophoresis (IFE) for IgG kappa. Daratumumab interference test is negative for IFE, and a complete response is suspected. His performance status greatly improves to 1.

Why might CyBorD be chosen as the initial regimen for this patient? How would you decide when to transition from a cytoreductive regimen to a more intensive induction strategy?

CyBorD is an adequate alternative in the setting of acute renal failure with light chain cast nephropathy, as the metabolism of cyclophosphamide does not depend on adequate renal function.

Because of renal recovery and high-risk cytogenetics, therapy was escalated to anti-CD38-KRd, supported by multiple trials in both transplant-eligible and -ineligible newly diagnosed myeloma.

How does improvement in functional status during therapy affect the decision of whether to pursue ASCT?

At this point, his improved ECOG performance status of 1 allowed safe administration of high-dose melphalan, making ASCT appropriate. Restaging confirmed a stringent complete response with MRD negativity at 10^{-6} by next-generation sequencing. He subsequently underwent ASCT, tolerating the procedure well aside from moderate mucositis.

Given the depth of response, consolidation was discussed but deferred.

For a patient with MRD negativity after ASCT and high-risk cytogenetics, what are the pros and cons of post-ASCT therapy?

Maintenance options mainly revolved around doublet maintenance choices due to high-risk disease and included:

- Carfilzomib and lenalidomide (FORTE trial[118])
- Carfilzomib, lenalidomide, and dexamethasone (Atlas trial[117])

- Isatuximab, carfilzomib, and lenalidomide (GMMG-CONCEPT and IsKia[5] trials)
- Daratumumab and lenalidomide (AURIGA trial[114]) (MRD-positive patients)

Considering that the patient underwent quadruplet induction therapy and harbored high-risk disease, single-agent maintenance options were not considered optimal. The patient was presented with several different options, including post-ASCT management strategies with carfilzomib and lenalidomide per FORTE trial; carfilzomib, lenalidomide, and dexamethasone per Atlas trial; and triplet maintenance with isatuximab, carfilzomib, and lenalidomide per GMMG-CONCEPT and IsKia trials. Applicability of daratumumab and lenalidomide per the AURIGA trial was also discussed, but the patient was deemed ineligible as the trial examined the role of dual versus single maintenance therapy in patients with MRD-positive disease post-ASCT. Ultimately, triplet maintenance with isatuximab, carfilzomib, and lenalidomide was selected for the initial post-ASCT period, with a likely plan to de-escalate therapy to the dual-drug maintenance approach with isatuximab and lenalidomide in an attempt to optimize convenience and personal quality-of-life goals.

HIGH-YIELD TAKEAWAYS

Monoclonal Gammopathy of Undetermined Significance

Diagnosis

- Serum M-protein <3 g/dL, <10% clonal plasma cells in marrow, no CRAB features (related end-organ damage)

Testing

- Low-risk IgG monoclonal gammopathy of undetermined significance (MGUS; M-protein <1.5 g/dL, normal FLC ratio): baseline marrow evaluation can be deferred
- Indications for marrow: M ≥1.5 g/dL, any IgA MGUS, or abnormal FLC ratio
- Bone imaging: can be deferred in low-risk MGUS or IgM MGUS if no clinical concerns

Treatment/Follow-Up

- No treatment is indicated.
- Low-risk MGUS should be observed at 6 months, and subsequently when symptoms occur that may indicate progression.
- All other MGUS patients should be observed at 6 months and, if stable, annually thereafter.

Smoldering Multiple Myeloma

Diagnosis

- Both of the following criteria must be met:
  1. Serum monoclonal protein (IgG or IgA) ≥30 g/L OR urinary monoclonal protein ≥500 mg per 24 hours AND/OR bone marrow clonal plasma cells 10% to 59%
  2. Absence of myeloma-defining events or amyloidosis

Monitoring (Risk-Stratified)

- Low/Intermediate risk: labs every 4 to 6 months (CBC, CMP, SPEP/UPEP/IFE, FLC); imaging annual MRI if no lesions, every 6 months if ≥1 focal lesion on MRI
- 7 labs every 2 to 3 months; imaging every 3 to 6 months; early intervention if progression

Multiple Myeloma

Diagnosis

- Essential Criterion: You need to have clonal bone marrow plasma cells ≥10% OR a biopsy-proven plasmacytoma, plus ≥ 1 myeloma-defining events

- CRAB criteria: hypercalcemia, renal insufficiency, anemia, and bone lesions
- Biomarkers of malignancy (≥1):
  - Clonal bone marrow plasma cells ≥60%
  - Involved/uninvolved serum FLC ratio ≥100
  - ≥1 focal lesion on MRI

Testing

- All suspected patients should be tested with complete blood count, complete metabolic profile, β2 microglobulin, lactate dehydrogenase, serum protein electrophoresis, serum immunofixation, 24-hour urine protein electrophoresis and urine immunofixation, serum FLC assay, bone marrow aspirate and biopsy with plasma-cell enriched FISH, and full body imaging with, whole-body low-dose computed tomography, whole-body MRI, or whole-body PET/CT (skeletal survey acceptable in limited resource environments).

Prognosis

- Driven by various staging systems at diagnosis, including International Staging System (ISS), revised-ISS (*R*-ISS), and R2-ISS
- Also driven by standard versus high-risk myeloma features that include cytogenetic abnormalities such as (1) del(17p) with a cutoff of 20% clonal fraction or TP53 mutation; (2) an IgH translocation including t(4;14), t(4;16) OR t(14;20) along with 1q+ and/or del(1p32); (3) monoallelic del (1p32) along with 1q+ or bialellic del(1p32), with all conferring poor prognosis

Treatment

- For TE NDMM, quadruplet regimens are the established frontline standard, with preferable early (vs. delayed) ASCT particularly in patients with high-risk features.
- For TIE NDMM, frontline quadruplet regimens, albeit triplet regimens such as DRd, remain the most frequently used regimen in frail patients.
- Treatment of RRMM is individualized based on patient and disease factors, prior exposures, and residual toxicities, as well as the patient's performance status and their personal preferences pertaining to logistics of therapy delivery and quality of life.
- CAR T-cell and bispecific antibody therapies have revolutionized our ability to treat multiclass refractory, previously treated MM, and patients who are not eligible for ASCT are frequently eligible for these T-cell–redirecting therapies.

Plasma Cell Leukemia

- Defined as ≥5% circulating plasma cells or absolute plasma cell count ≥5 × 10^9/L
- Primary plasma cell leukemia (PCL): arises de novo, aggressive
- Secondary PCL: evolves from MM, worse prognosis
- PCL is aggressive → treat with quad induction + ASCT when eligible; novel agents and CAR-T are increasingly used
- Prognosis: Poor overall; secondary PCL worse than primary

Solitary Plasmacytoma

- Localized plasma cell tumor (bone or extramedullary)
- Bone marrow plasma cells <10%, no systemic disease
- Treatment: definitive radiation therapy
- Follow-up/monitoring:
  - Risk of progression: ~10% within 3 years for solitary plasmacytoma alone
  - Higher risk if solitary plasmacytoma has minimal marrow involvement or HR cytogenetic
  - Periodic labs (CBC, CMP, SPEP/IFE, FLC) and imaging to monitor recurrence or progression

Primary Amyloidosis (Al Amyloidosis)

- Clonal plasma cell disorder → amyloid fibril deposition
- Clinical clues: nephrotic syndrome, restrictive cardiomyopathy, hepatomegaly, neuropathy
- Diagnosis: tissue biopsy with Congo red + mass spectrometry typing

- Treatment: similar to MM (eg, dara-CyBorD frontline)
- Prognosis: poor if cardiac involvement

Waldenström Macroglobulinemia (LPL/WM)

- IgM monoclonal gammopathy with marrow lymphoplasmacytic infiltration
- Clinical: hyperviscosity (visual changes, headache, bleeding), neuropathy, adenopathy, hepatosplenomegaly
- Diagnosis: IgM monoclonal protein + marrow infiltration by LPL
- Treatment: rituximab-based regimens (eg, BR, etc.); BTK inhibitors (ibrutinib, zanubrutinib)
- Plasmapheresis for acute hyperviscosity

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

MULTIPLE MYELOMA 21

CHAPTER SUMMARY GUIDE

KEY POINTS

- The diagnosis of MM requires evidence of one or more myeloma-defining effects: hypercalcemia, renal insufficiency, anemia, or bone lesions that can be attributed to the plasma cell proliferative disorder; clonal bone marrow plasma cells 60% or more; serum FLC ratio of involved to uninvolved at 100 or more, provided the involved FLC level is 100 mg/L or more; or more than one focal lesion on MRI scan.
- MGUS and SMM are asymptomatic plasma cell proliferative disorders that need to be distinguished from MM.
- MM accounts for 1% of all cancers and approximately 10% of all hematologic cancers.
- Myeloma is twice as common in the Black population as in the White population.
- Early intervention with lenalidomide or daratumumab[72] prolongs time to progression to active MM and is now considered a possible treatment option for patients with high-risk SMM (participation in clinical trials is preferred).
- MM is preceded by a premalignant phase that is clinically referred to as MGUS.
- The two principal pathogenetic steps are (1) transition from normal plasma cell to MGUS and (2) transition from MGUS to MM.
- The onset of MGUS is associated with IgH translocations (chromosome 14) in approximately 50% of cases and hyperdiploidy in the remaining 50%.
- The most common presenting symptoms of MM are fatigue and bone pain; other presenting features are hypercalcemia, infection, and renal failure.
- When MM is suspected, patients should be tested for the presence of M-proteins by serum and urine protein electrophoresis, serum and urine immunofixation, and serum FLC assay.
- Full-body skeletal imaging studies and a bone marrow biopsy are required if MM is suspected.
- Patients are staged using the variations of ISS (R-ISS or R2-ISS).
- Patients are considered to have high-risk MM if at least one of the following abnormalities is present: (1) del(17p), with a cutoff of >20% clonal fraction, and/or TP53 mutation; (2) an IgH translocation including t(4;14), t(14;16), or t(14;20) along with 1q+ and/or del(1p32); (3) monoallelic del(1p32) along with 1q+ or biallelic del(1p32); or (4) β2 microglobulin ≥5.5 mg/L with normal creatinine (<1.2 mg/dL). Patients with trisomies or translocations t(11;14) and t(6;14) are considered to have standard-risk MM.
- For TE patients, preferred regimens for initial MM treatment include PI, IMiD, and anti-CD38 antibody–containing quadruplet regimens such as DVRd, DKRd, Isa-VRd, Isa-KRd, and daratumumab, bortezomib, cyclophosphamide, and dexamethasone (DCybBorD; in case of inability to dose IMiDs optimally).
- CyBorD and VTd (less so) are alternatives, and may be preferred in the setting of acute renal failure with light chain cast nephropathy.
- For the TIE patients, recent FDA approval of Isa-VRd quadruplet with a category 1 recommendation, and availability of RCT phase 3 data with DVRd regimens adds these quadruplet combinations to the list of available, powerful induction combinations in this space. The triple combinations with either VRd or DRd remain category 1 options for those who are deemed unfit for frontline quadruplet therapy.
- Patients considered potential candidates for ASCT are typically treated with three to four cycles of quadruplet-based therapy (DVRd, DKRd, Isa-RVd, Isa-KRd, and DCyBorD), followed by a stem cell harvest. After stem cell harvest, patients with standard-risk disease can either proceed to early ASCT or continue the initial treatment regimen and delay ASCT until relapse.
- For patients with high-risk disease, ASCT should be pursued in the frontline setting and not deferred.
- After ASCT, patients can receive risk-adapted consolidation followed by maintenance therapy with lenalidomide; the addition of a proteasome inhibitor or anti-CD38 mAb is normally considered for high-risk patients.
- Even though it was incorporated in the post-induction approaches for TE NDMM, the role of the addition of anti-CD38 mAb to lenalidomide for maintenance after ASCT appears to be beneficial but requires confirmation from currently enrolling studies in daratumumab-exposed patients.
- Daratumumab and isatuximab (targeting CD38) and elotuzumab (targeting SLAMF7) are the first mAbs approved for the treatment of RRMM.

- Typical first-relapse therapies involve using a CD38 antibody (in anti-CD38 mAb-naive or -sensitive patients) with the addition of an IMiD or a PI with dexamethasone.
- CAR T-cell and BsAb therapies are novel forms of immunotherapy that rely on T-cell–dependent destruction of MM cells through gene modification or the formation of a link between T cells and MM cells, respectively. Both technologies are associated with CRS and immune effector–associated neurotoxicity syndrome, which, in turn, must be carefully monitored for and urgently treated.
- Venetoclax is an oral BCL-2 inhibitor that is particularly effective in patients who have MM and harbor a t(11;14).
- Selinexor with either dexamethasone alone or bortezomib and dexamethasone is approved for patients with RRMM. Weekly dosing, where applicable and appropriate, is critical to toxicity mitigation.
- CELMoDs, including iberdomide and mezigdomide, represent a promising group of oral agents that are being investigated in all phases of MM treatment. Although CELMoDs are designed for superiority in terms of efficacy compared with IMiDs, their toxicity profile resembles the IMiD class with predominant myelosuppression signals.
- Considerations for sequencing and bridging therapies (particularly relating to CAR T and BsAb use) should incorporate strategies for the preservation of T-cell health and the avoidance of factors leading to T-cell exhaustion to maximize long-term outcomes.[159]
- Patients with MM should receive bone-modifying agents prophylactically to prevent skeletal-related events.
- Severe hypercalcemia is a medical emergency and requires treatment with hydration, corticosteroids, and intravenous administration of bisphosphonates.
- The most common cause of acute renal failure is light chain cast nephropathy, which requires prompt therapy to lower SFLCs.
- Patients receiving IMiDs (thalidomide, lenalidomide, or pomalidomide) are at significant risk for venous and arterial thrombotic events and require routine thromboprophylaxis.
- When appropriate, modifications to reduce bortezomib-related neuropathy include a once-per-week schedule instead of a twice-per-week schedule; subcutaneous administration is always preferred to intravenous.
- The standard dose of steroids to be used in MM therapy usually should not exceed dexamethasone 40 mg once per week (or equivalent), unless there is an emergent need.

CHAPTER TABLES AND IMAGES

Table 21-1 Revised International Staging System for Multiple Myeloma

Publication Year	Stage	Criteria	Frequency (% of Patients)	Median Survival or 5-Year Survival Rate (%)
ISS stage	1	Serum albumin >3.5 g/dL, serum β2-microglobulin <3.5 mg/L	29	62 months
	2	Neither ISS stage I nor III	37.5	44 months
	3	Serum β2-microglobulin >5.5 mg/L	33.6	28 months
R-ISS stage	1	ISS-I No high-risk cytogenetics Normal LDH	28	82%
	2	Neither ISS stage I nor III	62	62%
	3	High-risk cytogenetics [t(4;14), t(14;16), or del17p13] or elevated LDH level	10	40%
R2-ISS stage*	1	0 points	19.2	Not reached
	2	0.5-1 points	30.8	109.2 months
	3	1.5-2.5 points	41.2	68.5 months
	4	3-5 points	8.8	37.9 months

Abbreviations: ISS, International Staging System; LDH, lactate dehydrogenase; R-ISS, revised ISS.
*ISS-III, 1.5 points; ISS-II, del17p13, high lactate dehydrogenase, or t(4;14), 1 point; and 1q1 0.5 points.

Table 21-5 **Current Classifications of the Main MGCS-Related Disorders by Mechanism**

Disorder	Mechanism	Main Characteristics of Monoclonal Gammopathy	Organs and Symptoms Involved
Autoantibody activity			
Type II mixed cryoglobulinemia[a]	Immune complex	IgM	Immune complex-mediated vasculitis; skin +++, kidney, peripheral nerve; may be systemic
C1 inhibitor deficiency	C1 inhibitor		Angioedema
von Willebrand disease	vW factor		Bleeding
Bullous skin disease	Dermoepidermal junction (collagen VII)		Skin
Xanthomatosis	Various lipoproteins	Usually IgG	Cholesterol accumulation in macrophages, skin and tendons, other localizations (necrobiotic xanthogranulomatous)
Cold agglutinin disease	Red blood cell (Ii)	IgM	Cold-induced skin manifestations + intravascular hemolysis
IgM-associated peripheral neuropathy	MAG +++	IgM	Peripheral nerve; ataxic polyneuropathy (anti-MAG)
	Gangliosides	IgM	CANOMAD
CAP[a] activation			
C3 glomerulonephritis atypical hemolytic-uremic syndrome	Mechanism to be determined; autoantibody activity against CAP regulator protein (factor H) in some cases	IgG	Kidney only; systemic
Cytokine mediated			
POEMS syndrome	VEGF	λ LC (~100%), IgA 50% Vλ1 (~100%); osteosclerotic bone lesions	Peripheral nerve (100%) and various other manifestations
Unknown mechanism			
Systemic capillary leak syndrome		IgG, IgA (rare)	Systemic
TEMPI syndrome		IgG	Systemic
Neutrophilic dermatosis[b]		IgA >80% (except Sweet syndrome)	Skin +++; different types and different associated manifestations
Acquired cutis laxa		Usually IgG; association with γ HCDD	Skin +++; other manifestations (lung, digestive tract)
Scleromyxedema		IgG with slow electrophoretic mobility	Skin +++; other localizations
Scleredema		IgG	Skin only
Schnitzler syndrome	Acquired autoinflammatory syndrome by IL-1 deregulation?	IgM	Skin +++; systemic symptoms; osteosclerotic bone lesions
Sporadic late-onset nemaline myopathy			Exclusively muscles (skeletal and possibly cardiac)

Abbreviations: +++, significant involvement; CANOMAD, chronic ataxic neuropathy, ophthalmoplegia, IgM paraprotein, cold agglutinins, and disialosyl antibodies; CAP, complement alternative pathway; HCDD, heavy chain deposition disease; IgM, immunoglobulin M; IL-1, interleukin 1; MAG, myelin-associated glycoprotein; MGCS, monoclonal gammopathy of clinical significance; POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes; TEMPI, telangiectasias, elevated erythropoietin level and erythrocytosis, monoclonal gammopathy, perinephric fluid collection, and intrapulmonary shunting; VEGF, vascular endothelial growth factor; vW, von Willebrand (disease).

[a]Type II mixed cryoglobulinemia was observed in 10% of patients with chronic virus C infection.

[b]Including pyoderma gangrenosum, Sweet syndrome, subcorneal pustular dermatosis, and erythema elevatum diutinum.

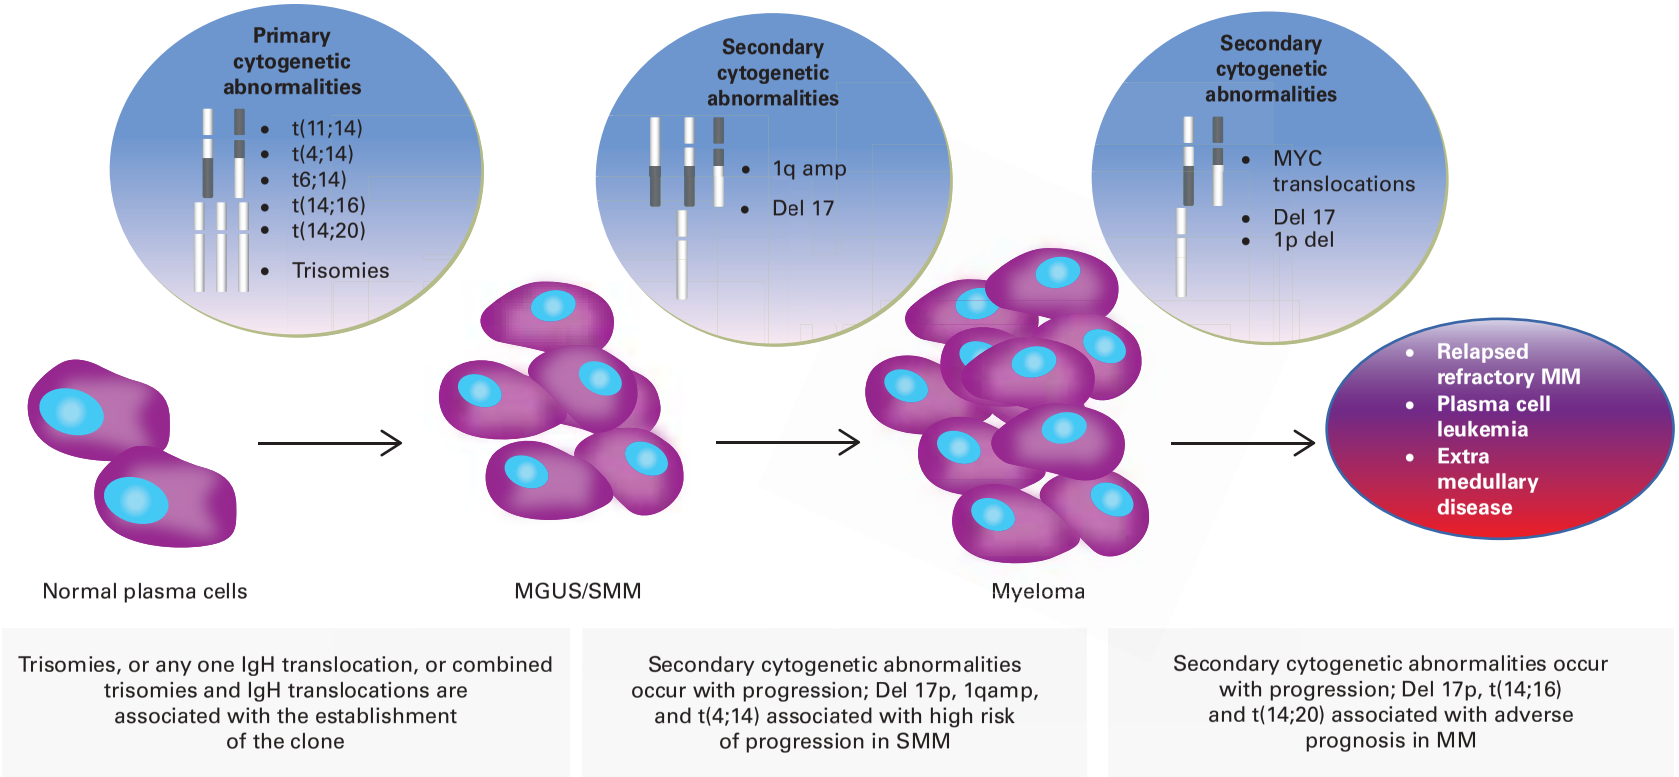
Figure 21-1 Cytogenetic Abnormalities in Multiple Myeloma



Primary cytogenetic abnormalities occur early when the normal plasma cell transitions to a clonal, premalignant stage. Most secondary cytogenetic abnormalities occur later in the disease course with malignant transformation or during progression of the malignancy. The effect of primary and secondary cytogenetic abnormalities on prognosis depends on the disease.

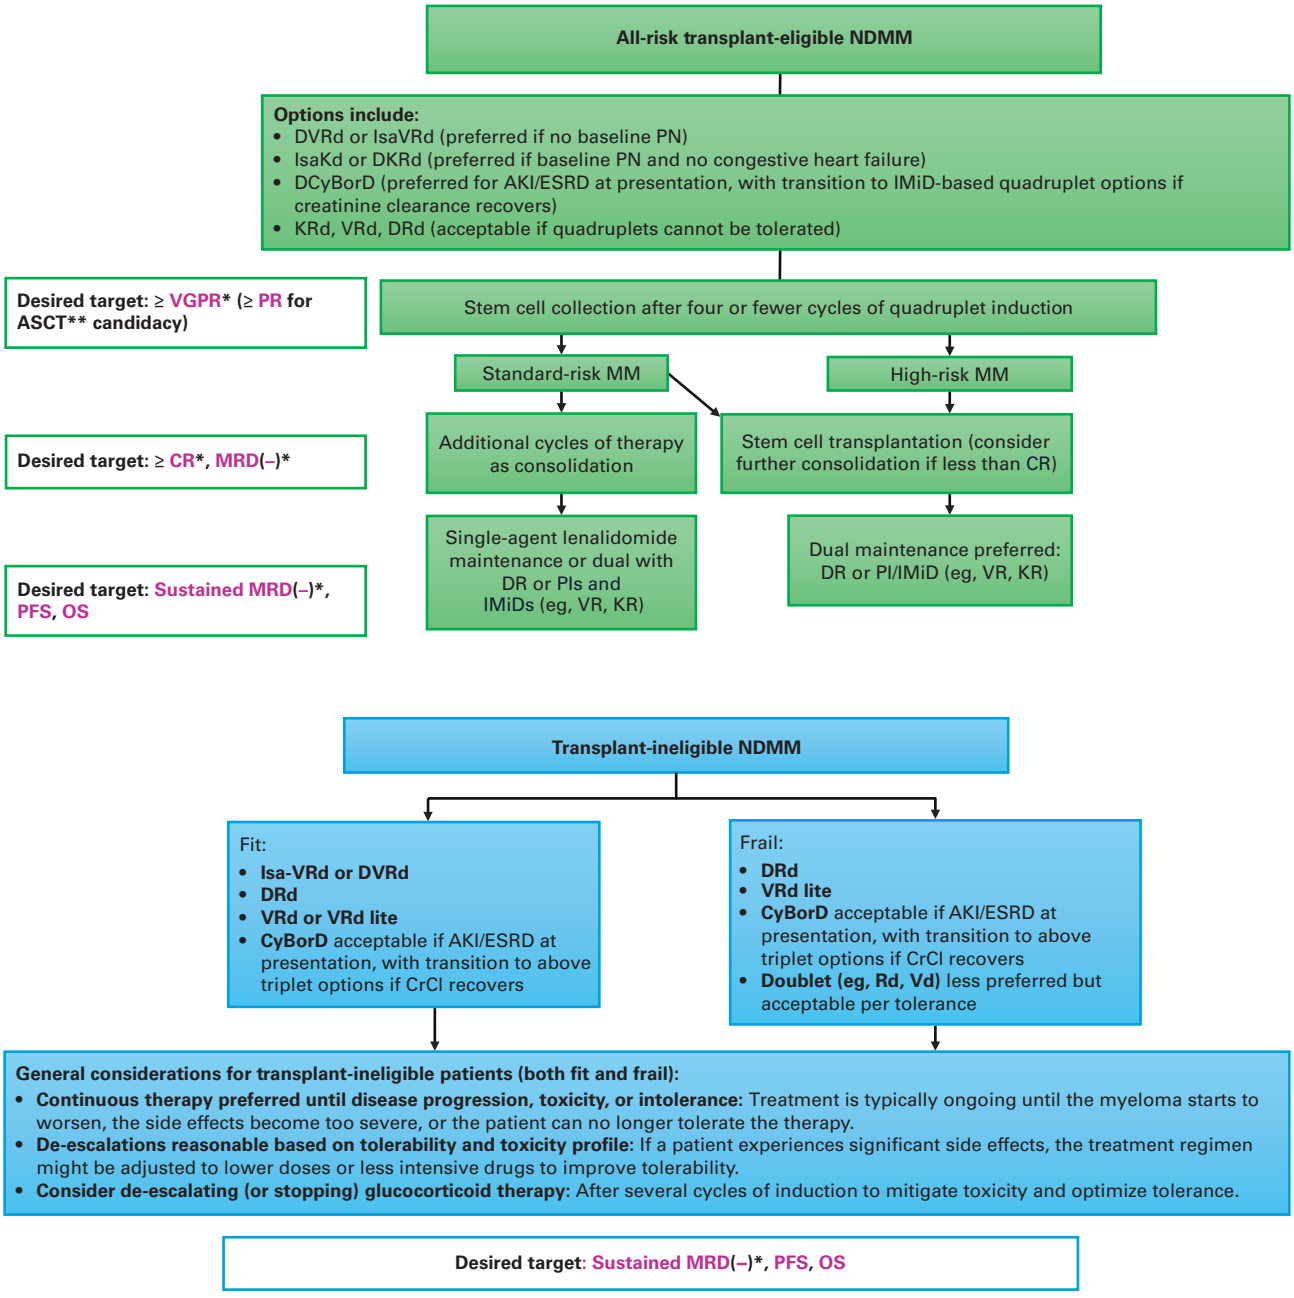
Figure 21-3 Treatment Approaches for Transplant-Eligible and Transplant-Ineligible Newly Diagnosed Multiple Myeloma



The primary goal of treatment for TE and TIE NDMM is to achieve a rapid, deep, and durable response. This aims to provide long-term disease control and ultimately improve patient prognosis.

Abbreviations: AKI, acute kidney injury; ASCT, autologous stem cell transplantation; CR, complete response; CrCl, creatinine clearance; CyBorD, cyclophosphamide, bortezomib, and dexamethasone; DCyBorD, daratumumab, daratumumab, cyclophosphamide, bortezomib, and dexamethasone; DKRd, daratumumab, carfilzomib, lenalidomide, and dexamethasone; DR, daratumumab and lenalidomide; DRd, daratumumab, lenalidomide, and dexamethasone; DVCd, daratumumab, bortezomib, cyclophosphamide, and dexamethasone; DVRd, daratumumab, bortezomib, lenalidomide, and dexamethasone; ESRD, end-stage renal disease; IMiD, immunomodulator (ie, lenalidomide or pomalidomide) drug; Isa-VRd, isatuximab, bortezomib, lenalidomide, and dexamethasone; Isa-KD, isatuximab, carfilzomib; and dexamethasone; KR, carfilzomib and lenalidomide; KRd, carfilzomib, lenalidomide, and dexamethasone; MM, multiple myeloma; MRD, minimal residual disease; NDMM, newly diagnosed multiple myeloma; OS, overall survival; PFS, progression-free survival; PI, proteasome inhibitor (ie, bortezomib, ixazomib, carfilzomib); PN, peripheral neuropathy; PR, partial response; Rd, lenalidomide and dexamethasone; Vd, bortezomib and dexamethasone; VGPR, very good partial responses; VR; bortezomib and lenalidomide; VRd, bortezomib, lenalidomide, and dexamethasone.

*Target indicates the desired level of response, and not a failure of treatment if not achieved.

**For ASCT step: minimum PR and ideally VGPR. Standard risk includes all cytogenetics that are not considered high risk; high risk includes any patient with one high-risk cytogenetic mutation such as del(17p), t(14;16), t(14;20), t(4;14), del(1p), amp(1q) or gain(1q); ultra-high risk includes any patient with more than one high-risk cytogenetic mutation.

CELLULAR THERAPIES 22

Eric J. Huselton, MD, and Mohamad Hussein, MD

RECENT UPDATES

- The FDA approved CD19-directed chimeric antigen receptor (CAR) T-cell therapy obecabtagene autoleucel for relapsed/refractory B-cell acute lymphoblastic leukemia based on high rates of complete remission and median duration of remission.[1]
- The FDA approved CD19-directed CAR T-cell therapy lisocabtagene maraleucel for mantle cell lymphoma, follicular lymphoma, and chronic lymphocytic leukemia after at least two previous lines of therapy based on the response rate and duration of response.[2]
- Motixafortide, a CXCR4 inhibitor, was approved by the FDA for use in the mobilization of stem cells with granulocyte-colony stimulating factor for use in autologous transplantation for multiple myeloma.[3]
- Axatilimab, a CSF1R-blocking antibody, was approved by the FDA for chronic graft-versus-host disease that has not responded to other treatments.[4]

OVERVIEW

The term hematopoietic cell transplantation (HCT) encompasses the transfer of lymphohematopoietic progenitors from an individual to themselves (autologous transplantation) or to another individual (allogeneic transplantation).[5] HCT serves various purposes, from replacing abnormal yet nonmalignant hematopoietic systems, such as in aplastic anemia, to treating a spectrum of hematologic malignancies. It achieves this by facilitating the administration of myeloablative doses of chemotherapy and/or radiotherapy and establishing an immunologic graft-versus-tumor (GVT) effect, particularly in the setting of allogeneic HCT. By 2021, an estimated 1.5 million HCTs had been performed worldwide, with rates increasing due in part to the availability of alternative donor sources such as partially matched, haploidentical donors and mismatched unrelated donors.[6,7] The frequency of HCT procedures varies significantly across countries, often correlating closely with the gross national income per capita. Nevertheless, substantial differences persist among countries with similar income levels, varying by HCT referral and frequency, disease indications, and donor choices. Furthermore, racial disparities have been identified within these practices, including differences in referral patterns.[8]

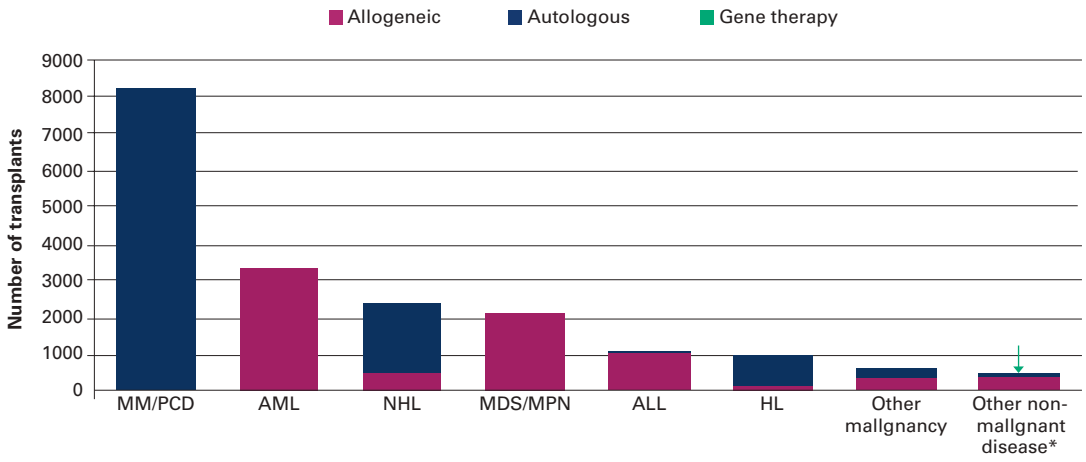
Chimeric antigen receptor (CAR) T-cell therapy shares similarities with HCT because both use cellular-based therapies to enhance immune responses against hematologic malignancies. Indeed, allogeneic donor lymphocyte infusion (DLI) in relapsed leukemia can be viewed as the first example of adoptive immune cell transfer. Subsequent advancements in gene-transfer techniques have enabled researchers to redirect T cells toward tumor-specific antigens. This chapter delves into the fundamental principles of cellular therapies, encompassing HCT, cell sources, preparative regimens, and associated complications. For a more comprehensive understanding of the role of HCT in treating specific diseases, further exploration is provided in dedicated chapters focusing on those ailments.

INDICATIONS

MALIGNANT DISEASES

The most frequent use of HCT has been for the treatment of malignant diseases.[9,10] The leading indication for autologous HCT in the United States is multiple myeloma (MM), followed by non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma (HL; Fig. 22-1). Prospective randomized trials have shown that autologous HCT, when used as part of initial therapy, prolongs remission for patients with MM. This finding still holds true in the era of modern myeloma therapy.[11-13]

Figure 22-1 Number of Hematopoietic Cell Transplantations in US (2023) Adults



Abbreviations: ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CLL, chronic lymphocytic leukemia; HL, Hodgkin lymphoma; MDS, myelodysplastic syndromes; MM, multiple myeloma; MPN, myeloproliferative neoplasms; NHL, non-Hodgkin lymphoma; PCD, plasma cell disorders.

Autologous HCT is curative for 40% to 50% of patients who have NHL or HL that recurred after first-line therapy; these results are superior to what would be expected with additional chemotherapy alone.[14-17] For patients who have diffuse large B-cell lymphoma (DLBCL) that is primary refractory to, or relapses within 12 months after initial chemotherapy, CD19-directed CAR T-cell therapies have shown superior event-free survival (EFS) and overall survival (OS) when compared with salvage chemotherapy and autologous transplantation in phase 3 trials.[18,19] Nonetheless, ongoing discussions persist regarding the role of high-dose chemotherapy with autologous HCT as part of initial therapy for patients who have high-risk NHL.[17-19] In addition, autologous HCT finds applications in primary central nervous system lymphoma and select chemotherapy-sensitive solid tumors with notable experiences in testicular cancer and neuroblastoma.[20] In the United States, the leading indications for allogeneic HCT are acute myeloid leukemia (AML; approximately 50% of cases), followed by myelodysplastic syndromes (MDS) and acute lymphoblastic leukemia (ALL).[10] HCT consistently yields 5-year disease-free survival (DFS) rates of 50% and 70% when performed during the first remission for AML and ALL, respectively.[21-23] Meta-analyses comparing matched-sibling allogeneic HCT versus conventional chemotherapy for adult patients who have these disorders have shown improved survival outcomes with HCT.[24-26] The benefits of HCT are most pronounced for patients who have higher-risk leukemia and are less so for those with lower-risk disease. Delaying HCT until the second remission in higher-risk patients results in less favorable outcomes, with cure rates limited to 25% to 40%. Relapse is the most common cause of post-transplantation mortality, and in general, patients who have better disease control and deeper remission before transplantation tend to experience better transplantation outcomes with less relapse. For patients who have MDS up to age 79 years, allogeneic HCT yields cure rates of 30% to 60% with improved OS compared with no HCT after hypomethylating agent therapy.[27-29] In patients with low-risk MDS who often live for long periods without treatment, HCT is typically reserved for those who have higher-risk disease.[30,31] Although more than 70% of patients who have chronic myeloid leukemia (CML) in the chronic phase can be cured with allogeneic HCT, it is usually restricted to patients whose disease has progressed after multiple tyrosine kinase inhibitor (TKI) therapies, those who cannot tolerate TKIs, or those with advanced disease states (ie, second chronic phase after blast crisis).[32] In addition, allogeneic HCT can reverse marrow fibrosis in primary myelofibrosis, serving as the sole potential curative option for these patients.[33] Allogeneic HCT is also used in the treatment of patients who have HL or NHL who have relapsed after autologous transplantation and/or CAR T-cell therapy, for recurrent chronic lymphocytic leukemia, and NHL with marrow involvement.[34] Although allogeneic HCT is used in a small subset of patients who have relapsed myeloma, considering the increased risk for transplant mortality in this setting, studies comparing reduced-intensity allogeneic transplantation with autologous transplantation have yielded conflicting results.[35,36]

NONMALIGNANT DISORDERS

The most prevalent data and best outcomes regarding allogeneic HCT for nonmalignant disorders of hematopoiesis are reported for severe aplastic anemia and thalassemia, with a growing experience in sickle cell anemia. Most patients who have severe aplastic anemia (90%) can be cured with allogeneic HCT from a matched sibling[37] or related haploidentical donor[38]; results are slightly less favorable if a matched unrelated donor (MUD) is used. Allogeneic HCT cures 70% to 90% of patients who have thalassemia

major, with the best results seen among patients who undergo transplantation before the development of hepatomegaly or portal fibrosis.[39] Although data on sickle cell disease are more limited, current reports document 5-year survival and DFS rates of 93% and 84%, respectively.[40,41] A recent Blood and Marrow Transplant Clinical Trials Network (BMT CTN) trial using reduced-intensity haploidentical bone marrow transplantation resulted in 2-year EFS of 88% and OS of 93%.[7] Cure has also been achieved in other nonmalignant disorders of hematopoiesis and immunodeficiency states, including Fanconi anemia, Diamond-Blackfan syndrome, chronic granulomatous disease, Kostmann syndrome, leukocyte adhesion deficiency, Wiskott-Aldrich syndrome, severe combined immunodeficiency disorders, and other immunodeficiency states. However, because allogeneic HCT has substantial and unpredictable complications, treatment recommendations should be based on identifying patients at high risk from their underlying diseases for whom the risk of HCT is justified.[42]

KEY POINTS

- All diseases of hematopoiesis, nonmalignant and malignant, are potentially curable with cellular therapy.
- The leading indication for autologous HCT in the United States is MM, followed by relapsed NHL and HL.
- Allogeneic HCT consistently leads to 5-year DFS rates of 50% to 70%, respectively, when performed for AML and ALL in first remission.

ELIGIBILITY

HCT is an intensive therapy with a high risk of adverse events and, in the case of allogeneic transplantation, transplantation-related nonrelapse mortality related to graft-versus-host disease (GVHD) and infectious complications. Patient evaluation for eligibility includes performance status, comorbidities, organ function, psychosocial status, social support, and disease status. Comorbidities can be associated increased risk of complications as scored by the HCT comorbidity index (HCT CI), which incorporates 14 comorbidities, including cardiac disease, arrhythmia, inflammatory bowel disease, diabetes, cerebrovascular disease, psychiatric conditions, hepatic dysfunction, obesity, active infection, rheumatologic disease, peptic ulcer, renal dysfunction, pulmonary dysfunction, and history of previous second cancer.[43] Having an HCT CI score of 3 or greater is associated with increased risk of treatment-related mortality following allogeneic transplant. Patients undergo assessment, including left ventricular function, pulmonary function testing, dental evaluation, infectious disease markers, social worker assessment, and laboratories assessing renal and hepatic function, as well as psychosocial factors such as the degree of caregiver support.

In earlier decades, various upper age limits of 65, 70, or 75 years were used for transplantation eligibility. With improvements in supportive care and use of reduced-intensity conditioning regimens, many centers no longer use an upper age cutoff, instead focusing on the aforementioned criteria for transplantation eligibility.

SOURCES OF STEM CELLS

Hematopoietic stem cells are $CD34^+$ progenitors used for HCT that can be categorized according to the relationship between the donor and the recipient or according to anatomic source (Table 22-1). In the rare instances in which the patient has an identical (syngeneic) twin, HCT can be conducted without the risk of graft rejection or GVHD because the individuals share genetic identity throughout the genome. However, these syngeneic HCTs confer fewer benefits of an immunologic effect, resulting in a higher risk of relapse of the underlying malignancy.[44]

Table 22-1 Cell and Donor Sources for Autologous and Allogeneic Hematopoietic Cell Transplantation

Type of Transplantation	Cell Source	Donor
Autologous	Bone marrow Peripheral blood	Recipient
Allogeneic	Bone marrow Peripheral blood Umbilical cord blood	Related Unrelated
Syngenic	Bone marrow Peripheral blood	Monochorionic twin

BONE MARROW

Because bone marrow is rich in hematopoietic stem cells, it was historically used as the source of stem cells for HCT. Typically, marrow for HCT is obtained through multiple aspirations from bilateral posterior iliac crests. The harvested marrow is treated

with heparin or anticoagulant citrate dextrose solution or both and filtered through screens to remove osseous spicules and fat globules before either being infused into the patient or being cryopreserved for later use. Some studies have explored pretreating the marrow before cryopreservation or infusion to investigate whether the removal of T cells or T-cell subsets from allogeneic marrow can improve outcomes by reducing GVHD or whether tumor cells can be eliminated before autologous stem cell transplant (SCT), although these kinds of product manipulations are not routinely done.[45] Bone marrow remains the preferred graft source when transplanting for aplastic anemia and other nonmalignant disorders due to its association with less GVHD.[37]

PERIPHERAL BLOOD

Hematopoietic stem cells circulate in the peripheral blood, albeit in small numbers. However, during recovery from drug-induced cytopenia or after exposure to hematopoietic growth factors, such as granulocyte-colony stimulating factor (G-CSF), the number of hematopoietic progenitor cells in the peripheral blood significantly increases.

Stromal cell-derived factor 1 (SDF-1 or CXCL12) produced by marrow stromal cells plays a critical role in regulating hematopoietic stem cell homing and retention in the marrow by interacting with the chemokine receptor CXCR4 found on stem cells. Plerixafor and motixafortide, antagonists of CXCR4, induce rapid mobilization of CD34 cells into the peripheral blood. In patients who have MM and NHL, phase 3 trials of stem cell mobilization with plerixafor in combination with G-CSF compared with G-CSF alone have demonstrated favorable safety and improved efficacy in the combination arm with respect to reaching target collection goals.[46,47] Comparisons with conventional chemotherapy mobilization have also suggested that the cost and risk of complications with chemotherapy-mediated mobilization outweigh the cost of plerixafor.[48] Other cost-containment approaches include using plerixafor on demand if $CD34^{6}$ stem cell numbers are suboptimal with G-CSF alone.[49] Motixafortide with G-CSF also resulted in higher collection yields than G-CSF alone in patients with MM. Factors associated with poor stem cell mobilization and collection include increasing age, underlying marrow disease, previous extensive radiotherapy to the marrow, and exposure to chemotherapies, including melphalan, fludarabine, and prolonged use of immunomodulatory agents such as lenalidomide.[50]

With the use of these and other mobilizing techniques, followed by leukapheresis, it has become feasible to collect sufficient stem cells from the peripheral blood to permit successful HCT. Peripheral blood has largely supplanted marrow as the preferred source of stem cells because of its association with faster engraftment, reduced cost, and improved safety. In allogeneic HCT, peripheral blood stem cell grafts are associated with more rapid engraftment but with a higher incidence of chronic GVHD, similar rates of acute GVHD and DFS, and perhaps improved OS, particularly for patients who undergo transplantation for more advanced-stage disease.[51] In the setting of unrelated donor transplantation, a large randomized study comparing marrow with peripheral blood after myeloablative conditioning showed faster engraftment but more chronic GVHD with peripheral blood, although with equivalent OS. However, this trial encompassed various hematologic malignancies, and limited data are available regarding reduced-intensity allogeneic transplantation.[52] A retrospective European study of peripheral blood SCT compared with bone marrow with reduced-intensity conditioning regimens for acute leukemia also showed an increase in chronic GVHD with peripheral SCT but better leukemia-free survival and OS.[51] Despite the necessity for a prospective randomized trial, the preference for many centers is to use peripheral blood stem cells over bone marrow for allogeneic transplantation, particularly for treating hematologic malignancies.

Donor risks differ depending on the stem cell source requested, with incidences of serious adverse events after bone marrow and peripheral blood stem cell donation reported at 2.4% and 0.6%, respectively. Severe adverse events after peripheral blood donation include pain, fatigue, and numbness/tingling, whereas for bone marrow donation, they are mainly pain, anemia, and complications related to anesthesia. Extremely rare serious events, including cardiac arrest, pulmonary embolism, and subdural hematoma, have been reported after marrow donations, and pulmonary embolism, supraventricular tachycardia, and splenic rupture have been reported with peripheral blood donation.[53,54]

Peripheral blood stem cell donation is safe and is not associated with an increased risk of cancer, autoimmune illness, or stroke. Guidelines have been developed to ensure the safety and suitability of unrelated adult donors and for the hematopoietic cell collection process.[55]

KEY POINTS

- In the MUD setting, use of mobilized peripheral blood stem cells showed faster engraftment, but more chronic GVHD compared with bone marrow. Use of plerixafor and motixafortide, antagonists of CXCR4, with G-CSF results in mobilization of CD34+ cells into the peripheral blood and high stem cell collection yields for autologous HCT.

AUTOLOGOUS TRANSPLANTATION

Over the past four decades, numerous clinical trials have been conducted to determine the suitability of high-dose therapy and autologous HCT for various diseases as well as the necessity for allogeneic HCT in certain cases. The use of a patient's own (ie, autologous) stem cells for HCT rescues them from the administration of myeloablative doses of chemotherapy. Approximately 60% of all HCTs are autologous. The leading indication for autologous HCT is MM[10] based on the studies dating back to the 1980s

that demonstrated the efficacy of high-dose melphalan conditioning followed by autologous HCT in achieving complete remission (CR). Subsequent trials in NHL have also shown superior progression-free survival (PFS) compared with traditional chemotherapy for relapsed disease, and that autologous transplant can be curative for a subset of patients with relapsed lymphoma.[56,57] Autologous HCT is also used in relapsed HL and occasionally in malignancies of nonhematopoietic origin, such as neuroblastoma and germ cell tumors.

ALLOGENEIC TRANSPLANTATION

Historically, the preferred source of allogeneic hematopoietic stem cells has been from a young human leukocyte antigen (HLA)-identical sibling, because greater HLA disparity and donor age are major drivers of post-HCT outcomes, specifically GVHD. HLA genes encode the major histocompatibility complex molecules that display exogenous peptides (eg, from an infecting organism) and endogenous peptides on nucleated cells, presenting them to T cells to initiate an immune response (Fig. 22-2). When two individuals are not HLA-identical, T cells from one person will vigorously react to the mismatched HLA molecules on the surface of cells from the other individual. Although non-twin siblings may be HLA matched, genetic polymorphisms in a wide range of genes can result in differences in the endogenous peptides presented by the HLA molecules. These differences lead to T-cell responses against minor HLA determinants, also known as minor histocompatibility antigens.

SIBLING DONORS

The genes encoding HLA class I (*HLA-A, HLA-B*, and *HLA-C*) and class II (*HLA-DP, HLA-DQ*, and *HLA-DR*) are located on chromosome 6, tightly linked, codominantly expressed, and inherited as haplotypes with low recombination frequency. Therefore, for any given patient, the following are true:

- The likelihood that a full sibling will be HLA matched with the patient is 25%.
- The likelihood of finding a matched sibling for a patient can be calculated by the formula $x = 1 - 0.75^n$, where x equals the probability of finding a matched sibling and n equals the number of siblings.
- Given the size of families in the United States, the chance that a matched sibling can be identified for any patient is approximately 30%.

HAPLOIDENTICAL DONORS

Family members who are genotypically identical to the patient for only one HLA haplotype are considered haploidentical. Whereas the chance of finding a fully matched sibling donor is 25% per sibling, and the chance of finding an MUD varies by patient ethnicity, most patients will have haploidentical donor options because there is a 50% chance of a sibling being HLA haploidentical and because biologic parents and children will always be haploidentical. Haploidentical HCT initially relied on ex vivo T-cell depletion to combat higher rates of severe GVHD and graft rejection; however, in vivo T-cell depletion using post-transplantation high-dose cyclophosphamide allows the safe use of haploidentical related donors as well as related, matched unrelated, or mismatched unrelated donors.[58] Over the past decade, haploidentical HCT with post-transplantation high-dose cyclophosphamide has become widely adopted because of the ease of finding donors, low cost, and favorable outcomes.[6,59] Retrospective analyses show similar outcomes between haploidentical and matched-sibling donors for patients who have AML in remission, haploidentical and sibling donors for patients who have ALL, and haploidentical donors and MUDs for patients who have MDS and HL and NHL.[60-65]

Furthermore, studies comparing alternative donors have shown similar outcomes between haploidentical HCT and umbilical cord blood transplantation.[66] Despite the early closure of a randomized phase 3 trial comparing umbilical cord blood transplantation with haploidentical transplantation because of poor accrual, the trial revealed improved 2-year OS and lower nonrelapse mortality with haploidentical HCT.[67]

UNRELATED DONORS

Given that most patients will not have an age-appropriate matched sibling donor, the most commonly used donors for allogeneic HCT are completely unrelated to the patient but are matched for *HLA-A, -B, -C*, *-DRB1*, and *-DQB1.* Since the establishment of the National Marrow Donor Program in 1986 and other international registries, more than 25 million healthy individuals have volunteered to serve as stem cell donors. However, the likelihood of finding a fully matched, available, unrelated donor varies among racial and ethnic groups, ranging from 75% for White individuals of European descent to a low of 16% for Black individuals of South and Central American descent.[68]

When compared with the outcomes of matched-sibling transplantation, transplantations from unrelated donors matched with the patient at *HLA-A*, *-B*, *-C*, and *-DRB1* are associated with greater morbidity, mostly from GVHD, but survival at 3 to 5 years after HCT is similar.[69] Initial studies of MUD HCT did not consider *HLA-DPB1* matching, but retrospective analyses suggest that a mismatch at *HLA-DPB1* is associated with increased risk of GVHD and reduced risk of disease relapse.[70] Subsequent studies investigating T-cell epitope matching at *HLA-DPB1* define mismatch as permissive (ie, sharing T-cell epitope groups) or nonpermissive (ie, mismatched T-cell epitope groups). When compared with nonpermissive mismatch, permissive *HLA-DPB1* mismatch was associated with improved rates of survival, nonrelapse mortality, and severe GVHD.[71,72] With advancements in HLA matching and management of post-transplantation complications, recent analyses have suggested comparable outcomes between matched-sibling and MUD transplantations, and even better outcomes when choosing a younger MUD compared to an older matched-sibling.[73] However, a single-antigen HLA mismatch still correlates with higher rates of GVHD and treatment-related mortality, resulting in a lower survival rate.[74] Whereas HLA matching plays a significant role in transplantation outcomes, other donor factors, including age, sex, parity, and cytomegalovirus (CMV) serology, have a measurable effect.[75] The use of post-transplantation cyclophosphamide for GVHD prophylaxis results in lower rates of GVHD and improved survival outcomes for many transplantation types, including patients undergoing mismatched unrelated transplantations, with similar transplant outcomes between HLA 10/10 MUDs and less than 10/10 matches.[76,77]

UMBILICAL CORD BLOOD

Cord blood stem cell units have a paucity of mature T cells, which allows for less-stringent criteria for HLA matching and permits the use of units with one or two antigen mismatches in comparison with the recipient. Studies have shown cord blood to be a viable source of abundant stem cells for HCT. Given the small number of mature T cells, the risk of GVHD with cord blood seems to be somewhat lower than the risk associated with similarly matched marrow, although the risk of graft rejection or failure may be greater. Matched-related cord blood can be used as a source of stem cells to treat family members who have hemoglobinopathies with survival rates similar to those of matched-sibling bone marrow HCT.[78] By far, the most common use of cord blood has been in the treatment of unrelated recipients who lack a matched donor.

Improved survival after cord blood transplantation is associated with higher cell dose, younger patient age, and a greater degree of matching.[79] A low cord blood cell dose increases the risks of graft failure, delayed hematopoietic engraftment, and delayed immune recovery, which historically limited cord blood HCT to children and smaller adults.[80] Trials exploring the use of double-cord transplantation (which provides a greater cord blood cell dose) have demonstrated that, whereas only one cord ultimately engrafts, the use of two cords reduces the risk of graft failure and is associated with an enhanced GVT effect.[81,82] However, there seems to be no advantage to using two cords in cases in which a single cord provides a sufficient number of cells, at least in children and young adults.[83] A phase 3 trial comparing transplantation with the nicotinamide-expanded umbilical cord blood product omidubicel with standard cord blood transplantation showed improved, faster neutrophil and platelet engraftment.[84] This product was FDA approved in 2023.[85]

ABO BLOOD GROUPS

Hematopoietic stem cells do not express ABO, so HCT can be carried out across ABO blood group barriers by removing incompatible red blood cells (RBCs) and/or isoagglutinins from the donor graft. However, even with appropriate manipulation of the donor graft, a major ABO mismatch (eg, recipient O and donor A) can result in immediate or delayed hemolysis of donor RBCs or red cell aplasia by persistent recipient isohemagglutinins (Table 22-2). On the other hand, a minor mismatch (eg, recipient B and donor O) can result in immediate hemolysis of recipient RBCs by donor-derived isohemagglutinins in the graft or delayed hemolysis of recipient RBCs by newly generated isohemagglutinins from donor lymphocytes, also known as passenger lymphocytes.

Table 22-2 **Table of Donor-Recipient ABO Compatibility With Potential Complications and Interventions**

Donor-Recipient ABO Compatibility				
	Blood Type			
Mismatch Type	Recipient	Donor	Potential Complications	Interventions
Major	O	A, B, AB	Acute hemolysis of donor RBCs	RBC reduction of the stem cell product
	A	AB	Delayed engraftment	
	B	AB	Pure red cell aplasia from recipient anti-donor isohemagglutinins	
Minor	A	O	Acute hemolysis from donor isohemagglutinin	Plasma reduction of the stem cell product
	B	O	Delayed hemolysis from passenger lymphocyte syndrome	
	AB	O, A, B		
Bidirectional	A	B	A combination of major and minor	A combination of major and minor
	B	A

AVAILABILITY OF ALLOGENEIC STEM CELL SOURCES

With the availability of matched-related donors, MUDs, single-antigen mismatched related donors, haploidentical donors, and cord blood units, a suitable source of allogeneic stem cells can be identified for the vast majority of patients requiring transplantation. Notably, alternative donor types offer expanded options for ethnic groups with limited access to unrelated donors. For most patients, a haploidentical donor is accessible because all biologic parents and children of a patient are haploidentical. One limitation in using haploidentical donors and mismatched unrelated donors is the presence of anti-donor HLA antibodies, usually stemming from parous women against paternal HLA antigens in their children or from exposure to multiple transfusions. In instances where another donor cannot be found, regimens for donor-specific antibody desensitization have been used successfully.[86] Although matched-related donors are generally preferred, there is a scarcity of prospective randomized trials comparing alternative donors.[67] Emerging evidence suggests relatively similar survival after matched-unrelated cord blood, unrelated cord blood, and haploidentical donor HCT, and choosing a younger donor may result in the best outcomes.[87-92] Thus, donor selection is often guided by donor characteristics such as age, sex, parity, CMV serostatus, and the experience of the transplantation center.

KEY POINTS

- Although GVHD after HCT is more common with MUDs than with matched siblings, survival rates seem similar.
- Methods have been developed that allow for the selection of permissive single-antigen mismatched donors.
- HCT using either a haploidentical or HLA-mismatched unrelated donor is feasible; subsequently, an allogeneic donor can be found for most patients in need.
- Use of post-transplantation cyclophosphamide results in a low rate of GVHD and similar outcomes between donor types.

PREPARATIVE REGIMEN

The chemotherapy, with or without radiotherapy, administered to patients directly before HCT is known as a high-dose conditioning for autologous transplant or preparative regimen for allogeneic transplant. The selection of a conditioning regimen depends on the disease being treated, the source of the stem cells, and the patient's comorbidities. The primary objectives of conditioning are to eradicate disease, create space for engraftment, and, in the case of allogeneic transplantation, sufficiently immunosuppress the host to prevent graft rejection. Patients who have severe combined immunodeficiency diseases often require no preparative regimen before HCT because of the absence of an abnormal cell population requiring eradication; their severely compromised immune system rarely rejects infused hematopoietic cells if the donor is an HLA-matched sibling. By contrast, patients who have aplastic anemia are sufficiently immunocompetent to potentially reject allogeneic stem cells without pretransplantation immunosuppression. More recently, the Hopkins team and the BMT CTN have shown excellent outcomes when using a regimen of fludarabine, cyclophosphamide, and total body irradiation (TBI) followed by PTCy, likely replacing high-dose cyclophosphamide

and antithymocyte globulin (ATG) as the preferred preparative regimen for allogeneic HCT in aplastic anemia.[93] When HCT is used in the treatment of leukemia or other malignant diseases, the regimen must include myelosuppression as well as immunosuppression (in the setting of allogeneic HCT) to contribute to the eradication of the malignant disease. In the case of autologous HCT for lymphoma and myeloma, eradication of the malignant clone is the main goal of the high-dose conditioning regimen.

Conditioning regimens for allogeneic HCT are typically classified into three main categories: myeloablative, nonmyeloablative, and reduced intensity. Myeloablative regimens induce irreversible marrow aplasia and require replacement of the hematopoietic system; nonmyeloablative regimens cause minimal marrow suppression, and reduced-intensity conditioning results in cytopenias of intermediate duration.[94-96] Initially, high-dose myeloablative preparative regimens were the primary approach to HCT to treat malignant diseases. However, the recognition that antitumor effects occur after allogeneic HCT because of a GVT response prompted investigations into reduced-intensity regimens that might demonstrate comparable efficacy with less toxicity. Evidence supporting a GVT effect includes lower relapse rates after allogeneic marrow HCT when acute or chronic GVHD develops, higher rates of relapse in the absence of GVHD, and even higher rates with syngeneic or T-cell–depleted allogeneic marrow transplantation.[44,97] Additional evidence of a potent GVT effect comes from the use of viable DLIs. A simple transfusion of as few as 1×10^7 viable donor lymphocytes per kg as treatment for patients whose disease relapses after allogeneic HCT can result in CR for as many as 70% of patients who have CML and for a smaller portion of patients who have AML or MDS.[98]

Compared with high-dose preparative regimens, nonmyeloablative and reduced-intensity regimens result in less or minimal mucositis, fewer bacterial infections, and a lower incidence of direct toxicities to the lung and liver. However, these benefits are offset by generally higher relapse rates associated with reduced-dose regimens. A prospective randomized phase 3 trial demonstrated increased relapse rates and shortened survival with the use of reduced-intensity conditioning compared with myeloablative conditioning in patients who have AML or MDS.[99] Consequently, reduced-intensity conditioning is generally reserved for older patients and those who have substantial comorbidities, whereas high-dose regimens are preferred for younger, fit patients. Patients who have experienced relapse after autologous transplantation and are candidates for an allogeneic approach often receive reduced-intensity conditioning in an attempt to maximize efficacy and minimize organ toxicity. Suggested dose adjustments for patients with renal or hepatic impairment have been published.[100,101]

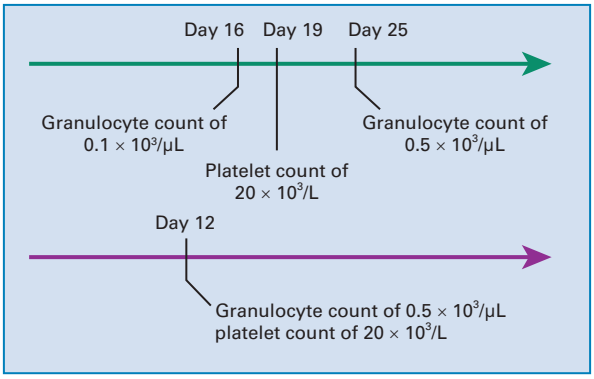
KEY POINTS

- The purpose of the high-dose regimen used before autologous HCT is to eradicate the underlying disease.
- The purpose of the preparative regimen in allogeneic HCT is to sufficiently immunosuppress the patient to prevent graft rejection and to eliminate residual disease.
- Evidence points to increased relapse rates and diminished survival with the use of reduced-intensity conditioning compared with myeloablative conditioning in patients with AML or MDS.

ENGRAFTMENT

After the administration of a preparative regimen and the infusion of stem cells, a period of profound myelosuppression ensues. Within 1 to 3 weeks after HCT, the peripheral neutrophil count begins to rise, indicating engraftment. When stem cells are procured from marrow without the use of hematopoietic growth factors after HCT, the granulocyte count typically reaches 0.1×10^3/mL by

Figure 22-3 Timeline of Granulocyte and Platelet Count Recovery After Hematopoietic Cell Transplantation Using Bone Marrow and Peripheral Blood Stem Cells



Graphical representation of a mechanism in which donor and recipient markers can mismatch (top) or match (bottom).

approximately day 16 and 0.5 × 10^3/mL by day 25, and platelets reach 20 × 10^3/L by day 19 (Fig. 22-3). Administration of daily G-CSF can accelerate the recovery of peripheral granulocyte counts by up to 1 week. Platelet count recovery typically lags behind neutrophil engraftment, usually by several days but possibly by several weeks for some patients.

When peripheral blood is the source of stem cells, engraftment is faster, with a granulocyte count of 0.5 × 10^3/mL and a platelet count of 20 × 10^3/mL achieved by day 12, on average. Engraftment after cord blood HCT is typically delayed by approximately 1 week compared with marrow HCT. Engraftment of allogeneic stem cells can be documented using fluorescence in situ hybridization of sex chromosomes if the donor and recipient are of opposite sexes, and DNA-based assays of short tandem repeat loci allow for routine monitoring of donor-versus-recipient cell origin (chimerism) post-transplantation. Loss of chimerism is an indicator of graft failure and disease relapse.

KEY POINTS

- By using in situ hybridization with sex chromosome–specific probes or typing of the variable number of tandem repeat polymorphisms, the donor-versus-recipient origin of populations of cells can be determined in virtually all cases in allogeneic HCT to assess engraftment and monitor for disease relapse.
- Loss of chimerism is an indicator of graft failure and/or disease relapse.

COMPLICATIONS OF HCT

The nature and the degree of complications associated with HCT depend on the age and health of the patient, the specific preparative regimen used, and the source of stem cells (Fig. 22-4). The frequency of complications is higher, and the rate of survival is lower for patients who have a Karnofsky performance score less than 80% and for patients who have substantial comorbidities.[102] GVHD is normally seen only after allogeneic HCT, although it can, in rare cases, be a complication of autologous transplantation, and subsequent infections related to the immunosuppression used to prevent or treat GVHD are leading causes of nonrelapse morbidity and mortality. The extent of other specific organ toxicities depends largely on the specific preparative regimen used. HCT-specific scoring systems have been developed that can predict the overall likelihood of GVHD and overall mortality after allogeneic HCT. Such systems are useful in the selection of preparative regimens for individual patients, allowing those who have few comorbidities to have the benefit of more intense regimens and selecting safer, less intense regimens for those with substantial comorbidities. The following sections discuss the major complications of HCT.

GRAFT FAILURE

Failure to engraft occurs when there is no engraftment of donor cells. In some instances, the transplanted graft functions briefly, but after a period of days or weeks, marrow function is lost, and myeloid elements are absent on evaluation of marrow obtained by biopsy. In the setting of allogeneic HCT, failure of the graft is usually the result of residual host immune elements rejecting the donor marrow, a phenomenon termed graft rejection. After HCT involving an HLA-identical donor, graft rejection occurs most commonly when the patient has received multiple transfusions before HCT and little previous chemotherapy, and when the preparative regimen is less immunosuppressive. In general, the greater the disparity in HLA antigens between donor and recipient, the higher the chance of rejection. Donor-specific anti-HLA antibodies are found in approximately 10% of patients before partially matched cord blood HCT, in mismatched unrelated-donor HCT, and in haploidentical donor HCT, when their presence predicts a high rate of graft rejection, and use of such donors should be avoided.[103] Desensitization techniques can reduce these antibodies to levels permissible for donor engraftment.[104]

Because donor T cells help eliminate host immunocompetent cells not eradicated by the preparative regimen, T-cell depletion of donor stem cells before HCT can lead to persistence of host immunity, resulting in an increased chance of graft rejection.

Graft failure rarely occurs in recipients of autologous transplants.[105] A single cause is often difficult to identify, but several have been implicated, including the following:

- Previous exposure to stem cell poisons
- Marrow damage during in vitro processing and cryopreservation
- Drug toxicity after HCT
- Viral infections

Patients who have graft failure but not immunologically mediated graft rejection sometimes have a response to treatment with a hematopoietic growth factor, such as G-CSF, with an increase in the granulocyte count that may be sustained even after discontinuation of the growth factor. If persistent host lymphocytes are detected that document graft rejection, a second marrow transplantation after an immunosuppressive preparative regimen may be successful.

GRAFT-VERSUS-HOST DISEASE

GVHD is a complication mediated by allogeneic T and B cells, which are transfused with the graft, reacting against non-hematopoietic tissues on the genetically different host that they regard as foreign. The evolution of clinical immunology has brought additional insight into the pathogenesis of GVHD and identified, in addition to the genetic component (ie, HLA compatibility), an immunobiologic component, including the intestinal epithelium and gut microbiome. A National Institutes of Health consensus report recognizes two categories of GVHD, acute and chronic, each with two subcategories (Table 22-3).[106] Acute GVHD usually develops 2 to 42 weeks after allogeneic HCT and typically presents with an erythematous or maculopapular rash, nausea, vomiting, anorexia, diarrhea (sometimes profuse), ileus, and/or cholestatic jaundice. Sometimes, the diagnosis can be less straightforward, and a skin, liver, or gastrointestinal biopsy specimen may be required.

Table 22-3 Categories of Acute and Chronic GVHD

Category[107]	Time of Symptoms After HCT	Presence of Acute GVHD Features	Presence of Chronic GVHD Features
Acute GVHD			
Classic acute	≤100 days	Yes	No
Late onset	>100 days	Yes	No
Chronic GVHD			
Classic Chronic	No time limit	No	Yes
Overlap	No time limit	Yes	Yes

Abbreviations: GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation.

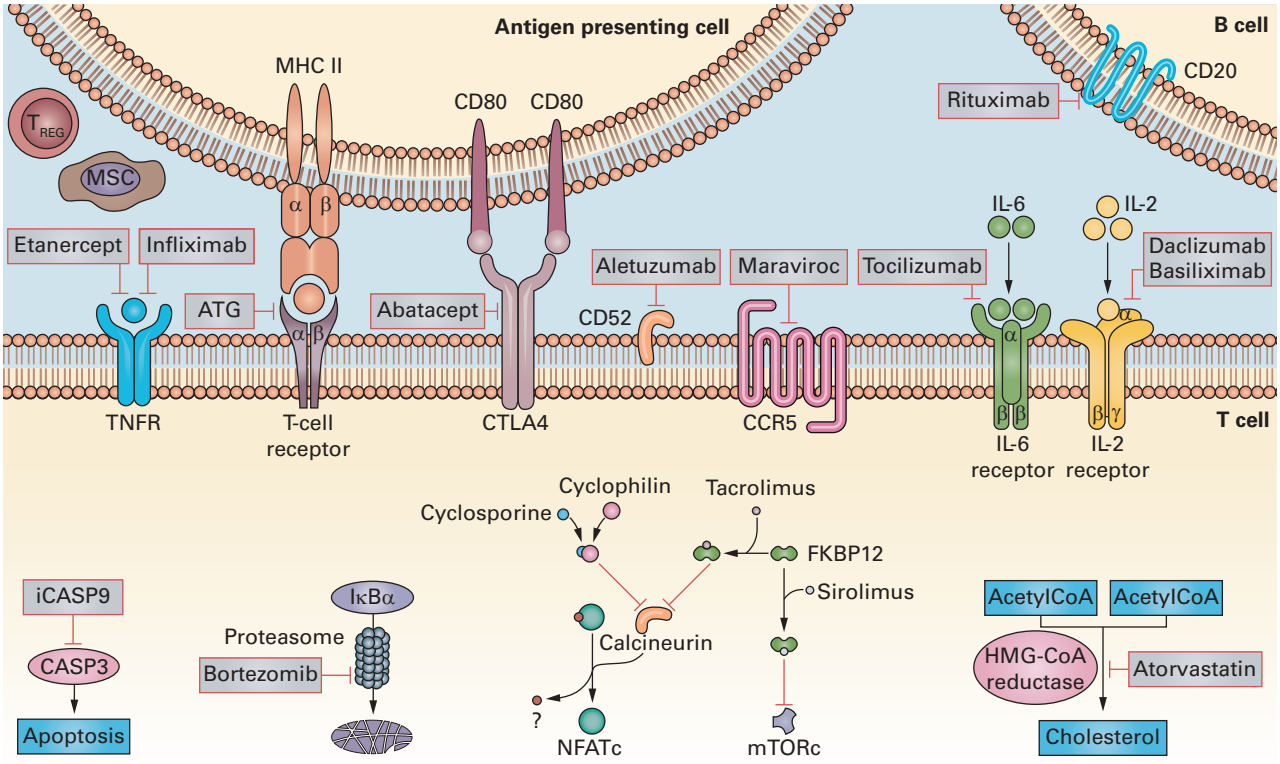
Factors associated with an increased risk of moderate or severe acute GVHD include the following:

- HLA mismatching
- Choice of GVHD prophylaxis regimen
- Older age of patient and donor
- A multiparous woman as the donor
- Exposure to more intensive conditioning regimens

GVHD PROPHYLAXIS

Immunosuppression remains the main prophylactic approach in GVHD (Fig. 22-5). The most commonly used regimens to prevent GVHD include a combination of a calcineurin inhibitor (cyclosporine or tacrolimus) and an antimetabolite (methotrexate [MTX] or mycophenolate mofetil) and/or post-transplantation cyclophosphamide.[108]

Figure 22-5 Standard and Emerging Therapies for the Prevention of Acute GVHD



Abbreviations: Acetyl CoA, acetyl coenzyme A; ATG, anti-thymocyte globulin; CCR5, C-C chemokine receptor 5; CLTA4, cytotoxic T lymphocyte antigen 4; FKBP12, FK506 binding protein 12; GVHD, graft-versus-host disease; HMG CoA reductase, 3-hydroxy-3-methyl-glutaryl coenzyme A reductase; iCasp9, inducible caspase 9; IkB, nuclear factor of kappa light polypeptide gene enhance in B cells inhibitor; IL, interleukin; MHC II, major histocompatibility class II; MSC, mesenchymal stem cell; mTORC, mammalian target of rapamycin complex; NFATc, nuclear factor of activated T cells cytoplasmic; TNFR, tumor necrosis factor receptor; TREG, regulatory T-cell.
The different medications and their targets against B cells and T cells are illustrated in this figure. MSC and TREG infusions are depicted extracellularly.

Post-transplantation cyclophosphamide is increasingly used to target proliferating alloreactive T cells stimulated early after transplantation. Although initially developed for haploidentical transplantation, post-transplantation cyclophosphamide can serve as the only GVHD prophylaxis after HLA-matched HCT and is associated with a similar incidence of acute GVHD and OS and reduced chronic GVHD rates compared with traditional calcineurin-based prophylaxis.[109,110] In a randomized phase 3 trial of patients with AML or MDS who are undergoing transplantation from a closely matched donor with reduced-intensity conditioning, use of post-transplantation cyclophosphamide with tacrolimus and mycophenolate resulted in lower rates of severe acute and chronic GVHD when compared with tacrolimus and methotrexate.[111,112] A randomized phase 3 trial of patients receiving myeloablative conditioning with an HLA-matched marrow graft showed that single-agent post-transplantation cyclophosphamide resulted in rates of chronic GVHD and OS similar to rates achieved with tacrolimus and MTX with less relapse.[113] Three prospective randomized trials reported that the addition of ATG to standard prophylaxis led to lower rates of acute and chronic GVHD without affecting OS with myeloablative conditioning.[114] Although the European trials did not show a higher risk of relapse, the US prospective trial with reduced-intensity conditioning did.[115] Other approaches to preventing GVHD include the ex vivo removal of T cells from the donor marrow, but this approach is not widely used because of concerns of increased risk of relapse.[116] Abatacept, a CTLA-4 immunoglobulin that blocks T-cell costimulation, is an FDA-approved agent for GVHD prophylaxis in combination with calcineurin inhibitors and MTX based on the studies that show lower rates of severe acute GVHD.[117] Ongoing trials are evaluating the role of extended-dose abatacept in the prevention or treatment of steroid-refractory chronic GVHD.

ACUTE GVHD

With standard regimens, such as MTX plus tacrolimus, moderate acute GVHD requiring therapy occurs in approximately 30% of patients who have undergone HCT with a matched-sibling donor. Acute GVHD is usually staged and graded using a modification of the original Seattle system, which uses a four-stage system in which a higher stage is associated with worse mortality.[118]

Standard treatment of acute GVHD is prednisone at a daily dose of 2 mg/kg, although a lower dose of 1 mg/kg may be used for grades 1 to 2 acute GVHD; nonabsorbable steroids such as budesonide or beclomethasone for gastrointestinal GVHD and steroid ointments for skin GVHD are beneficial.[119] The optimal duration of steroid therapy is unknown, but it should be as limited as possible to avoid the adverse effects of prolonged therapy. However, approximately 35% to 45% of patients will be refractory to steroid therapy.[120] Steroid-refractory acute GVHD is defined as failure of GVHD to clinically respond to standard steroid therapy, and care of these patients remains a major challenge. Treatment options include secondary immunosuppressive agents, JAK inhibitors, or ATG. The JAK inhibitor ruxolitinib showed a greater overall response rate (ORR) with longer failure-free survival in a randomized phase 3 trial of steroid-refractory acute GVHD.[121] Other treatment options with limited data or that are currently in clinical trials include sirolimus, abatacept, etanercept, extracorporeal photopheresis, alpha 1 antitrypsin, and monoclonal antibodies.

In an effort to prognosticate acute GVHD at its onset and better risk-stratify treatment of patients with GVHD, a scoring system (Ann Arbor score) based on three biomarkers (TNFR1, ST2, and REG3a) was developed and validated.[122] The GVHD biomarker-based classification (Ann Arbor score 1-3), combined with a refined clinical risk score by one group,[123] has been incorporated into a few therapeutic clinical trials for newly diagnosed acute GVHD.

PRESENTING CASE STUDY

A 55-year-old woman was diagnosed with acute myeloid leukemia (AML) with a normal karyotype and mutations in ASXL1, IDH1, and SRSF2. She received 7+3 and achieved complete remission that was negative for measurable residual disease by flow cytometry. She subsequently received a cycle of high-dose cytarabine and a matched-unrelated donor allogeneic stem cell transplant with myeloablative conditioning. Her conditioning regimen includes busulfan and fludarabine, and graft-versus-host disease (GVHD) prophylaxis including tacrolimus, mycophenolate mofetil, and post-transplant cyclophosphamide. On day 30 after stem cell infusion, she develops abdominal discomfort, persistent nausea, and 10 episodes of watery diarrhea per day and presents to the hospital. Infection was ruled out, and sigmoidoscopy demonstrates erythema, aphthous lesions, and denudation of the mucosa. Biopsy is notable for crypt cell necrosis.

How would these findings inform your treatment decision?

Given the risks associated with GVHD therapy, making the correct diagnosis is critical. The patient's clinical history, combined with negative evidence of infection, physical examination, endoscopic evaluation, and histology confirm a diagnosis of gut GVHD. Her volume of diarrhea qualifies this as grade 3 acute GVHD of the gut. Corticosteroids, both topical and systemic, are first-line therapy for grade 3/4 acute GVHD. She is started on methylprednisolone 2 mg/kg/day and oral budesonide three times daily. Her symptoms failed to improve after 7 days.

How would her response influence your next treatment recommendations?

Many patients respond to corticosteroid therapy, in which case steroids can be gradually tapered. GVHD symptoms that worsen within 5 days or do not improve after 7 days are considered steroid-refractory disease. Based on the REACH2 trial, a randomized, open-label phase 3 trial that evaluated ruxolitinib versus the best available therapy in patients with steroid-refractory acute GVHD, ruxolitinib therapy led to significant improvements in overall response at day 28 and durable overall response at day 56 (40% vs 22%) with longer median failure-free survival and overall survival. Other treatment options include ATG, extracorporeal photopheresis, sirolimus, and abatacept, although data for these approaches are lacking.

CHRONIC GVHD

Chronic GVHD affects 20% to 40% of matched-sibling HCT recipients and manifests as a condition resembling collagen vascular disease involving skin, liver, eyes, mouth, upper respiratory tract, and esophagus, and, less frequently, serosal surfaces, female genitalia, and fascia.[124] A National Institutes of Health consensus project developed a detailed staging system for chronic GVHD

in which 12 organ systems are graded from 0 (no symptoms) to 3 (severe involvement), and these 12 scores are then combined into a severity score for chronic GVHD.[125]

Factors associated with increased risk of chronic GVHD include the following:

- Higher degree of HLA mismatching
- Use of peripheral blood stem cells instead of marrow
- Older patient age
- Increasing donor age
- Sex disparity between donor and recipient (especially a female donor to a male recipient)
- Previous donor alloimmunization through pregnancy or blood transfusion in the donor
- Previous episodes of acute GVHD

If chronic GVHD develops while the calcineurin inhibitor is being tapered, increasing the inhibitor to therapeutic levels may be effective in resolving GVHD. Mild chronic GVHD can sometimes be managed using local therapies alone (eg, topical steroids to the skin and cyclosporine eye drops). More severe diseases usually require prednisone alone or in combination with a calcineurin inhibitor, which can control chronic GVHD in 50% to 70% of cases. Steroid-refractory chronic GVHD remains a clinical challenge. A randomized controlled phase 3 trial comparing ruxolitinib with best available therapy for patients with moderate or severe chronic GVHD refractory to or dependent on steroids showed better ORR (50% vs 26%) and longer failure-free survival (>18.6 months vs 5.7 months) with ruxolitinib. The Bruton TKI ibrutinib is currently approved to treat refractory chronic GVHD based on a single-arm trial showing an ORR of 69% and a complete response rate of 31% in patients with steroid-refractory or -dependent GVHD.[126] The Rho-associated protein kinase 2 inhibitor belumosudil was approved to treat chronic GVHD that persists after two or more lines of treatment based on a phase 2 study showing an ORR of 74% with 44% of patients continuing to receive therapy for more than 1 year. Notably, responses were seen when treatment with ruxolitinib and ibrutinib failed.[127] Axatilimab, a monoclonal antibody targeting CSF-1R primarily on macrophages, was associated with an ORR of 74%, with 60% of the responses being durable for more than 12 months.[128] Other treatment options for patients who have multiply refractory chronic GVHD include mycophenolate mofetil, sirolimus, extracorporeal photopheresis, rituximab, or low-dose interleukin (IL)-2.[129,130]

Eventually, immunosuppression can be tapered and discontinued in 80% to 90% of patients. However, achieving tolerance may require many months to several years of immunosuppressive therapy, with the median duration of treatment typically ranging from 2 to 3 years. Bacterial infections frequently occur in patients with chronic GVHD who are receiving immunosuppressive therapy, thereby requiring the use of prophylactic antimicrobials. A commonly used regimen includes trimethoprim and sulfamethoxazole plus penicillin, which provides protection against both *Pneumocystis jirovecii* and encapsulated organisms. The choice of antifungal prophylaxis varies among medical centers but may include agents such as fluconazole, isavuconazole, posaconazole, or voriconazole. Invasive molds, predominantly aspergillosis, are a major cause of post-transplantation mortality in patients with chronic GVHD who require long-term steroids.

AUTOIMMUNE DISORDERS

After allogeneic HCT, an autoimmune disorder may develop in 3% to 5% of patients, most commonly in the form of autoimmune hemolytic anemia or idiopathic thrombocytopenic purpura. Unrelated-donor source and chronic GVHD are risk factors. Treatment potentially involves cyclosporine, prednisone, or rituximab.

KEY POINTS

- T cells in the donor graft, combined with allogeneic targets on the genetically different host, are a major driver in the development of GVHD.
- Biomarker approaches for diagnosis and risk stratification are under study.
- Post-transplantation cyclophosphamide and ATG reduce rates of acute and chronic GVHD.
- Ruxolitinib is an effective treatment for steroid-refractory acute and chronic GVHD.

INFECTIOUS COMPLICATIONS

Infection is a major risk for nearly all transplant recipients. Recipients of autologous transplants are at risk for the early bacterial and fungal infections common to all patients who have granulocytopenia. Recipients of allogeneic hematopoietic grafts, particularly patients in whom GVHD develops, are also at risk for late-onset bacterial, fungal, and viral diseases. Use of prophylactic antimicrobials is an important part of managing infectious risks in these patients.[131]

BACTERIAL AND FUNGAL INFECTIONS

During the early neutropenic period after HCT, patients are likely to become febrile, and in approximately 50% of patients with febrile neutropenia, a bacterial source can be identified. Before engraftment, a fluoroquinolone is often administered if myeloablative conditioning regimens are used because they result in severe mucosal damage that facilitates bacterial translocation under profound immunosuppressive conditions. After engraftment, fluoroquinolone prophylaxis is typically discontinued, but patients who remain at risk for infection may receive antibiotics, including penicillin and trimethoprim plus sulfamethoxazole. Prophylaxis against fungal pathogens has been shown to reduce rates of fungal infection and improve OS. Prophylaxis with fluconazole is generally recommended for patients at standard risk, whereas prophylaxis with a mold-active agent should be considered for patients who have higher-risk disease, including patients who have had a previous fungal infection or recipients of a cord-blood or unrelated-donor transplantation. Although approaches vary, one standard approach is to continue fungal prophylaxis for 75 days after allogeneic HCT and until resolution of neutropenia after autologous HCT. Although having had a previous invasive fungal infection increases transplantation risk, with current methods of prophylaxis, it should not be considered a contraindication for HCT.[132] Patients who become or remain febrile despite treatment with broad-spectrum antibiotics and who have no obvious source of infection are usually treated with alternative antifungal agents (eg, voriconazole, isavuconazole, micafungin, or amphotericin lipid formulation, depending on the clinical situation).

With current methods of supportive care, the risk of death as a result of infection during the early granulocytopenic period after HCT is less than 3% for recipients of either allogeneic or autologous transplantations. Protective environment rooms incorporate the use of high-efficiency particulate air filters with 99.97% efficiency in removing particles larger than 0.3 mm to minimize the risk of infection from spores.

HERPES SIMPLEX INFECTION

Herpes simplex infection, which can contribute to the severity of oral mucositis, can be prevented with the use of systemic acyclovir, beginning during conditioning. At many centers, acyclovir is continued for up to 1 year to prevent late infection or reactivation with varicella zoster virus and is often continued even longer in patients receiving immunosuppression therapy. The new zoster vaccine containing varicella zoster virus glycoprotein E and the ASo1B adjuvant system was shown to be safe and effective in a phase 3 trial that included patients who had undergone autologous transplantation.[107] This finding led to the addition of this vaccine to the post-autologous HCT immunization schedule. Single-center cohort studies have suggested that it is safe to use after allogeneic HCT and does not increase the rate of GVHD, although its immunogenicity may be decreased.[133]

CMV INFECTION

In the past, symptomatic CMV infection, which typically involved either the gastrointestinal tract or the lungs, occurred in approximately 25% of patients who received allogeneic transplantations and led to death (typically resulting from CMV pneumonia) in 10% to 15% of patients. The improvement in control and prevention of CMV in HCT has had a substantial effect on the improvement in OS.

A randomized trial evaluated the prophylactic use of ganciclovir until day 100 after transplantation and demonstrated no difference in CMV infection by day 180 and similar OS. In addition, patients in the ganciclovir arm had a higher incidence of fungal and bacterial infections.[134] Therefore, preemptive therapy using blood polymerase chain reaction monitoring is standard practice rather than prophylactic therapy. However, even with this approach, early CMV reactivation remains associated with increased mortality.[135,136] Use of letermovir, an oral agent that inhibits CMV replication, led to a reduction in clinically significant CMV infection (37.5% vs 60.6% in the control group) in a placebo-controlled trial. It was well-tolerated and did not have the myelotoxic effects associated with ganciclovir; moreover, it offers a small survival advantage. Therefore, the use of letermovir was approved for prophylaxis in seropositive recipients after transplantation until day 100. Extended use may also be considered in high-risk patients.[137] Maribavir is approved for the treatment of CMV infections refractory to standard therapy.[138] Foscarnet is effective for some patients in the context of ganciclovir resistance, as well as for patients who cannot tolerate ganciclovir. Foscarnet, however, can be associated with severe electrolyte wasting and renal compromise.

PNEUMONIA

Pneumonia resulting from infection with *P. jirovecii*, previously seen in 5% to 10% of transplant recipients, can be prevented by treatment with oral trimethoprim and sulfamethoxazole for 1 week before HCT, with resumption of prophylaxis once the granulocyte count exceeds 0.5×10^3/mL. Treatment 2 days per week when patients are receiving immunosuppressive drugs after HCT is usually sufficient to prevent *Pneumocystis* infection. Allergic reactions to trimethoprim and sulfamethoxazole are common, and dapsone, atovaquone, or pentamidine can serve as a substitute for trimethoprim plus sulfamethoxazole.

COMMUNITY-ACQUIRED VIRAL INFECTIONS

Community-acquired viral infections, including COVID-19, respiratory syncytial virus (RSV), influenza virus, and parainfluenza virus, can cause lethal pneumonias in patients undergoing transplantation. Patients with upper respiratory symptoms before

HCT should be screened by nasopharyngeal lavage for viral infections before proceeding to HCT. If COVID-19, RSV, influenza virus, or parainfluenza virus is found, HCT should be delayed. Ribavirin and anti-RSV antibody, although unproven, are used by some centers in treating established RSV infection in patients undergoing transplantation.

VACCINE-PREVENTABLE DISEASE

Antibody titers to vaccine-preventable diseases decline after allogeneic or autologous HCT if the patient is not revaccinated. Therefore, post-transplantation revaccination against SARS-CoV-2, influenza, *Haemophilus influenzae*, Varicella Zoster, meningococcus, pneumococcus, polio, diphtheria, tetanus, pertussis, hepatitis A and B, and human papillomavirus, among others, is generally recommended.[139] Live-virus vaccines such as measles, mumps, and rubella (MMR) are usually given 2 years after HCT and when the patient has stopped receiving immunosuppression to avoid complications. The choice of vaccines and schedule may vary depending on patient age, underlying diagnosis, and degree of continuing immunosuppression. Therefore, although several guidelines have been written, decisions regarding whom, when, and how to vaccinate should be made in consultation with infectious disease experts and institutional transplantation guidelines.[131,140]

KEY POINTS

- Fungal infections can be prevented, and survival can be improved with the use of antifungal prophylaxis during the first few months after HCT.
- Letermovir prophylaxis can reduce the incidence of CMV infection.
- Patients should be screened for viral infections; a positive result may be cause for delaying HCT.
- Revaccination after HCT is generally recommended.

TOXICITIES RELATED TO THE PREPARATIVE REGIMEN

After most standard preparative regimens, patients commonly experience immediate toxic effects such as nausea, vomiting, fever, and mild skin erythema. Unusual toxic effects associated with high-dose cyclophosphamide include hemorrhagic cystitis and, rarely, acute hemorrhagic carditis. TBI commonly results in parotiditis.

Oral mucositis frequently results following conditioning containing melphalan, busulfan, and/or radiation. Cryotherapy, by having patients suck on ice chips, is an effective way to reduce mucositis following melphalan by restricting blood flow to the oropharynx, given the short half-life. Mucositis requiring narcotic analgesia typically develops 5 to 7 days after HCT that uses high-dose preparative regimens. Patient-controlled analgesia is preferred, providing superior patient satisfaction and minimizing cumulative narcotic doses.

Sinusoidal obstruction syndrome (formerly termed veno-occlusive disease) can develop within 1 to 4 weeks after treatment with many high-dose preparative regimens, as well as treatment with antibodies conjugated with calicheamicin (eg, inotuzumab ozogamicin and gemtuzumab ozogamicin); its symptoms include weight gain, ascites, tender hepatomegaly, and jaundice. The current overall incidence of sinusoidal obstruction syndrome is approximately 2%, but varies widely based on the patients, the preparative regimen, and the type of prophylaxis used.[141,142] In general, the incidence is higher for patients who have abnormal liver function tests before HCT and those with an active infection at the time of HCT. Defibrotide, a mixture of single-stranded oligonucleotides (not generally recognized as the dominant mechanism of action), has been approved by the FDA for treatment of sinusoidal obstruction syndrome based on retrospective controlled trials.[143] Prophylaxis with low molecular weight heparin and ursodeoxycholic acid may reduce the incidence of sinusoidal obstruction syndrome.[141]

Pulmonary complications after HCT pose significant risks to patient health, often leading to substantial morbidity and mortality and impacting long-term function. Idiopathic pneumonia syndrome, believed to stem directly from chemoradiotherapy toxicity, occurs 30 to 90 days after HCT in up to 5% of patients. As with other toxicities, the incidence of idiopathic pneumonia syndrome is influenced by various factors, including the preparative regimen; higher occurrences are observed after regimens involving elevated doses of TBI. Additional risk factors include preexisting lung conditions, previous thoracic irradiation, and advanced age, whereas the use of fractionated radiotherapy seems to lower the risk. Idiopathic pneumonia syndrome carries a mortality rate of approximately 50%, and currently available treatments lack clear effectiveness, although initial findings with tumor necrosis factor blockade show promise.[144]

Two categories of chronic pulmonary dysfunction are seen among patients who survive more than 3 months after allogeneic HCT: restrictive lung disease and obstructive lung disease. The most common cause of restrictive lung disease is cryptogenic organizing pneumonia, which presents with symptoms such as dry cough, shortness of breath, fever, and radiographic findings showing a diffuse, fluffy infiltrate. Histology shows patchy fibrosis, granulation tissue within alveolar spaces and small airways, and absence of identifiable infectious agents. Treatment with corticosteroids often yields a favorable response with the potential for complete reversal of the condition.[145] Conversely, bronchiolitis obliterans is an obstructive defect marked by progressive dyspnea, nonproductive cough, and radiologic evidence of airway trapping. Histology typically shows enhanced deposition of

collagen and granulation tissue in and around bronchial structures, ultimately leading to obliteration of small airways. This condition represents the pulmonary manifestation of chronic GVHD. Management generally involves increasing immunosuppression. Initially, promising results have been reported with a combination treatment comprising fluticasone, azithromycin, and montelukast. However, more recent updates, such as the ALLOZITHRO study, have raised concerns about an increased risk of hematologic malignancy relapse in the azithromycin arm, prompting an FDA alert against its use as prophylaxis for bronchiolitis obliterans.[146,147]

LATE EFFECTS AND LONG-TERM SURVIVORSHIP

The combined effects of therapeutic exposures before HCT and conditioning regimens during transplantation lead to cumulative damage to normal tissues. This damage contributes to the premature onset of various health conditions, including secondary neoplasms, infections, chronic GVHD, respiratory diseases, metabolic syndrome, cardiac and neurovascular diseases, and musculoskeletal abnormalities.[148-150] The 15-year cumulative incidence of chronic health conditions exceeds 40% in those who have undergone HCT, and a study by Martin et al[151] reported in 2010 demonstrated that the mortality rates of those undergoing HCT more than 5 years out from HCT are fourfold to ninefold higher than expected with an estimated 30% lower life expectancy compared with that of the general population regardless of current age. In addition, a study by Chow et al[152] in 2017 compared HCT survivors with a matched population of patients with cancer who did not undergo transplantation, revealing significantly higher rates of serious health outcomes among HCT survivors, including substantially greater rates of hospitalization (280 vs 173 episodes per 1,000 person-years), hospitalization or death resulting from infection (10-year cumulative incidence, 31% vs 22%), and respiratory complications (27% vs 20%).

Additional delayed complications include decreased growth velocity in children and delayed development of secondary sexual characteristics. Postpubescent women commonly experience ovarian failure, and few men regain spermatogenesis after HCT that uses high-dose preparative regimens. However, there are instances in which fertility is restored even after myeloablative conditioning, highlighting the importance of counseling patients about this possibility. Cataracts affect up to one-third of patients, with an increased risk among patients receiving high doses of TBI and those requiring steroids for treatment of GVHD. In addition, thyroid dysfunction and osteoporosis may occur, albeit usually well-compensated. Significant psychosocial difficulties accompany HCT, and survivors have increased rates of anxiety, depression, sleep and sexual disorders, and post-traumatic stress disorder.[153]

The Center for International Blood and Marrow Transplant Research and European Society for Blood and Marrow Transplantation have developed consensus guidelines to assist providers in screening and preventive care for infectious, cardiovascular, metabolic syndrome, and bone disease, as well as ocular, neurocognitive, and other late effects of HCT.[154] Collaboration between HCT providers and primary care physicians is crucial in using a patient-centered approach that considers individual risk factors and adheres to evidence-based screening, prevention, and intervention strategies for chronic conditions.

KEY POINTS

- Common chemoradiotherapy toxicities include nausea, vomiting, fever, and mild skin erythema. High-dose regimens, especially when combined with TBI, lead to more severe oral mucositis.
- Sinusoidal obstruction syndrome and idiopathic pneumonia syndrome are serious potential complications requiring careful clinical management.
- As survival improves for HCT recipients, additional attention should be paid to long-term complications, especially cardiovascular disease and endocrine effects.

RELAPSE AFTER TRANSPLANTATION

There is a substantial risk of recurrent malignant disease after HCT, particularly when HCT is performed after failure of conventional therapy rather than earlier in the course of the disease. The appropriate treatment of patients who experience relapse after HCT depends on the disease and type of transplantation. Patients with lymphoma whose disease recurs after autologous HCT may have a response to subsequent chemotherapy, and occasionally such responses are surprisingly complete and prolonged, particularly if the duration of remission after HCT was long. Newer agents, such as targeted antibody therapy or checkpoint inhibitors, can be used for relapses after autologous transplantation and may induce responses that then serve as a bridge to allogeneic transplantation.[155-157]

On occasion, patients who are receiving immunosuppressive drugs and have recurrent disease after allogeneic HCT will have a second CR after discontinuation of immunosuppressive therapy. Infusions of viable lymphocytes from the original stem cell donors (donor leukocyte infusion) can result in CR for many patients. In a European study involving 135 patients, the rate of CR was 70% for patients with chronic-phase CML, 12% for patients with advanced-phase CML, 29% for patients with AML or MDS, and 0% for

patients with ALL.[98] Results of a small study suggest better OS with TKIs than with donor leukocyte infusion, representing another option for CML relapse after allogeneic HCT.[158] Most experts recommend that patients who have recurrent acute leukemia undergo reinduction chemotherapy before donor leukocyte infusion to decrease the leukemia cell burden and provide sufficient time for a graft versus leukemia (GVL) effect to develop. Some form of GVHD develops in approximately 60% of patients after infusion of donor lymphocytes; of these patients, 50% require therapy for GVHD, and 15% experience life-threatening GVHD. In addition, marrow aplasia occurs in 35% of patients, and the overall mortality associated with the infusion of donor lymphocytes is 20%. Limiting the dose of $CD3^+$ lymphocytes to less than 10×10^7 can decrease the risk of GVHD and life-threatening complications without impairing the GVL effect.[159] CD19 CAR T-cells are effective in the treatment of patients with ALL who have experienced relapse after HCT (discussed in the next section).[160] Responses have also been seen after treatment with ipilimumab, but immune-mediated toxicity and GVHD flares were also seen.[161]

Patients with AML or MDS may undergo a second allogeneic HCT as treatment for relapse after the first HCT. Such HCTs, if performed within 1 year of the original HCT, have been associated with a high risk of severe or fatal transplantation-related toxicities, including sinusoidal obstruction syndrome and idiopathic interstitial pneumonia. Results are more favorable when the second HCT is performed more than 1 year after the original HCT, with prolonged subsequent remissions reported for as many as 25% of patients.[162]

APPROACHES TO REDUCE RELAPSE AFTER TRANSPLANTATION

In general, HCT is delivered with curative intent. However, relapse remains a leading cause of treatment failure after HCT, and the prognosis of hematologic malignancies that relapse after HCT is extremely poor, particularly after allogeneic HCT. Therefore, there have been a number of approaches used to prevent post-transplantation relapse, such as intensification of conditioning regimens, consolidation therapies, and maintenance therapies.

In an attempt to intensify conditioning regimens, novel conditioning therapies in allogeneic HCT have been evaluated, including the incorporation of newer chemotherapeutic agents (eg, clofarabine and bendamustine), CD45-targeting radioimmunotherapy, and dose-intensified total-marrow irradiation. A phase 3 study evaluating the radioimmunoconjugate Iomab-B in patients with relapsed/refractory (R/R) AML demonstrated that a higher percentage of patients receiving Iomab-B were able to proceed to transplantation and remained in remission at 6 months compared with patients who received conventional care, although Iomab-B does not have FDA approval.[163]

In MM, consolidation therapy and maintenance therapy have been extensively studied, partly because of the limitation of single autologous HCT with a high rate of relapse.[164] Nonmyeloablative allogeneic HCT as a consolidation therapy after standard autologous HCT was evaluated by a few groups with mixed results.[36,165,166] A recent large clinical trial supported by the Blood and Marrow Transplant Clinical Trial Network (trial 0702) demonstrated that second autologous HCT (tandem autologous) or a combination of lenalidomide, bortezomib, and dexamethasone consolidation was not associated with improved PFS or OS.[167] In myeloma, maintenance therapy after autologous HCT using lenalidomide improves PFS and OS and remains the standard therapy.[168] A phase III trial evaluating daratumumab and lenalidomide versus lenalidomide as maintenance in patients who are positive for minimal residual disease (MRD) after autologous HCT and are anti-CD38 naive showed higher rates of MRD negativity and improved PFS with daratumumab and lenalidomide.[13,169]

In lymphoma, the most commonly studied agent for post-HCT maintenance is rituximab. A phase 3 trial in recurrent large-cell lymphoma did not show an advantage in relapse-free survival (RFS) or OS,[170] and a study in follicular lymphoma (FL) demonstrated an improvement in PFS without a difference in OS.[171] Brentuximab vedotin was evaluated in high-risk HL after HCT, in which it substantially improved PFS compared with placebo.[172] More recently, checkpoint inhibitors have been evaluated in this setting with promising data.[173]

The role of maintenance therapy after allogeneic HCT has not been well-defined. Low-dose azacitidine, a hypomethylating agent, was evaluated in a phase 1 trial as maintenance therapy starting at 6 weeks after HCT, and it established an optimal dosing schedule with a promising 1-year OS rate of 77%.[174] Although TKIs have been widely used as maintenance after allogeneic HCT for Philadelphia chromosome-positive ALL, data supporting their use are conflicting and are largely from single-arm trials or retrospective registries.[175-177] For AML with FMS-like tyrosine kinase 3 (*FLT3*) internal tandem duplication, several *FLT3* TKIs have been evaluated as maintenance after allogeneic HCT, including sorafenib, quizartinib, and gilteritinib.[178,179] A randomized placebo-controlled phase 2 trial of sorafenib maintenance after allogeneic HCT showed an improved 2-year PFS rate (85% vs 53%). However, a randomized, placebo-controlled phase 3 trial of gilteritinib failed to show improvement in RFS, with benefit limited to patients who have detectable MRD.[180]

KEY POINT

- Patients who experience relapse after allogeneic HCT can potentially respond to subsequent immunologic manipulation, including withdrawal of immunosuppression, DLIs, and treatment with checkpoint inhibitors.

CAR T-CELLS FOR HEMATOLOGIC MALIGNANCIES

CAR T-cell therapy has revolutionized the management of many hematologic malignancies and provided long-lasting responses (Table 22-4). CAR T-cells are engineered T cells with receptors designed to target and eliminate cells that express a specific antigen. The foundation of CAR T-cell therapy comprises second-generation cells that include both the T-cell–activating domain and chimeric costimulatory receptors to enhance proliferation and expansion of T cells. The pioneering application of CAR T-cell therapy in hematologic malignancies was CD19 targeting for B-cell ALL. Subsequently, several trials demonstrated response rates of up to 90% in adults and children with relapsed ALL.[193,194] Trials in CLL and NHL have also yielded positive responses, including CRs in a substantial proportion of patients with lymphoma.[181,195] Subsequently, commercial CAR T-cell constructs have been approved in the United States for R/R B-cell ALL, R/R DLBCL, relapsed mantle cell lymphoma (MCL), relapsed FL, relapsed CLL, and relapsed MM.

Axicabtagene ciloleucel and lisocabtagene maraleucel were the first products approved for relapsed DLBCL. Phase 3 trials evaluating these CD19-directed CAR T-cell products for DLBCL that is primary refractory to initial therapy or with early relapse within 12 months both demonstrated improved EFS and OS when compared with standard salvage chemotherapy followed by autologous HCT.[18,19] In patients with FL for whom two or more lines of therapy failed, axicabtagene ciloleucel, lisocabtagene maraleucel, and tisagenlecleucel are approved for therapy based on the high rates of overall response.[186] Brexucabtagene autoleucel was approved for R/R MCL with an ORR of 87% in a single-arm trial, and it seemed to be effective even in patients with high-risk disease, including TP53 mutant and blastoid variant.[196] Data for all of the CAR-T products show long-term PFS is achieved in about 30% of patients with R/R NHL.

The success of CD19-directed CAR T-cell therapy led to the development of new constructs targeting other diseases, such as B-cell maturation antigen (BCMA) for MM.[197] Anti-BCMA–directed CAR T-cell therapies, idecabtagene vicleucel and ciltacabtagene autoleucel, were approved for patients with R/R MM after 1 or 2 lines of therapy, respectively, on the basis of trials showing higher rates of overall response when compared with standard therapies.[191,192]

CAR T-cell products have unique toxicities distinct from those associated with checkpoint inhibitors or other immune activators. Newer CAR T-cell products that use 4-1BB costimulatory domains seem to have less toxicity and better persistence in some studies. B-cell aplasia is an anticipated on-target effect of CD19-directed CAR T-cells, resulting in long-term compromised humoral immunity. Lymphodepletion given before CAR T-cell infusion can result in myelosuppression. An effect seen across all CAR T-cell therapies is a clinical syndrome termed cytokine-release syndrome (CRS), characterized by elevations in serum cytokine levels (eg, IL-6 and interferon gamma) and expansion of CAR T cells in the peripheral blood and clinically manifested as fevers, hypotension, and, in severe cases, capillary leakage and hypoxia.[198] To address CRS, the FDA-approved tocilizumab, an anti–IL-6 receptor antagonist, is used for treatment either alone or in combination with steroids.[199] Siltuximab (an anti–IL-6 antibody rather than one directed against the IL-6 receptor) and anakinra (IL-1 receptor antagonist) have been used in CRS refractory to tocilizumab and steroids.

Immune effector cell-associated neurotoxicity syndrome (ICANS) is another distinct complication of CAR T-cells across all targets. Early signs often include tremor, dysgraphia, and mild expressive aphasia, especially with reversible memory deficits. In addition, patients may experience decreased levels of consciousness, ranging from mild lethargy to complete obtundation. Management includes diagnostic workup to rule out seizures and imaging of the brain to rule out cerebral edema. The use of levetiracetam, either prophylactically or after the onset of ICANS, and high-dose dexamethasone is recommended for treatment. Tocilizumab is not effective for ICANS in the absence of accompanying CRS and may worsen symptoms.[200] The American Society for Transplantation and Cellular Therapy has provided instructive consensus grading for both CRS and ICANS.[199]

Hemophagocytic lymphohistiocytosis (HLH), also known as macrophage activation syndrome, is another complication of CAR T-cell therapy, characterized by proliferation of morphologically benign lymphocytes and macrophages that secrete high levels of inflammatory cytokines. Symptoms and laboratory findings can overlap with those of CRS. Monitoring ferritin and C-reactive protein (CRP) levels are key component of treatment. Emerging evidence supports ruxolitinib as a treatment of choice for HLH because of its immunosuppressive effects.[201-203] Prolonged cytopenias are common, likely related to ongoing CAR T-cell activity and direct immune effects on the bone marrow. This toxicity is managed with supportive care, including growth factors, transfusions, and antibiotic and antiviral prophylaxis. ASCO offers guidance on the recommended management of immune-related adverse events in patients treated with CAR T-cell therapy.[204,205] Finally, there have been reports of an increased rate in second primary malignancies after CAR T-cell therapy, particularly myeloid and T-cell neoplasms.[206]

In short, CAR T-cell therapy has led to a new array of treatment options for patients with relapsed hematologic malignancies. Although they offer promising outcomes, these therapies come with distinct toxicities, including risk of second primary malignancies, underscoring the need for oncologists to be well-versed in recognizing, grading, and managing these adverse effects. Looking ahead, it is expected that this transformative technology, including research into allogenic CAR T-cells, will have expanded applications to address a broader spectrum of malignancies in the future.

Table 22-4 **Summary of Clinical Trials of FDA-Approved CAR T-Cells in NHL**

Disease	Product (Costimulatory Domain, Target)	Indication (Approval Year)	Study: Phase (No. of Patients)	% ORR (% CR)	Median PFS (Months)	Median OS (Months)	% CRS (% Grade 3+)	% Neurologic Toxicity (% Grade 3+)	References

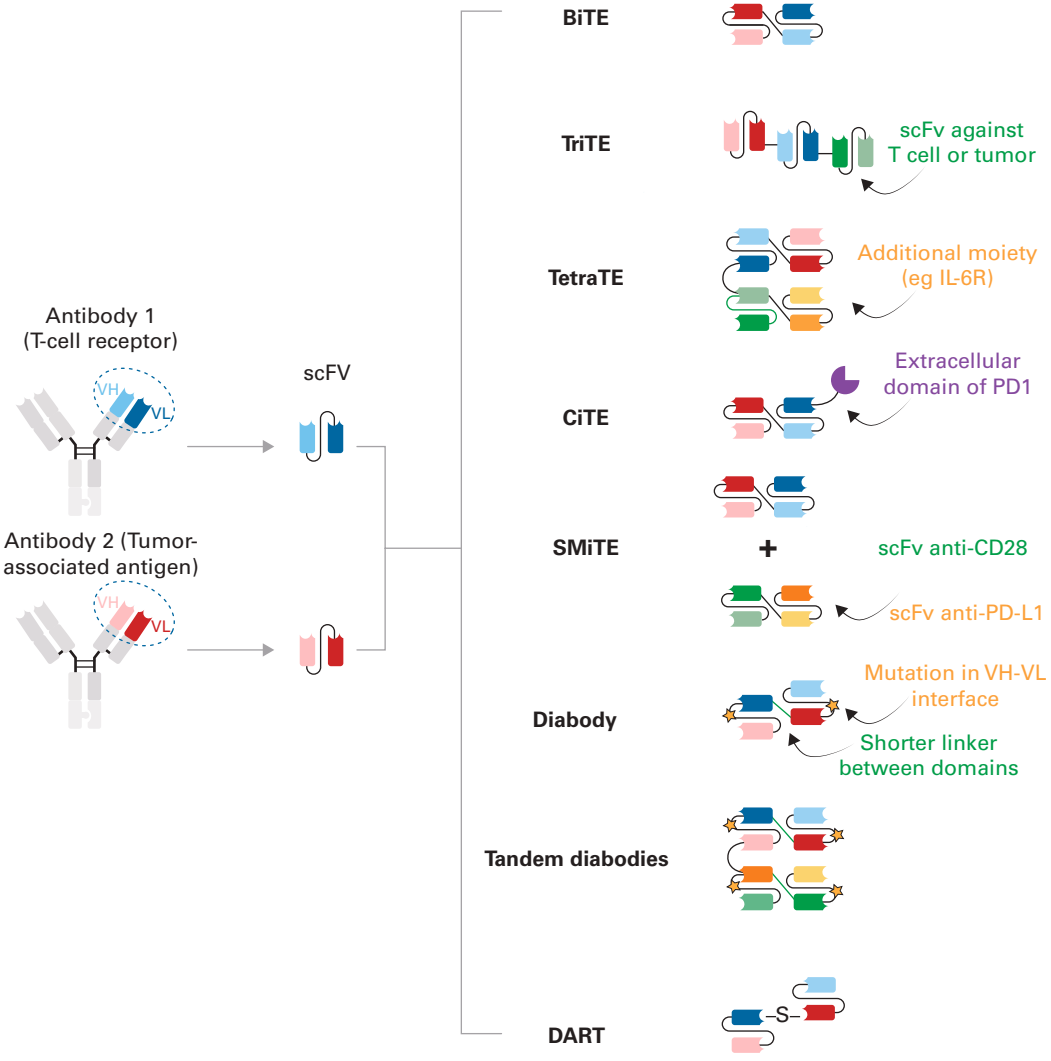
IN VIVO CELLULAR THERAPY BY BISPECIFIC ANTIBODY AND IN VIVO CAR-T THERAPY

Historically, the development of bispecific antibodies (BsAbs) began in the early stages of antibody engineering with the first bispecific constructs described in the 1980s. The field has seen significant growth with advances in genetic engineering, leading to a variety of BsAb formats with different characteristics suited for specific applications.[207] BsAbs have emerged as a potent tool in cancer immunotherapy, providing the advantage of dual antigen recognition, which can be tailored to meet various therapeutic needs. This dual targeting approach allows for novel mechanisms of action, such as redirecting immune cells to cancer cells, dual inhibition of signaling pathways, and simultaneous blockade of immune checkpoints; in some bleeding disorders, they function as the inhibited or deficient factor.

Immune cell engagers are engineered antibodies with at least one arm binding a tumor-associated antigen and at least one other one directed against an activating receptor in immune effector cells: CD3 for recruitment of T cells and CD16a for natural killer (NK) cells.[208]

Figure 22-6 Various TCE Formats Described in Immuno-Oncology



Abbreviations: BiTE, bispecific T-cell engager; CiTE, checkpoint inhibitor T-cell engager; DART, dual affinity retargeting; scFv, single-chain variable fragment; SMiTE, simultaneous multiple interaction T-cell engager; TCE, T-cell engager; TetraTE, tetraspecific T-cell engager; TriTE, trispecific T-cell engager; VH-VL, variable heavy and variable light.

Various TCE formats described in immuno-oncology. scFvs derived from T-cell receptor antibodies (blue) and from tumor-associated antigen antibodies (red) can associate to form BiTEs. BiTEs can be combined with a third scFv (green) to form a TriTE and with an additional moiety to form a TetraTE. BiTEs can also be complemented with the extracellular domain of PD1 to form a CiTE or administered with a second molecule, such as an anti-CD28 × anti-PDL1, as in the SMiTE. Various molecular modifications, such as mutations of the VH-VL interface, shorter links between domains and the addition of disulfide bonds, have led to the development of additional formats, such as diabody, tandem diabody, and DART. Created with Biorender.

BsAbs can be categorized by their structural format; for instance, bispecific T-cell engagers are characterized by their small size and lack of an Fc region, which allows for effective tumor penetration but necessitates continuous administration because of a short half-life (Fig. 22-6). Conversely, full-length immunoglobulin G–like (IgG-like) BsAbs maintain an Fc domain, providing a longer serum half-life and the capacity for antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity, and phagocytosis. This format diversity is crucial for optimizing pharmacokinetics and efficacy.[209,210]

The first bispecific T-cell engager approved by the FDA was the anti-CD19 blinatumomab for the treatment of B-cell precursor ALL in 2014. A landmark in the field, this bispecific T-cell engager targets CD19 on B cells and CD3 on T cells, significantly enhancing T-cell–mediated cytotoxicity against cancer cells.[211]

SOLID TUMORS

Amivantamab, a bispecific monoclonal antibody targeting EGFR and MET, was approved for non–small cell lung cancer (NSCLC) in 2021. In 2022, tebentafusp—a bispecific T-cell engager targeting gp100 on uveal melanoma cells and CD3 on T cells—also received FDA approval.

Most recently, in 2025, the FDA approved ErbBicT (GEN1057/BNT327) for metastatic NSCLC with EGFR mutations following progression on osimertinib. By targeting both EGFR and c-MET, ErbBicT addresses key resistance pathways that develop after earlier EGFR inhibitor therapies, fulfilling a significant unmet need for this patient population.

HEMATOLOGIC MALIGNANCIES

T-cell engagers are revolutionizing the treatment of hematologic malignancies, with several agents approved since 2022. These BsAbs redirect a patient's own T cells to attack malignant cells, offering new options for difficult-to-treat diseases. Approved therapies include the following:

- Mosunetuzumab (CD20×CD3) for R/R FL.
- Teclistamab and Elranatamab (BCMA×CD3) for relapsed MM.
- Epcoritamab and Glofitamab (CD20×CD3) for DLBCL.
- Talquetamab (GPRC5D×CD3) for R/R MM.

Emerging agents like RO7616789 (CD123×CD3) are extending this approach to AML, particularly for patients with biomarkers such as FLT3 mutations or high CD123 expression, highlighting the expanding potential of this therapeutic class.

NONMALIGNANT DISEASES

Tibulizumab, which gained FDA approval in 2025, marks a therapeutic milestone as the first BsAb for an autoimmune disease. Targeting moderate-to-severe systemic lupus erythematosus (SLE) and lupus nephritis, its dual mechanism—simultaneously blocking BAFF and IL-6—provides coordinated control over pathogenic B-cell activity and the inflammatory response.[212]

T-cell engagers will likely revolutionize the treatment of hematologic malignancies, for which several have been approved since 2022. Mosunetuzumab targets CD20 and CD3 and is used for R/R FL, whereas teclistamab and elranatamab target BCMA and CD3 and are used for relapsed MM. Linvoseltamab-gcpt (Lynozyfic) was approved in July 2025 (anti-BCMA). Epcoritamab and glofitamab target CD20 and CD3 and are used for treating DLBCL. Talquetamab targeting GPRC5D and CD3 is used in R/R MM.[208,213,214]

INTRODUCTION TO IN VIVO CAR-T THERAPY

In vivo CAR-T therapy represents an innovative advancement in cancer treatment by streamlining the CAR-T cell manufacturing process. Instead of the traditional approach, which involves extracting a patient's T cells, genetically modifying them outside the body (ex vivo), and then reinfusing them, in vivo CAR-T therapy delivers the gene-editing components directly into the patient's bloodstream. This approach enables the patient's own T cells to be genetically reprogrammed within the body (in vivo) to express CARs. These CARs are designed to target myeloma cells, typically recognizing antigens such as BCMA or GPRC5D. By bypassing the ex vivo manufacturing process, this strategy significantly reduces complexity and cost.

At ASH 2025, a breakthrough presentation highlighted the first preliminary results of a novel in vivo CAR-T therapy, KLN-1010, in patients with R/R MM. KLN-1010 is administered intravenously and utilizes an improved lentiviral vector to generate fully human, anti-BCMA CAR-T cells inside the patient's body. This innovation eliminates the need for apheresis, ex vivo manufacturing, or lymphodepleting chemotherapy. Notably, removing the requirement for lymphodepleting therapy is a major advantage, alongside simplifying the logistical challenges historically associated with CAR-T therapy.

Key findings from the inMMyCAR study include the following:

- Promising Efficacy: All three initial patients achieved MRD negativity, with sensitivity levels of 10^{-5} or 10^{-6} at 1 month following treatment. Over time, these patients experienced deepening partial or very good partial responses, and no cases of disease progression were observed.

- Manageable Safety: The main adverse events reported were infusion-related reactions and Grade 2 CRS. Importantly, there were no instances of neurotoxicity or cytopenias graded 3 or higher. In addition, CAR-T cell expansion was observed without the need for preconditioning chemotherapy.

SUMMONING OTHER IMMUNE CELLS

Bispecific NK cell engagers are also in early-stage clinical studies and may offer efficacy similar to that of bispecific T-cell engagers with milder adverse effects. An attractive target for NK cells is CD16a, the receptor that recognizes the Fc fragment of IgG antibodies and confers to NK cells their ability to perform ADCC.[215] Bispecific and trispecific antibodies have been developed to target not only tumor and T or NK cells, but more recently, myeloid cells in cancer and infectious diseases, as well as macrophages.[213] Several bispecific NK cell engagers have been developed for hematologic malignancies and solid tumors.[216-221] This area has potential to grow not from the direct effect of the engagement but from learning about how to educate those NK cells to become guards against the recurrence of the tumor.

Altogether, these engineered molecules may change the paradigm of treatment for R/R hematologic malignancies. The clinical development of BsAbs has expanded significantly; there are now ongoing trials that explore their use in various cancers, including solid tumors, in which antigen heterogeneity and a complex tumor microenvironment present unique challenges. Despite their potential, challenges persist, such as immunogenicity, off-target effects, and production complexities because of the need for correct chain pairing. Innovations like the "knob-into-hole" method for stable heterodimer formation and the use of scFv or diabodies have been critical in overcoming these hurdles.[222]

Management of a Bispecific Therapy Adverse Effect Profile

Managing toxicities associated with BsAb therapies is critical, and physicians should familiarize their teams with that challenge, especially if this therapy becomes widespread and is used in the outpatient setting. Adverse effects, particularly CRS and neurotoxicity, could be minimized or totally alleviated by offering detailed recommendations on pretreatment evaluation, monitoring, and treatment strategies.[223]

The recommendations for mitigating toxicity associated with BsAbs, as highlighted by Crombie et al[223] include the following:

Cytokine-Release Syndrome

- Step-up dosing: Initiate treatment with gradually increasing doses to minimize the risk of CRS.
- Premedication: Administer corticosteroids (eg, dexamethasone), antipyretics, and antihistamines as prophylactic measures.
- Monitoring: Observe patients closely, especially after initial doses, and manage symptoms based on the severity (grade 1 to 4 CRS).
- Therapeutics: Use tocilizumab or other anti-cytokine agents for severe or refractory CRS.

Neurological Toxicities

- Educate patients and caregivers to recognize symptoms like headache, dizziness, and confusion.
- In severe cases, administer corticosteroids and consider a neurology consult.
- Use monitoring tools like immune effector cell-associated encephalopathy scores for assessment.

Tumor Flare Reaction

- Rare but severe cases require corticosteroids and possibly localized irradiation for bulky tumors near vital structures.

Cytopenias

- Monitor and provide growth factor support if necessary.
- Balance treatment continuation against the risk of neutropenia.

Infectious Complications

- Administer prophylaxis for *P. jirovecii* pneumonia and varicella zoster virus.
- Manage hypogammaglobulinemia with Ig replacement if infections are recurrent. Based on expert consensus, IV immunoglobulin (IVIg) is recommended during BsAb therapy when patients develop hypogammaglobulinemia (IgG <400 mg/dL) and experience recurrent or severe bacterial infections. Prophylactic use is often considered if IgG falls below 300 to 350 mg/dL. The standard regimen is 400 to 500 mg/kg every 3 to 4 weeks, maintaining a trough IgG level above 500 to 600 mg/dL. IVIg should be continued during therapy and typically for 6+ months after treatment ends, as immune suppression can be prolonged. Regular monitoring of IgG levels (every 4-8 weeks) is essential.

Patient and Facility Preparedness

- Educate patients on home monitoring for symptoms and provide contact points for emergencies.
- Ensure that necessary medications such as tocilizumab are available at treatment sites.
- Tailor the treatment location (outpatient vs inpatient) based on the patient's risk profile.

Other Precautions

- Screen for latent infections such as hepatitis B and ensure that standard vaccinations (eg, influenza, COVID-19) are available.
- Proactively manage tumor lysis syndrome based on the risk.

These strategies reflect a combination of prophylactic, monitoring, and reactive measures to ensure the safe administration of BsAbs and should be helpful in guiding healthcare teams in their management strategy.

In summary, BsAbs represent a dynamic and evolving field in cellular therapy and leverage the precision of dual targeting to enhance treatment outcomes. Although their efficacy in hematologic malignancies may not match the depth or response rates of CAR T-cell therapy, BsAbs offer the significant advantage of being available as an off-the-shelf treatment. This makes them a timely option, and they generally show better tolerability with lower severity and frequency of CRS, ICANS, and myelosuppression. However, they are associated with a higher rate of infections.[223-225]

Regulatory frameworks are also adapting to accommodate these complex molecules, with guidance that focuses on target selection, safety, and efficacy assessments to ensure that BsAbs can be brought to market efficiently while maintaining high safety standards.[207] Because of the ongoing research and clinical trials regarding BsAbs coupled with advancements in antibody engineering, BsAbs hold considerable promise for personalized, timely, and effective cancer treatments.

GENE THERAPY

The emergence and clinical application of cell-based gene therapy mark a significant advancement in the treatment of inherited diseases such as sickle cell disease and transfusion-dependent beta thalassemia. Current approaches in gene therapy involve using viral vectors to introduce new genes into stem cells or deleting suppressors for fetal hemoglobin. Both approaches involve collecting the patient's stem cells, which are subsequently edited with a lentivirus vector or by using CRISPR/CAS9 technology. After the gene modification process, patients undergo myeloablative conditioning. The gene-modified stem cell product is then infused, akin to an autologous SCT procedure. Clinical studies that evaluate these products demonstrate high levels of efficacy with notable resolution of severe veno-occlusive events. However, it is essential to recognize that patients treated with these gene therapy products may experience complications similar to those of patients undergoing traditional transplantations and could potentially face an increased risk of subsequent hematologic malignancies. Hence, ongoing monitoring and comprehensive management are crucial aspects of their care. The FDA-approved therapies for sickle cell and thalassemia should be discussed in more detail. The two therapies for sickle cell are exagamglogene autotemcel, which uses CRISPR/Cas9 gene-editing to modify the patient's hematopoietic stem cells to produce HbF and essentially generate HPFH to prevent sickling; and lovotibeglogene autotemcel, which uses a lentiviral vector to insert a norml copy of the beta-globin gene into the patient's hematopoietic stem cells. For thalassemia, exagamglogene autotemcel is also approved for patients age 12 years and older with transfusion-dependent beta thalassemia (TDBT). Betibeglogene autotemcel is approved for adult and pediatric patients with TDBT. It introduces a normal beta-globin gene to the patient's hematopoietic stem cells, which results in normal or almost normal levels of hemoglobin.

KEY POINTS

- CAR T-cell therapy results improved EFS and OS for patients with DLBCL refractory to first-line therapy or who relapse within 12 months when compared with standard salvage therapy and autologous transplantation.
- Bispecific T-cell engagers can be used to engage a host immune response against a target antigen, which has led to the development of many new products that can treat both hematologic and solid cancers.

HIGH-YIELD TAKEAWAYS

- Post-transplantation cyclophosphamide for GVHD prophylaxis results in comparable outcomes between haploidentical, matched sibling, MUD, and mismatched unrelated donor transplants.
- Ruxolitinib is effective for steroid-refractory acute and chronic GVHD.
- CAR T-cell therapy is effective for primary refractory or early relapsed DLBCL and lenalidomide refractory MM, with approximately 30% of patients having long-term PFS.
- BsAb therapy (T-cell and NK-cell engagers) provides the convenience of off-the-shelf accessibility and is slightly better tolerated compared with CAR T-cell therapy. However, the response rates are lower than what is expected with CAR T-cell–based modalities.

Acknowledgments

We acknowledge the valuable contributions of all individuals who helped shape previous iterations of this chapter.

CELLULAR THERAPIES 22

CHAPTER SUMMARY GUIDE

KEY POINTS

- All diseases of hematopoiesis, nonmalignant and malignant, are potentially curable with cellular therapy.
- The leading indication for autologous HCT in the United States is MM, followed by relapsed NHL and HL.
- Allogeneic HCT consistently leads to 5-year DFS rates of 50% to 70%, respectively, when performed for AML and ALL in first remission.
- In the MUD setting, use of mobilized peripheral blood stem cells showed faster engraftment, but more chronic GVHD compared with bone marrow. Use of plerixafor and motixafortide, antagonists of CXCR4, with G-CSF results in mobilization of CD34+ cells into the peripheral blood and high stem cell collection yields for autologous HCT.
- Although GVHD after HCT is more common with MUDs than with matched siblings, survival rates seem similar.
- Methods have been developed that allow for the selection of permissive single-antigen mismatched donors.
- HCT using either a haploidentical or HLA-mismatched unrelated donor is feasible; subsequently, an allogeneic donor can be found for most patients in need.
- Use of post-transplantation cyclophosphamide results in a low rate of GVHD and similar outcomes between donor types.
- The purpose of the high-dose regimen used before autologous HCT is to eradicate the underlying disease.
- The purpose of the preparative regimen in allogeneic HCT is to sufficiently immunosuppress the patient to prevent graft rejection and to eliminate residual disease.
- Evidence points to increased relapse rates and diminished survival with the use of reduced-intensity conditioning compared with myeloablative conditioning in patients with AML or MDS.
- By using in situ hybridization with sex chromosome–specific probes or typing of the variable number of tandem repeat polymorphisms, the donor-versus-recipient origin of populations of cells can be determined in virtually all cases in allogeneic HCT to assess engraftment and monitor for disease relapse.
- Loss of chimerism is an indicator of graft failure and/or disease relapse.
- T cells in the donor graft, combined with allogeneic targets on the genetically different host, are a major driver in the development of GVHD.
- Biomarker approaches for diagnosis and risk stratification are under study.
- Post-transplantation cyclophosphamide and ATG reduce rates of acute and chronic GVHD.
- Ruxolitinib is an effective treatment for steroid-refractory acute and chronic GVHD.
- Fungal infections can be prevented, and survival can be improved with the use of antifungal prophylaxis during the first few months after HCT.
- Letermovir prophylaxis can reduce the incidence of CMV infection.
- Patients should be screened for viral infections; a positive result may be cause for delaying HCT.
- Revaccination after HCT is generally recommended.
- Common chemoradiotherapy toxicities include nausea, vomiting, fever, and mild skin erythema. High-dose regimens, especially when combined with TBI, lead to more severe oral mucositis.
- Sinusoidal obstruction syndrome and idiopathic pneumonia syndrome are serious potential complications requiring careful clinical management.
- As survival improves for HCT recipients, additional attention should be paid to long-term complications, especially cardiovascular disease and endocrine effects.
- Patients who experience relapse after allogeneic HCT can potentially respond to subsequent immunologic manipulation, including withdrawal of immunosuppression, DLIs, and treatment with checkpoint inhibitors.
- CAR T-cell therapy results improved EFS and OS for patients with DLBCL refractory to first-line therapy or who relapse within 12 months when compared with standard salvage therapy and autologous transplantation.
- Bispecific T-cell engagers can be used to engage a host immune response against a target antigen, which has led to the development of many new products that can treat both hematologic and solid cancers.

Table 22-2 **Table of Donor-Recipient ABO Compatibility With Potential Complications and Interventions**

Donor-Recipient ABO Compatibility				
	Blood Type			
Mismatch Type	**Recipient**	**Donor**	**Potential Complications**	**Interventions**
Major	O	A, B, AB	Acute hemolysis of donor RBCs	RBC reduction of the stem cell product
	A	AB	Delayed engraftment	
	B	AB	Pure red cell aplasia from recipient anti-donor isohemagglutinins	
Minor	A	O	Acute hemolysis from donor isohemagglutinin	Plasma reduction of the stem cell product
	B	O	Delayed hemolysis from passenger lymphocyte syndrome	
	AB	O, A, B		
Bidirectional	A	B	A combination of major and minor	A combination of major and minor
	B	A		

Abbreviation: RBC, red blood cell.

Table 22-3 **Categories of Acute and Chronic GVHD**

Category[107]	Time of Symptoms After HCT	Presence of Acute GVHD Features	Presence of Chronic GVHD Features
Acute GVHD			
Classic acute	≤100 days	Yes	No
Late onset	>100 days	Yes	No
Chronic GVHD			
Classic Chronic	No time limit	No	Yes
Overlap	No time limit	Yes	Yes

Abbreviations: GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation.
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Table 22-4 **Summary of Clinical Trials of FDA-Approved CAR T Cells in NHL**

Disease	Product (Costimulatory Domain, Target)	Indication (Approval Year)	Study: Phase (No. of Patients)	% ORR (% CR)	Median PFS (Months)	Median OS (Months)	% CRS (% Grade 3+)	% Neurologic Toxicity (% Grade 3+)	References
DLBCL	Axicabtagene ciloleucel (CD28, CD19)	DLBCL 3L (2017)	ZUMA-1: P1-2 (108)	83 (58)	5.9	NR	92 (11)	67 (33)	181

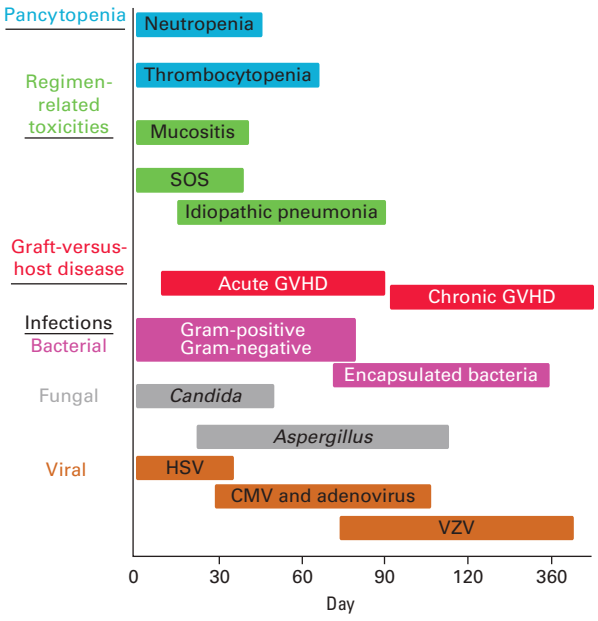
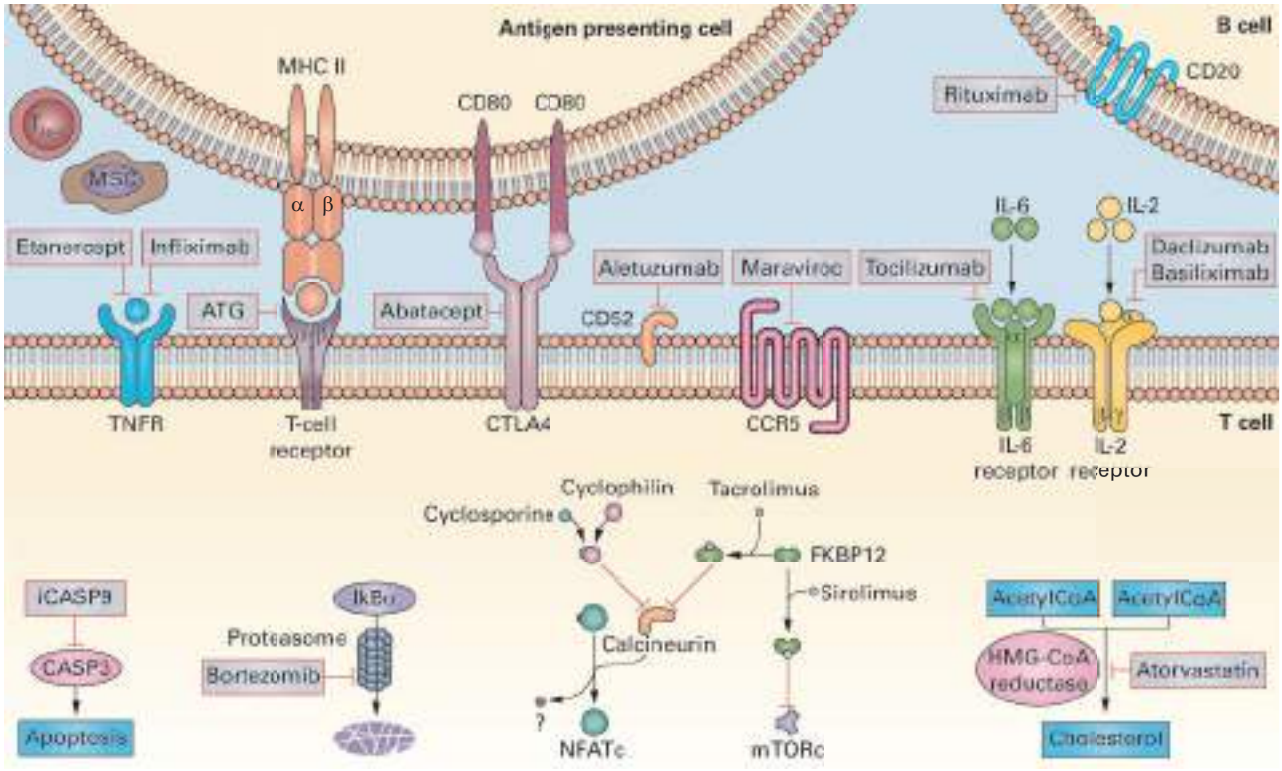
Figure 22-4 The Approximate Timing of Possible Toxicities After Allogenic Transplantation Using a Typical Intensive Preparative Regimen



Abbreviations: CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSV, herpes simplex virus; SOS, sinusoidal obstruction syndrome; VZV, varicella zoster virus.

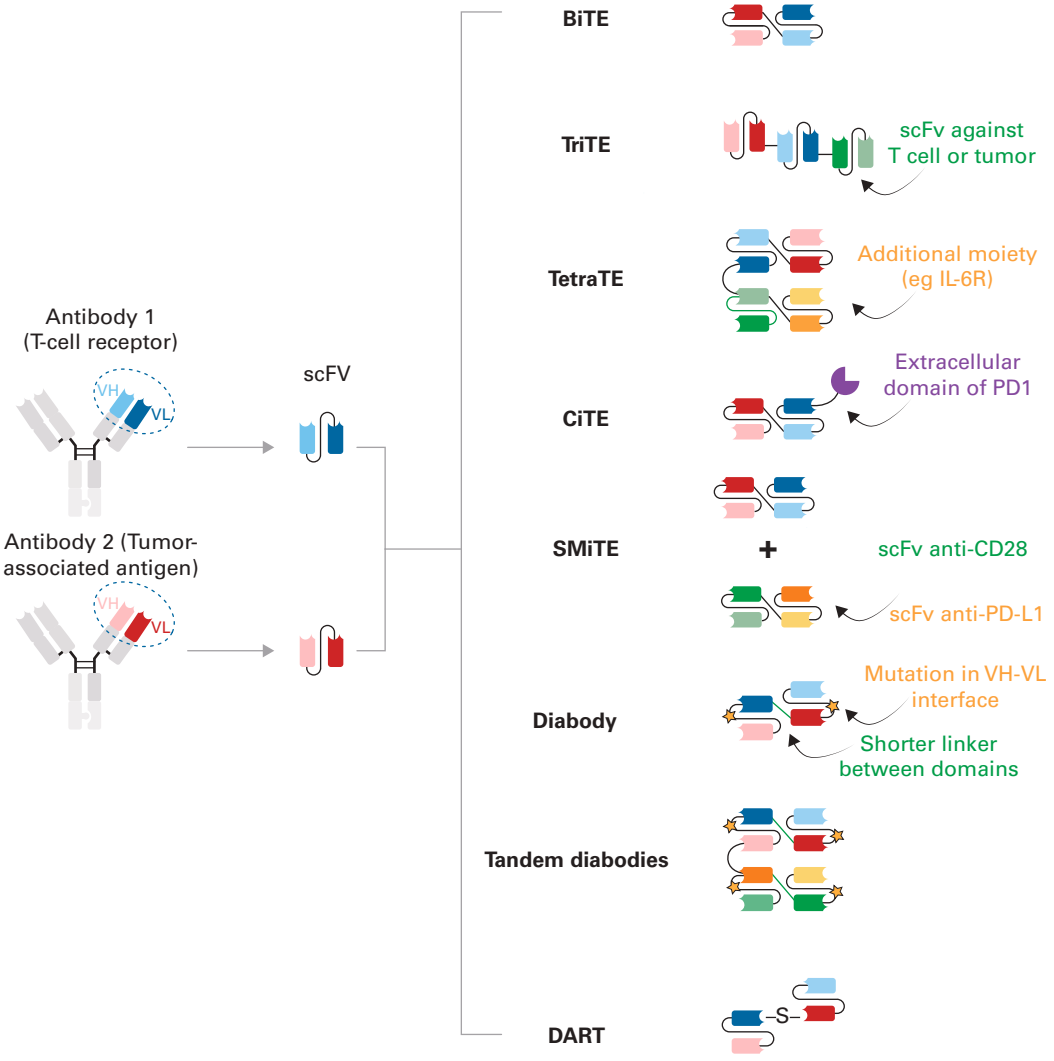
Created for ASCO. Copyright © 2026 by American Society of Clinical Oncology.

Figure 22-5 Standard and Emerging Therapies for the Prevention of Acute GVHD



Abbreviations: Acetyl CoA, acetyl coenzyme A; ATG, anti-thymocyte globulin; CCR5, C-C chemokine receptor 5; CLTA4, cytotoxic T lymphocyte antigen 4; FKBP12, FK506 binding protein 12; GVHD, graft-versus-host disease; HMG CoA reductase, 3-hydroxy-3-methyl-glutaryl coenzyme A reductase; iCasp9, inducible caspase 9; IkB, nuclear factor of kappa light polypeptide gene enhance in B cells inhibitor; IL, interleukin; MHC II, major histocompatibility class II; MSC, mesenchymal stem cell; mTORC, mammalian target of rapamycin complex; NFATc, nuclear factor of activated T cells cytoplasmic; TNFR, tumor necrosis factor receptor; TREG, regulatory T-cell.
The different medications and their targets against B cells and T cells are illustrated in this figure. MSC and TREG infusions are depicted extracellularly.
Reprinted from Choi SW, Reddy P. Current and emerging strategies for the prevention of graft-versus-host disease. *Nat Rev Clin Oncol*. 2014;11(9):536-547. doi:10.1038/nrclinonc.2014.102 [additional rights language TK].

Figure 22-6 Various TCE Formats Described in Immuno-Oncology



Abbreviations: BiTE, bispecific T-cell engager; CiTE, checkpoint inhibitor T-cell engager; DART, dual affinity retargeting; scFv, single-chain variable fragment; SMiTE, simultaneous multiple interaction T-cell engager; TCE, T-cell engager; TetraTE, tetraspecific T-cell engager; TriTE, trispecific T-cell engager; VH-VL, variable heavy and variable light.

Various TCE formats described in immuno-oncology. scFvs derived from T-cell receptor antibodies (blue) and from tumor-associated antigen antibodies (red) can associate to form BiTEs. BiTEs can be combined with a third scFv (green) to form a TriTE and with an additional moiety to form a TetraTE. BiTEs can also be complemented with the extracellular domain of PD1 to form a CiTE or administered with a second molecule, such as an anti-CD28 × anti-PDL1, as in the SMiTE. Various molecular modifications, such as mutations of the VH-VL interface, shorter links between domains and the addition of disulfide bonds, have led to the development of additional formats, such as diabody, tandem diabody, and DART. Created with Biorender.
