Contents

About the editors, viii

Contributor's list, x

Preface to the eighth edition by Adam J Mead, xiv

Preface to the eighth edition by A Victor Hoffbrand, xv

Preface to the first edition, xvi

About the companion website, xvii

Part I General principles of haematology, 1

1 Human stem cells and haemopoiesis, 3
Petter S Woll and Adam J Mead

2 Phagocytes, 15
Fernando O Martinez, Giuseppe Teti and Siamon Gordon

3 Erythropoiesis in the human, 43
Douglas R Higgs, Christian Babbs and Mira Kassouf

4 Lymphocyte development and function, 56
Sean Hua Lim

5 The spleen, 71
Catherine Hildyard and Daniel Royston

6 Cancer immunotherapy, 82
Charlotte O'Brien-Gore, Sophie Papa and Shahram Kordasti

7 Clinical applications of gene editing and therapy, 96
Mohsin Badat and James Davies

8 Application of next-generation sequencing in haematology, 106
Angela Hamblin and Adele Timbs

9 The molecular basis of haematological malignancies, 121
Meng Wang, Niccolo Bolli and George S Vassiliou

10 Laboratory diagnosis of haematological neoplasms, 142
Barbara J Bain and Torsten Haferlach

Part II Red blood cell disorders and blood transfusion, 163

11 Iron metabolism, iron deficiency and disorders of haem synthesis, 165
Clara Camaschella and Chaim Hershko

12 Iron overload, 188
Clara Camaschella and Maria Domenica Cappellini

13 Megaloblastic anaemia, 201
A Victor Hoffbrand

14 Haemoglobin and the inherited disorders of globin synthesis, 222
Swee Lay Thein and David Rees

15 Sickle cell disease, 249
Neha Bhasin and Elliott P Vichinsky

16 Hereditary disorders of the red cell membrane and disorders of red cell metabolism, 269
Paola Bianchi and Narla Mohandas

17 Acquired haemolytic anaemias, 292
Rachel Kesse-Adu and Anietie Ekong

18 Red cell immunohaematology, 309
Nicole Thornton, Tom Bullock and Shubha Allard

19 Clinical blood transfusion, 328
Andrew Charlton, Shruthi Narayan and Shubha Allard

Part III Lymphoid disorders, 361

20 The classification of lymphomas, 363
Elias Campo, Gerard Frigola and Stefano A Pileri

21 Adult acute lymphoblastic leukaemia, 395
Clare J Rowntree and Adele K Fielding

22 Childhood acute lymphoblastic leukaemia, 409
Sujith Samarasinghe, Anthony Moorman and Ajay Vora

23 Chronic lymphocytic leukaemia and other chronic B-cell lymphoproliferative disorders, 428
Emili Montserrat

24 T-cell lymphoma and lymphoproliferative disorders, 452
Alessandro Broccoli and Pier Luigi Zinzani

25 Hodgkin lymphoma, 468
Beth Phillips and Graham P Collins

26 Indolent non-Hodgkin lymphomas, 482
Kim Linton and William Townsend

27 Aggressive B-cell non-Hodgkin lymphoma, 501
Matthew R Wilson, Jessica Okosun and Kate Cwynarski

28 Multiple myeloma, 524
Karthik Ramasamy and Sagar Lonial

29 Amyloidosis, 547
Ashutosh D Wechalekar

Part IV Stem cell and myeloid disorders, 561

30 Inherited aplastic anaemia/bone marrow failure syndromes, 563
Inderjeet S Dokal

31 Acquired aplastic anaemia and paroxysmal nocturnal haemoglobinuria, 583
Austin G Kulasekararaj, Neal S Young and Judith CW Marsh

32 Acute myeloid leukaemia, 605
Tumas Beinortas, Paolo Gallipoli and Brian J P Huntly

33 Chronic myeloid leukaemia, 630
David T O Yeung and Timothy P Hughes

34 The myelodysplastic syndromes, 652
Johanna Ungerstedt, Magnus Tobiasson and Eva Hellström Lindberg

35 Myeloproliferative neoplasms, 673
Claire N Harrison, Anna L Godfrey, Mary Frances McMullin and Deepti H Radia

36 Macrophages, dendritic cells and histiocytic disorders, 704
Matthew Collin, Venetia Bigley and Chris Bacon

37 Stem cell transplantation, 719
Charles Craddock and Ronjon Chakraverty

38 Clonal haematopoiesis, 745
Margarete A Fabre and George S Vassiliou

Part V Haemostasis and thrombosis, 757

39 Normal haemostasis, 759
Keith Gomez and John H McVey

40 The vascular function of platelets, 782
Stephen P Watson, Neil V Morgan, Paul Harrison and Gillian Lowe

41 Haemophilia and von Willebrand disease, 798
Michael A Laffan

42 Rare inherited coagulation disorders, 819
Flora Peyvandi and Marzia Menegatti

43 Acquired coagulation disorders, 829
Peter W Collins and Jecko Thachil

44 Congenital platelet disorders, 848
Maurizio Margaglione and Paul RJ Ames

45 Primary immune thrombocytopenia, 861
Nichola Cooper and Drew Provan

46 Thrombotic thrombocytopenic purpura (congenital and acquired) and haemolytic–uraemic syndrome, 872
Pier Mannuccio Mannucci, Massimo Cugno and Flora Peyvandi

47 Antithrombotic agents, 886
Jeffrey I Weitz

48 Pathogenesis of venous thromboembolism, 902
Henry G Watson

49 Prevention and management of venous thromboembolism, 921
Nicola Curry and Susan Shapiro

50 Pathogenesis and management of arterial thrombosis, 932
Willem L Bor, Dean RPP Chan Pin Yin, Jurriën M ten Berg, Constance Baaten and Hugo ten Cate

Part VI Consultative haematology, supportive care and miscellaneous disorders, 947

51 Haematological aspects of conditions that occur primarily in tropical countries, 949
Imelda Bates and Ivy Ekem

52 Lysosomal storage disorders, 966
Derralynn A Hughes

53 Obstetric haematology, 974
Gillian Swallow and Sue Pavord

54 Neonatal haematology, 989
Irene Roberts and Subarna Chakravorty

55 Supportive care in the management of leukaemia, 1005
Renuka Palanicawandar and Jiří Pavlů

56 General consultative haematology, 1024
John Willan

57 Consultative haemostasis and thrombosis, 1036
Michael A Laffan and Peter MacCallum

Index, 1055

About the editors

A Victor Hoffbrand qualified in medicine in 1959 at the University of Oxford. After 10 years research at the Royal Postgraduate Medical School, he was appointed in 1974 as professor of Haematology at the Royal Free School of Medicine where he was to spend the rest of his career.

He has published over 700 peer-reviewed scientific papers and chapters in the fields of megaloblastic anaemia, iron chelation, the biochemical, immunological, and molecular biological aspects of leukaemia and lymphoma and stem cell transplantation. He has authored nine editions of *Hoffbrand's Essential Haematology*, five of *The Color Atlas of Clinical Hematology*, four of *Haematology at a Glance* and has edited seven editions of *Postgraduate Haematology*. He authored the haematology section of the *British National Formulary* (1971–1999) and was Chairman of the Editorial Board of the *British Journal of Haematology* from 1990 to 2000. With Robin Foa, he edited *Reviews in Clinical and Experimental Haematology* (2000–2005) and also co-edited with Malcolm Brenner seven editions of *Recent Advances of Haematology*. In 2023, he authored *The Folate Story: A Vitamin Under the Microscope*.

He is a past-president of the British Society for Haematology and was one of the two UK founding councillors of the European Haematology Association. He has lectured in over 40 countries and been visiting professor in Melbourne, Toronto, Rawalpindi, Chandigarh and South Africa. He has advised the Ministries of Health in Kuwait, Cyprus, Hong Kong and Lebanon on their haematology services.

He has been awarded Honorary DSc degrees from Queen Mary (2012) and University College (2019), London. In 2018, he received the Sultan Bin Khalifa International Thalassemia Award, the President's Medal of the Royal College of Physicians and the Wallace H. Coulter Award for Lifetime Achievement, the American Society of Hematology. In 2019, he was awarded the British Society for Haematology Lifetime Achievement Award. He was elected F. Med. Sci. in 2000 and from 2012 to 2013 he was a fellow commoner at The Queen's College, Oxford.

Adam J Mead is a Professor of Haematology in the University of Oxford. Professor Mead is the Clinical Lead for Myeloproliferative Neoplasms (MPN) at Oxford University Hospitals NHS Foundation Trust and has been the Principal or Chief Investigator of over 50 clinical trials in MPN and chronic myeloid leukaemia (CML). He chaired the National Cancer Research Institute MPN subgroup from 2016 to 2022. Professor Mead leads a research group at the MRC Weatherall Institute of Molecular Medicine. The overarching focus of his research group is to discover novel and rational therapeutic strategies to address the current unmet need in persons with MPN, fuelled by a better understanding of the biological principles underlying disease development and progression. He has published over 150 peer-reviewed scientific papers and was elected F. Med. Sci in 2024.

Professor Graham P Collins is an associate professor of Haematology at Oxford University and lead of the Haematology and Lymphoma service at Oxford University Hospitals NHS Foundation Trust. He is deputy chair of the National Cancer Research Institute (NCRI) lymphoma clinical study group, past chair of the Hodgkin and T-cell lymphoma study groups and clinical expert on the National CAR-T Clinical Panel for lymphoma. His academic interests are in Hodgkin and high-grade non-Hodgkin lymphoma, and he is chief investigator on a number of investigator-initiated and commercial clinical trials. He has worked with the National Institute for Health and Care Excellence on guidelines for non-Hodgkin lymphoma and has also co-authored British Society of Haematology guidelines on Hodgkin lymphoma and T-cell lymphoma. Professor Collins is founder and co-course director of the national Lymphoma Management Course and is a supervisor for a number of PhD and MD students. He speaks widely at national and international congresses on a variety of lymphoma-related topics.

Deborah Hay qualified in medicine from the University of Oxford and completed postgraduate training in London, Glasgow and Oxford. After a period of research training in red cell haematology at the Weatherall Institute of Molecular Medicine, she was appointed as the clinical tutor for Laboratory Medicine and Pathology at Oxford University Medical School, and subsequently as deputy director of the graduate-entry medical course. Clinically, her time is divided between consultant practice in diagnostic laboratory haematology and haematopathology in Oxford.

Professor Michael A Laffan is a visiting professor of Haemostasis and Thrombosis at Imperial College London. He was previously consultant haematologist at the Imperial College Healthcare NHS Trust and director of the Hammersmith Hospital Haemophilia Centre. He received his medical degree from the University of Oxford and later trained in Haematology at the Hammersmith and Royal Free Hospitals in London before joining the Royal Postgraduate Medical School, later Imperial College Medical School, as senior lecturer and honorary consultant in 1992.

Professor Laffan is the author of numerous guidelines and contributions to textbooks and is an editor of Practical Haematology. He chaired the British Society for Haematology Task Force on Haemostasis and Thrombosis for six years and the United Kingdom Haemophilia Centre Doctors' Organisation (UKHCDO) von Willebrand disease working party until 2020. He is currently chair of the BSH Guidelines Executive and has been a senior examiner for the RCPath, chair of the North London Training committee and training programme director.

His research interests have been on the structure–function relationship of von Willebrand factor, with a focus on the role of glycosylation, the role of von Willebrand factor in angiogenesis and the mechanisms and regulation of thrombin generation. He was a lead investigator on the BRIDGE study of genetics in bleeding disorders, precursor to the 100k genomes project and on gene therapy trials for haemophilia.

Contributor's list

Shubha Allard
NHS Blood and Transplant, London, UK

Paul RJ Ames
Immune Response and Vascular Disease Unit, Nova University Lisbon, Lisbon, Portugal
Haematology Department, Dumfries & Galloway Royal Infirmary, Dumfries, Scotland, UK

Constance Baaten
Department of Biochemistry, Maastricht University Medical Center (MUMC+) and CARIM School of Cardiovascular Diseases, Maastricht, the Netherlands
Institute for Molecular Cardiovascular Research (IMCAR), University Hospital RWTH Aachen, Aachen, Germany

Christian Babbs
The Laboratory of Gene Regulation, The MRC Weatherall Institute of Molecular Medicine, The University of Oxford, Oxford, UK

Chris Bacon
Translational and Clinical Research Institute, Newcastle University, Newcastle upon Tyne, UK

Mohsin Badat
Centre for Genomics and Child Health, Blizard Institute, Queen Mary University of London, UK

Barbara J Bain
Centre for Haematology, Department of Immunology and Inflammation, St Mary's Hospital, London, UK

Imelda Bates
Liverpool School of Tropical Medicine, Liverpool, UK

Tumas Beinortas
Department of Haematology and Wellcome Trust – MRC Cambridge Stem Cell Institute, University of Cambridge and Haematology Service, Cambridge University Hospitals, Cambridge, UK

Jurriën M ten Berg
Department of Cardiology and Heart Center, St Antonius Hospital, Nieuwegein, the Netherlands
Department of Cardiology, Maastricht University Medical Center (MUMC+) and CARIM School of Cardiovascular Diseases, Maastricht, the Netherlands

Neha Bhasin
Department of Pediatrics, Division of Hematology, UCSF Benioff Children's Hospital Oakland, Oakland, CA, USA

Paola Bianchi
Hematology Unit, Pathophysiology of Anemias Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico Milano, Milan, Italy

Venetia Bigley
Translational and Clinical Research Institute, Newcastle University, Newcastle upon Tyne, UK

Niccolo Bolli
Fondazione IRCCS Istituto Nazionale dei Tumori, University of Milan, Milan, Italy

Willem L Bor
Department of Cardiology and Heart Center, St Antonius Hospital, Nieuwegein, the Netherlands

Alessandro Broccoli
IRCCS Azienda Ospedaliero-Universitaria di Bologna, Istituto di Ematologia "L. e A. Seràgnoli", Bologna, Italy

Tom Bullock
Red Cell Immunohaematology, NHS Blood and Transplant, Bristol, UK

Clara Camaschella
San Raffaele Hospital and Scientific Institute, Milan, Italy

Elias Campo
Hospital Clinic, University of Barcelona, Barcelona, Spain

Maria Domenica Cappellini
Foundation IRCCS Ca' Granda Policlinico and DISSCO University of Milan, Milan, Italy

Hugo ten Cate
Department of Biochemistry, Maastricht University Medical Center (MUMC+) and CARIM School of Cardiovascular Diseases, Maastricht, the Netherlands
Internal Medicine, Maastricht University Medical Center (MUMC+) and CARIM School of Cardiovascular Diseases, Maastricht, the Netherlands
Thrombosis Expertise Center, Maastricht University Medical Center (MUMC+) and CARIM School of cardiovascular diseases, Maastricht, the Netherlands
Center for Thrombosis and Haemostasis, Gutenberg University Medical Center, Mainz, Germany

Ronjon Chakraverty
MRC Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, UK

Subarna Chakravorty
Department of Paediatric Haematology, King's College Hospital, London, UK

Andrew Charlton
NHS Blood and Transplant and The Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle upon Tyne, UK

Matthew Collin
Translational and Clinical Research Institute, Newcastle University, Newcastle upon Tyne, UK

Graham P Collins
Department of Haematology, Oxford Cancer and Haematology Centre, Oxford, UK

Peter W Collins
School of Medicine, Cardiff University, University Hospital of Wales, Cardiff, UK

Nichola Cooper
Imperial College, London, UK and Queen Mary University of London, London, UK

Charles Craddock
Centre for Clinical Haematology, Queen Elizabeth Hospital, Birmingham, UK

Massimo Cugno
Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Università degli Studi di Milano, Milan, Italy

Nicola Curry
Oxford University Hospitals NHS Foundation Trust, Oxford University, Oxford, UK

Kate Cwynarski
Department of Haematology, University College Hospital, London, UK

James Davies
MRC Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, UK
National Institute of Health Research Blood and Transplant Research Unit in Precision Cellular Therapeutics, Oxford, UK

Inderjeet S Dokal
Barts and The London School of Medicine and Dentistry, Queen Mary University of London, Barts Health NHS Trust, London, UK

Ivy Ekem
School of Medical Sciences, University of Cape Coast, Cape Coast, Ghana

Anietie Ekong
Guy's and St Thomas' Hospital, Great Maze Pond, London, UK

Margarete A Fabre
Department of Haematology, Cambridge Stem Cell Institute, University of Cambridge, Cambridge, UK

Adele K Fielding
Centre for Blood Research, Hull York Medical School, University of York, UK

Gerard Frigola
Hospital Clinic, University of Barcelona, Barcelona, Spain

Paolo Gallipoli
Centre for Haemato-Oncology, Barts Cancer Institute, Queen Mary University of London, London, UK

Anna L Godfrey
Department of Haematology, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK

Keith Gomez
Haemophilia Centre and Thrombosis Unit, Royal Free London NHS Foundation Trust, London, UK

Siamon Gordon
Graduate Institute of Biomedical Sciences, College of Medicine, Chang Gung University, Taoyuan City, Taiwan
Sir William Dunn School of Pathology, University of Oxford, Oxford, UK

Torsten Haferlach

Preface to the eighth edition by Adam J Mead

It is a huge honour to take on the role of Editor-in-Chief of *Postgraduate Haematology* for its eighth edition. The book has been an important text in haematology for over five decades, with the fourth edition providing essential reading during my postgraduate exams in haematology 20 years ago. It was a particular pleasure therefore to edit the book alongside Professor Victor Hoffbrand, who edited the first seven editions since the book's inception in 1972. For the eighth edition, we have renamed the book *Hoffbrand's Postgraduate Haematology* in honour of Victor's incredible contribution to the text over so many years. We have also established a new editorial team with a broad range of expertise across different areas in haematology. We have extensively updated the book for the new edition which now includes 57 chapters written by international experts in their respective fields, with chapters divided across 6 themes. Haematology remains at the forefront of the application of advances in molecular biology to the management of human disease, and reflecting this, we have introduced a number of entirely new chapters covering important advances in clinical applications of gene editing and therapy, application of next-generation sequencing in haematology and cancer immunotherapy. Additional new chapters are focussed on clonal haematopoesis, macrophages, dendritic cells and histiocytic disorders, obstetric haematology and consultative haemostasis and thrombosis.

In this digital age, I firmly believe that *Hoffbrand's Postgraduate Haematology* will remain a crucial text for those undergoing postgraduate training in haematology, as well as practising clinicians and scientists working in the field. Faced with the challenge of keeping up to date with an increasingly complex landscape across the wonderfully diverse areas encompassed by clinical and laboratory haematology, we hope that *Hoffbrand's Postgraduate Haematology* will provide a useful resource of authoritative information.

It is an enormous collaborative effort putting together a 57-chapter textbook, and I am immensely grateful to my co-editors, chapter authors and the team at Wiley for their help and patience along the way.

Preface to the eighth edition by A Victor Hoffbrand

Postgraduate Haematology began life 52 years ago as *Haematology: Tutorials in Postgraduate Medicine*. The authors were all members of the Department of Haematology at the Royal Postgraduate Medical School (RPMS), Hammersmith Hospital. John Dacie, Head of the Department, was first invited to edit the book but with other major book writing commitments, *Practical Haematology* and *The Haemolytic Anaemias*, he suggested Mitchell Lewis and me as editors.

The chapters of this first edition were all written by distinguished colleagues in Dacie's Haematology Department including Ted Gordon-Smith (haemolytic and aplastic anaemias), David Galton (leukaemias, myeloma and lymphomas), John Goldman (leucocytes), Leon Szur (myeloproliferative diseases), Bob Pitney (coagulation), and Sheila Worlledge (blood transfusion). They were based on the lectures we gave in the annual Diploma in Clinical Pathology Course at the RPMS.

The book was not intended as a reference to me but as an easily read text for learning about the blood diseases – their pathogenesis, clinical and laboratory features, relevant diagnostic tests, treatment and prognosis. A suggested reading list was given at the end of each chapter but references in the text were avoided. The title *Postgraduate Haematology* was adopted for the second and subsequent editions published by William Heinemann, Butterworth Heinemann, Arnold, Oxford University Press, Blackwell and now Wiley-Blackwell.

With the vast increase in knowledge of blood and its diseases, the book has inevitably increased in size but all editions have followed the same formula. *Postgraduate Haematology* is intended to provide a comprehensive, well-illustrated text, suitable for higher examinations and to the level of consultant haematologist.

Inevitably, a wider range of editors and authors have been needed since the first edition. Edward Tuddenham joined the original two editors to cover the coagulation section for editions four to six; both Daniel Catovsky (editions five and six) and Anthony Green (edition six) were editors for the neoplastic diseases. The editors of the seventh edition included Douglas Higgs, David Keeling and Atul Mehta. The authors, experts in their respective fields, are from around the world, especially from the UK, Europe and North America.

It has been my privilege to edit the first seven editions of *Postgraduate Haematology*. I am delighted to have been replaced as 'editor-in-chief' for the eighth edition by a younger colleague, the talented Oxford haematologist Adam Mead and to welcome his distinguished team of co-editors. They can be just proud of this superb new edition. Finally, I thank the publisher Wiley-Blackwell for adding my name to the book's title.

Victor Hoffbrand, London, 2024

Preface to the first edition

In this book the authors combine an account of the physiological and biochemical basis of haematological processes with descriptions of the clinical and laboratory features and management of blood disorders. Within this framework, each author has dealt with the individual subjects as they thought appropriate. Because this book is intended to provide a foundation for the study of haematology and is not intended to be a reference book, it reflects, to some extent, the views of the individual authors rather than providing comprehensive detail and a full bibliography. For these the reader is referred to the selected reading given at the end of each chapter. It is hoped that the book will prove a particular value to students taking either the primary or the final part of the examination for membership of the Royal College of Pathologists and the Diplomas of Clinical Pathology. It should also prove useful to physicians wishing to gain special knowledge of haematology and to technicians taking the Advanced Diploma in Haematology of the Institute of Medical Laboratory Technology, or the Higher National Certificate in Medical Laboratory subjects.

We acknowledge kind permission from the editors and publishers of the *British Journal of Haematology*, the *Journal of the Royal College of Physicians of London* and the *Quarterly Journal of Medicine* to reproduce Figures 4.1, 4.5, 4.10, 4.11, 4.12, 9.4 and 9.10, the publishers of *Progress in Haematology* for Figure 7.2 and many other publishers who, together with the authors, have been acknowledged in the text. We are particularly grateful to Professor J. V. Dacie for providing material which formed the basis of many of the original illustrations in Chapters 4–8. We are greatly indebted to Mrs T. Charalambos, Mrs J. Cope and Mrs D. Haysome for secretarial assistance and to Mrs P. Schilling and the Department of Medical Illustration for photomicrography, art work and general photography.

Finally, we are grateful for the invaluable help and for bearance we have received from Mr R. Emery and William Heinemann Medical Books.

The website includes the following:

- Bonus chapter 58
- PDFs of the tables
- PowerPoints of the figures

PART I

General principles of haematology

CHAPTER 1

Human stem cells and haemopoiesis

1

Petter S Woll[1] and Adam J Mead[2]

[1]Center for Hematology and Regenerative Medicine, Department of Medicine Huddinge, Karolinska Institutet, Stockholm, Sweden
[2]Haematopoietic Stem Cell Biology Laboratory, Medical Research Council Molecular Haematology Unit, Medical Research Council Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, UK

Introduction

The regenerative potential of tissues in the human body has fascinated researchers for many years, perhaps sparked by the ancient Greek myth describing Prometheus's fate, punished by Zeus to have a vulture feed off his liver during the day, only for the liver to be regenerated and the process repeated daily. Although the ancient Greek myth at that time was unlikely to be based on knowledge on the regenerative potential of the liver, we now know that most tissues in the human body contain regenerative potential to replace cells lost due to their normal limited lifespan, stress, disease or injuries, and that this process depends on tissue-specific stem cells. Of these, the stem cells responsible for the production and maintenance of mature blood cells, the haemopoietic stem cell, remains the most well characterised stem cell system to date. The routine clinical use of bone marrow transplantation to rescue diseased haemopoiesis highlights the impressive power of stem cell therapy, facilitated by the culmination of decades of biological and clinical research. Although representing the only curable treatment option for several disease conditions, it still is not possible to offer this treatment to all patients in need. As such, more research towards both the biology and clinical application of human haemopoietic stem cells are required to further improve our understanding and clinical application of haemopoietic stem cell therapies.

Human haemopoietic stem cells and the haemopoietic differentiation hierarchy

Blood is one of the most regenerative tissues in the body, where every minute millions of mature blood cells need to be replaced in a normal healthy individual due to their finite lifespan. In contrast to solid tissues, blood cells are dispersed throughout the body. Although the majority of mature blood cells are found in peripheral blood and haemopoietic organs such as the bone marrow, spleen, thymus and lymph nodes, mature blood cell infiltration in other organs and tissues are also important for prevention of infections and response to injury. With the exception of long-lived memory B and T cells, and some tissue-resident macrophages, mature blood cells have a short lifespan, ranging from just a few days for mature granulocytes, monocytes and platelets to 120 days for red blood cells (Figure 1.1). Ensuring the continuous replacement of lost cells is critical to maintain normal homeostasis, as insufficient blood cell production results in cytopenia and increased risk for infection, and if not corrected threatens the ability to sustain life. The process of blood cell production, haemopoiesis, results in the daily generation of 10^{11}–10^{12} mature blood cells in an adult healthy individual, numbers which can increase in response to acute stress such as large blood loss, infection or disease conditions.

Haemopoiesis is a tightly regulated cellular process that depend on the lifelong pool of haemopoietic stem cells (HSCs) defined by their ability to self-renew and potential to generate

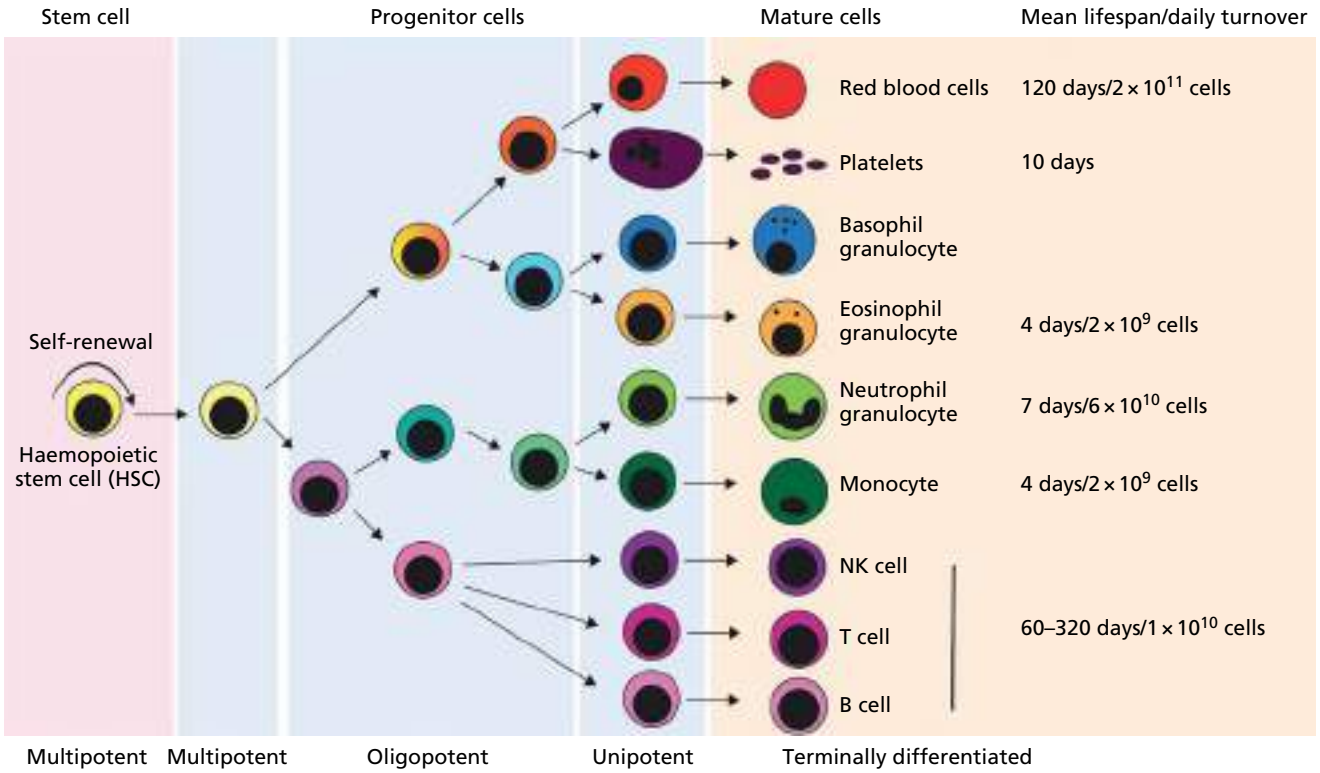

Figure 1.1 The human haemopoietic hierarchy. The human haemopoietic hierarchy has a unidirectional differentiation path (arrows going from left to right only) with the haemopoietic stem cell at the apex and the mature blood cells at the end. Due to the short lifespan and daily turnover of mature blood cells, continuous replenishment of lost cells is facilitated by haemopoietic stem cells through the generation of series of haemopoietic progenitor cells which gradually lose lineage potential. This process of active haemopoiesis is dependent on a limited pool of quiescent and long-lived haemopoietic stem cells in the bone marrow with life-long self-renewal potential and potential to generate all mature blood cells.

all blood cell lineages (multipotent). In adults, this process takes place in the bone marrow, the major site of residency for HSCs after birth. HSCs represent an infrequent population of cells in the bone marrow, and studies to understand how such a rare population of cells can generate trillions of cells on a daily basis has been at the centre of research since their existence was proposed. Studies in model organisms and on material from human subjects have demonstrated that the impressive production of blood cells is achieved through a unidirectional cellular hierarchy where HSCs are located at the apex and give rise to the mature blood cells through the generation of series of intermediate progenitor cell stages. In contrast to HSCs, the majority of these intermediate progenitor cells are short-lived as they lack self-renewal potential and therefore depend on continuous replenishment from the HSCs. The generated progenitor cells are highly proliferative and as they differentiate through the haemopoietic hierarchy, they gradually lose potential to generate one or more lineages. Although the cellular differentiation pathway from human HSCs is still under investigation, studies have suggested that HSCs first give rise to progenitor cells that carry the same potential as HSCs (multipotent) but have lost or reduced ability for self-renewal and therefore will not be sustained for an extended period of time. The multipotent progenitor then gives rise to oligo-potent progenitors that has lost potential for one or more blood cell lineages, which ultimately gives rise to unipotent progenitors restricted towards one blood cell lineage. In both mouse and human bone marrow, many of these intermediate progenitor cell stages have been identified suggesting that the first lineage-restriction that occurs after a multipotent progenitor cell results in division between progenitors with potential to generate lymphoid cells (B, T and NK cells), neutrophils and monocytes/macrophages and progenitors with potential to generate erythroid, megakaryocyte/platelets, eosinophils and basophils. Identification and characterisation of these stages is important not just for understanding the underlying cell biology, but also since these intermediate stages often are perturbed in diseases and haematologic malignancies, they remain relevant for understanding how haemopoietic dysregulation leads to clinical

disease. Although the haemopoietic hierarchy often is displayed as discrete stages of cellular intermediates (Figure 1.1), it is probable that a more gradual continuum of lineage restriction exists, rather than the binary distinct stages typically displayed in figures in the literature.

Human haemopoietic stem cell characteristics

HSCs, similar to stem cells responsible for the regeneration of other tissues, are defined functionally by their ability to self-renew, meaning that they can persist for the duration of life through generation of daughter HSCs, and their capacity for multipotent differentiation, meaning they have the potential to generate all mature haemopoietic cell types. In light of the dependence of blood production on HSCs it is critical that the number of HSCs and their activity is tightly controlled, both under steady-state conditions and under stress conditions. In response to signals from HSCs themselves (intrinsic) and the surrounding environment (extrinsic), HSCs can undergo different fates that regulate the number of HSCs in the body (Figure 1.2). In response to proliferative signals HSCs undergo cell division, where an asymmetric division generates two daughter cells, one which is an exact HSC copy of the parental HSC, endowed with both self-renewal and multipotency, and a differentiated progeny which has lost self-renewal. Such a cell division would result in neither gain or loss of HSCs and therefore preserve the number of HSCs in the bone marrow. Alternatively, HSCs can undergo two different types of symmetric cell divisions. If a HSC undergo a symmetrical self-renewal division, two new daughter HSCs will be generated from the parental HSC, both with self-renewal and multi-potency, resulting in an expansion of HSC numbers. However, if a parental HSC undergo a symmetric differentiation division, two differentiated daughter cells without self-renewal will be generated, resulting in HSC loss. In addition to cell division, HSCs can also undergo apoptosis which similar to symmetric differentiation division results in HSC loss.

Although cell division is required for the progeny generation, cell divisions are infrequently performed by HSCs during steady-state conditions. Instead, most HSCs remain dormant in a quiescent state, referred to as G_0 in the cell cycle. Quiescence is a hallmark feature of HSCs in steady-state conditions, defined

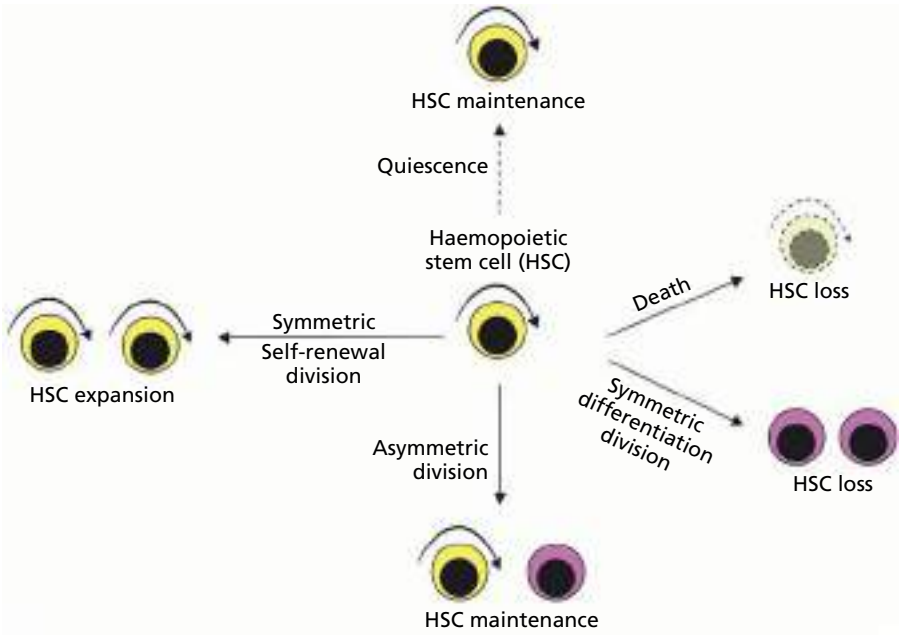

Figure 1.2 Haemopoietic stem cell fate options. Controlling the number of haemopoietic stem cells is critical for preserving normal blood cell production. During steady-state, the majority of haemopoietic stem cells are highly quiescent, protecting the haemopoietic stem cells from the potential harmful effects actively dividing cells are exposed to and preserving the haemopoietic stem cell pool. Upon stimulation, haemopoietic stem cells can be activated and undergo cell division. Symmetric division can either result in haemopoietic stem cell expansion or loss, dependent on the generated progeny being haemopoietic stem cells or differentiated progenitor cells. Asymmetric division, where cell division generated one daughter haemopoietic stem cell and one differentiated progenitor cell, preserve the haemopoietic stem cell pool. Upon exposure to harmful effects, lack of appropriate stimulation or haemopoietic stem cell exhaustion, haemopoietic stem cells can undergo programmed cell death. The fate of haemopoietic stem cells is regulated by the complex interplay between extrinsic (environmental) and intrinsic (inside haemopoietic stem cells) factors.

by infrequent cell cycle divisions and low metabolic activity. This is a critical cellular mechanisms that maintain HSC functional integrity by protecting against HSC exhaustion, harmful substances and DNA damage that can result in leukemic transformation. Quiescence is therefore a critical mechanism for preserving the HSC pool. In light of the high degree of cellular dormancy associated with HSCs, it is proposed that primitive multipotent progenitor cells to a large degree actively contribute to steady-state haemopoietic. Although these progenitors depend on generation from HSCs, they can sustain blood production for long but finite periods of time, reducing the need for a continuously active HSC pool. However, under stress-conditions, also the HSCs are activated and proliferate until normal blood production is restored.

Assays for human haemopoiesis

The existence of HSCs was already proposed in the early 1900s where a common progenitor was proposed to explain the heterogeneity among different blood cells. However, the experimental proof for HSCs was not established until after the post-World War II era when the impact of large-dose irradiation was explored and the lethal effect of irradiation was found to be rescued by bone marrow transplantation. In part, this led to the clinical use of haemopoietic stem cell transplantation which is widely used in the clinic today, but also sparked the development of experimental assays that led to the identification of HSCs. These were spearheaded by two Canadian researchers, James Till and Ernest McCulloch, who first developed an assay that demonstrated the existence of cells with ability to self-renew and produce cells of different blood lineages. These initial studies were performed in mice which after receiving a lethal dose of irradiation were transplanted with bone marrow harvested from a non-irradiated mouse. Upon termination of the mice following transplantation, they noticed distinct nodules in the spleen resembling colonies where an individual colony was demonstrated to originate from a single cell (clonal), contain progeny of multiple blood cell lineages (multipotent) and could be serially transplanted into new irradiated recipients (self-renew). Cells that contained this potential were referred to as colony forming unit (CFU) spleen and formed the birth of stem cell biology and development of additional assays that allowed for the identification and characterisation of HSCs in mouse and man.

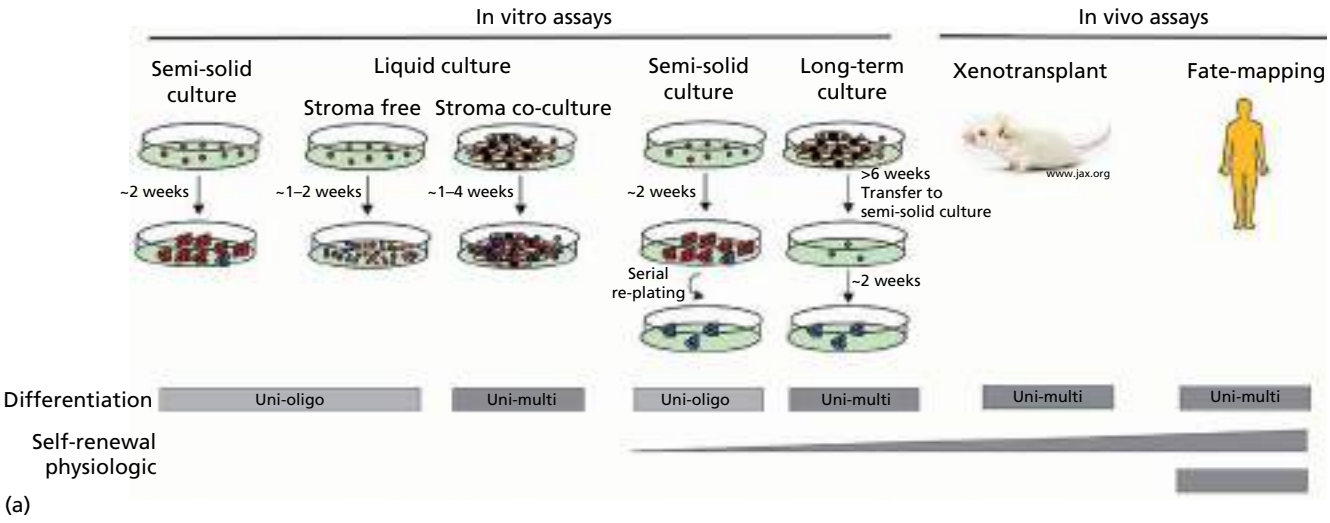
Short-term in vitro assays

In vitro assays (Figure 1.3a) have been instrumental for both identification of distinct haemopoietic stem and progenitor cell populations and the cytokines, as well as other growth factors, that regulate their ability to generate different mature blood cell lineages. Culture of haemopoietic cells in a semi-solid medium composed of methylcellulose supplemented with haemopoietic growth factors supports the proliferation and subsequent differentiation of haemopoietic stem or progenitor cells following short-term culture. Similar to the colonies observed in the spleen (CFU-spleen) of irradiated mice following transplantation of non-irradiated bone marrow, as the proliferation from stem and progenitor cells are physically restricted within the semisolid medium this results in the generation of multiple distinct colonies, where each colony originates from one single stem or progenitor cell. The characteristic colonies can be both classified into different blood cell lineages based on morphology and size, and enumerated in order to quantify the number colony forming cells (CFCs), representing primitive haemopoietic stem and progenitor cells, within the investigated population of cells. Although first developed in the 1960s, this assay is still widely used and even frequently applied in clinical laboratories to enumerate the functional integrity of haemopoietic stem and progenitor cells in cell preparations used for clinical transplantations. This assay was also central for the identification and characterisation of the impact of different haemopoietic growth factors on proliferation and differentiation from progenitor cells. In fact, many haemopoietic growth factors carry names that reflect this, including the cytokines granulocyte colony-stimulating factor (G-CSF), granulocyte-monocyte colony-stimulating factor (GM-CSF) and monocyte colony-stimulating factor (M-CSF).

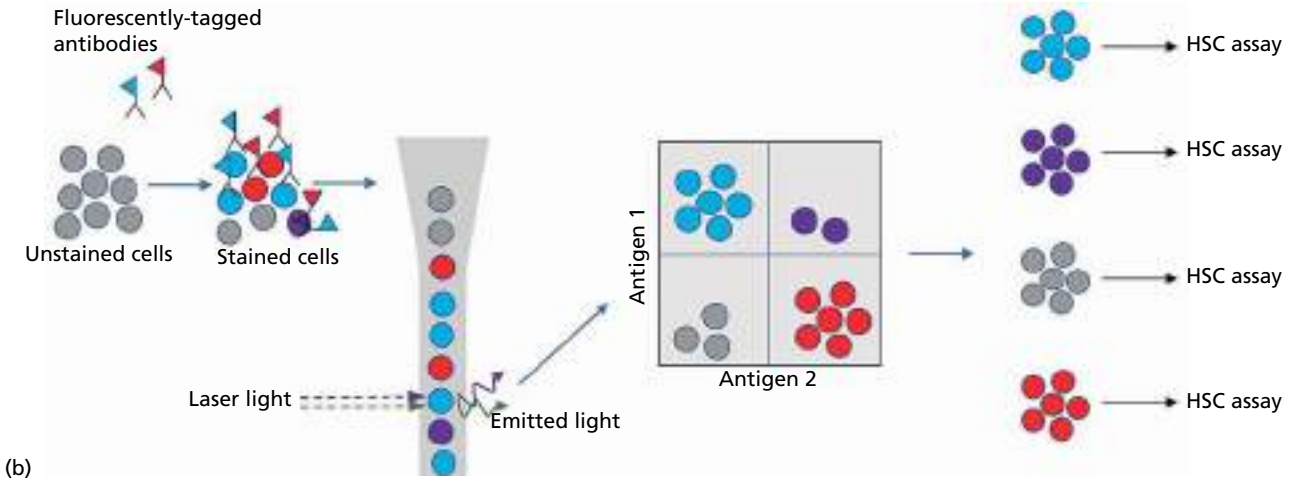
Culture of haemopoietic stem and progenitor cells in short-term liquid cultures can also be applied to evaluate their potential towards one or more lineages. These liquid culture assays come in two flavours, with or without supporting stromal cells. Although several stromal-free conditions can support the generation of myeloid and erythroid cells, the generation of lymphoid cells appears more dependent on stromal-cell support. For human stem and progenitor cells, differentiation towards B cells can be supported by OP9 stromal cells that were derived from the calvaria of newborn mice lacking M-CSF expression, whereas in order for the OP9 stromal cells to support differentiation towards the T cell lineage, transduction of the OP9 stromal cells with the Notch ligands Delta-like 1 or Delta-like 4 is required. Although culture in semi-solid medium allows quantification of single progenitors within a population, qualitative evaluation of lineage-potentials are primarily obtained from liquid cultures seeded with bulk populations. However, quantitative assessment can also be achieved by either plating cells by limiting dilution or through single-cell plating.

Long-term in vitro assays

Although useful for evaluating lineage-potentials, short-term cultures in liquid or semi-solid media are limited in their ability to evaluate self-renewal potential, and as such does not allow assessment of HSCs or long-lived progenitor cells. Instead, self-renewal potential can be assessed either by serial-replating of



(a)



(b)

Figure 1.3 Human haemopoietic stem and progenitor cell assays. (a) Overview of haemopoietic stem and progenitor cell assays where differentiation potential towards one or more blood cell lineages are explored (unipotent, oligopotent or multipotent) *in vitro* and *in vivo*. The ability to assess self-renewal potential is indicated where the scale indicates the relative longevity of the assay. Although in vitro assays and xenotransplantation are important for addressing the potential of haemopoietic cells, fate-mapping cells in human individuals is the only assay that provides information on behaviour of the cells under physiologic conditions. (b) Flow cytometry allows high-throughput analysis of protein expression on single cells within complex tissues by staining with fluorescently-tagged antibodies that bind to specific antigens expressed on the cell surface. Following exposure to specific laser light that excites the fluorescent marker, emitted light will be detected, where the level of emitted light is proportional to the number of molecules (antigens) expressed on the cell surface and bound the different fluorescently-tagged antibodies. As a result, different cells can be purified based on their cell surface expression patterns and then compared for their ability to read out in haemopoietic stem cell assays.

colonies generated in semi-solid medium, or by extended culture in liquid medium. Serial replating of colonies in semi-solid medium has in particular been applied to investigate self-renewal potential of leukemic stem cells which in contrast to HSCs, have reduced ability to differentiate and in some leukaemia can preserve their stem-like activity in the culture following several passages. Following serial replating, progenitor cells that lack self-renewal will not generate colonies that can be replated, whereas colonies derived from HSCs or leukemic stem cells can go through additional passages.

In long-term culture assays, such as the long-term culture initiating-cell assay, the ability of cells to sustain CFC activity is assessed after an initial stromal cell co-culture period of 6 weeks or longer. Following such long culture, the only cells that can

sustain ability to generate either myeloid or erythroid colonies upon transfer to semi-solid CFC culture are the cells that are endowed with extensive self-renewal potential. Cells that lack self-renewal potential, such as short-lived progenitor cells, are not able to sustain this long period of stromal cell co-culture, and therefore not able to produce colonies when transferred to the semi-solid medium. Three-dimensional scaffold cultures have also been applied to support long-term differentiation cultures.

Xenotransplantation assay

In vitro assays have been essential for the identification and characterisation of candidate human haemopoietic stem and progenitor cells, as well as providing a system where manipulations of extrinsic (cytokines, stromal cells and extracellular matrix proteins) and intrinsic (transcription factors, cytokine receptors and DNA integrity) factors can be investigated under controlled experimental settings to evaluate their impact on haemopoietic functional potential. However, mimicking the complex three-dimensional environment where HSCs reside in the human bone marrow is challenging to recapitulate with *in vitro* conditions. In particular, maintaining the quiescent nature of HSCs in adult BM has so far been unsuccessful *in vitro*. Furthermore, no single *in vitro* assays, neither after short- and long-term culture, have been demonstrated to fully address the potential to generate all blood cell lineages (multipotency). As a result, the development of an *in vivo* assay that allows assessment also of human haemopoietic stem and progenitor cells has been important.

Delineation of the haemopoietic hierarchy has been explored in mouse models, where single HSC transplantations have conclusively established the existence of truly multipotent HSCs with long-term self-renewal potential by the ability of a single HSC to reconstitute all mature lineages of the haemopoietic system, and can sustain this ability following serial transplantation. An important factor for allowing such experiments in mice is the ability to transplant donor cells that do not elicit an immunological rejection response by the recipient cells following transplantation. This has been possible through the use of mice on the same genetic background whilst still allowing the ability to distinguish between donor- and recipient-derived cells. Establishing such an *in vivo* assay for human cells, however, required further development, as it is not possible to perform similar controlled experiments in human recipients, and transplantation into wild-type mice will result in the immediate rejection of human cells due to species incompatibility (xeno-rejection). Realising the importance of an *in vivo* assay that enables investigation of human haemopoiesis, much efforts have been focused towards the development of immune-compromised mouse models that would not reject transplanted human cells.

Initial studies exploring the possibility of engrafting human haemopoietic cells in mice were performed using severe combined immune-deficient (*Scid*) mice that lack B and T cells. These studies demonstrated that human cells indeed could engraft in immunocompromised mice but it was not possible to demonstrate whether engraftment originated from multipotent human HSCs, as only lymphoid cells were observed in these early studies. Only by combining transplantation of human cells with infusion of human haemopoietic growth factors, including interleukin 3 (IL-3), GM-CSF and stem cell factor (SCF) was the long-term generation of lymphoid and myeloid cells observed, supporting that also multipotent and long-lived human stem or progenitor cells can engraft mice. However, as Scid mice were not fully immunocompromised, with spontaneous emergence of both mouse B and T cells, the immunocompromised mouse models have gone through series of genetic modifications to further enhance their ability to support long-term *in vivo* studies of human cells.

By crossing Scid mice to nonobese diabetic (NOD) mice to generate NOD/Scid mice, the rejection mediated by the mouse innate immune system was inhibited as the protein Sirpa expressed on NOD/Scid myeloid cells could bind to CD47 expressed on human cells, thereby preventing phagocytosis of human cells. Additionally, the NOD/Scid mice have been further modified to ablate expression of the common γ chain receptor, critical for transmitting signals from haemopoietic growth factors required for lymphoid differentiation. In addition to being more immunocompromised than the NOD/Scid mice, as NOD/Scid/common γ chain knockout (NSG) mice lack B, T and NK cells, the NSG mouse model also allows for more long-term studies as the risk for spontaneous lymphoma development is dramatically reduced in comparison to what seen in ageing NOD/Scid mice. Both NOD/Scid and NSG mice support long-term multipotent differentiation from transplanted human HSCs, including development of mature myeloid, lymphoid and erythroid cells. However, as several mouse haemopoietic growth factors are not cross-reactive to human cells, several critical components for supporting maintenance, propagation and differentiation of human haemopoietic cells are lacking. As a result, even newer generations of mice have been developed where factors supporting human haemopoietic growth and differentiation are expressed in the mouse bone marrow environment, including haemopoietic growth factors, as well as human leukocyte antigens (HLA) critical for allowing generation of mature T lymphocytes.

Fate-mapping

The use of immunocompromised mice has enabled *in vivo* studies of human HSC and progenitor cells, even down to the single cell level, and as such represent an essential tool for the characterisation of human haemopoiesis. However, this still is an assay where human cells are transferred into a stressed environment which lack several factors critical for supporting human haemopoiesis due to species incompatibility. As a

result, xenotransplantation does not necessarily reflect the behaviour of human cells under normal physiological conditions in the human bone marrow. Studies on mouse haemopoiesis using elegant genetically-modified mouse models have highlighted differences in the contribution of mouse haemopoietic stem and progenitor cells to active blood production under normal unperturbed conditions (steady-state) as compared to following stress, such as after transplantation. These studies, where the fate of different haemopoietic stem and progenitor cells are tracked over time (fate-mapping), have until recently been challenging to apply to studies of human haemopoiesis as the they depend on genetic modification of the mouse genome to generate suitable mouse strains for this purpose. However, with the advances in next-generation DNA sequencing, fate-mapping approaches can now be applied to study human haemopoiesis. Although X chromosome inactivation provided some insights, the advancement of DNA sequencing has allowed the ability to track the fate of single HSCs and long-lived progenitor cells within an individual, as will be explained in a separate section later.

Identification of human haemopoietic stem cells

As HSCs are rare in adult bone marrow, where as few as only one in a million bone marrow cells in human bone marrow represent a transplantable HSC, further enrichment is required in order to separate these cells from other cells in the bone marrow. In addition to the assays for evaluation of the functional behaviour of human haemopoietic cells, the development and application of fluorescently tagged antigen-specific antibodies combined with fluorescent activated cell sorting (FACS), has allowed the prospective identification and purification of haemopoietic stem and progenitor cells with different functional characteristics (Figure 1.3b). As haemopoietic cells in bone marrow and peripheral blood already are in single-cell suspension and easily accessible for collection from healthy and diseased individuals, these are particularly amenable to FACS. By staining haemopoietic cells with fluorescently tagged monoclonal antibodies recognising and specifically binding cell surface antigens, the protein expression on thousands of single cells can be analysed per second and viable cells with different expression patterns can be extracted for investigation in different haemopoietic assays. In initial studies, only a few cell surface markers could be investigated simultaneously, but with development of new fluorescent colours that can be tagged to antibodies and separated from one another based on the wavelength of emitted light following excitation of focused laser lights, current technology allows for the simultaneous analysis of more than 20 cell surface markers on single cells.

By combining FACS with the haemopoietic assays described above, it has been possible to enrich cells with HSC properties based on their cell surface expression pattern. In addition to enriching human HSCs by exclusion of known markers expressed on mature blood cells (so-called lineage markers), expression of the cell surface glycoprotein CD34, expressed by approximately 5% of the cells in adult human bone marrow, allows for purification of human HSCs. Although studies have reported that some human HSC activity can be found also outside of the $CD34^+$ cells, it is proposed that at least 99% of human HSCs are confined within the $CD34^+$ compartment. However, as the majority of the $CD34^+$ cells represent non-HSCs, including multipotent and oligopotent progenitor cells, additional markers have been identified to further separate HSCs from $CD34^+$ non-HSCs. The culmination of this work has led to the current phenotype allowing for the highest enrichment of human HSCs from both cord blood and adult bone marrow to encompass cells that lack expression of lineage markers ($Lineage^-$), are positive for CD34 and CD90, and negative for CD38 and CD45RA. By further sub-fractionating $Lineage^-CD34^+CD38^-CD90^+CD45RA^-$ cord blood cells-based expression of CD49f and ability to exclude the triarylmethane dye Rhodamine, a further enrichment can be achieved, where 14–28% of $Lineage^-CD34^+CD38^-CD90^+CD45RA^-CD49f^+Rhodamine^-$ cord blood cells were able to long-term reconstitute myeloid and lymphoid lineages following single cell transplantation into NSG mice. To date, this represent the most stringent and highest enrichment of human HSCs that have been demonstrated experimentally through single cell transplantation, where the inclusion of additional candidate markers, such as EPCR, could allow even further enrichment of bona fide human HSCs.

The application of cell surface molecules to enrich for human HSCs will be important for further functional characterisation of human HSCs. Although previously viewed as a relatively homogenous population, the mouse HSC compartment has recently been shown to include multiple HSC subsets, all endowed with long-term self-renewal potential but with different preferences in their contribution towards mature blood cell lineages. Single mouse HSC transplantation experiments have revealed that all mouse HSC subsets actively contribute to the platelet lineage, but with the exception of HSCs contributing to all mature blood cell lineages, these studies have demonstrated that the adult mouse bone marrow contains a high frequency of HSCs which lack contribution towards one or more blood cell lineages. HSCs exclusively contributing to mature platelets were the only uni-lineage HSC detected in these studies. Platelets generated from megakaryocytes are critical for preserving normal body function and life through their ability to prevent life-threatening bleeding. Mature megakaryocytes undergo multiple rounds of endomitosis, increasing ploidy and cytoplasm to ultimately allow platelet formation (see Chapter 40 for

more details on platelet formation and function). Although platelets are the second most abundant cell in blood (after red blood cells), they have the shortest lifespan and critically dependent on efficient production from HSCs. Interestingly, both in human and mouse haemopoiesis alternative differentiation pathways for the generation of mature platelets from haemopoietic stem and progenitor cells have been proposed, including so-called emergency pathways which bypass intermediate multipotent progenitor cell stages and allow the generation of megakaryocyte progenitor cells directly from HSCs. The identification of human HSC subsets generating platelets through alternative and potentially faster differentiation pathways has clinical relevance as these represent candidate pathways that can be exploited therapeutically to expedite platelet production in patients with life-threatening platelet deficiencies.

The ability to enrich human HSCs has not only been important for allowing cellular, molecular and functional characterisation of human HSCs, but has also been applied in clinical practice. Allogeneic bone marrow transplantation, where the donor bone marrow originates from a person that has a similar but not fully identical HLA match to the recipient, carries the risk of promoting a graft-versus-host-disease (GvHD) mediated by the donor T cells included in the transplant which mediate an allogeneic immune reaction against the recipient's own cells. In the worst case, such a reaction can have deadly outcome. In an effort to minimise the severity of the GvHD reaction, identifying a way to reduce the number of T cells included in the transplant without impacting the number of HSCs required for the reconstitution of recipient haemopoiesis was explored. Towards this, CD34 enrichment is sometimes used for this purpose, allowing the simultaneous enrichment of HSCs and depletion of T cells from whole bone marrow, as well as peripheral blood following donor-conditioning with a HSC mobilising agent that recruits $CD34^+$ cells from the bone marrow into peripheral blood.

Development of haemopoietic stem cells

Although the bone marrow is the primary site of HSCs and blood cell production in the adult, the emergence, expansion and differentiation of HSCs takes place at different sites and time points during embryonic development. Studies in mice and human embryos have shown a conserved appearance of the first haemopoietic cells, which are first detected in the human extra-embryonic yolk sac already 16–18.5 days post-conception. However, these cells lack bona fide HSC activity as the direct isolation of cells capable of reconstituting all blood lineages so far has not been possible from these first haemopoietic cells found in the developing yolk sac and are referred to as primitive haemopoiesis. Instead, the first HSCs and definitive haemopoiesis originate from within the human embryo around 19–27 days post-conception, where emerging haemopoietic cells can be found as budding off from endothelial cells lining the dorsal aorta in the aorta-gonad mesonephros region. Upon establishment of circulation, these cells migrate to and seed the fetal liver, which represent the major site of HSCs and haemopoietic differentiation during the embryonic period. In contrast to the highly quiescent HSCs in adult bone marrow, HSCs are during embryonic development highly proliferative and to a large degree undergo symmetric self-renewal divisions resulting in the rapid expansion of the number of HSCs in the embryo. This is critical, as the pool of HSCs required to sustain haemopoiesis through adult life are formed during this period. Shortly before birth, HSCs migrate from the fetal liver and other embryonic haemopoietic sites to seed the bone marrow which now takes over as the primary haemopoietic organ. In the mouse, bone marrow HSCs still remain in a proliferative phase for a period of around 3–4 weeks after birth, whereupon they enter the quiescent phase of the cell cycle and remain largely dormant unless stimulated to exit quiescence following exposure to stress.

In light of the challenges with recovery of sufficient HSCs for clinical application, including bone marrow transplantation, the mechanisms regulating the distinct proliferative states and symmetrical self-renewal divisions during embryonic and adult haemopoiesis has been a major focus. Uncovering the conditions and regulatory mechanisms that allow for rapid HSC expansion without loss of multipotency and self-renewal potential represents a key to unlocking the ability to expand HSCs for clinical use. Recent techniques have been developed which allow the *ex vivo* expansion of human and mouse HSC and now awaits clinical validation. Several transcription factors have been implicated towards this and this remains a major interest for translational biologists. Although the site of HSC and active haemopoiesis does not change following birth, ageing is associated with altered HSC performance and output. Both in mice and humans, the number of phenotypic HSCs expands with age. However, they appear to loose both proliferative potential and capacity for multi-lineage differentiation. In particular lymphoid potential is reduced with ageing, resulting in skewed myeloid differentiation from aged HSCs. Similarly, the frequency of single mouse HSCs capable of reconstituting mouse haemopoiesis declines with age.

Regulation of haemopoietic stem cells

The preservation of the normal HSC pool in the adult bone marrow, including maintaining their predominant quiescent state during steady-state haemopoiesis and the activation of

HSCs in response to stress, is tightly controlled by a complex interplay of intrinsic (internal to HSCs) and extrinsic (environmental) factors. This tightly regulated process is critical for protecting the HSCs from exhaustion or expansion, and dysregulation of factors impacting on HSC self-renewal and multi-lineage differentiation potential are frequently seen in haematologic diseases and malignancies.

Several intrinsic factors have been demonstrated to be critical for maintaining HSC self-renewal potential and ability to generate all blood cell lineages (multipotency). Particularly through work in genetically modified model organisms, the role of several transcription factors for ensuring HSC self-renewal capacity (e.g. Pbx1 and Evi1) and quiescence (Egr1, Gfi1 and FoxO) has been identified, where deficiency of these factors leads to HSC exhaustion as revealed through loss of ability to undergo serial transplantation in mice. Furthermore, epigenetic regulators involved in reshaping accessibility of the genome and the transcriptional activity, including the methyl-cytosine dioxygenase TET2, DNA methyltransferase 3A (DNTM3A) and Polycomb repressive complex members such as EZH2, are critical for regulating HSC activity. The importance of transcription factors and epigenetic regulators, as well as their impact on haemopoiesis, is demonstrated by the recurrent nature of mutations targeted to these genes in haematologic malignancies, leading to clonal outgrowth of mutated cells and reduced differentiation potential.

In addition to the tight transcriptional regulation of HSCs, it is also critical to protect the genomic integrity in HSCs. Cell division requires replication of DNA and although DNA damage repair mechanisms are critical for minimising the number of mutations acquired by each cell division, it is estimated that each human HSC accumulate on average 17 mutations per year. In addition, cell divisions result in shortening of telomere length. Both excessive DNA damage and telomere shortening are associated with HSC exhaustion. Maintaining HSC quiescence is, therefore, a key mechanism for preserving the HSC genome and maintenance of normal HSC activity. In addition to genetic factors controlling HSC metabolic activity where quiescent HSC undergo glycolysis, rather than the mitochondrial oxidative phosphorylation-driven metabolism utilised by actively dividing cells, the DNA damage repair machinery safeguards the genomic integrity in HSCs. In conditions where components of the DNA damage repair pathway are mutated, such as in Fanconi anaemia, the ensuing genomic instability results in a progressive HSC dysfunction leading to bone marrow failure, where bone marrow transplantation remains the only curative option.

As described above, the use of *in vitro* cell culture assays has facilitated the identification of haemopoietic growth factors supporting differentiation, as well as maintenance of HSCs. Although several of the haemopoietic growth factors might be produced from haemopoietic and non-haemopoietic cells residing in the bone marrow, there are also several growth factors critical for bone marrow haemopoiesis that are secreted from non-haemopoietic cells outside of the bone marrow. Thrombopoietin, a cytokine required to maintain bone marrow HSC function and preserve HSC quiescence is secreted by hepatocytes in the liver. This cytokine therefore regulates HSC by binding to and activating the thrombopoietin receptor (MPL) expressed on the HSC cell surface primarily through systemic, rather than local, delivery. In addition to being a critical cytokine for supporting HSC self-renewal *in vitro*, the critical role for preserving HSCs is demonstrated in human individuals with congenital amegakaryocytic thrombocytopenia, where inherited mutations in the thrombopoietin receptor results in HSC deficiency and multilineage haemopoietic defects which only can be rescued by bone marrow transplantation.

Another critical cytokine for regulating HSC activity is stem cell factor (SCF, or Kit-ligand). In mice, mutations in both SCF and the receptor for SCF, KIT, results in HSC loss, and the importance of SCF in supporting HSC self-renewal has also been supported by *in vitro* cultures. Interestingly, SCF can be produced as both a secreted and membrane-bound form, where in fact the membrane-bound form is believed to be particularly important for regulating HSC activity and in contrast to thrombopoietin acting primarily through local effects in the bone marrow microenvironment.

In addition to the haemopoietic growth factors, several components surrounding the HSCs in the bone marrow are important for maintaining the HSCs in their quiescent state, including interaction with extracellular matrix components and direct cell-to-cell interactions with niche components such as endothelial cells and mesenchymal stromal cells. Genetically modified model systems combined with advanced imaging technology, allowing high resolution imaging and localisation of distinct cellular and molecular components in the bone marrow, have revealed that HSCs are not randomly distributed throughout the bone marrow microenvironment, but rather appear physically embedded within distinct anatomic locations. This has resulted in the hypothesis that HSCs reside and depend on a distinct bone marrow niche, composed of a defined set of cell types responsible for maintaining the HSC pool through local interactions. These studies suggest a complex interplay among different cellular and secreted factors. Furthermore, it remains unclear to what degree HSC depend on a specific anatomically defined niche cell type or factor as HSC can be detected outside of the bone marrow microenvironment. During embryonic development, several sites can support HSC propagation, and functional HSCs can be isolated from peripheral blood. The latter is exploited in clinical practice, where stimulation with G-CSF or compounds that disrupt interaction between stromal-derived factor (SDF) and the chemokine receptor CXCR4, result in mobilisation of transplantable HSCs from bone marrow to the peripheral blood.

Fate-mapping human haemopoiesis

The delineation of the human haemopoietic hierarchy has so far depended on experimental assays where the potential of human cells to sustain self-renewal and multi-lineage differentiation has been explored following *in vitro* culture or transplantation into immunocompromised mice. Although these assays can provide important insight towards the functional potential of the investigated human cells under these experimental conditions, it is also important to remember that these represent artificial assays and conditions that do not necessarily reflect the natural habitat of human cells. Furthermore, the behaviour of the human cells under these conditions, might not reflect their actual behaviour or fate under normal physiological conditions in the human body. Such studies require fate-mapping approaches whereby the contribution (multipotency) and longevity (self-renewal) can be monitored under normal unperturbed conditions, as well as under stress. Genetically modified model organisms have provided important insights to both establishment of the haemopoietic system during embryonic development, as well as the contribution of distinct stem and progenitor cells towards steady-state haemopoiesis. Until recently the possibility to apply such approaches to human haemopoiesis was limited. However, with advances in next-generation DNA sequencing, it is now also possible to apply this approach and track the fate of single haemopoietic stem and progenitor cells in human subjects through genetic fate-mapping (Figure 1.4).

Genetic fate-mapping relies on the inheritance of the parental genome to each generated daughter cell, and by utilising genetic marks unique to each single parental cell, the contribution of one original cell can be investigated over time (Figure 1.4a). If a genetic mark is targeted to a parental cell with self-renewal and multi-lineage potential, the genetic mark will be inherited to the downstream daughter cells, as well as any progeny generated from these, and be sustained over long period of time. However, if a genetic mark is targeted to a cell that lacks self-renewal ability, this genetic mark will be lost over time when the parental cell reaches its defined lifespan. Furthermore, if targeted to a downstream progenitor cell, the genetic mark will not be detected further upstream in the hierarchy as differentiation is unidirectional.

In model organisms, trackable genetic marks have been introduced to the genome through elegant genetic engineering approaches, which allows introduction of genetic marks to specific cellular compartments and different time points during embryonic or adult development. In human haemopoiesis, a similar strategy can be achieved in clinical gene therapy trials, whereby the integration site of the lentiviral vector carrying the modified gene into the genome of the haemopoietic stem and progenitor cells transplanted into the patient provides a trackable genetic marker (Figure 1.4b). As the lentiviral integration site is unique for each donor HSC and progenitor cell transplanted into the patient, the single cell fate can be tracked following transplantation by DNA sequencing strategies that allow quantification of each unique integration site in different cellular compartments at different time points following transplantation. A donor cell that has self-renewal, multipotency and active contribution to haemopoiesis will result in high detection levels of specific integration site in all nucleated blood cell lineages and over extended period of time. In contrast, a unique integration site targeted to a progenitor could perhaps be detected at an early time point following transplantation, but would be lost at later time points. Such studies have revealed that short-lived progenitors can contribute to multi-lineage reconstitution at early stages following transplantation, but upon long-term follow-up these are lost, and contribution from HSC takes over as the major source of post-transplantation haemopoiesis.

Although tracing genetically distinct haemopoietic clones in gene therapy trials allows assessment of haemopoietic stem and progenitor contribution to distinct blood cell lineages, this strategy depend on *ex vivo* genetic modification of haemopoietic stem and progenitor cells. Furthermore, the conditioning associated with transplantation can alter the bone marrow environment and activate otherwise dormant HSCs, and as such, might not reflect their contribution or behaviour during steady-state haemopoiesis. In order to accomplish genetic fate-mapping of normal human haemopoiesis, one therefore needs to obtain reliable genetic markers that can be tracked without any *ex vivo* manipulation or introduction of cellular stress. Due to imperfect DNA repair mechanisms, each cell will acquire new DNA mutations with each DNA replication and it is estimated that human HSCs accumulate on average 17 mutations per year. The vast majority of these mutations are targeted to non-coding regions of the genome and has no functional impact on cell biology. As these mutations will be inherited each time the cell divide, the mutations will be transferred to all generated daughter cells. These somatically acquired mutations therefore represents unique genetic marks or barcodes that can be exploited for fate-mapping approaches (Figure 1.4c), where the number of mutations detected for each single cell also provide insight to the longevity of the unique clone. By first performing genetic profiling of single cells by DNA sequencing, the genetic profile (barcode) of a single cell can be established. The contribution of cells with unique genetic barcodes can then be quantified within different cell compartments in the haemopoietic hierarchy. Advanced computational analysis of the contribution of distinct genetic barcodes has also allowed predictions over the expansion and size of the HSC pool during early stages of embryonic development up to old age. Current estimates suggest that adult human normal bone marrow contain 50,000–200,000 HSCs that actively contributes to haemopoiesis. Further advances in DNA sequencing and computational analysis will likely continue to provide new and important insight to the establishment and maintenance of the human haemopoietic system, during steady-state, during stress and in haematologic disease.

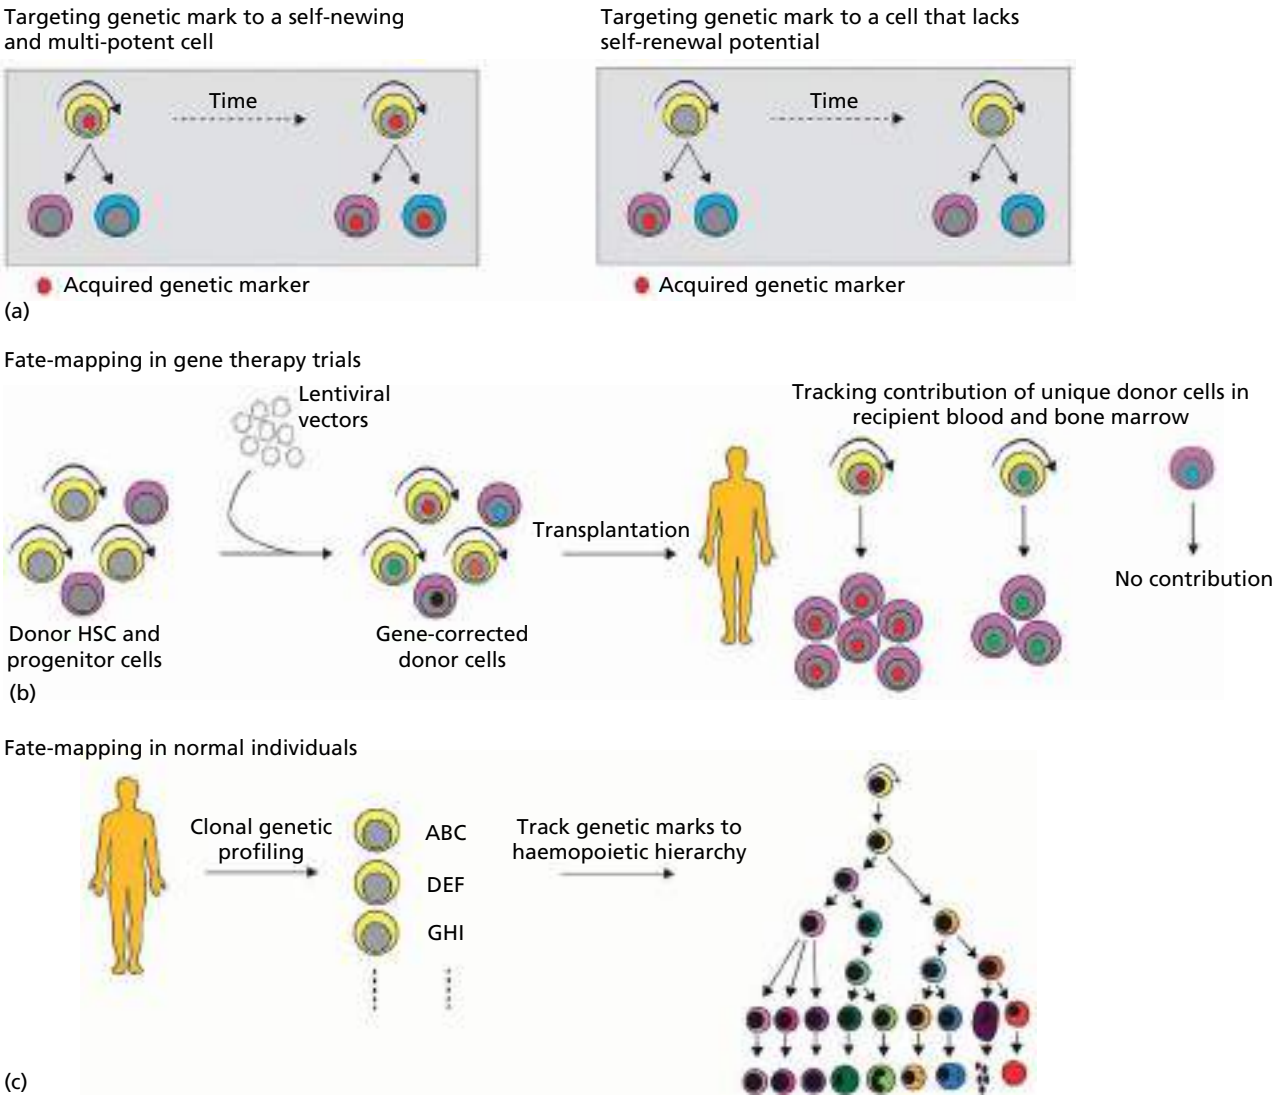


Figure 1.4 Genetic fate-mapping of human haemopoiesis. (a) Overall principle of genetic fate-mapping approaches where a permanent acquired genetic mark is tracked within different haemopoietic compartments over time. If the genetic mark is introduced to a self-renewing and multipotent haemopoietic stem cell, the genetic mark will be inherited to the downstream progeny and be detected over a long period of time. However, if a genetic mark is acquired in a cell that lacks self-renewal, such as a downstream progenitor cell, the genetic mark will not be sustained over time. (b) As a result of the random integration of the lentiviral vectors in the human genome, the integration site of can be used to track the fate of individual cells originating from the gene corrected pool of cells transplanted into the patient. The contribution to different stem/progenitor and mature lineages can be tracked over time, allowing identification of clones which actively contribute to haemopoiesis following transplantation. (c) Errors in DNA replication results in accumulation of DNA mutations which are unique to individual cells, providing a genetic barcode that can be tracked through DNA sequencing. Similar to viral integration sites, the fate of the different mutations/barcodes can be investigated in different cellular compartments and over time.

Clinical relevance of haemopoietic stem cells

Dysregulation of HSCs is linked to development of haematologic disease and leukaemia, where HSC exhaustion is associated with cytopenia and HSC expansion is associated with risk for leukemic transformation. In light of the regenerative potential for HSCs, their clinical relevance for potentially correcting conditions with dysregulated haemopoiesis has been explored through bone marrow and HSC transplantations. HSC transplantation represent to-date the only curative treatment for several haematologic malignancies and diseases. However,

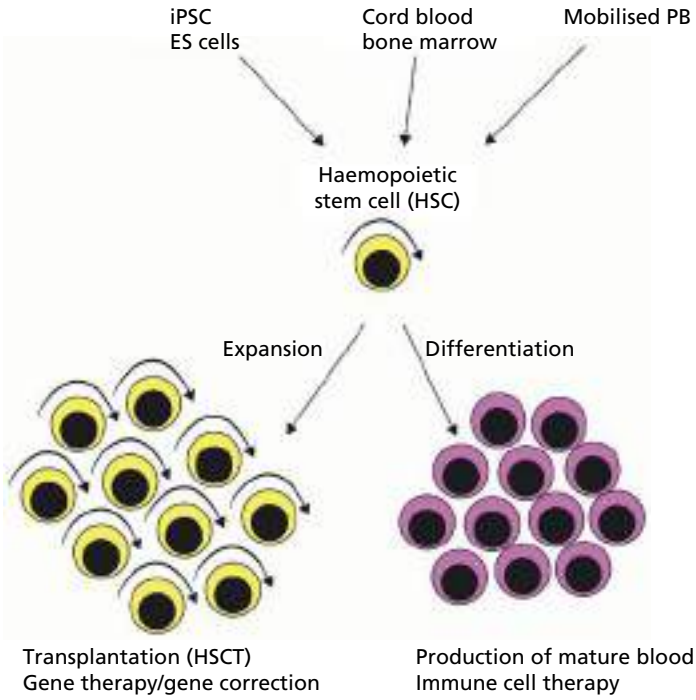

Figure 1.5 Clinical use of haemopoietic stem cells. Haemopoietic stem cells are already widely used in the clinic to replace or correct diseased haemopoiesis following transplantation and/or gene therapy. Sources of haemopoietic stem cells are limited, currently originating from matched donor cord blood, bone marrow or mobilised peripheral blood. The *ex vivo* expansion of HSCs from such sources or from induced pluripotent stem cells or embryonic stem cells could in the future expand the availability of this treatment to more patients. Furthermore, as differentiated progeny such as red blood cells, platelets and immune cells are used clinically, the *ex vivo* production of these could be expanded for future use.

access to sufficient and suitably matched donor HSCs still remains a challenge for the extension of this therapy to all patients. Both autologous and allogeneic bone marrow transplantation is used for a wide range of haematologic conditions, where autologous transplantations are favoured in gene therapy trials, whereas allogeneic transplantations are favoured for treatment of leukaemia due to their associated graft-versus-leukaemia effect. In addition, cord blood and mobilised peripheral blood represent additional sources of HSCs for clinical use in transplantation (Figure 1.5).

In allogeneic transplantations, careful matching of donor human leukocyte antigen (HLA) profile to that of the patient's HLA pattern is critical to avoid overactivation of donor-derived immune cells towards the patient's own cells, resulting in GvHD. As a result, both the expansion of HSCs *ex vivo*, as well as the generation of HSCs from alternative sources that could represent more universal source of donor HSC, such as generation from embryonic stem cells or induced pluripotent stem cells, compared to HSCs isolated from healthy individuals, still represent attractive options for expanding the clinical use for HSC therapies. Furthermore, considering the multi-lineage differentiation potential, HSCs also represent a source that can generate mature blood cell products for clinical use, including platelets and red blood cells following acute bleeding, and immune cells for immune therapies. Much research is therefore focused at *ex vivo* conditions that allow for the expansion and/or differentiation of HSCs for clinical use.

Introduction

Phagocytes owe their name to their ability to ingest and destroy material such as pathogens and dead cells. Professional phagocytes include granulocytes and mononuclear cells. The granulocyte family includes acute-acting cells such as Neutrophils, Eosinophils, Basophils and Mast cells, exceptionally equipped to deal immediately with intracellular and extracellular pathogens, their granules loaded with preformed antimicrobial proteins. The mononuclear myeloid leucocyte family referred to as the Mononuclear phagocyte system (MPS), includes Monocytes, Dendritic cells (DCs), tissue Macrophages and Multinucleated Giant Cells in tissues and bone.

Granulocytes and MPS cells are versatile cells of the immune system and their heterogeneous functions span homeostasis, acute and chronic inflammation, host defence against infection and repair after injury. In the steady state, they clear senescent and apoptotic cells as part of their trophic functions in tissue growth and remodelling. Phagocytes play an essential role in innate and adaptive immunity; they recognise, kill and clear invading microorganisms, and nurse as well as destroy tumour cells. Phagocytes produce a variety of secretory products, including enzymes, cytokines, chemokines and metabolites, that regulate tissue functions, mediating cellular and humoral responses such as hypersensitivity and allergy. In this chapter, we consider the steady state production and function of phagocytes, biomarkers to study their properties and describe molecular pathways that underlie their properties. Finally, we address defects in molecules of the phagocyte, from proliferation in bone marrow, to migration, phagocytosis and microbial killing.

The phagocyte lineage at a glance

Phagocytes originate in bone marrow, from quiescent long-term haematopoietic stem cells (LT-HSC), through short-term HSC (ST-HSC) and haematopoietic multipotent progenitor (MPP) cells and more committed progenitor and precursor cells (Figure 2.1; see also Chapter 1). Subsets of MPPs give rise to the lineage-committed common myeloid progenitors (CMP; surface markers: Lin-CD34+CD38+IL-3Rα+CD45RA-) that further differentiate into the granulocyte macrophage progenitors (GMP; Lin-CD34+CD38+IL-3Rα+CD45RA+). CMP are defined as CFU-GEMM (colony-forming-unit–granulocyte, erythrocyte, monocyte, megakaryocyte), whilst the more committed GMP is termed CFU-GM (granulocyte, monocyte) (Figure 2.1). Downstream of the myeloid progenitors, myeloblasts give rise to all circulating phagocytes.

Lineage cytokine receptors drive the commitment of precursors. Granulocyte development and proliferation are largely driven by Colony Stimulating Factor 3 (CSF3), better known as Granulocyte colony-stimulating factor G-CSF. CSF3 binds to CSF3R (CD114, G-CSFR), a homodimer receptor of the

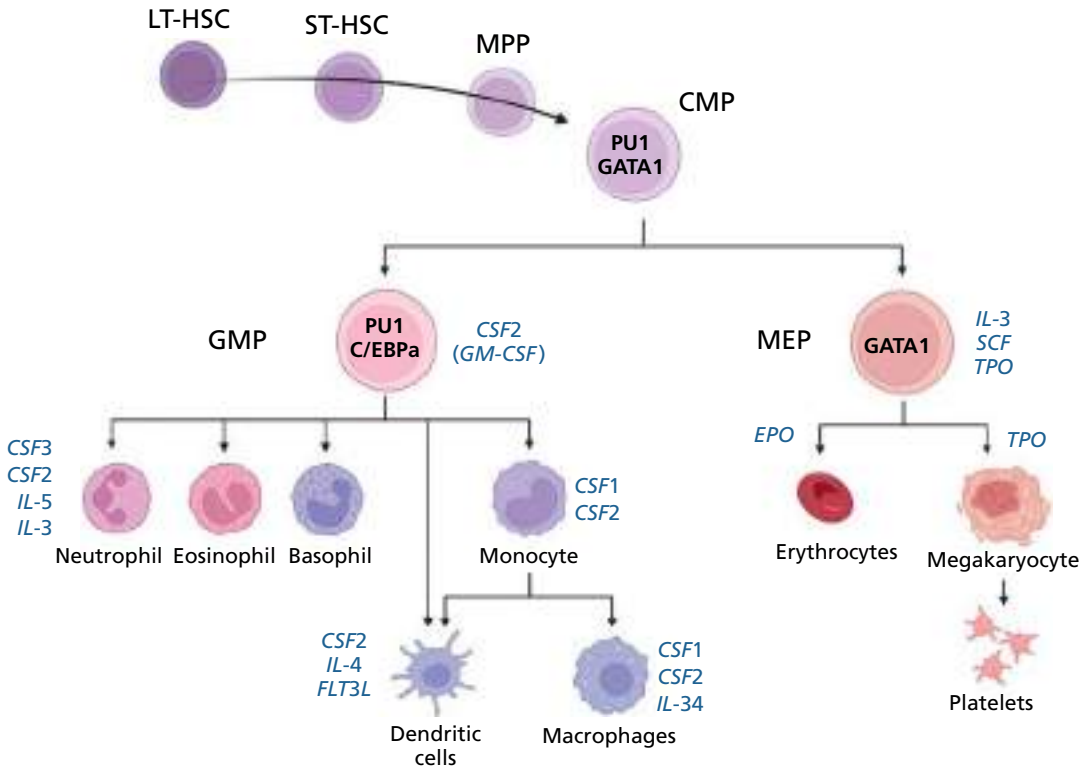

Figure 2.1 Haematopoiesis is controlled by lineage-determining cytokines and specific transcription factors. Stem cells progress down the line of mature haematopoietic cells with the aid of cytokines present in the bone marrow milieu. How specific stem cells acquire the expression and activate specific lineage receptors is until now considered a stochastic process. In this figure, the main stages are highlighted, the transcription factors appear in bold and the cytokines that drive the commitment in blue. PU1 Is the most important transcription factor for the phagocyte family. M-CSF, GM-CSF and G-CSF control the differentiation to monocyte, neutrophil or DCs.

cytokine family, that signals through the JAK/STAT pathway. CSF3R is highly expressed in mature neutrophils. Monocytes and macrophages are controlled by CSF1 (macrophage colony-stimulating factor M-CSF). CSF2 (Granulocyte-macrophage Colony stimulating factor GM-CSF) is important for both monocytes and granulocytes. CSF2 binds its receptor CSF2R (CD116, or GM-CSFR), a Type I interleukin receptor. CSF2 is a potent inflammatory cytokine contributing to damage in auto-inflammatory conditions. CSF1 promotes monocyte survival and stimulates macrophage maturation by binding to its receptor CSF1R CD115, or M-CSFR, a homodimeric Type III receptor tyrosine kinase of the PDGF family. CSF1, together with Receptor activator of nuclear factor kappa-B ligand (RANKL), are associated with osteoclast development in bones. IL-34 is another ligand for CSF1R in the skin and brain, where it is involved in the development of the resident MPS cells, the Langerhans cells and microglia, respectively. Other important receptors for phagocytes are FLT3 (CD135) and stem cell factor receptor (SCFR, CD117 or cKIT). SCFR is involved in early haematopoiesis, at the stem cell stage, and the development of mast cells. FLT3 is involved in early cell differentiation and in DC development. IL-5 is the main lineage cytokine for eosinophils. IL-3, a lineage cytokine involved in the early stages of haematopoiesis, drives development of several haematopoietic cells.

Granulocytes are the most abundant phagocytes in blood. They are terminally differentiated cells, and with the exception of mast cells, they tend to have a short life span. Neutrophils are the most abundant in human blood, making up 50–70% of all leucocytes. Due to their short half-life, coupled with their requirement, 1 billion neutrophils must be produced per day per kilogram of body weight to maintain steady-state conditions in humans. Eosinophils make up 1–4% of all leucocytes in the steady state. Eosinophils also derive from bone marrow stem-cell-derived myeloid progenitors in response to IL-3, GM-CSF and IL-5. IL-5 is the most eosinophil-specific factor and plays an important role in regulating terminal differentiation and post-mitotic activation of the cells. Basophils make up only 0.5–1% of all circulating leucocytes. They develop under the influence of IL-3 in the bone marrow and circulate in the blood. They specialise in fighting helminth infections. Mast cells, which derive

from CD34+, c-Kit-positive progenitors, leave the marrow before terminal maturation and home to vascularised peripheral tissues, where they mature. Mast cell growth and development require the presence of SCF.

The MPS is a more complex system and the first phagocytes to appear are macrophages, arising from the endothelium of the dorsal aorta, gonad, mesonephros (AGM) region, appear in the yolk sac, and in later weeks, in the fetal liver. Embryonic macrophages give rise to resident tissue macrophage populations which persist in many organs after birth. Embryonic yolk sac-derived macrophages/fetal liver monocytes migrate to the brain (microglia), heart and skin epidermis (Langerhans cells). After birth, there is an initial expansion of monocytes which become the most abundant blood MPS cell, representing 2–8% of the total number of leucocytes. Monocytes are differentiated cells but have the ability to enter tissues and mature into macrophages.

DCs appear in subsets according to the expression of membrane markers. The main types are myeloid/conventional DC1 and DC2 and plasmacytoid DC (pDC). DCs are less abundant in the circulation and usually represent 0.1–0.35% of mononuclear cells. Myeloid and plasmacytoid DCs are usually referred to as peripheral blood DC, because the largest DC pool resides in tissues. Precursor DC are released from the bone marrow and enter tissues in which they differentiate into functional antigen-presenting DCs. DC-specific cytokines include FLT3, IL-3 and IL-4. Finally, also in the MPS, multinucleated giant cells arise by fusion of monocyte/macrophages to form osteoclasts in bone, giant cells in granulomata and in response to foreign bodies as well as adipoclasts in adipose tissue.

Phagocyte identification and quantification

Phagocytes are routinely enumerated in the clinic for diagnosis, prognosis and treatment of a variety of pathologies. With microscopy (Figure 2.2), neutrophils appear as small granular cells with a multi-lobulated nucleus, eosinophils with red granules and a bilobulated nucleus, and basophils with purple granules. Monocytes instead appear as slightly larger cells with no evident granules, a kidney shape and less condensed nucleus. By electron microscopy the features can be discerned in more detail. Although many pathologies still need confirmation by microscopy, the Coulter counter and other modern forms of haematology analysers enable faster and more accurate measurement of complete blood counts. These instruments provide cell numbers, cell size and cell width. Cell size can be influenced by infection, apoptosis, phagocytosis and steroid treatment. An increase in monocyte width for example can be an early indicator in sepsis. Many parameters beyond cell numbers can be included in the Coulter output including cell volume, nuclear morphology, cell width and cytoplasmic light scattering.

For research and clinical applications, flow cytometry can be used to distinguish phagocytes (FACS-Flow assisted cell sorting), Figure 2.3. Neutrophils are most granular and large, followed by monocytes that adopt an intermediate position. HLA-DR staining further separates monocytes and DCs versus neutrophils. In a single step, neutrophils can be recognised by the expression of CD15 Lewis x antigen, a fucosylated antigen, posttranslationally modified by fucosyltransferases. Whole blood staining for Siglec-eight labels a glycan moiety, selective for eosinophils; it is an inhibitory receptor that induces apoptosis in eosinophils, important to control excessive tissue damage. CD123 (ILR3A) is the main cytokine receptor driving commitment of basophils and plasmacytoid DCs. An alternative method to distinguish eosinophils and basophils from neutrophils and monocytes by FACS is use of the IL-5R. Cells of the MPS in blood can be distinguished by labelling CSF1R. Further staining with CD14, an LPS receptor, and CD16, an Fc receptor, separates monocytes into their main subsets. CD1c, marker for the main DC subsets, is a transmembrane glycoprotein presenting lipids at the cell surface for recognition. FACS and conventional microscopy have improved in recent years; Mass Cytometry applications such as CyTOF (Cytometry by time of flight) and imaging, as well as in situ RNA sequencing and single-cell RNAseq, make it possible to investigate many markers and cells at the same time.

General phagocyte molecules and functions

Phagocytosis

High phagocytic ability distinguishes phagocytes from other cells. In the steady state, efferocytosis or elimination of apoptotic cells is one of the main functions of phagocytes. The membrane of apoptotic cells binds increased amounts of thrombospondin, a macrophage secretory product recognised by the scavenger receptor CD36, thrombospondin receptor, and integrin αvβ3, vitronectin receptor. CD36, in addition, recognises the exposed phosphatidylserine. Other phagocytic lectin receptors bind carbohydrate determinants exposed on the surface of apoptotic cells. Conserved apoptotic cell-associated molecules are recognised by innate immune receptors such as CD14, CD91, C1q, C3bi, collectins and pentraxins.

During infection, phagocytosis is mediated by the recognition of ligands of pathogens and is enhanced by opsonins, soluble receptors that serve as a bridge between the particle and specialised cell receptors, listed in Table 2.1. Opsonins include immunoglobulin molecules such as IgA, IgE and IgG and the complement cascade elements C3b, C3bi, C3d and C4b, recognised by the CR1 and CR3 complement receptors. Phagocytosis can also be mediated directly by non-opsonic phagocytic receptors. These receptors recognise microbial

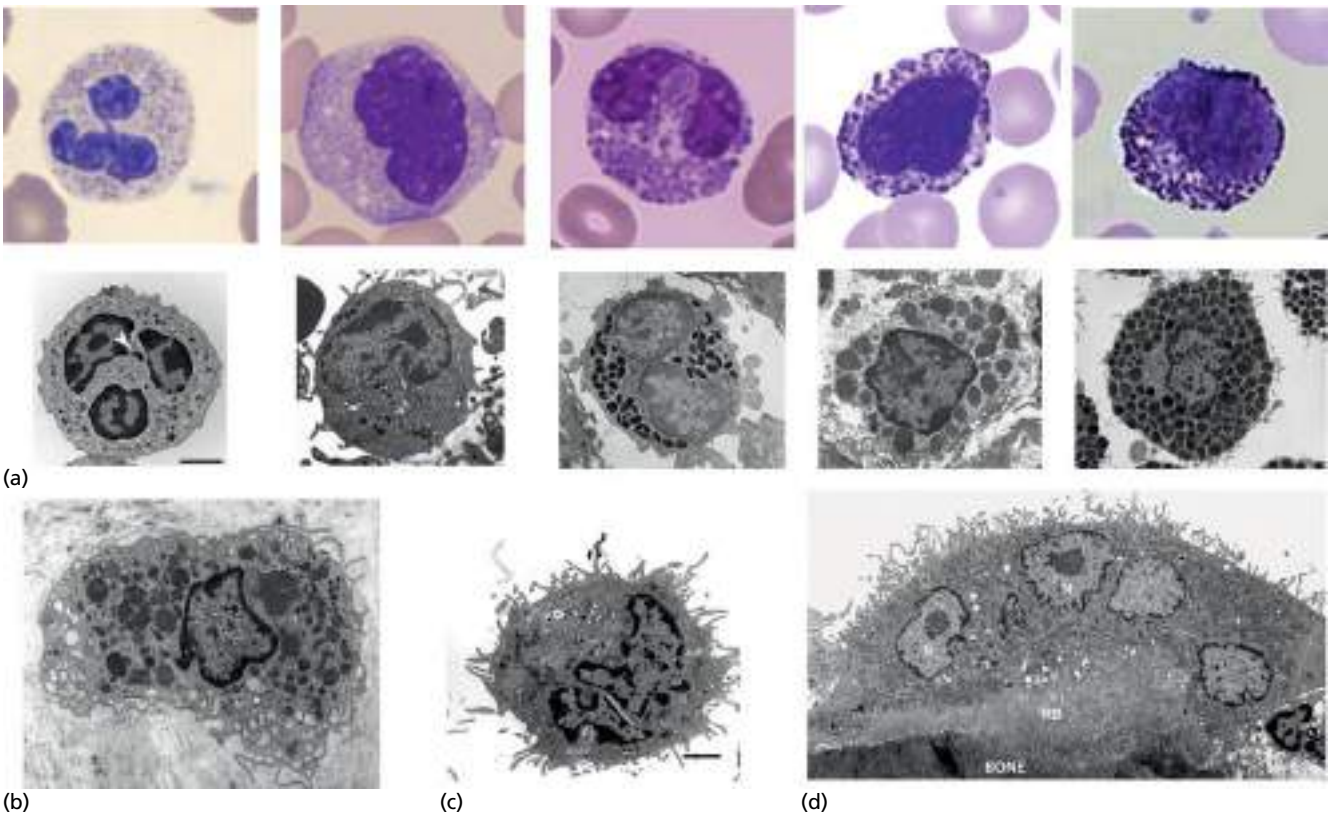

Figure 2.2 Morphology of the main phagocytes. (a) PMN or neutrophils appear with a multi-lobulated nucleus in H&E. The complexity of microgranules in their cytoplasm becomes apparent in electron microscopy. Monocytes instead display a less dense kidney-shaped nucleus and dense cytoplasm. Eosinophils appear as bi-lobulated cells with a pink cytoplasm. In electron microscopy, we can observe larger granules. Basophils appear as mononucleated cells with a dark blue cytoplasm full of larger vesicles. Mast cells, which are rare in circulation, appear as dark blue cells in H&E with a complex network of granules in their cytoplasm. (b and c) Macrophages do not circulate per se and in tissues it is hard to distinguish them based on H&E alone. An exception is the mucosal macrophages in the lung, here exemplified by bronchiole macrophages, atop the columnar epithelia. (d) Multinucleated osteoclast. Electron micrographs show a complex cytoplasm, with prominent vacuoles in different stages of maturation and ample extracellular processes. These are representative images and apply to several species, including human, mouse, rat and rabbit.

surface molecules, as well as altered tissue components and apoptotic bodies. Miscellaneous phagocytic receptors include various scavenger receptors and lectin-like molecules such as Dectin-1, a myeloid phagocytic receptor for fungal ß-glucan and macrophage-restricted mannose receptors (MMR) that bind mannosyl and fucosyl residues on the surface of yeast, bacteria and parasites.

The process of phagocytosis is regulated by activation of various receptors such as the FcγRs initiating downstream signalling through immunoreceptor tyrosine-based activation motifs (ITAMs). The complement receptor CR3 recognises targets opsonised by C3bi, inducing cytoskeletal rearrangement due to actin polymerisation via Rho kinases. As a result of cross-linking, downstream effector functions are activated, resulting in phagocytosis, stimulation of the respiratory burst, degranulation of bactericidal proteins and activation of transcription factors, in turn leading to enhanced expression of genes encoding cytokines and other inducible proteins, discussed under inflammation. Defective uptake of pathogens and dying cells can lead to infection, autoimmunity and malignancy.

Adhesion and chemotaxis

Adhesion and chemotaxis are closely linked in phagocytes. The signals generated by chemical gradients activate the cytoskeleton of cells leading to propulsion and retraction of pseudopodia similar to those required for locomotion and adhesion. Locomotion is achieved by contraction of an actin filamentous network in the cortical gel at the leading front of the cell. Phagocytes possess a

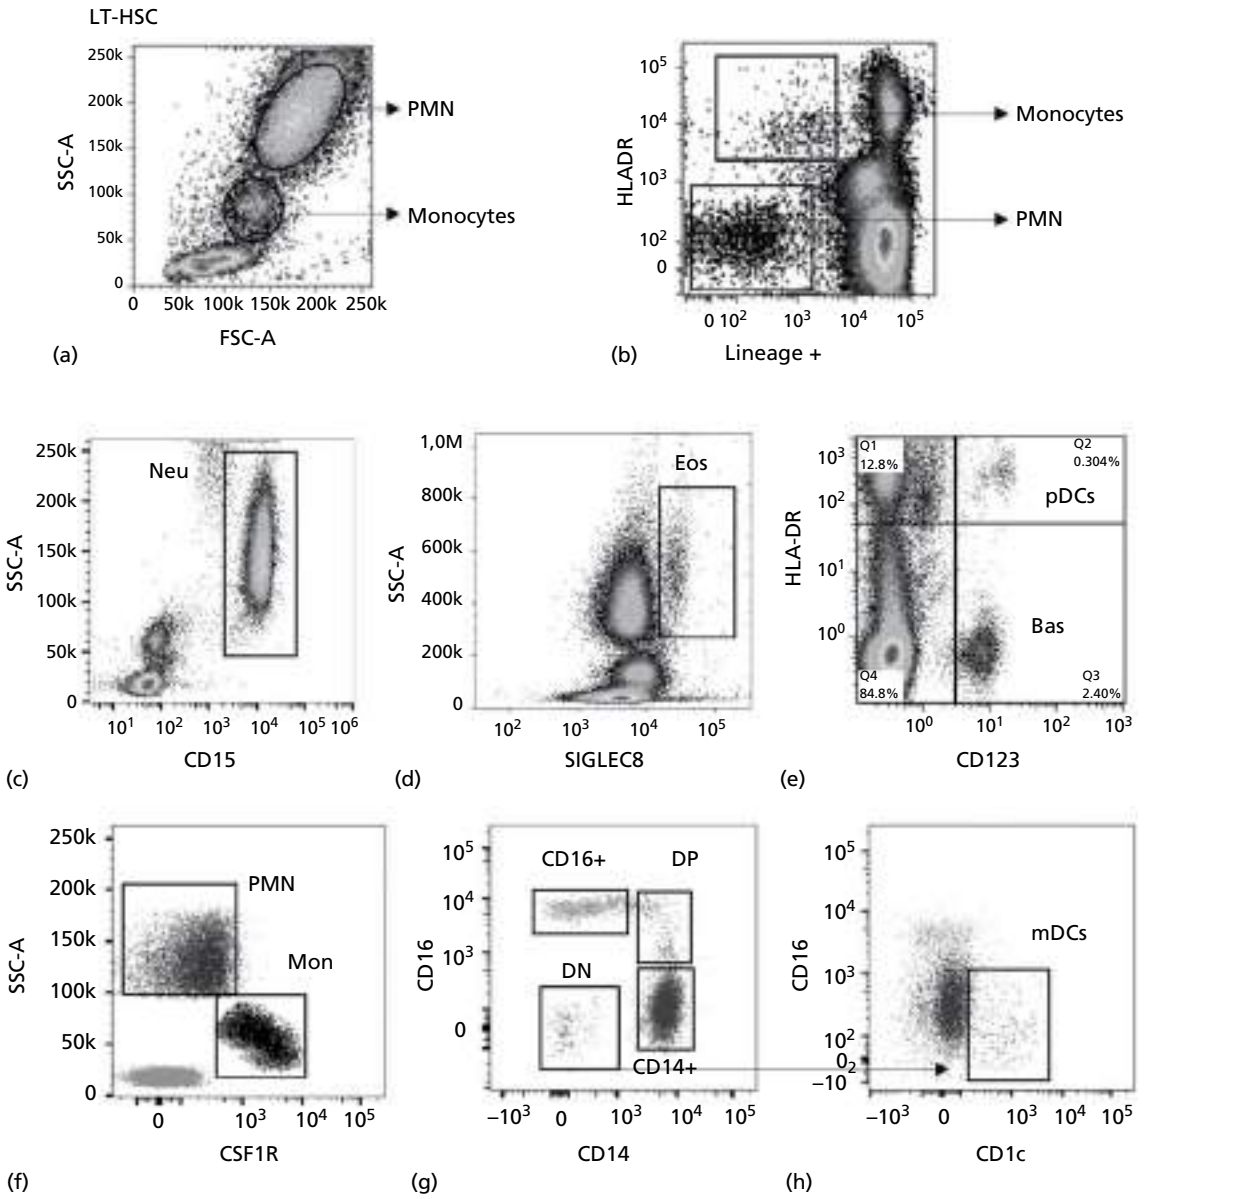

Figure 2.3 Origin and morphology of the circulating phagocyte family. (a) Scatter plot of white blood cells showing granulocytes, monocytes and lymphocytes. (b) All phagocytes are negative for lymphoid lineage cocktail markers containing anti-CD3, CD19, CD20 and CD56 antibodies. Further staining with HLADR shows MPS cells as positive and granulocytes negative. (c) CD15 stains neutrophils selectively. (d) SIGLEC 8 enables capture of eosinophils. (e) CD123 vs HLA-DR staining distinguishes HLADR-CD123+ basophils and HLADR+CD123+ plasmacytoid DCs. (f) MPS cells can be identified by CSF1R staining. (g) CSF1R+ cells can be further subdivided into 4 subsets based on CD14 and CD16 expression. (h) mDCs can be identified as CSF1R+ CD14-CD16-CD1c+ cells. DP, double positive; DN, double negative; mDC, myeloid DC.

number of cell–cell adhesion receptors and ligands, which mediate their recruitment, migration and interaction with other immune cells (Table 2.2). Phagocytes interact with the endothelium, slowly roll over and finally adhere firmly to endothelial cells (EC), to enter affected areas. Cells then spread their cytoplasm over the endothelium and crawl until they reach a suitable space to traverse the vessel wall, in a process called diapedesis. Diapedesis can be paracellular (between EC) or transcellular (across an EC), (Figure 2.4). Integrins (such as LFA1 and MAC1), immunoglobulin superfamily members (such as ICAM1 and VCAM1, which bind β_2 integrins) and selectins (such as L-, E- and P-selectins) mediate this process.

Table 2.1 Selected opsonic and non-opsonic receptors of phagocytes.

Receptor	Opsonic ligand and affinity	Cell type	Function
OPSONIC			
FcγRI (CD64)	IgG1-High (50 nmol/L)	Mon, Mac, Neu	Phagocytosis, respiratory burst
FcγRII (CD32)	IgG1 = IgG3 ≥ IgG4 = IgG2 Low (1 μmol/L)	Neu, Mon, Mac	Phagocytosis, respiratory burst
FcγRIII (CD16); FcγRIIIA (CD16a); FcγRIIIB (CD16b)	IgG1 = IgG3 Low (110 nmol/L); Low (470 nmol/L)	Neu, Mon, Mac	Phagocytosis
FcαR (CD89)	IgA1, IgA2, secretory IgA1 and IgA2	Neu, Mon, Mac	Phagocytosis, respiratory burst, bacterial killing
CR1 (CD35)	C3b and C4b dimers	Neu, Mon, Mac,	Phagocytosis
CR3 (CD11b/CD18)	C3bi	Neu, Mon, Mac,	Phagocytosis, respiratory burst
NON-OPSONIC			
Dectin 1	ß -glucan	DCs, Mon, Mac, Neu	Phagocytosis
Mincle	Dimycolate	DCs, Mon, Mac, Neu	Phagocytosis
MCL	α-mannan	DCs, Mon, Mac, Neu	Phagocytosis
DC SIGN	Fucosylated and Mannosylated ligands	DCs, Mon, Mac	Phagocytosis
CD14	LPS	Mon, Mac, Neu	Lipid recognition
Scavenger Receptor A	LPS, polyanionic, apolipoproteins A1/E, oxidised LDL	Mac	Phagocytosis, endocytosis, adhesion
CD36	PS	Mac, Mon, ECs, adipocytes, thrombocytes, megakaryocytes, skeletal and cardiac muscle	Phagocytosis, fusion
MARCO	Trehalose Dimycolate, LPS	Mac, DCs	Phagocytosis, innate activation
Mannose receptor (CD206)	Mannosylated proteins (mannosyl-, fucosyl- or GlcNAc ligands)	Mac, immature DCs	Phagocytosis, endocytosis
CD163	Haemoglobin-haptoglobin complexes	Mac, Mon, DCs	Phagocytosis, endocytosis

Integrins recognise extracellular and intracellular stimuli, mediating 'outside-in' and 'inside-out' signalling. The affinity of integrins for extracellular ligands, such as ICAM-1 or fibrinogen, is greatly increased by inside-out signalling. Inside-out signalling is activated by mechanical stress and plays a crucial role in neutrophil arrest during chemotaxis. In fact, during phagocyte rolling on endothelial cells, β2 integrins are progressively stretched, increasing inside-out signalling and culminating in high-affinity adherence to endothelium. The β_2 integrin family consists of three leucocyte-restricted integrins, LFA-1 (CD11a/CD18), CR3 (MAC-1, CD11b/CD18) and p150/95 (CD11c/CD18). Mutations causing defects in the expression and function of β2 integrins or selectins increase susceptibility to infection, through defective migration of neutrophils to infected sites.

Selectins are expressed on all leucocytes (L-selectins) as well as postcapillary endothelial surfaces (E-selectins) and in platelet α-granules and endothelial cell Weibel–Palade bodies (P-selectins). The interaction of E- and P-selectins on cytokine-activated endothelial cells, and L-selectins, targets phagocytic cells to the endothelium at sites of vascular injury and initiates the rolling movement of leucocytes along the vessel wall. In addition, a newly characterised leucocyte family of seven transmembrane G protein-coupled adhesion receptors (GPCRs) contains several members implicated in myeloid phagocyte adhesion, differentiation and activation.

After diapedesis phagocytes migrate directionally in response to spatial gradients of chemical substances in a process known as chemotaxis. Chemotactic stimuli include microbial products and inflammatory stimuli secreted by cells. Chemotactic GPCRs include chemokine receptors such as CXCR1, 2 and CXCR4, which bind CXC chemokines in PMN and CCR2 and CCR1 which bind CC chemokines in MPS cells (Table 2.3). Non-chemokine chemotactic receptors include the

Table 2.2 Phagocyte adhesion molecules.

Adhesion molecule	CD number	Cellular distribution	Ligand	Function
Integrin family				
Very late-acting antigens				
αβ (VLA-1)	CD49a/29	Mon, EC	Collagen I, IV, laminin	Cell adherence to ECM
$\alpha_2 \beta_1$ (VLA-2)	CD49b/29	Mon, EC, platelets	Collagen I, IV, laminin	Recruitment to extravascular tissue
$\alpha_3 \beta_1$ (VLA-3)	CD49c/29	Mon	Collagen I, laminin, fibronectin	Cell adherence to ECM
$\alpha_4 \beta_1$ (VLA-4)	CD49d/29	Mon, eos, bas	Fibronectin, VCAM-1	Cell adherence to ECM and cell–cell adhesion matrix
$\alpha_5 \beta_1$ (VLA-5)	CD49e/29	Mon, neu, EC	Fibronectin	Cell adherence to ECM
$\alpha_6 \beta_1$ (VLA-6)	CD49f/29	Mon	Laminin	Cell adherence to ECM
Leucocyte integrins (LFA-1 family)				
$\alpha_D \beta_2$	–/18	Mac	ICAM3, VCAM-1	Cell adherence to ECM
$\alpha_L \beta_2$ (LFA-1)	CD11a/18	Mon, Mac, granulocytes	ICAM-1, ICAM-2, ICAM-3	Cell–cell adhesion and cell–matrix adhesion
$\alpha_M \beta_2$ (CR3, Mac-1)	CD11b/18	Mon, Mac, granulocytes	ICAM-1, C3bi, fibronectin, factor X, microbial antigens	Endothelium adherence/ extravasation
$\alpha_X \beta_2$ (p150,95)	CD11c/18	Mon, Mac, granulocytes	C3bi, fibronectin	Adhesion during inflammatory response
Cytoadhesins $\alpha_V \beta_3$ (vitronectin receptor)	CD51/61	Mon, EC	Vitronectin, fibronectin, collagen, thrombospondin, vWF	Cell adherence to ECM
$\alpha_R \beta_3$ (leucocyte response integrin)		Mon, granulocytes	Vitronectin, fibronectin, collagen, thrombospondin, vWF	Cell adherence to ECM

$\alpha_V \beta_7$	CD51/–	Mac	?	
Immunoglobulin superfamily				
ICAM-1	CD54	Mon, EC	$\alpha_L \beta_2$, $\alpha_M \beta_2$	Cell–cell adhesion
ICAM-2	CD102	Mon, EC	αβ	Cell–cell adhesion
ICAM-3	CD50	Mon, granulocytes	$\alpha_{L2} \alpha_L \beta_2$	Cell–cell adhesion
VCAM-1	CD106	Mac, EC, dendritic cells	$\alpha_4 \beta_1$	Recruitment
PECAM-1	CD31	Mon, EC, platelets	CD31, $\alpha_V \beta_3$	Transmigration
HCAM	CD44	Ubiquitous	Collagen I, IV, fibronectin	Extravasation
Selectin family				
L-selectin	CD62L	Mon, granulocytes	Carbohydrate determinants on EC	Migration, rolling on vessel wall
E-selectin	CD62E	Neutrophil, EC	Mo, Neu, Eos	Migration, rolling on vessel wall
P-selectin	CD62P	EC, platelets	Mo, Neu, Eos	Adhesion to activated platelets and EC

Bas, basophil; CD, cluster of differentiation; EC, endothelial cell; Eos: eosinophil; ICAM, intercellular adhesion molecule; Mac, macrophage; Mon, monocyte; Neu, neutrophil.

leukotriene B_4 receptor BLT1 and platelet-activating factor (PAF) receptor and formylated peptide receptors 1 and 2, recognising not only formylated peptides, but also other products from bacteria or mitochondria and finally complement receptors such as the C5a receptor. All three major GPCR-activated pathways (i.e. the PLCβ, PI3K and Src pathways) converge in triggering phagocyte responses, including superoxide production, degranulation and chemotaxis.

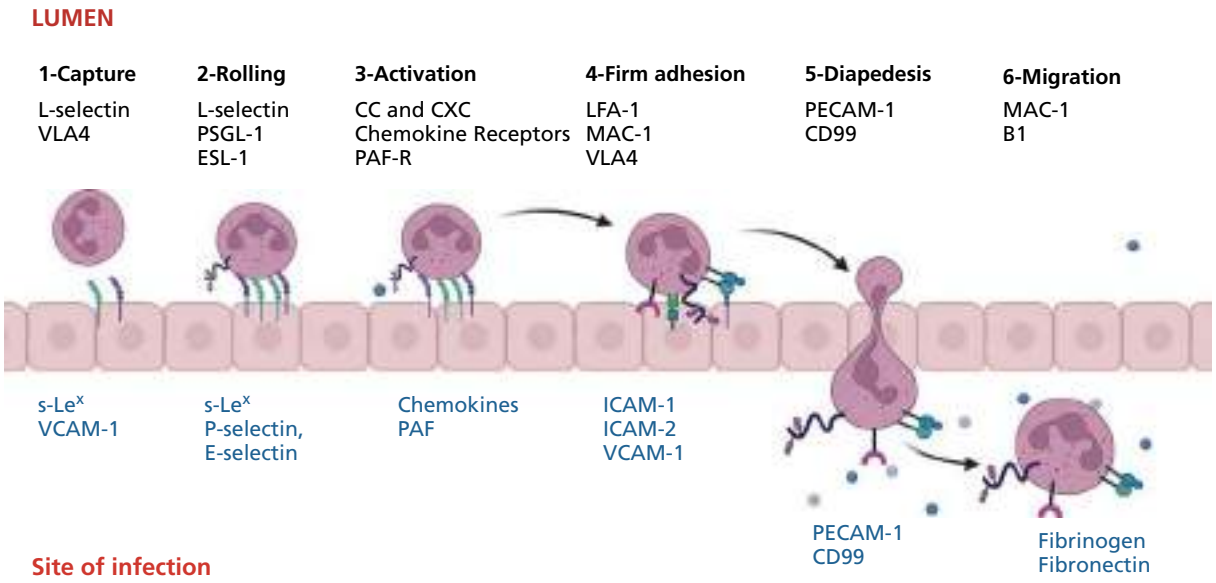

Figure 2.4 Diapedesis and chemotaxis. In inflammation, phagocytes migrate towards the location of the specific stimulus. The process starts with rolling of the leucocytes to the wall vessel. Paracellular diapedesis is the purposeful coordinated movement of leucocytes though the endothelial lining towards sites of inflammation. Selectin-mediated leucocyte tethering and rolling across endothelial surfaces is followed by integrin-mediated firm adhesion and leucocyte polarisation at endothelial cell junctions. With increased contact provided by adhesion molecules, the interaction between leucocytes and endothelial cells increases, leading to rolling of the cells. Increased integrin activation supports firm adhesion and enables transmigration. We present the main steps, and adhesion molecules involved. Phagocyte molecules appear in black, and endothelial cell or ECM molecules in blue.

Table 2.3 Examples of Chemotactic factors controlling phagocytes.

Chemokine receptors	Ligands	Cells
CC receptors, CCR1, CCR2, CCR5, CCR7	CC chemokines, CCL2, CCL3, CCL4	Mainly monocytes and DCs
CXC Receptors CXCR1, CXCR2, CXCR4	CXC Chemokines, CXCL1, CXCL2, CXCl8	Mainly granulocytes
Complement receptors		
C5aR	C5a complement component	All phagocytes
C3aR	C3a complement component	All phagocytes
Formyl peptide receptors		
FPR1, FPR2	High and low affinity for Bacteria and Mitochondria – derived formyl peptides, Lipoxin A4	All phagocytes
Lipid receptors		*All phagocytes*
BLT1 and BLT2	Leukotriene B4 high-affinity receptor BLT1 or the low-affinity receptor BLT2	All phagocytes

Pattern recognition receptors and inflammation

Phagocytes efficiently detect the presence of microbes or cell damage whilst patrolling tissues. This is accomplished via Pattern recognition receptors (PRRs), which bind selectively to evolutionary conserved microbial molecules, pathogen-derived molecular patterns (PAMPS), or to products expressed or released by damaged cells, damage-derived molecular patterns (DAMPS). Important PRRs in phagocytes include the membrane Toll-like receptors and C-type lectin receptors, and cytosolic receptors such as Nod-like receptors and AIM2. TLRs are the best-studied PRR in phagocytes. TLR activation triggers signalling pathways involving MyD88 and MAP kinases, and activation of the transcription

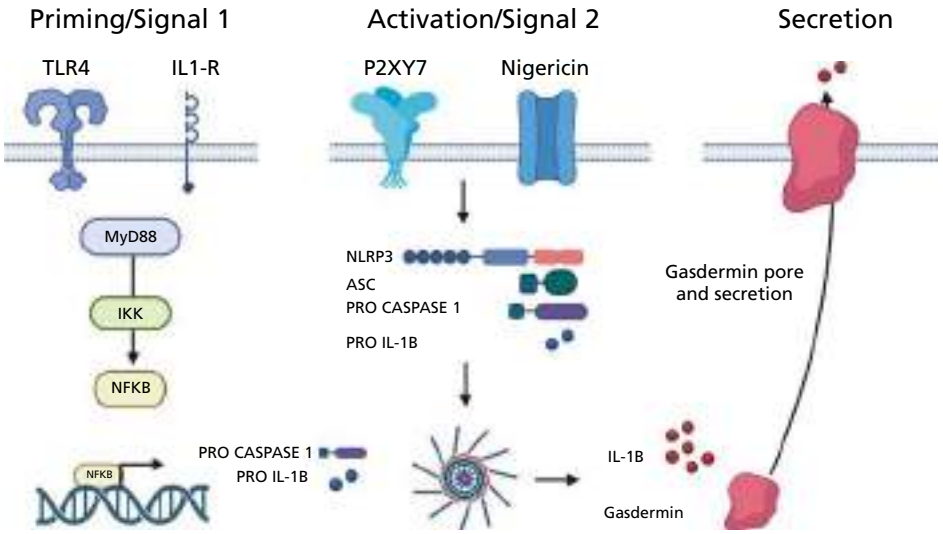

Figure 2.5 Priming and activation of the NLRP3 inflammasome. Phagocytes require two signals to produce and secrete IL-1β and IL-18. The first step is priming, provided by LPS recognised by TLR4, which leads to activation of NF-κB and synthesis of pro-IL-1β and pro-IL-18. NLRP3 expression itself can be regulated and increased in this reaction. The second signal involves cell damage sensed in a variety of forms such as extracellular ATP, presence of intracellular bacteria or insoluble crystals. These signals activate pattern receptors such as NLRP3. The ASC adaptor amplifies the response and activates pro-caspase 1. Inflammatory caspases cleave gasdermin, which forms pores and leads to pyroptosis (Source: Groslambert and Py 2018; Zhang *et al*. 2020.)

factors NF-κB and AP-1, which lead to the production of proinflammatory cytokines, and TRIF-associated IRF responses that activate interferon production. The cascades alter the transcriptome of the cells and result in increased secretion of inflammatory products and enzymes.

Secretion is a specialty of phagocytes. TNF is secreted from two pathways directly or by shedding action of Adam17. IL-10 and IL-6 are secreted directly into secretory vesicles. Another important mechanism is inflammasome activation which leads to secretion of IL-1β and IL-18. IL-1β and IL-18 are synthesised as a proproteins and activated by caspases in the cytosol. Nod-like receptors such as NLRP3 or sensors of aberrant RNA or DNA, promote assembly of multiprotein complexes, called inflammasomes, which further lead to caspase activation (Figure 2.5). Caspases cleave the pro forms of IL-1β and IL-18. Gasdermin, a membrane lytic agent implicated in IL-β release, is a product of DNA sensing and activation of the STING pathway. TLR activation also increases enzymes that process cellular lipids into inflammatory or anti-inflammatory products, including prostaglandins, leukotrienes, lipoxins and maresins.

Killing via lytic enzymes and production of reactive radicals

The ultimate purpose of phagocytosis is killing microbes. Several mechanisms lead to bulk product release by neutrophils, monocytes and macrophages, e.g. lysozyme acting on muramyl peptidoglycan in bacterial walls. Neutral proteinases initiate plasma protein cascades involved in coagulation, fibrinolysis, complement activation and generation of kinins and angiotensin to control infection. Neutrophil granules are secreted by a process called degranulation. Some granules contain receptors that can be mobilised to the cell surface and enable neutrophils to respond rapidly to environmental cues. Other molecules contained in the granules, such as leukotriene B4, function as secondary chemoattractants. Neutrophils contain four types of granules that are produced sequentially during their maturation and can be identified by marker enzymes or proteins (Table 2.4). In addition, certain vacuoles that are part of the endosomal system, such as multivesicular bodies, can be used by neutrophils to deliver various products extracellularly by a process called reverse endocytosis. We discuss neutrophil granules in detail in the next section.

Monocytes have rudimentary granules and can be induced to synthesise and secrete a variety of products *de novo*. They instead carry their antimicrobial peptides and digestive enzymes in the lysosome. Lysosomes are organelles with specific membrane proteins, a complex biogenesis, and contain over 50 lytic enzymes that can be secreted into the phagosome or the extracellular space. Many of these enzymes underlie phagocyte disorders. Upon phagocytosis, pathogens in phagosomes are killed by the release of granules and specialised lysosomal content. For example, many of the proteins stored in PMN granules display antimicrobial activities,

Table 2.4 Neutrophil microbicidal proteins.

Protein	Characteristics	Target organisms	Effects on target
Non-enzymatic proteins			
BPI	Highly cationic, neutralises LPS, most potent microbicidal protein, not released from granule	Gram-negative bacteria	Binds lipid A region of LPS, increases bacterial membrane permeability, activates bacterial degradative enzymes
Defensins	Comprise 30–50% of azurophil granule protein	Gram-positive > Gram-negative bacteria, fungi, viruses, mammalian cells	Increases membrane permeability
Lactoferrin	Cationic, stimulates hydroxyl radical formation	Gram-positive and Gram-negative bacteria, fungi	Oxidative damage
Catalytic proteins and analogues			
Proteinase 3	Serine proteinase	Escherichia coli, Streptococcus faecalis, Candida albicans	Growth inhibition
Cathepsin G	Serine proteinase	Gram-positive and Gram-negative bacteria, fungi	Inhibition of peptidoglycan synthesis
Azurocidin	Serine proteinase	Gram-negative bacteria	Non-catalytic mechanisms
Lysozyme	Cationic	Gram-negative bacteria, few Gram-positive bacteria	Potentiation of complement and H_2O_2 killing, cleavage of cell wall peptidoglycans
Elastase	No direct microbicidal activity		Coactive with lysozyme, potentiation of MPO–halide–H_2O_2 system

BPI, bacterial permeability-inducing factor; LPS, lipopolysaccharide; MPO, myeloperoxidase.

summarised in Table 2.4. After phagocytosis, the granule contents are released into the phagosome resulting in bacterial killing.

The respiratory burst generates superoxide anion (O_2^-), the highly reactive hydroxyl radical ($OH^\cdot$) and other reactive oxygen species (ROS). These oxidative products kill microbes both directly and indirectly, possibly through their ability to activate metalloproteinases such as elastase and collagenase. Production of (O_2^-) results from activation of NADPH oxidase, a multicomponent enzyme with several subunits located in various regions of the quiescent phagocytes (Figure 2.6).

Generation of reactive nitrogen intermediates through nitric oxide synthase (NOS) is another mechanism for phagocytic killing of microbes. Nitric oxide (NO) is the highly reactive free radical product of the oxidation of L-arginine in phagocytes during inflammation. Three distinct isoforms of NOS have been described in blood cells. Two are found in endothelial and neuronal cells and the third, inducible NOS, is induced by cytokines, such as IFN-γ, in a number of cell types. NO has an important role in the antimicrobial activity of both neutrophils and activated mononuclear phagocytes. NOS is located in the cytoplasm and mediates defence against facultative intracellular pathogens, as well as other prokaryotic and eukaryotic pathogens.

Phagocyte particulars

Neutrophils

Neutrophils are the first leucocytes to be recruited to inflammatory sites and their rapid deployment is essential to clear infection. They are essential for life and neutropenia brings a serious risk of fatal infection. The term *neutrophil* derives from the staining characteristics of their specific granules. Neutrophils are also referred to as *polymorphonuclear* (Greek, 'having a nucleus with various shapes') leucocytes owing to the characteristic lobular nucleus that is segmented into two to five lobes connected by thin chromatin strands. A curved, but not lobular, nucleus is present in band neutrophils, an immature cell type in transition to segmented neutrophils, (Figure 2.7). Very few or no band cells are normally detected in the blood, although their number may increase during severe infections. Neutrophils have a diameter of 8–10 μ in circulation.

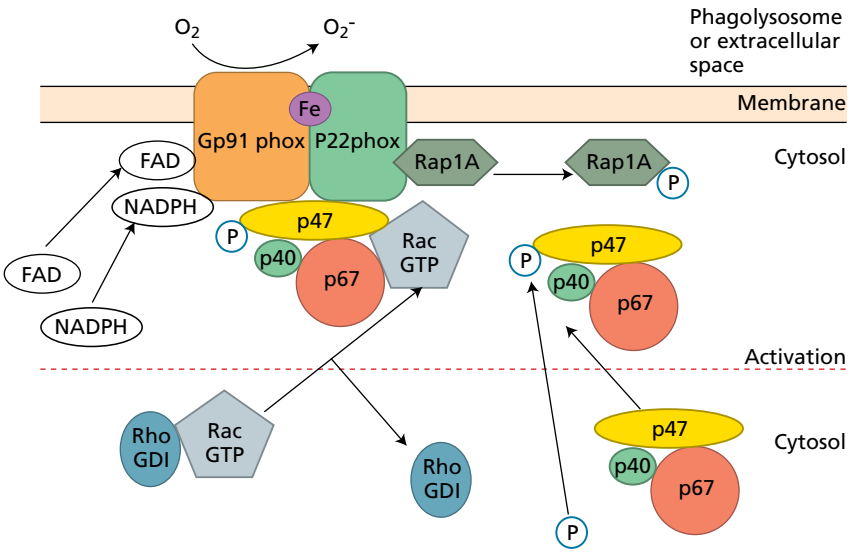

Figure 2.6 Components of the NADPH oxidase system. The components include a 47-kDa cytosolic protein (p47), a 67-kDa cytosolic protein (p67), a 40-kDa cytosolic protein (p40), cytosolic G-proteins (Rac and Rap1) and a membrane-bound cytochrome (b_{558}). The cytochrome consists of haem-containing p22-phox and gp91-phox. The gp91 subunit is a FAD-dependent flavoprotein shuttling electrons to molecular oxygen, forming O_2^-. The p47 component can be phosphorylated to various extents. In activated cells, the p40, p47 and p67 proteins translocate to the membrane to form an activation complex with cytochrome b_{558}. Similarly, the Rac and Rap1 proteins also translocate. The activated oxidase passes electrons from NADPH via FAD to oxygen, thereby generating superoxide.

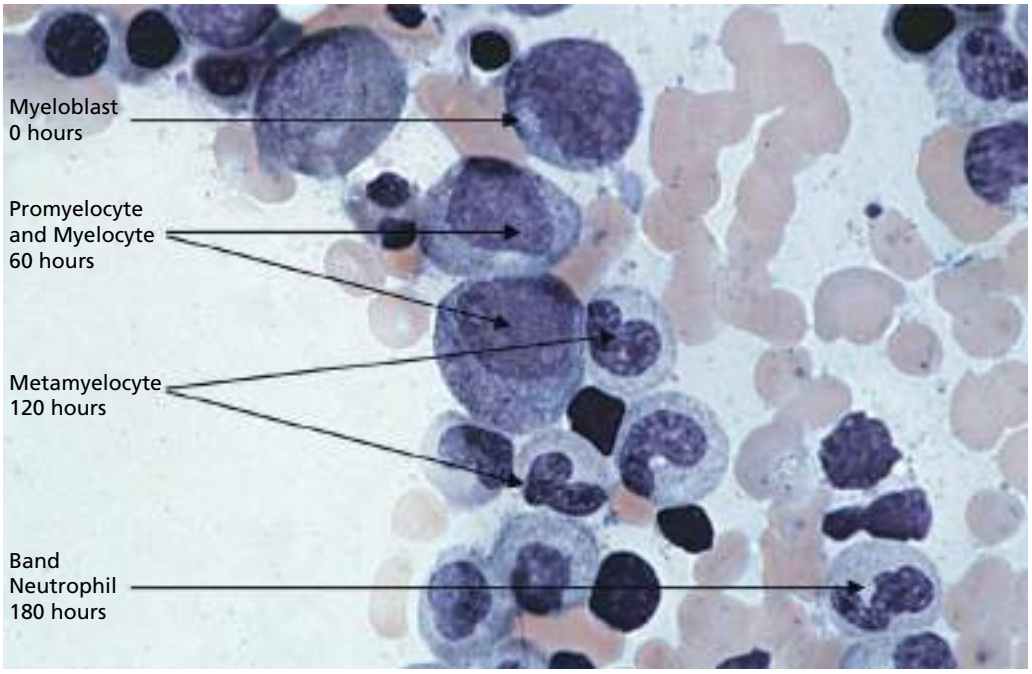

Figure 2.7 Stages of neutrophil maturation. Stages of neutrophil maturation, showing a myeloblast, a promyelocyte, several myelocytes and metamyelocytes, a band cell and a segmented neutrophil in a bone marrow aspirate.

In bone marrow, neutrophil-committed progenitors can be divided into neutrophil progenitors (Lin-CD34+/-CD86-CD15+ CD66b+) and pre-neutrophils (Lin-CD34-CD101-CD15+ CD66b+). Pre-neutrophils differentiate into immature neutrophils, which make up the post-mitotic pool and consist of metamyelocytes (kidney-shaped nucleus and light cytoplasm) and band cells (both Lin-CD34-CD101+CD15+CD66b+ CD10-CD16-). The bone marrow also contains a large pool of mature neutrophils (CD101+CD15+CD66b+ CD10+CD16+) that can be readily released into the circulation.

Neutrophil maturation is orchestrated by several transcription factors, such as PU.1, growth factor independence 1 (GFI1), and members of the CCAAT/enhancer binding protein family (C/EBPα-ζ). As previously mentioned, CSF3 or G-CSF is a crucial mediator of neutrophilic granulopoiesis that also induces the release of mature granulocytes from the bone marrow into the circulation and is used as a drug to increase neutrophil production in patients with neutropenia. G-CSF is produced through a cytokine circuit initiated by macrophage-derived IL-23, which triggers IL-17 release from γδ T cells and the ILC_3 subset of innate lymphoid cells. In turn, IL-17A induces G-CSF production by bone marrow stromal cells, macrophages and endothelial cells. Notably, the production of IL-23-dependent IL-17A is greatly increased by the proinflammatory cytokines IL-1β or IL-18, which contribute, by this mechanism, to boost neutrophil production during acute inflammation and infection.

Retention of mature neutrophils in the bone marrow and release in the circulation are governed by two opposing chemokine/chemokine receptor systems (respectively, CXCL12/CXCR4 and CXCL8/CXCR2). G-CSF increases the expression of CXCR2 and downregulates CXCR4 on neutrophils and HSC, thereby inducing the release of neutrophils into the bloodstream and migration of HSC to the spleen, liver and inflamed tissues under emergency granulopoiesis. The G-CSF-chemokine axis can also be exploited to harvest HSCs for therapeutic purposes. For example, coadministration of G-CSF and a CXCR4 antagonist effectively mobilises HSCs from the bone marrow into the peripheral blood.

In performing their defensive functions, neutrophils can produce considerable collateral damage to host tissues, particularly by releasing their contents extracellularly. Azurophilic granules, otherwise known as primary granules, are produced first and are present in promyelocytes and all further stages of neutrophil differentiation (Table 2.5). They contain microbicidal proteins, including the protease azurocidin, and acid hydrolases (e.g. myeloperoxidase and lysozyme) involved in oxidative and non-oxidative killing of bacteria and fungi. Azurophilic granules also contain various amounts of defensins and can be classified in humans into $defensin^{high}$ and $defensin^{low}$ granules.

Specific or secondary granules are smaller than azurophilic granules and contain lactoferrin, cysteine-rich secretory protein 3, ficolin 1 and haptoglobin as well as chemotactic, opsonic and adhesion protein receptors. The release of haptoglobin from specific granules after neutrophil activation at sites of inflammation may reduce local tissue injury. Tertiary granules contain matrix metalloproteinase 9, also known as gelatinase B, and are therefore also called gelatinase granules. Preformed proteins, including activation receptors, are present in secretory vesicles, which can be rapidly mobilised to the cell surface, where their contents are incorporated in the plasma membrane. The presence of multiple kinds of granules can be explained by the need of neutrophils to release different proteins at different times during their activation process.

Neutrophils are short-lived after entering the bloodstream. Their exact lifetime in humans can be estimated at 36 hours (18 hours each in the circulation and in peripheral organs, where they die). In the steady state, neutrophils patrol organs (e.g. the liver, spleen and lung) and body surfaces (e.g. the skin, mucosa and mucus layers) to detect the presence of microbial products or tissue damage. Comparatively few neutrophils enter the central nervous system and the gonads. The lifespan of neutrophils in tissues can be extended up to tenfold by microbial products and proinflammatory mediators, including G-CSF, GM-CSF, IL-8, C-reactive protein and serum amyloid A. Whilst migrating through the vessel wall neutrophils produce factors such as IL-8 that act as secondary attractants. This relay of signals between neutrophils choreographs dynamic cell aggregation in a process called 'swarming' (Figure 2.8), which can be visualised by intravital microscopy and extends the recruitment range of neutrophils over long distances.

Efferocytosis of recruited neutrophils is essential to resolve inflammation and repair damaged tissues. In contrast, lytic forms of cell death, such as necroptosis, pyroptosis and NETosis (see below) often occur during various pathological conditions, resulting in amplification of the inflammatory response and in potential tissue injury. At least one billion neutrophils per kg of body weight undergo efferocytosis every day in various organs, especially the bone marrow, followed by the liver and spleen. Thus, the bone marrow is both the main haematopoietic organ and the dominant site of neutrophil efferocytosis. The latter process attenuates granulopoiesis in a negative feedback loop involving G-CSF-mediated regulation.

Neutrophils are described as 'quiescent', 'primed' or 'fully activated'. Neutrophils circulate in the quiescent state, thus limiting potential damage to vascular walls. Various agonists are responsible for priming and activating neutrophils, including contact with other cells, chemotaxins, antigen-antibody complexes, complement components, inflammatory cytokines, growth factors, microbial components and products of damaged tissues. In an extreme form of activation, neutrophils release their nuclear material extracellularly. This results

Table 2.5 Neutrophil granules and their contents.

Granule	Azurophilic (primary)	Specific (secondary)	Gelatinase (tertiary)	Secretory vesicles
Marker enzyme	Myeloperoxidase	Lactoferrin	Gelatinase	Alkaline phosphatase
Membrane	CD63, granulophysin, CD68, V-type H^+ -ATPase	CD15, CD66, CD67, CD11b/CD18, cytochrome b, fMLP-R, fibronectin-R, G-protein α-subunit, laminin-R, NB-1 antigen, 19-kDa protein, 155-kDa protein, Rap-1, Rap-2, SCAMP, thrombospondin-R, TNF-R, urokinase-type plasminogen activator-R, VAMP-2, vitronectin	CD11b/CD18, cytochrome b, diacylglyceroldeacylating enzyme, fMLP-R, SCAMP, urokinase-type plasminogen activator-R, VAMP-2, V-type H+ -ATPase	CD10, CD13, CD45, CD14, CD16, CD35 (CR1), CD11b/CD18, alkaline phosphatase, fMLP-R, SCAMP, urokinase-type plasminogen activator-R, V-type H+ -ATPase, VAMP-2, C1q-receptor, decay activating factor
Matrix, microbicidal	Myeloperoxidase, nitric oxide synthase, lysozyme, BPI protein, defensins, serpocidins, elastase, cathepsins, proteinase 3, azurocidin (CAP 37)	Lactoferrin, lysozyme	Lysozyme	
Matrix, hydrolases	Acid β-glycerophosphatase, α-mannosidase, β-glucuronidase, β-glycerophosphatase, N-acetyl-βglucosaminidase, sialidase	Gelatinase, collagenase, histaminase, heparanase, NGAL, sialidase	Gelatinase, acetyltransferase	
Matrix, other	Acid-mucopolysaccharide, heparin-binding protein	β2-Microglobulin, urokinase-type plasminogen activator, vitamin B12-binding protein	β2-Microglobulin,	Plasma proteins (including tetranectin)

fMLP, f-Met-Leu-Phe; NGAL, Neutrophil gelatinase-associated lipocalin; R, receptor; SCAMP, secretory carrier membrane protein; VAMP, vesicle-associated membrane protein.

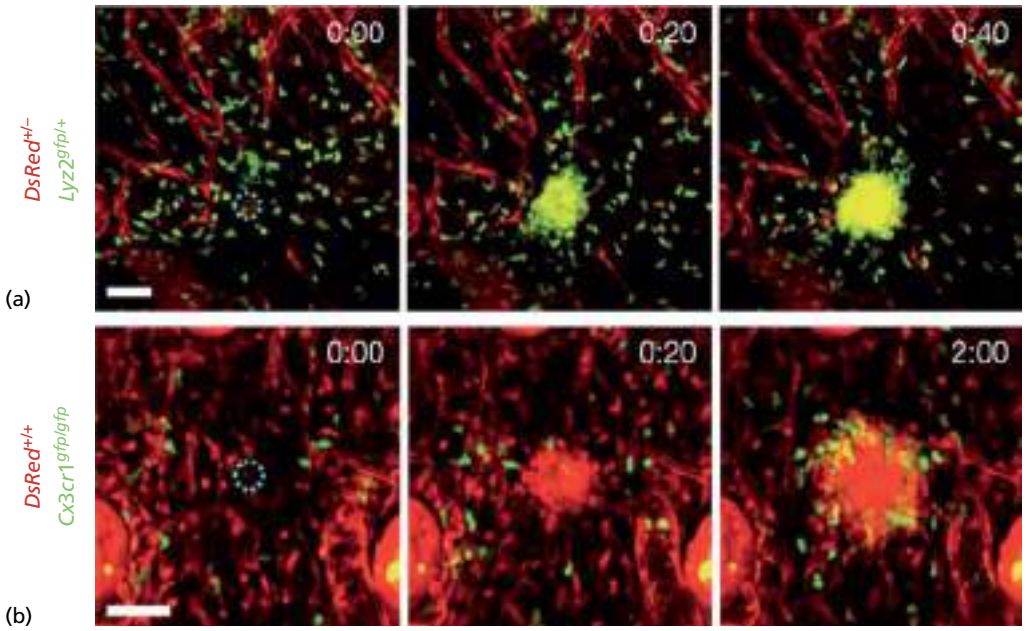

Figure 2.8 Neutrophil and monocyte swarming. The recruitment of neutrophils and monocytes to injury sites is incremental and comparable to swarming. Cells that have infiltrated leave an activation trail that other cells follow. (a) Shows intravital microscopy on an injury performed in the ear dermis of anaesthetised mice. A time-lapse shows infiltration of yellow and green Lyz2gfp/+ myelomonocytic cells, into red stroma. (b) Shows infiltration of Cx3cr1gfp macrophages and monocytes in yellow–green, and neutrophils and stroma in red. Scale bars, 50 μm. Time, h:min (Lämmermann *et al*. 2013).

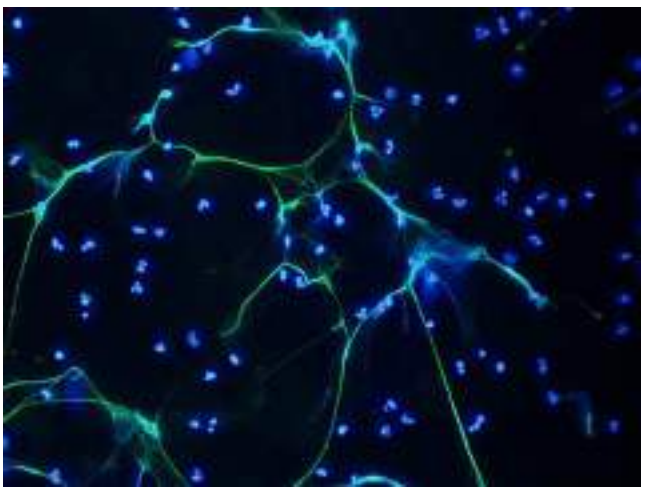

Figure 2.9 Neutrophils produce DNA extracellular traps. Representative images of NETs induced in vitro by LPS in human neutrophils. NETs are visualised by co-staining of neutrophil elastase (green) and nuclear material (DAPI, blue). Original magnification ×40 (Kaplan and Radic 2012).

in the formation of 'neutrophil extracellular traps' (NETs) consisting in core DNA and histone filaments decorated with antimicrobial proteins and enzymes (Figure 2.9). NETs trap microorganisms allowing their phagocytosis by other neutrophils and macrophages. This process often triggers a form of programmed cell death called NETosis.

Eosinophils, basophils and mast cells

Eosinophils, basophils and mast cells are the less abundant, yet powerful granulocytes. The three are specialised in defence against nematodes and other parasites and are implicated in allergic responses. The eosinophil precursors are positive for IL-5Rα+CD34+CD38+ and can be found in bone marrow, adult and cord blood. IL-5, IL-3 or GM-CSF promote their maturation. The eosinophil precursors expand in eosinophilic patients. Basophils are produced from IL-5Rα−CD34+CD38+ progenitors. Eosinophils and basophils go through promyelocyte, myelocyte and metamyelocyte stages. Mast cell progenitors migrate from the bone marrow, homing to tissues where they mature. Mast cell progenitors instead, express the stem cell factor (SCF) receptor c-kit and the high-affinity IgE receptor FcεRI.

In the steady state, eosinophils are present in a variety of tissues including the lung, thymus, adipose tissue and gastrointestinal tract to mention a few. As for PMN several activation stages have been suggested. There are three distinct eosinophilic granules, the round uniformly electron-dense primary granules present mainly in the eosinophilic promyelocyte/myelocyte stages, secondary or specific granules, and finally less well-characterised small granules (Table 2.6).

Table 2.6 Contents of eosinophil granules.

Granule	Protein content	Comment
Primary granule (Charcot–Leyden granule)	Charcot–Leyden crystal (CLC) protein	Weak lysophospholipase, carbohydrate-crystal protein-containing binding properties
Specific granule (secondary granule)	Eosinophil peroxidase Major basic protein (MBP) Eosinophil cationic protein (ECP)	Toxic to parasites Ribonuclease, bactericidal, toxic to parasites
	Eosinophil-derived neurotoxin (EDN)	Ribonuclease, toxic to parasites
	Eosinophil peroxidase (EPO)	Antibacterial
	Lysophospholipase	
	Acid phosphatase	
	Arylsulfatase B	
	Phospholipase A_2 (secretory)	Antibacterial
	BPI protein	LPS binding, antibacterial
	NAMLAA	Antibacterial
	FAD	
	Catalase	
	Urokinase	
	CD63	Tetraspanin
	Proteoglycan	
	α_1 -Antitrypsin	
Small-type granule	Arylsulfatase B	Lysosomal hydrolase
Secretory vesicle	Cytochrome b_{558}	NADPH oxidase component
	CR3	β_2 integrin

BPI, bactericidal permeability-increasing protein; FAD, flavin adenine dinucleotide; LPS, lipopolysaccharide; NAMLAA, *N*-acetylmuramyl-L-alanine amidase.

Primary granules contain eosinophil peroxidase and Charcot–Leyden crystal protein. The eosinophil peroxidase is distinct from neutrophil MPO and can mediate damage to microorganisms, host tissues and induce bronchoconstriction in asthma. The large specific granules contain the eosinophil's cytotoxic and proinflammatory proteins and account for more than 95% of granules in the mature eosinophils, conferring the characteristic appearance of the cell. Eosinophil granules contain a number of enzymes similar to those found in the primary lysosomes of the neutrophil, but eosinophils lack lysozyme. Different cationic polypeptides are the major constituents of eosinophil granules and include major basic protein (MBP), eosinophil cationic proteins (ECP) and eosinophil-derived neurotoxin (EDN).

Eosinophils are recruited in response to early- and late-phase components of immediate hypersensitivity reactions. Their activation and recruitment involve the interaction of several adhesion pathways and chemotactic agents, including the complement fragment C5a, PAF, IL-3, IL-5, GM-CSF, IL-2, RANTES, eotaxins and the CD8+ T-cell-derived lymphocyte chemoattractant factor (LCF). The specificity and intensity of the microbicidal function of eosinophils differ from those of other leucocytes. Eosinophils preferentially assemble NADPH oxidase in the plasma membrane to generate extracellular O_2–, (Figure 2.10). The major role of eosinophils in host defence is the destruction of metazoan parasites. Eosinophils readily degranulate in response to stimulation by antigens, cytokines and complexed or secretory IgA, IgE and IgG (Hirsch 2022). Proteins released from eosinophils result in histamine release from basophils and mast cells and amplify the inflammatory response (Table 2.7). These proteins are also powerful toxins towards host cells, leading to tissue injury.

Basophils and mast cells

Basophils and mast cells express the receptor that binds with high affinity to the Fc portion of IgE antibodies (FcεIR) and have large metachromatic (purple–black) granules rich in histamine, serotonin and leukotrienes. Basophils have a bilobed nucleus, in contrast to mast cells, which have a unilobed nucleus. More recent studies have demonstrated that despite their significant similarities, basophils and mast cells are terminally differentiated progeny of distinct bone marrow progenitors. Basophils mature in the marrow over a period of 2–7 days and after their release into the

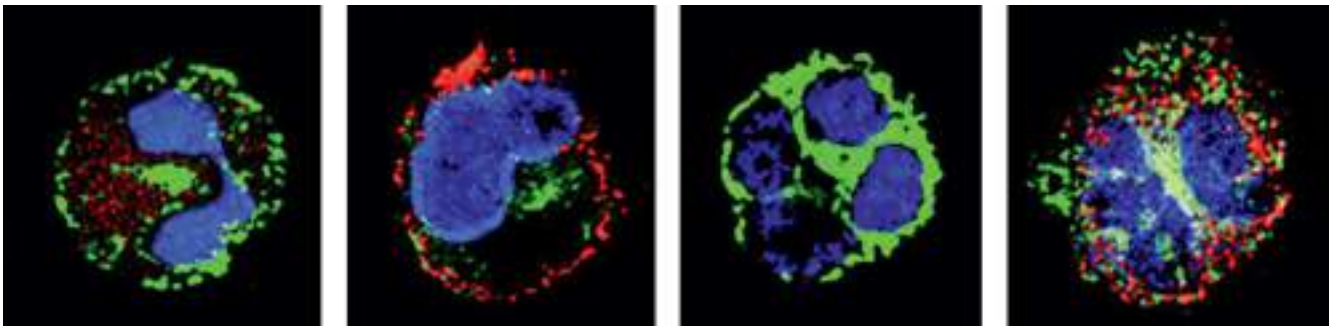

Figure 2.10 The respiratory burst in eosinophils and neutrophils is assembled in different locations. Eosinophils are specialised in dealing with extracellular pathogens. Rac GTPase (red) binds GTP to stimulate NADPH oxidase activity p22phox (green) and becomes associated with their plasma membrane upon cell activation. Nuclei are shown in blue. Resting eosinophils shown in (a–c), versus PMA-stimulated eosinophil in (d), show that p22phox and Rac colocalise in the cell membrane. In neutrophils the complex forms intra-cellularly. Original magnification, ×40 (Lacy *et al.* 2003).

Table 2.7 Biologic activities of selected Eosinophil granule proteins.

Granule protein	Biologic activities
Major Basic Protein (MBP)	Helminthotoxin and cytotoxin; bactericidal, platelet agonist; causes histamine release from basophils and rat mast cells; neutralises heparin; increases bronchial reactivity to methacholine; provokes bronchospasm; activates neutrophils
Major Basic Protein-2 (MBP-2)	Cytotoxin; causes histamine release and LTC_4 release from basophils; causes superoxide and IL-8 release from neutrophils
Eosinophil Cationic Protein (ECP)	Helminthotoxin, neurotoxin, weak RNase activity, bactericidal, virucidal; inhibits cultures of peripheral blood lymphocytes; causes histamine release from rat mast cells; neutralises heparin, alters fibrinolysis
Eosinophil –Derived Neurotoxin (EDN)	Neurotoxin, RNase activity, virucidal, weak helminthotoxin; inhibits cultures of peripheral blood lymphocytes; same as eosinophil protein X
Eosinophil Peroxidase (EPX)	In presence of H_2O_2 plus halide: kills microorganisms and tumour cells; causes histamine release and degranulation from rat mast cells; inactivates leukotrienes in absence of H_2O_2 plus halide; kills *Brugia* microfilariae; damages respiratory epithelium; provokes bronchospasm in primates. Generates reactive oxidants and free radicals

circulation persist for up to 2 weeks. They are the key mediators of immediate hypersensitivity reactions such as asthma, urticaria and anaphylaxis. In addition, they have been implicated in the delayed cutaneous hypersensitivity reaction. Basophils are stimulated by a number of mediators, such as IgE, IL-3, C5a, GM-CSF, insect venoms and morphine, to release the contents of their granules such as histamine.

The interaction between IgE and basophil/mast cell FcεIR and antigen bridging results in basophil degranulation and initiation of their effects on granule contents. The granules of basophils and mast cells contain sulfated glycosaminoglycans, responsible for their intense staining, as well as histamine, LTD_4, PAF, eosinophil chemotactic factor and kallikreins, responsible for type I immediate hypersensitivity reactions and chronic inflammation (Table 2.8). The primary protease presents in mast cells, tryptase, is mainly released during the early phase of allergic responses and is a marker of mast cell activation in chronic inflammatory diseases. Basophil and mast cell activation leads to the elaboration of cytokines such as GM-CSF, TNF-α, IFN-γ, IL-3, IL-4 and IL-5, which serve to amplify the inflammatory response.

MPS-Monocytes, macrophages, DCs and multinucleated cells

Embryonic macrophages give rise to resident tissue macrophage populations which persist in many organs after birth. Embryonic yolk sac- derived macrophages/fetal liver monocytes migrate to

Table 2.8 Basophil and mast cell granules and their contents.

Component	Function	Main physiological role	Other properties	Cell specificity
Histamine	Binds to H_1, H_2, H_3 receptors	Hypersensitivity reactions and inflammation		Basophils, mast cells
Proteoglycan Heparin	Package of basic proteins into granules	Potent anticoagulant by the activation of anti-thrombin	Binds and stabilises proteases	Connective tissue mast cells
Chondroitin sulfates	Package of basic proteins into granules	Potent mast cell inhibitor	Binds and stabilises proteases	Basophils
Enzymes Chymase	Activates precursor IL-1β	Affects microcirculation, Inflammation Modulates microcirculation Modulates skin inflammation	Apoptosis	Connective tissue mast cells
Tryptase	Activates metalloproteinase 3, inactivates fibrinogen, degrades calcitonin gene-related peptide	Proinflammatory, stimulates neutrophil chemotaxis and adherence, regulates collagenase, attenuates fibrin deposition	Tetrameric when bound to heparin, monomer inactive, restricted substrate specificity, raised levels in mast cell disorders	Mast cells
Cathepsin G-like protease Carboxypeptidase	Inactivates bradykinin	Affects microcirculation	Bactericidal	Connective tissue mast cells
Other				
Charcot–Leyden crystal protein	Lysophospholipase	Phospholipid metabolism	Neutralises pulmonary surfactant	Basophil
Major basic protein, Exoglycosidase protein Sulfatase		Disrupts membranes		Basophil

the brain (microglia), heart and skin epidermis (Langerhans cells). The brain remains relatively autonomous from bone marrow after the initial phase and microglia are maintained in adulthood by limited self-renewal. Stem cells and precursors migrate to the bone marrow in later embryonic phases and become the main source of newly recruited MPS cells in the adult, especially in the form of monocytes that mature into macrophages and DCs.

After birth, there is an initial expansion of monocytes which become the most abundant blood MPS cell, representing 2–8% of the total number of leucocytes. Monocytes are differentiated cells, but they have the ability to enter tissues and mature into macrophages. As discussed in the introduction, Monocytes originate from bone marrow pluripotent haematopoietic stem cells that commit to haematopoietic progenitor cells termed CFU-GEMM and the more committed CFU-GM). M-CSF is the most important factor in the development of monocytes although GM-CSF and IL-3 also support commitment along monocytic pathways. The CSF1R receptor, also called CD115, is a sensitive pan MPS marker, which varies in selected inflammatory states. Most CSF1R+ monocytes appear in subsets often referred to as classical and non-classical, based on CD14 and CD16 expression. CD14 is a receptor for bacterial ligands and CD16 for immunoglobulins. CSF1R+ CD14- CD16- monocytes comprise DCs in inflammation. M-CSF, IL-34 and GM-CSF are the cytokines more associated with macrophage development and GM-CSF and IL-4 for monocyte- derived DCs.

Monocytes and macrophages express a broad range of plasma membrane receptors in addition to those shared with neutrophils and described above (Figure 2.11). Particles are recognised by a combination of scavenger receptors, integrins (complement receptors), and lectins binding directly or via opsonins such as LBP, TSP, or collectins. Most of these receptors are able to recognise both pathogens and altered self-ligands such as apoptotic cells. In addition, phagocytes have specific receptors that discriminate pathogen-associated components causing inflammatory responses. For example, recognition of gram-positive bacteria is mediated by TLR2 and TLR6 and of gram-negative

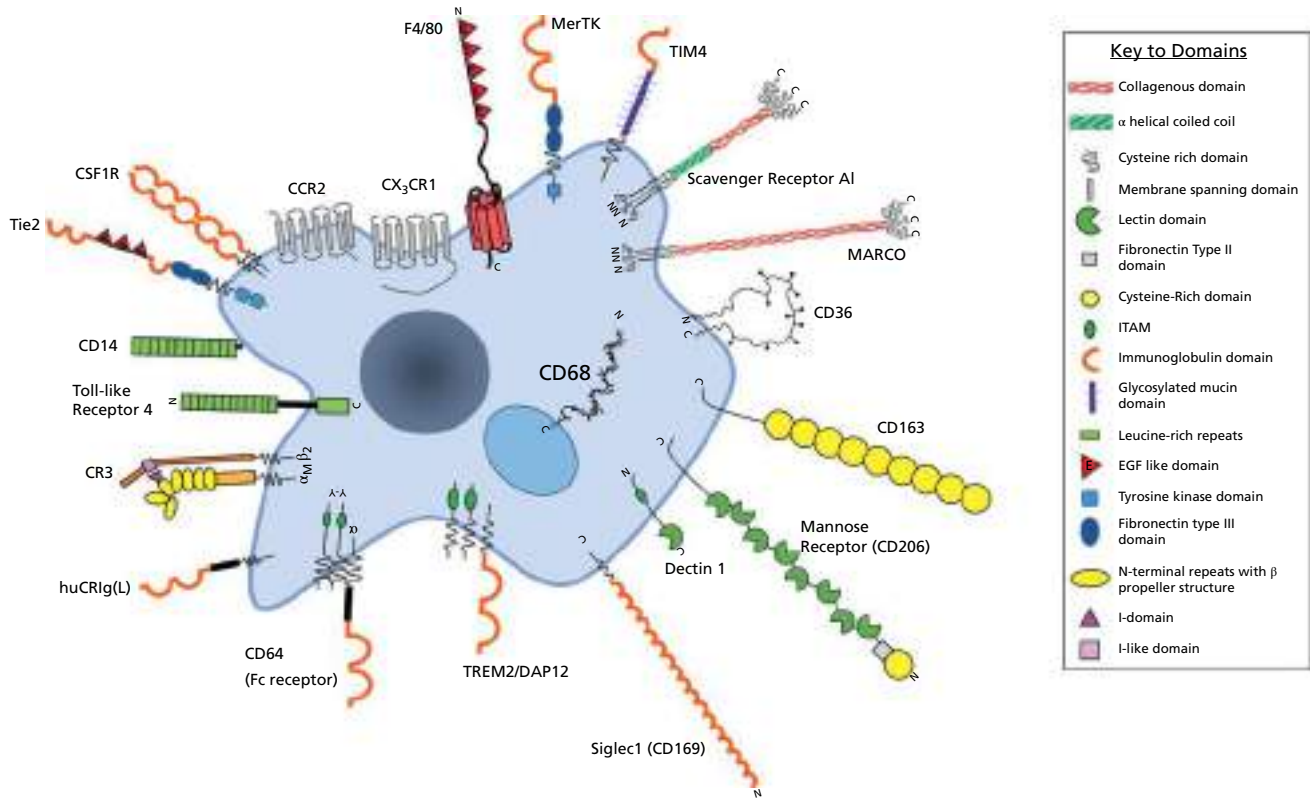

Figure 2.11 Plasma membrane antigens and receptors expressed by macrophages. Macrophages express a large number of receptors that are functionally active and can be used as markers for immunocytochemistry and FACS analysis (e.g. F4/80, CD68, CSF1 receptor, Mer-TK, CD64). The phagocytic receptors mediate elimination of microbes (e.g. MARCO), apoptotic cells (e.g. CD36, SR-A and TIM4), and circulating ligands. Other receptors bind lineage-determining cytokines, such as CSF-1. CD163 mediates the elimination of haptoglobin–haemoglobin complexes. TLR4, CD14, Dectin-1 recognise PAMPs leading to inflammation. CCR2 and CX3CR1 are chemokine receptors highly expressed in macrophages. Siglec-1 (CD169), a receptor for sialic acid terminal glycoconjugates, mediates adhesion of host cells and microbes, whereas CD206, a receptor for clearance of mannosyl terminal glycoproteins, is a prototypical marker of M2-type activation. The scavenger receptor SR-A binds polyanionic ligands such as oxidised LDL, as well as microbes. CD36 mediates adhesion and giant cell formation. For further details, see BMC, with permission (Source: Gordon *et al.* 2020/John Wiley & Sons.)

bacteria by TLR4. In contrast, anti-inflammatory signals are triggered after binding of apoptotic cells that expose phosphatidyl-serine (PS) on their cell surface. Ligation of receptors for apoptotic cells (especially the receptor for PS) causes liberation of TGFβ and other immunomodulatory cytokines. Hence, multiple receptors are involved in recognition with certain common receptors mediating internalisation of both pathogens and self-ligands. Together these receptor complexes contribute to discriminating and initiating appropriate responses.

Activation of macrophages with IFN-γ, produced by NK and Th1 cells results in a microbicidal 'classical' macrophage activation state, whilst IL-4 and IL-13 produced by the Th2 population of T lymphocytes induce an 'alternative' form of macrophage activation, promoting antigen-presentation (Figure 2.12). These cytokines then enhance macrophage stimulation of T and B lymphocytes by inducing class II MHC antigen and costimulatory molecule expression. Activated macrophages, in turn, produce cytokines that stimulate both types of helper T cells. Several cytokines, including IL-4, IL-10, IL-13 and TGF-β, can inhibit different aspects of macrophage function. Furthermore, prostaglandin (PG)E_2, elaborated by macrophages, as well as corticosteroids can suppress various actions of macrophages. These provide a feedback mechanism for control of the immune response.

Dendritic cells (DCs) were first described as rare, distinct mononuclear cells in mouse spleen by Steinman and Cohn in 1973. The new cell type was characterised by large size, relatively smooth surface and a convoluted nucleus containing small nucleoli. In addition, these motile cells presented a cytoplasm rich in large mitochondria and vesicles arranged in multiple plasma membrane processes of various extensions that

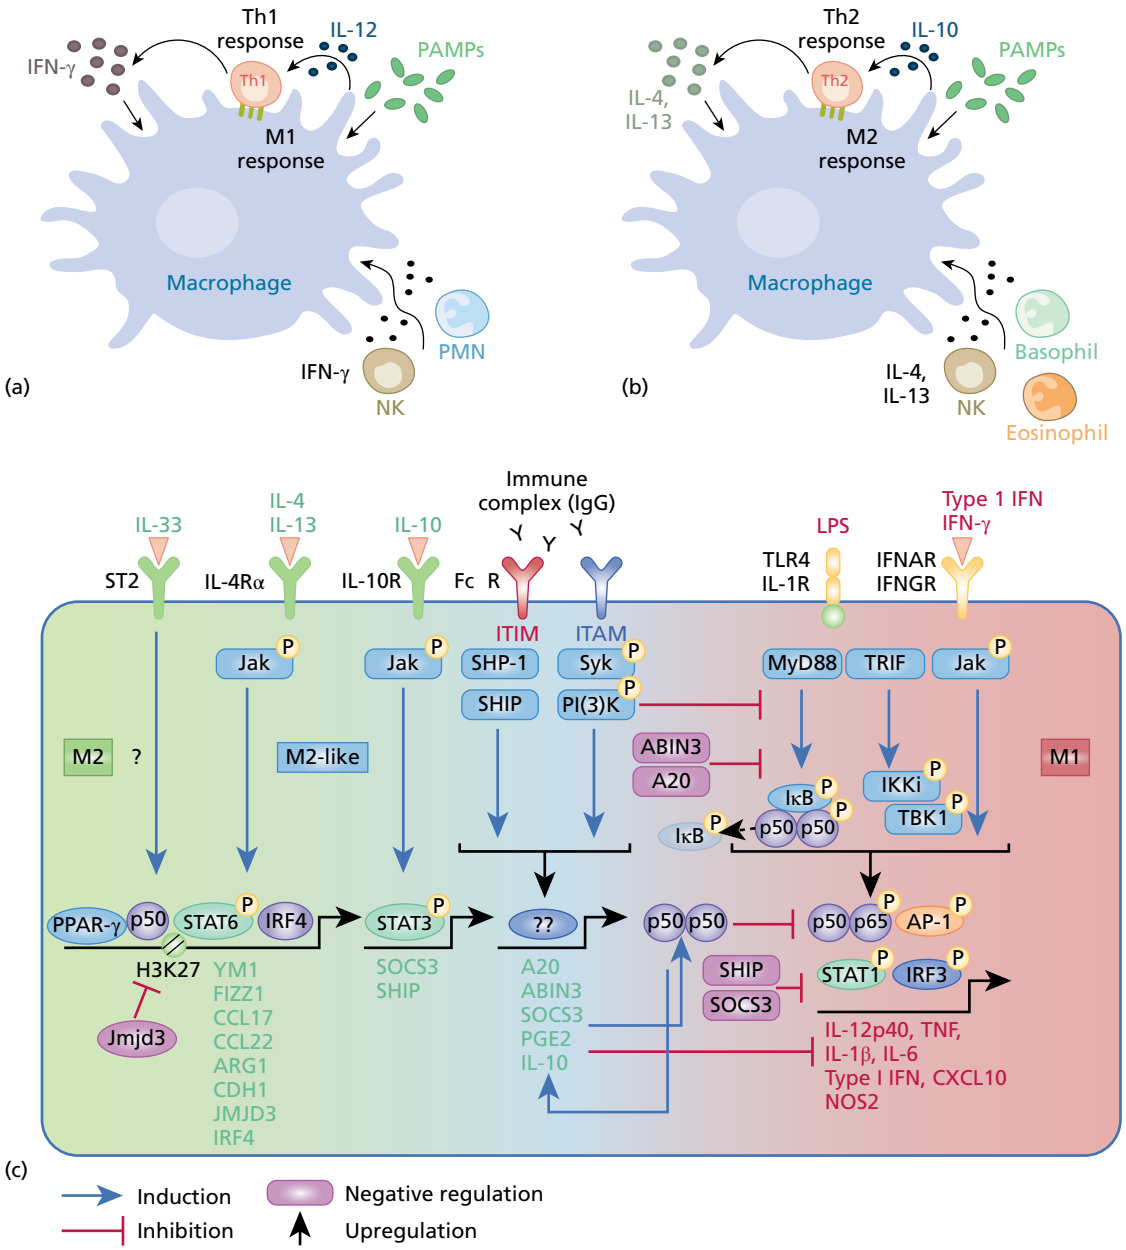

Figure 2.12 Two-signal macrophage activation model in the context of the immune response. (a) Macrophage full activation requires two major signals, recognition of PAMPs by PRRs and stimulation with IFN-γ or IL-4, in a cycle that determines the development of specificity and effector functions in the immune response. For Th2 responses. (b), uncharacterised PRRs induce the recruitment of IL-4 and IL-13, producing innate immune cells such as eosinophils and basophils and naive T lymphocytes. IL-4 and IL-13 produced by innate immune cells induce a first wave of innate alternative activation in macrophages but also provide the secondary signal for Th2 development. (c) The major pathways of macrophage polarisation are outlined (Source: Adapted from Martinez *et al.* 2009; Sica and Mantovani 2012.)

they termed 'dendrites'. Unlike macrophages, DCs lacked abundant membrane ATPase, digestive bodies and lysosomes, and displayed less FcR-dependent phagocytic activity compared with macrophages, both *in vivo* and *in vitro*. Although far less numerous than tissue macrophages, DCs expressed a potent and unique ability to induce primary immune responses to foreign antigens in naive lymphocytes, whereas both DCs and macrophages can activate primed lymphocytes by capture, processing and presentation of MHC-bound peptides to T and B cell antigen-specific receptors. DCs have a rapid turnover in

the spleen, and are only transiently adherent to culture vessels, compared with macrophages, and are difficult to maintain in standard media in vitro.

Tissue-based DC performs predominantly antigen-presenting rather than phagocytic clearance functions. Langerhans cells are found in virtually all tissues except the brain and are the major immunological cellular components of the skin and mucosa. Their racquet-shaped ultrastructural inclusions (Birbeck bodies) distinguish them from other tissue cells. They interact with and process antigen, then migrate to lymphoid organs where, through interaction with T cells, they generate cellular and humoral immune responses. This ability of DCs to interact with T cells and other inflammatory cells contributes to the often-varied clinical manifestations of the histiocytic disorders.

The presence and functions of DCs have been described in many organs and animal species, as well as in human blood. Further studies revealed that human DC constitutively expresses high levels of class I and II major histocompatibility complex (MHC) molecules and many other markers, such as CD58, CD54, CD50, CD40, CD80 and CD86. CD58, CD54, CD50 and CD40 are adhesion molecules essential for the binding with T cells; they bind to CD2, CD11a, integrin LFA-1 and CD154, respectively. CD80 and CD86 are costimulatory molecules for T cell activation; they both bind to CD28. DCs were soon found to be in the T-cell areas of peripheral lymphoid organs such as the spleen, lymph nodes and Peyer's Patches, the ideal location for initiating immune responses.

Disorders of the phagocyte system

Neutrophil congenital disorders (Table 2.9)

Primary neutropenic disorders are rare and heterogeneous conditions presenting as *Severe Congenital Neutropenia* (SCN) or as *Cyclic Neutropenia* (CyN), a milder disease. A unifying feature of these conditions is premature apoptosis of neutrophil progenitors and precursors, leading to differentiation/maturation blockade. Half of SCN cases are linked to defects in the gene encoding neutrophil elastase (*ELANE*), one of the four major serine proteases synthesised in neutrophil granule formation. Various SCN forms can predispose to the myelodysplastic syndrome (MDS) and acute myelogenous leukaemia (AML) by mechanisms involving acquired, activating mutations in the G-CSF receptor gene and in other leukaemia-associated genes. SCN is usually diagnosed in infancy in the setting of recurrent severe infections. First-line treatment of infections in such patients is antibiotics with G-CSF. Stem cell transplantation offers the potential to cure for those who do not respond to antibiotics and G-CSF.

Multisystemic disorders with neutropenia comprise conditions in which neutropenia is only one of the consequences of alterations in general cell functions, such as primary mitochondrial dysfunctions (Table 2.9). Examples are the *Shwachman–Diamond–Oski syndrome* and *Charcot-Marie-Tooth disease*, a relatively common inherited disorder of the peripheral nervous system. WHIM (warts, hypogammaglobulinaemia, infection, myelokathesis) is characterised by increased retention (kathésis) of myeloid cells in the bone marrow due to increased sensitivity of the CXCR4 receptor to CXCL12.

Neutrophil dysfunction disorders involve defects in specific neutrophil functions such as adherence to the vascular endothelium (*Leucocyte Adhesion Deficiency* or LAD) and generation of reactive oxygen species (*Chronic Granulomatous Disease* or CGD). LAD is characterised by defects in adhesion of neutrophils to blood vessel walls with decreased migration from the bloodstream to sites of infection despite persistent leucocytosis, delayed separation of the umbilical cord and impaired wound healing. CGD is characterised by defects in the phagosomal and plasma membrane-associated NADPH oxidase, resulting in impaired superoxide formation, decreased killing of catalase-positive organisms and chronic infection.

Myeloperoxidase (MPO) deficiency, the most common inherited disorder of phagocytes, is associated with a higher incidence of fungal infections.

Secretory granule and lysosome disorders involve defects in endosomal/lysosomal maturation, trafficking and content. *Chédiak–Higashi syndrome* is a rare autosomal recessive disorder characterised by oculocutaneous albinism, recurrent and severe bacterial infections and giant blue–grey granules in the cytoplasm of white blood cells (Figure 2.13).

Autoinflammatory disorders are caused by an increased activation of the innate immune system, leading to episodes of fever and localised or systemic inflammation in the absence of infection or other inflammatory stimuli (see Table 2.10). These conditions should be distinguished from autoimmune diseases, which are caused by increased activation of the adaptative (as opposed to innate) immune system with the production of antibodies or T cells reacting against autologous or self-antigens.

Disorders of monocyte/macrophages: a genetic perspective

The recruitment of bone marrow-derived monocytes by sterile, infectious and immune stimuli gives rise to inflammation, with local and systemic impacts on tissue perfusion, thermoregulation and hepatic biosynthesis, innate and acquired immune activation, tissue injury and repair (Nathan 2022). Macrophages are extensively activated by pro-inflammatory cytokines such as IL-1β, IL6, TNF alpha and type 1 interferons, as well as anti-inflammatory IL-10, TGF beta cytokines and arachidonate metabolites. Widespread vaccination with live BCG brought to light the importance of macrophage activation by gamma interferon, IL-12 and IL-18 cytokines in

Table 2.9 Inherited neutrophil disorders.

Gene protein	Disease name	Inheritance pattern	Molecular mechanisms
Disorders with primary neutropenia			
ELANE neutrophil elastase	Congenital neutropenia or cyclic neutropenia	AD or somatic	Maturation arrest, premature apoptosis unfolded protein response, ER stress
JAGN1 Jagunal homolog 1	Congenital neutropenia	AR	Differentiation defect, premature apoptosis ER secretory pathway
CSF3R colony-stimulating factor receptor	Congenital neutropenia	AR and AD	Bone marrow production and release signalling defect
GFI1 growth factor independence 1	Congenital neutropenia	AD	Myeloid cell differentiation Transcription repressor
G6PC3 Glucose-6-phosphatase	Congenital neutropenia	AR	Bone marrow retention, apoptosis ER stress, glycosylation defect
HAX1 HS1-associated protein X1	Kostmann syndrome	AR	Bone marrow production and release
Multisystemic syndromes with neutropenia			
AK2 Adenylate kinase 2	Reticular dysgenesis	AR	Differentiation defect Mitochondrial metabolism dysfunction
RMRP RNAase mitochondrial RNA processing	Cartilage hair hypoplasia	AR	Bone marrow dysfunction Preribosomal RNA processing
SBDS Shwachman–Bodian–Diamond syndrome protein	Shwachman–Bodian–Diamond syndrome	AR	Differentiation defect, premature apoptosis Ribosome biogenesis
DNM2 Dynamin 2	Charcot-Marie-Tooth disease	AD	Membrane trafficking, microtubules
TAZ1 Tafazzin	Barth syndrome	XLR	Mitochondrial membrane dynamics
G6PT Glucose-6-phosphate transporter	Glycogen storage disease type 1b	AR	Premature apoptosis ER stress, mitochondrial dysfunction
Immunodeficiency syndromes with neutropenia			
BTK Bruton's tyrosine kinase	X-linked agammaglobulinaemia	XLR	Chemotaxis defect, reactive oxygen defect
WAS Wiskott-Aldrich syndrome	X-linked neutropenia Wiskott-Aldrich syndrome	XLR	Decreased proliferation, increased apoptosis Actin polymerisation
CD40L CD40 ligand	Hyper-IgM syndrome	XLR	Adhesion and transmigration
CXCR4 Chemokine receptor CXCR4	WHIM (warts, hypogammaglobulinaemia, immunodeficiency, and myelokathexis)	AD	Bone marrow and tissue homing abnormality Defective chemokine receptor function
STK4 Serine/threonine kinase 4	STK4 deficiency	AR	Increased apoptosis Mitochondrial dysfunction
GINS1 Go-ichi-ni-san complex subunit 1	GINS1 deficiency	AR	Impaired cell cycle Defective DNA repair

(*Continued*)

Table 2.9 (*Continued*)

Gene protein	Disease name	Inheritance pattern	Molecular mechanisms
Neutrophil dysfunction disorders			
ITGB2 Leucocyte integrin β2 chain	LAD-I	AR	Neutrophil adhesion/migration defects Adhesion molecule deficiency
GFTP *GDP* fucose transporter	LAD-II	AR	Selectin deficiency Defect in fucose transport
FERMT3 *KINDLIN*-3	LAD-III	AR	Neutrophil adhesion defect
CYBB Cytochrome b-245β; gp91phox	Chronic granulomatous disease	XLR	Defective oxidative burst NADPH oxidase enzyme defect
CYBA Cytochrome b-245α; p22phox	Chronic granulomatous disease	AR	Defective oxidative burst NADPH oxidase enzyme defect
NCF1 Neutrophil cytosolic factor-1; p47phox	Chronic granulomatous disease	AR	Defective oxidative burst NADPH oxidase enzyme defect
NCF2 Neutrophil cytosolic factor-2; p67phox	Chronic granulomatous disease	AR	Defective oxidative burst NADPH oxidase enzyme defect
NCF4 Neutrophil cytosolic factor-4; p40phox	Chronic granulomatous disease	AR	Defective oxidative burst NADPH oxidase enzyme defect
G6PD Glucose-6-phosphate dehydrogenase	G6PD deficiency	AR	Defective oxidative burst, NETosis defect Enzyme deficiency
RAC2 Ras-related C3 botulinum toxin 3	Neutrophil immunodeficiency syndrome	AR	GTPase deficiency, defective oxidative burst Secretory and phagocytosis defect
MYD88 Myeloid differentiation 88	MyD88 deficiency	AR	Neutrophil aging TLR and IL-1R signalling defect
IRAK4 Interleukin-1 receptor-associated kinase 4	IRAK4 deficiency	AR	Defective migration and phagocytosis Impaired TLR and IL-1 receptor responses
Secretory lysosome/granule defects			
LYST Lysosomal trafficking regulator	Chediak-Higashi syndrome	AR	Neutrophil signalling defect Abnormal lysosome and melanosome trafficking
RAB27A *RAB27a*	Griscelli syndrome type 2	AR	Reduced mature neutrophils Membrane trafficking/phagosome secretion defect
UNC13D *MUNC13*-4	Familial haemophagocytic lymphohistiocytosis type 3	AR	Neutropenia, vesicular trafficking, and secretion defects
STXBP2 Syntaxin binding protein 2 (MUNC18-2)	Familial haemophagocytic lymphohistiocytosis type 5	AR	Secretion and bactericidal defects
WDR1 Actin-interacting protein 1 (Aip1)	WDR1 deficiency	AR	Mild neutropenia, impaired chemotaxis Normal bacterial killing and increased oxidative burst
MLK1 Megakaryoblastic leukaemia 1 (MKL1)	MLK1 deficiency	AR	Decreased phagocytosis and impaired migration

AP3B1 Adaptor-related protein complex β1	Hermansky-Pudlak syndrome	AR	Reduced mature neutrophils Abnormal vesicular trafficking of proteins
LAMTOR2 Late endosomal/lysosomal adaptor, MAPK and MTOR activator 2	Immunodeficiency due to defect in MAPBP-interacting protein (p14 deficiency)	AR	Abnormal neutrophil maturation and function Late endosome biogenesis
CEBPE CCAAT enhancer binding protein ε	Specific granule deficiency	AR	Neutrophil chemotaxis defect Abnormal or absent granule formation
Autoinflammatory disorders			
NLPR3 Cryopyrin	Cryopyrin-associated periodic syndromes (CAPS)	AD or somatic	Neutrophil homeostasis dysregulation Inflammasome mediated IL-1β release/cell death
MEFV Pyrin	Familial Mediterranean fever	AR or rarely AD	Neutrophil chemotaxis and phagocytosis defect Enhanced apoptosis and altered adhesion Hyperactive inflammasome-mediated IL-1β release Alterations in F-actin dynamics
MVK Mevalonate kinase	Mevalonic aciduria and hyper-IgD syndrome	AR	Pyrin inflammasome activation due to RhoA inactivation and compromised phosphatidylinositol 3-kinase activity secondary to prenylation defect
TNFRSF1A Tumour necrosis factor receptor–1A	Tumour necrosis factor receptor–associated periodic syndrome	AD	Neutrophil apoptosis resistance TNFR signalling or shedding defect
NOD2 Nucleotide oligomerisation domain 2	Blau syndrome	AD	Increased ocular neutrophil rolling and adherence Activation of nuclear factor κB/IL-1β –mediated inflammation
IL1RN Interleukin-1 receptor antagonist	Deficiency of IL-1 receptor antagonist	AR	Neutrophil mobilisation and activation Unregulated IL-1 receptor activation
CD2BP1 CD2 binding protein 1	Pyogenic arthritis pyoderma gangrenosum and acne (PAPA)	AD	Neutrophil mobilisation and activation Defective actin dynamics
PSMB8 Proteasome subunit β type 8	Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE)	AR	Neutrophil mobilisation and activation IFN dysregulation
TMEM173 Stimulator of interferon genes (STING)	STING-associated vasculopathy with onset in infancy (SAVI)	AD	Neutrophil mobilisation and activation IFN dysregulation
Other disorders			
DNASE1 Deoxyribonuclease 1	Monogenic systemic lupus erythematosus	AR	Defective NET degradation Increased ROS production IFN dysregulation
DNASE1L3 Deoxyribonuclease 1L3	Monogenic systemic lupus erythematosus	AD	Defective NET degradation Increased ROS production IFN dysregulation
CFTR Cystic fibrosis transmembrane regulator	Cystic fibrosis	AR	Delayed neutrophil apoptosis Impaired MPO activity

genetic resistance mediated by cellular adaptive immunity to infection. The discovery of inflammasome assembly and activation of IL-1 processing in macrophages by Tschopp and Martinon Figure 2.5 and (Martinon *et al*. 2002),) catalysed subsequent elucidation of the mechanisms that underlie a growing number of innate auto-inflammatory genetic syndromes (Table 2.10). This occurred in parallel with the link observed between type1 interferons, auto-immune diseases and antiviral resistance, especially in severe COVID-19 susceptibility (Zhang *et al*. 2022).

Table 2.10 lists monogenic inflammatory syndromes associated with inflammasome and other pro-inflammatory cytokine receptor and signalling disorders, cytoskeletal dysregulation and phospholipase C gamma2 function. Further details of age of onset and clinical manifestations are given in (Savic *et al*. 2022). Table 2.11 lists monogenic Type 1 interferonopathies (Savic *et al*. 2022; Zhang *et al*. 2022) and Figure 2.14 categorises putative functions of genes involved in this cellular pathway (Crow and Stetson 2021). IL-1 R antagonist and a range of anti-cytokine/R antibodies provide important therapeutic options, supplemented by corticosteroids and bone marrow transplantation where indicated. Type1 interferon genetic deficiency has been found in about 2% of subjects infected by COVID-19, exacerbating the risk of severe illness and death; anti-interferon antibodies arise during infection in about 10% of individuals without a genetic deficiency in the type1 interferon pathway, mimicking the effect of its absence (Zhang *et al*. 2022).

Table 2.11 Monogenetic interferonopathies.

Disease	Gene	Affected protein/ function	Mode of inheritance	Treatment
		Interferonopathies		
CANDLE/PRAAS	*PSMA3*, *PSMB4* *PSMB8-9*, *POMP*	Proteasome	AR	Glucocorticoids, Jak inhibition
Aicardi Goutieres syndrome (AGS)	*TREX1*, *RNASEH2A-2C*, *SAMHD1ADAR1IFIH1*	Exonuclease subunits of the RNase H2 endonuclease complex Control of dNTP pool	AR/AD	Symptomatic treatment, Jak inhibition, reverse transcriptase inhibitors
SAVI	*TMEM173*	Stimulator of Interferon Genes (STING)	AD, SM	Jak inhibition
DNASE2 deficiency	*DNASE2*	Deoxyribonuclease	AR	Jak inhibition

AD, autosomal dominant; AR, autosomal recessive; CANDLE, chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature syndrome; DADA2, deficiency of adenosine deaminase 2; SAVI, sting-associated vasculopathy with onset in infancy (Savic *et al.* 2022).

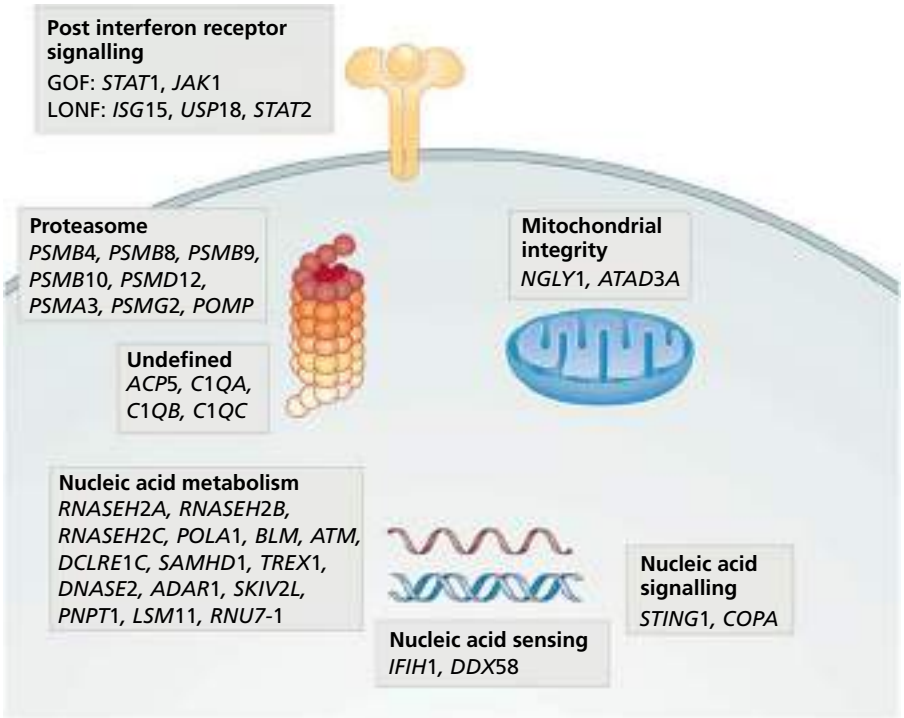

Figure 2.14 Type I interferonopathy genotypes according to the function of the encoded gene products. Putative type I interferonopathy mutated gene products act directly on nucleic acid substrates (nucleic acid 'metabolism') or are involved in nucleic acid sensing; others have a primary role in transducing a DNA signal to an innate immune response, are involved in downstream regulation of type I interferon receptor signalling or contribute to the maintenance of mitochondrial integrity. Further genes relate to the proteasome, where the precise link to type I interferon induction remains unclear. The relationship of mutations in *ACP5* and *C1QA*, *C1QB*, and *C1QC* mutations to disease remains unproven. GOF, gain of function; LONF, loss of negative feedback. Further details are given in (Source: Crow and Stetson 2021/Springer Nature).

Conclusion

Phagocytes provide a unique and integral contribution to all aspects of haematologic research and clinical practice. Ready access to blood has brought new insights into the origin, differentiation and activation of the distinct, but related phagocyte lineages. Hitherto, haematologists have focussed mainly on cells in blood and bone marrow, yet all mature leucocytes have a significant presence and functional role within lymphohaematopoietic and other organs, contributing to homeostasis as well as pathology. Tissue phagocytes must not be overlooked. Many of the rare monogenic genetic disorders listed above become manifest in early life, obscuring the contribution of genetics to diseases associated with later life. Common pathologies such as atherosclerosis, malignancy and neurodegenerative disease develop gradually over many years and mononuclear phagocytes contribute substantially to their pathogenesis in blood and tissues.

CHAPTER 3

Erythropoiesis in the human

3

Douglas R Higgs, Christian Babbs and Mira Kassouf

The Laboratory of Gene Regulation, The MRC Weatherall Institute of Molecular Medicine, The University of Oxford, Oxford, UK

Introduction

Erythropoiesis is the production of red blood cells carrying the respiratory pigment haemoglobin for the transport of oxygen to tissues. This process involves the commitment of multipotent haematopoietic stem cells (HSCs) to the erythroid lineage followed by expansion and differentiation of committed erythroid cells. The early stages of erythropoiesis are governed by complex transcriptional and epigenetic programmes which respond to extracellular and intracellular signalling. In the later phases of erythropoiesis, multiple events occur including the synthesis of haemoglobin, condensation and extrusion of the nucleus, and the elimination of most organelles to produce reticulocytes. Reticulocytes then undergo membrane and cytoskeletal remodelling and removal of any remaining organelles before forming mature erythrocytes. This entire process normally maintains the steady state of an individual's red cell mass, producing $1–2 \times 10^{12}$ new red cells (25–50 mL of packed red cells) per day to replace those that are lost through senescence or premature destruction. Any failure to maintain the balance between production and loss results in anaemia which is one of the most common manifestations of a very wide range of inherited and acquired disorders affecting up to a third of the world's population at some time and commonly for a long period of their lives.

Understanding the basic biology of erythropoiesis provides a logical framework for the diagnosis and treatment of inherited and acquired anaemias. Many of the principles underlying normal erythropoiesis have been established by studying model organisms particularly mouse, chicken and zebrafish. Important information has also been obtained by studying cell lines, from a variety of species, which can expand and differentiate along the erythroid pathway. However, the details of erythropoiesis in these experimental models often differ between species, and cell lines do not always reflect the mechanisms that underly normal erythropoiesis *in vivo*. In addition, cell models usually recapitulate red cell production at specific developmental stages (embryonic, fetal or adult) at which times certain aspects of erythropoiesis may be regulated quite differently. Over the last 20 years, our understanding of erythropoiesis in humans has been greatly improved via human genetic studies. Genes and pathways mutated in individuals with erythroid disorders can now be rapidly identified by DNA sequencing. Furthermore, genome-wide association studies have identified many new modifiers of erythropoiesis. In addition, we can now expand primary erythroid cells from progenitors obtained from peripheral blood and this has enabled detailed molecular and cellular analysis of both normal and disordered erythropoiesis in humans. Such developments are not only increasing our understanding of normal erythropoiesis, but also improving our ability to diagnose and treat red cell disorders. In this chapter, we outline the normal mechanisms underlying erythroid specification, differentiation and maturation in human erythropoiesis and highlight some points at which this complex system may fail.

The developmental origins of erythropoiesis

Based on analysis of both human and mouse, erythropoiesis has been shown to occur in three successive waves during development. Each wave emerges from a different site in the developing embryo, and the first wave begins at the same time

as development of the circulatory system. Primitive erythropoiesis (PE) is first evident in humans at around 3 weeks post conception and arises from the blood islands of the extra-embryonic yolk sac. By analogy to the mouse, a second wave of haemopoietic activity is thought to emerge from erythromyeloid progenitor (EMP) cells in the yolk sac at approximately 4 weeks of gestation and this marks the onset of definitive erythropoiesis (DE). Erythroid progenitors released into the circulation at this time pass to the liver, which becomes the main site of definitive erythropoiesis in the fetus. A final wave of definitive haemopoietic activity occurs in the aorta-gonad–mesonephros (AGM) region, the placenta and the major blood vessels at approximately 4–6 weeks of gestation. By 10–12 weeks, haemopoiesis starts to migrate to the bone marrow, where blood formation becomes fully established during the last 3 months of gestation (see Chapter 1 for further details).

Primitive and definitive erythroid cells are distinguished by their morphology, cytokine responsiveness, growth kinetics, transcription factor programmes, epigenetic programmes, regulation of cell cycle and patterns of gene expression. Definitive fetal erythroid cells also differ from adult erythroid cells. Importantly, the types of haemoglobin produced are quite distinct in human embryonic (Hb Gower I $\zeta_2\varepsilon_2$, Gower II $\alpha_2\varepsilon_2$ and Hb Portland $\zeta_2\gamma_2$), fetal (HbF $\alpha_2\gamma_2$) and adult (HbA $\alpha_2\beta_2$ and HbA2 $\alpha_2\delta_2$) erythroid cells (Figure 3.1). These specific patterns of globin expression provide key markers for identifying the developmental stages of erythropoiesis: in particular, embryonic haemoglobins are not produced at all in normal definitive cells (EMP and DE). It remains unclear whether primitive and definitive haemopoiesis in mammals have entirely separate origins or if they are both derived from common stem cells that arise during very

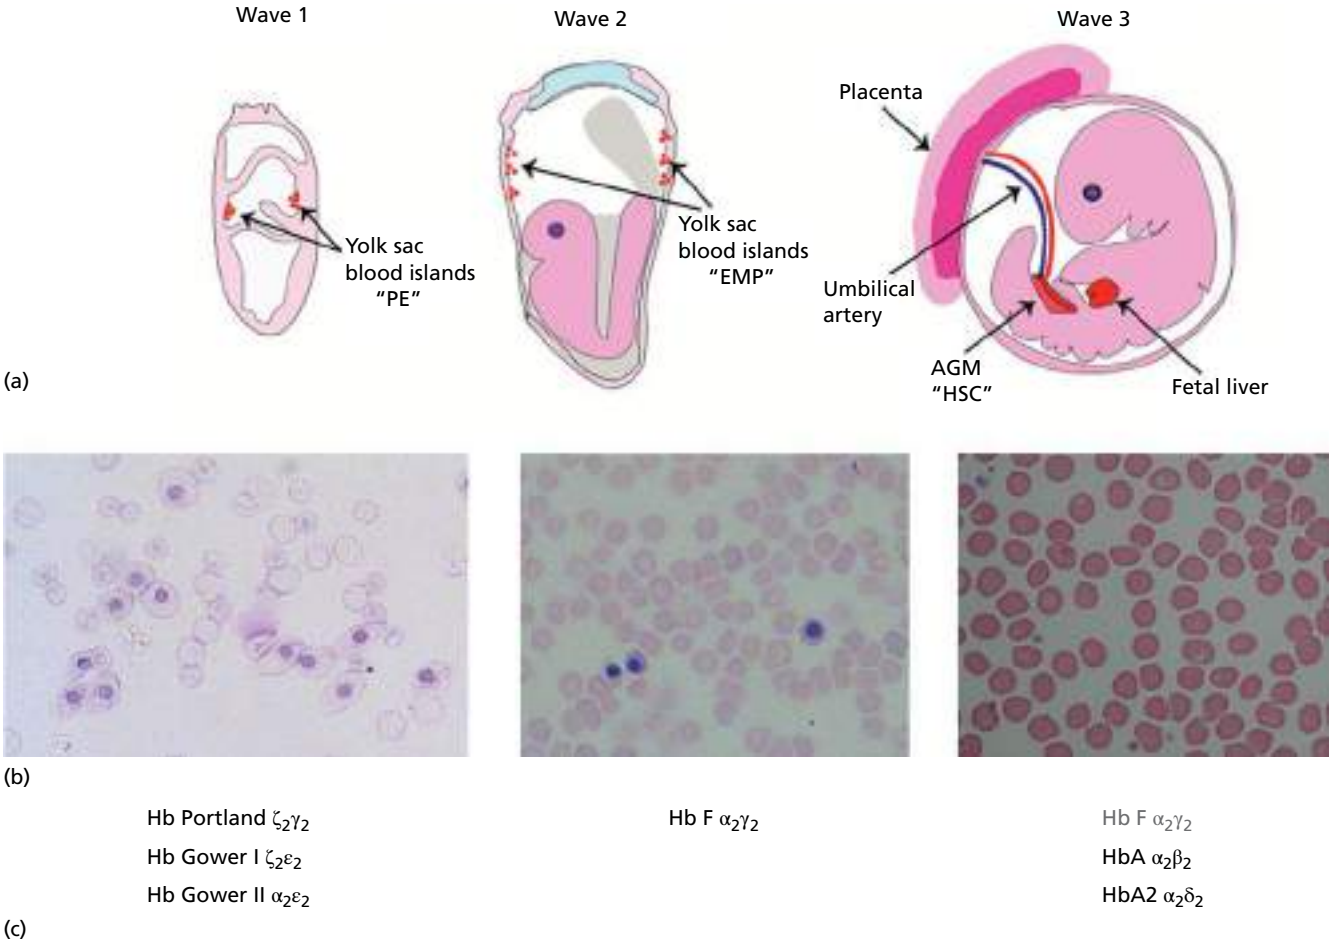

Figure 3.1 The three waves of primitive (PE), erythromyeloid (EMP) and definitive erythropoiesis. (a) shows the origins of erythropoiesis during PE, EMP and DE. (b) shows the appearance of human peripheral blood at 8 and 14 weeks post conception and in the adult. At 14 weeks some nucleated embryonic cells are still found in the circulation amidst polychromatic red cells of fetal DE. (c) illustrates the major types of haemoglobin seen at each stage of development.

early development. The close proximity of the blood and endothelial cells in the yolk sac suggests that haematopoietic cells and blood vessels originate from a common precursor. Accurately defining the embryological origins of these lineages (see Chapter 1) will be important for understanding the normal mechanisms that establish and maintain HSCs and how these programmes are subverted in common haematological disorders.

The cellular and molecular pathways leading to definitive erythropoiesis

Multipotent HSCs represent about 1 in 10,000 nucleated cells in the bone marrow. The precise mechanism by which definitive, AGM-derived HSCs undergo lineage commitment to multipotential and bi-potential populations of progenitors in the bone marrow is still under investigation and several models are currently proposed (see Chapter 1). The original concept of a strict hierarchical, stepwise progression of lineage specification and differentiation has been replaced over recent years by more nuanced and diverse models. For example, it has been suggested that commitment may be a continuous rather than a stepwise process and that some HSCs are primed to progress immediately to form erythroid cells, megakaryocytes and platelets rather than pass through the more extensive network of intermediate stages. However, at least some HSCs differentiate by passing through early stages as multipotential progenitors such as colony forming units (CFUs) that have the ability to produce granulocytes (G), erythrocytes (E), monocytes (M) and megakaryocytes (Meg) (CFU-GEMM). Further differentiation progressively restricts the lineage potential of these cells and reduces their proliferative capacity, resulting in bi-potential progenitors with the ability to form megakaryocytes (Meg) or erythroid (E) cells (MEPs). MEPs further differentiate along one (Meg) or another (E) lineage, the latter producing fully committed erythroid precursors (Figure 3.2).

These committed erythroid progenitors are defined by their growth potential and characteristics as assayed by *in vitro* cultures: this explains their names 'burst-forming' erythroid units (BFU-E) and 'colony-forming' erythroid units (CFU-E) (Figure 3.2). They are not morphologically recognisable but can be defined as discrete cell populations in cord blood, bone marrow and peripheral blood using combinations of cell surface markers (Figure 3.2). CFU-Es defined in these culture systems most closely correspond *in vivo* to proerythroblasts (see below), the earliest morphologically recognisable erythroid precursor, representing 20–60 per 10,000 nucleated cells in the bone marrow. Each of these differentiating cell types can be isolated and, to some extent, purified via their cell surface markers (Figure 3.2) and more recently, it has been shown that single cells from each population can be clustered and classified on the basis of their individual transcriptional and epigenetic profiles.

Over the past few years, it has emerged that a small number of key haemopoietic transcription factors play a major role in regulating the formation, differentiation, proliferation and survival of multipotent stem cells as they develop into red cells. These transcription factors may operate on their own or as members of multicomponent complexes involved in the activation and/or repression of gene expression. At present, the key transcription factors involved in the specification and maintenance of HSCs and their multipotent progenitors are complex and under intense investigation. During normal erythroid development, it is thought that GATA2 is one of many factors that initiate the erythroid programme and plays an important role in the expansion and maintenance of haematopoietic progenitors. The subsequent formation and differentiation of erythroid cells are under the control of a specific subset of key transcription factors including GATA1, FOG1, LMO2, LDB1, SCL1, E2A, MYB1, KLF1, NF-E2 and FOXO3. The most important transcription factor orchestrating changes in this programme is GATA-1 which reaches its highest levels in CFU-Es and proerythroblasts. These factors bind in various combinations to the regulatory elements that switch erythroid-specific genes on and off and thereby control gene expression during erythropoiesis. Additional, more minor roles in refining the erythroid programme are played by long non-coding RNAs and microRNAs. One emerging principle in our understanding of lineage commitment is that factors affiliated with different 'master' regulators such as GATA1 (erythroid) and PU.1 (lymphocytes and granulocytes) are both present in uncommitted progenitors, reflecting the potential of these cells to develop along alternative pathways (so-called multilineage priming). It is now known that, for example, GATA1 and PU.1 interact and cross-antagonise each other. Therefore, as cells differentiate, reinforcement of the transcriptional programme of one lineage may actively suppress that of alternative lineages.

Differentiation and terminal maturation

The earliest recognisable committed erythroid precursor in the bone marrow is the proerythroblast, a large cell (diameter 20–25 μm) with prominent nucleoli. Division of proerythroblasts leads to progressively smaller basophilic erythroblasts (16–18 μm), early polychromatic erythroblasts (10–15 μm), and finally late polychromatic/orthochromatic erythroblasts (8–10 μm). Again, each of these cells can be identified morphologically and via their cell surface markers (Figure 3.2). Early and late erythroblasts can be separated using antibodies directed against the transferrin receptor (TfR, CD71) which decreases during terminal differentiation, and glycophorin A (CD235a) which increases during maturation. Recently, alpha4-integrin (CD49d) and band 3, have been shown to further improve the resolution of the various stages of terminal erythroid differentiation. The majority

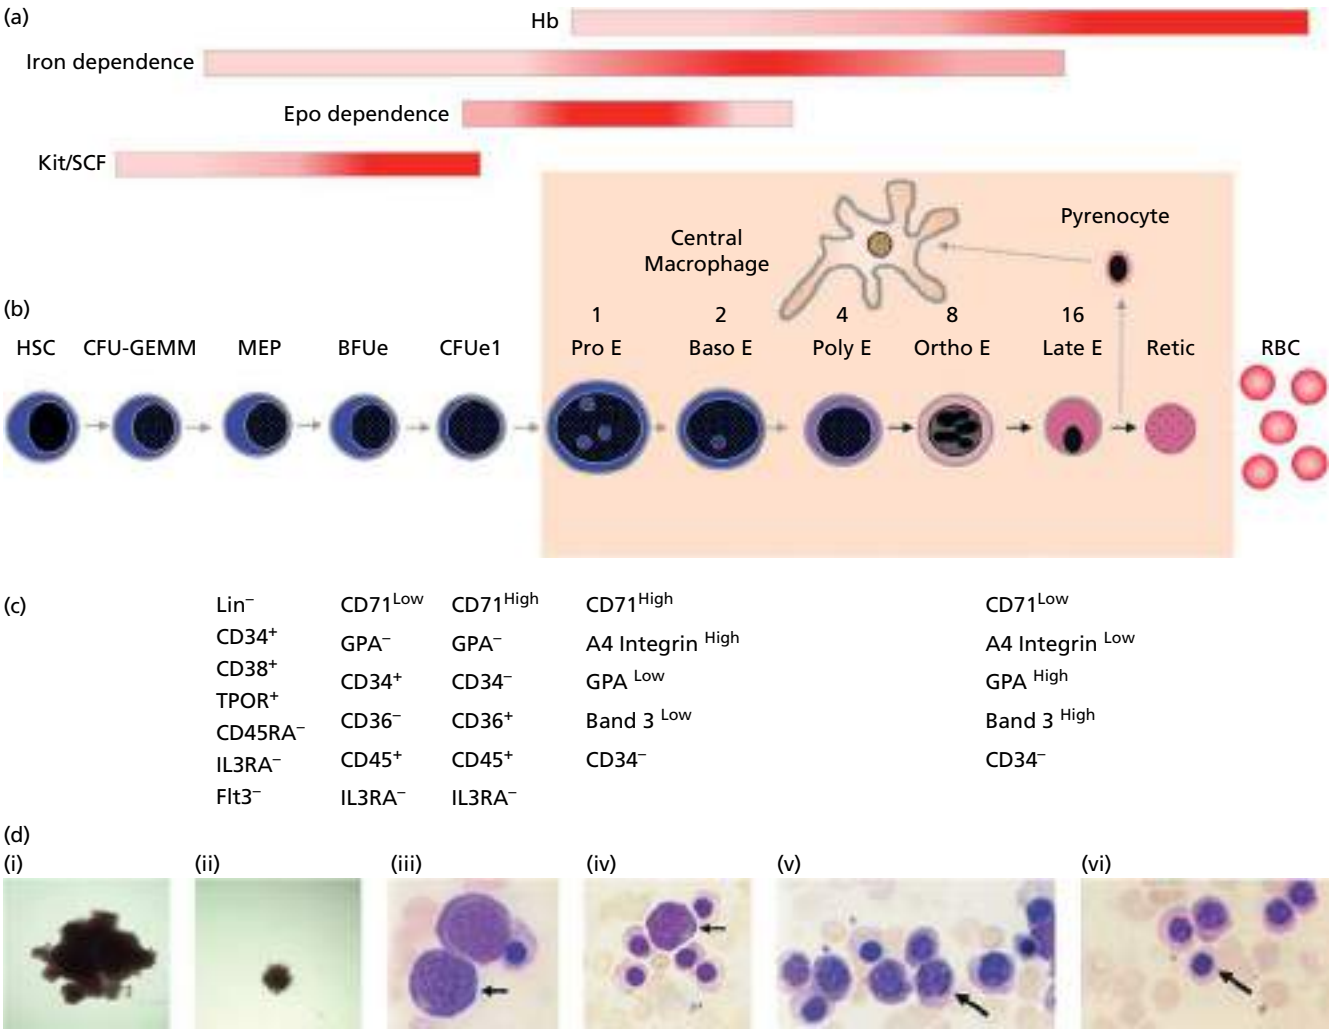

Figure 3.2 The process of erythropoiesis as cells differentiate and mature into red blood cells. (a) shows the key cytokines and processes associated with the progressive stages of erythropoiesis. (b) shows the defined cellular stages of erythropoiesis. The numbers above indicate the number of progeny arising from one proerythroblast. The transition from proerythroblast to reticulocytes occurs in a specific niche in the bone marrow (shown boxed), a process that occurs in clusters of 30 erythroblasts around a central macrophage. Small blue circles represent nucleoli. (c) shows changes in some cell surface markers at different stages of erythropoiesis. (d) photo micrographs of cells from cell cultures (i) BFUe (ii) CFUe, and arrowed cells at progressive stages of differentiation (iii) proerythroblast (iv) basophilic erythroblast (v) poly and ortho erythroblasts (vi) late erythroblasts.

(60–80%) of proerythroblasts, basophilic erythroblasts and early polychromatic erythroblasts are in active phases of the cell cycle. By contrast, late polychromatic/orthochromatic erythroblasts are postmitotic, non-dividing cells. On average, approximately 16 late erythroblasts arise from each proerythroblast although some early erythroblasts may be lost via apoptosis (Figure 3.2).

During the later stages of erythropoiesis, histones are partially released into the cytoplasm and degraded by the proteasome pathway. Eventually, extrusion of the condensed, pyknotic nucleus from orthochromatic erythroblasts gives rise to pyrenocytes (the expelled nucleus surrounded by a thin rim of cytoplasm) and immature reticulocytes (8–10 μm), which retain some mitochondria and polyribosomes. When stained with May Grunwald Giemsa, reticulocytes have a bluish tint and give rise to polychromasia in the peripheral red blood cells. When stained with new methylene blue, the cytoplasm has a characteristic reticular appearance. Reticulocytes undergo further maturation in the bone marrow for up to 48 hours before entering the circulation. Membrane remodelling occurs through a process referred to as internalisation, followed by exocytosis of the membrane and cytoplasmic fragments. Ferritin-laden vacuoles and transferrin receptors are also removed by exocytosis in clathrin-coated pits. In normal human blood, reticulocytes constitute approximately 1–2% of the total erythrocyte count. Haemoglobin synthesis

begins at the proerythroblast stage of erythropoiesis and reaches a maximum in the intermediate phases: haemoglobin continues to accumulate, even in enucleated reticulocytes containing RNA, and confers an increasingly pink colouration to erythroid cells following Wright–Giemsa staining.

Changes in the expression of key erythroid proteins during terminal differentiation

As multipotent progenitors enter terminal differentiation and the erythroid transcriptional programme becomes consolidated, the expression of many genes (~6000) is downregulated, reflecting the commitment to a single specialised lineage. By contrast ~600 genes encoding proteins central to red cell biology are upregulated. Examples include most notably haemoglobin and genes regulating the haem synthesis pathway, together with proteins of the red cell membrane including blood group antigens. There are also changes in the enzymes of the red cell energy pathways; a notable example of this is the pyruvate kinase, encoded by the *PKLR* gene. Mutations in the *PKLR* gene are found in rare cases of haemolytic anaemia.

Key among the genes characteristically upregulated during erythroid maturation are those of alpha- and beta-globin. The globin genes are first expressed in proerythroblasts and early basophilic erythroblasts, with the number of RNA transcripts reaching ~20,000 per cell in late polychromatic and orthochromatic erythroblasts. During the latest stages of erythroid maturation, the amount of RNA per cell and the rate of total protein synthesis declines, but the unusual stability of globin mRNA ensures that globin remains the predominant protein made in late erythroblasts and reticulocytes. The synthesis of globin is accurately matched with the synthesis of haem. As discussed in Chapter 11, some steps of haem synthesis occur in the cytoplasm and others in the mitochondria (see Figure 3.3). mRNAs encoding many components of the haem biosynthetic pathway (e.g. ALA synthase and porphobilinogen deaminase) are coordinately upregulated in terminal erythroid differentiation and their genes contain similar *cis*-regulatory elements activated by the same set of erythroid-specific transcription factors that activate the globin genes. Haem synthesis is in turn closely regulated by iron status (see below) via iron-responsive elements that control translation of some key enzymes in this pathway. Abnormal synthesis of haemoglobin (affecting globin, haem and iron) underlies the most frequent causes of anaemia throughout the world.

Changes in gene expression are also reflected in the cell-surface proteins present on erythroid progenitors and precursors, some of which mediate the different signalling programmes of erythroid cells as they differentiate. Differentiating erythroid cells also express cell-surface adhesion molecules (α4β1 integrin, ICAM-4 and erythroid macrophage protein EMP) which interact with equivalent molecules present on macrophages (VCAM-1, αV and erythroid macrophage protein EMP). Cell surface signalling and adhesion molecules are found at higher levels on early precursors and are lost as maturation proceeds, freeing

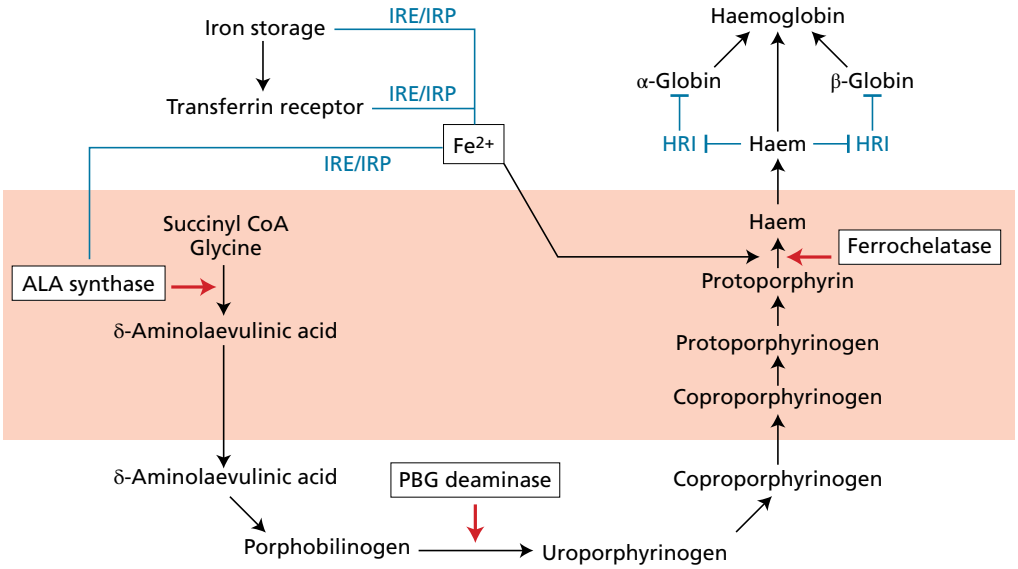

Figure 3.3 The coordinated synthesis of haem and globin to assemble haemoglobin. Some aspects of the synthetic pathway take place in the mitochondria (pink square) and others in the cytoplasm. Blue lines indicate some of the known regulatory feedback systems. Rate-limiting controls of haem synthesis are shown in black boxes. ALA, δ-aminolaevulinic acid; PBG, porphobilinogen. IRP; iron regulatory proteins. IRE; iron regulatory elements present in mRNA. HRI; Haem-regulated eIF2α kinase (HRI) controls translation by phosphorylating eIF2α.

erythroid cells from the bone marrow niche (see below) to enter the circulation. Among many changes that occur in the membranes of erythroid cells during differentiation, receptors for the key erythroid hormone erythropoietin (Epo, see below) first appear in small numbers on late BFU-Es, increasing in CFU-Es and pro-normoblasts and subsequently declining and disappearing in later erythroid precursors (Figure 3.2). Similarly, CD71 (the transferrin receptor, TfR) which allows transferrin-bound iron to be taken into the cell, is present in early haematopoietic cells but is considerably upregulated on cells that are actively synthesising haemoglobin, reaching a peak of 800,000 molecules per cell on polychromatic normoblasts. CD71 levels diminish in the late phase of terminal differentiation and the receptor is undetectable on mature erythrocytes, which no longer have a need for iron uptake.

Erythroblasts contain mitochondria and generate energy via oxidative phosphorylation. During differentiation, the number of mitochondria is reduced and mature red cells contain none but still require energy for a variety of processes. These include maintaining electrolyte gradients, synthesising glutathione, maintaining iron in its functional ferrous state, and protecting enzymes, haemoglobin and membrane proteins from oxidative denaturation. Mature red cells therefore depend on the anaerobic conversion of glucose by the Embden-Meyerhof (glycolytic) pathway for the generation and storage of high-energy phosphates.

The high levels of protein synthesis and rapid cell proliferation that characterise the erythroid compartment, even in a steady state, render these cells sensitive to perturbations in levels of the key substrates required for erythropoiesis. Among these are a variety of nutritional factors and cofactors, particularly iron (see Chapters 11 and 12), vitamin B12 and folate (Chapter 13), but also copper, manganese, cobalt, vitamin C, vitamin E, vitamin B6 (pyridoxine), thiamine, riboflavin, pantothenic acid and amino acids. Absolute or relative deficiencies of any of these factors can impair normal erythropoiesis and result in anaemia.

The erythroid niche

The control of erythropoiesis ultimately depends on integration of the internal transcriptional and epigenetic programme, modified by information delivered by cell–cell contacts, local growth factors, fine tuning of metabolism, a supply of iron and systemic hormonal signalling. Although erythropoiesis can be largely recapitulated using liquid cultures to which appropriate nutrients, cytokines and hormones have been added, it is nevertheless significantly less efficient in this context than *in vivo*, particularly in terms of proliferation and terminal enucleation, suggesting that erythropoiesis in its natural setting is modified by additional factors.

Inspection of the bone marrow architecture *in vivo* shows that maturing erythroblasts are not randomly distributed; rather, they are arranged in characteristic 'erythroid islands' made up of a central macrophage surrounded by up to 30 erythroid cells at various stages of differentiation (see Figures 3.2 and 3.4). This cellular structure is referred to as the 'erythroid niche'. Proerythroblasts enter this niche as large cells with active nuclei and mitochondria producing haem and energy. They attach to the central macrophage via a range of adhesion molecules: for example, integrins (such as α4β1) facilitate the attachment of

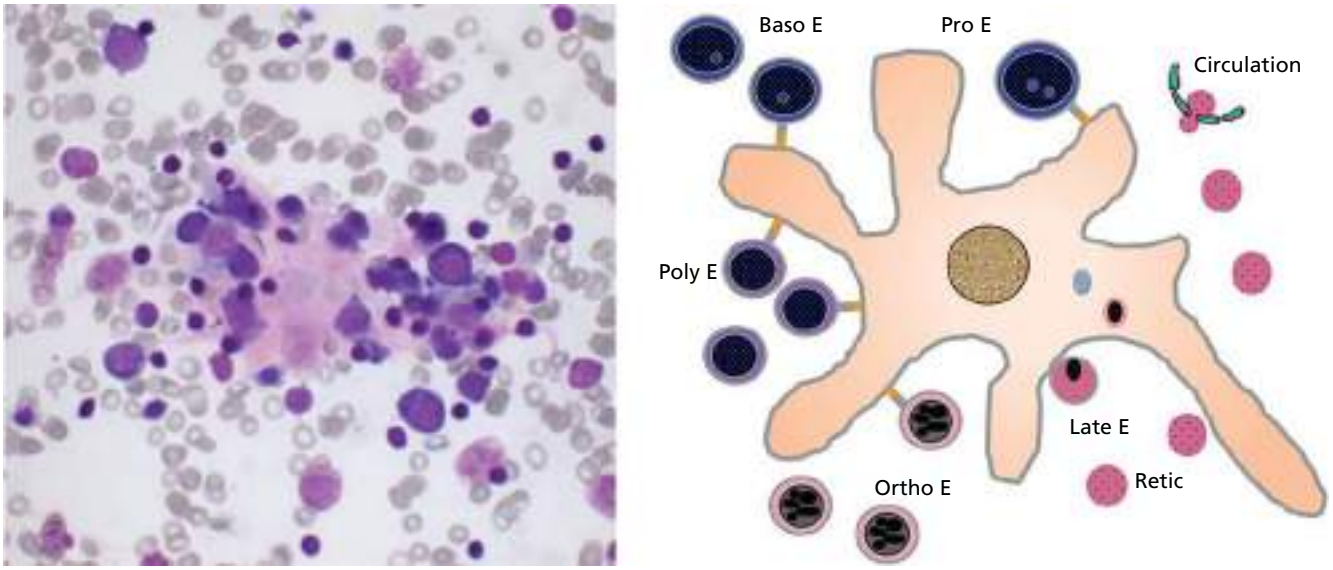

Figure 3.4 The erythroid niche. Left is a photomicrograph showing erythroid cells clustered around a central macrophage in the bone marrow. Right shows the differentiation of erythroid cells in this context. Erythroid cells attach to the central macrophage via a variety of adhesion molecules including VCAM-1, VCAM-4, α4β1integrin, αV and erythroid macrophage protein (EMP).

erythroblasts to adhesion molecules (such as VCAM-1) expressed by central macrophage, and this appears to be critical for normal red cell maturation. Soluble factors secreted by central macrophages add another layer of positive regulation within erythroblastic islands. Macrophage cytokines, including burst-promoting activity (including BMP4) and insulin-like growth factor-1 (IGF-1), induce growth of both BFU-Es and CFU-Es. Within the erythroid niche, proerythroblasts mature into later erythroblasts and, following enucleation, autophagy of mitochondria (mitophagy) also occurs. When reticulocytes exit the erythroblastic island, they are relatively small cells, without nuclei and with few mitochondria; they possess some polyribosomes and have a profoundly altered array of cell surface proteins, partly due to reassortment of cell surface molecules between the reticulocyte and pyrenocyte, enabling the release of reticulocytes from the macrophage.

The central macrophage not only provides erythropoietic signals but also plays a key role in enucleating the erythroblast. Pyrenocytes display phosphatidylserine (PS) on the surface of the cell membrane that surrounds the condensed erythroblast nucleus and this serves as a signal for macrophages to engulf and phagocytose the pyrenocyte whose nucleus is then degraded via a process involving an endonuclease (DNAse II) provided by the macrophage. It has also been suggested that the macrophage functions as a 'nurse' cell, providing iron to developing erythroblasts for haem synthesis (see below). The central macrophage may play other important roles in normal erythropoiesis. Some adhesive linkages may activate cell signalling pathways coordinating adhesion and gene expression. The juxtaposition of erythroid cells may also facilitate the action of molecules presented on cell surfaces mediating cell–cell interactions and apoptosis (see below).

It appears that the central macrophage of the erythroid niche may be a specialised cell and different from other macrophages. Central macrophages have unique properties compared to mature macrophages in other organs. For example, the central macrophage does not engulf and destroy the entire erythroid cell as splenic red pulp macrophages do. Thus, phagocytic activity of the central macrophage appears to be restricted to engulfing and processing pyrenocytes. Reticulocytes eventually enter the circulation via diapedesis through the bone marrow capillaries (Figure 3.4).

The regulation of erythropoiesis by cytokines and cell signalling

The differentiation of haematopoietic stem cells into mature blood cells is tightly regulated by the actions of both stimulatory and inhibitory cytokines. Perhaps the most important of these in erythropoiesis is erythropoietin (Epo). Erythropoietin is a 166-amino-acid 34.4-kDa glycoprotein, found in the plasma at baseline levels of 1–30 mU/mL that can be elevated 1000-fold by severe anaemia. It contains about 40% carbohydrate is rich in sialic acid residues and has a half-life of 7–8 hours in plasma. The main site of Epo production is the interstitial cells of the kidney. Under normoxic conditions, little or no Epo mRNA is detectable in the kidneys. Hypoxia results in the rapid induction of its expression such that levels may increase up to 200-fold over baseline within 30 minutes. Quite low numbers (20–50) of Epo receptor (EpoR) homodimers are present on BFU-Es, explaining the relative Epo unresponsiveness of these cells; much higher levels (~1000 EpoRs) are found on CFU-E, proerythroblasts and basophilic erythroblasts which are the main targets for Epo (Figure 3.2).

Late BFU-Es, CFU-Es and proerythroblasts all require continuous signalling via the EpoR to proliferate, differentiate and prevent programmed cell death (apoptosis). When the EpoR is bound by Epo it activates the JAK2–STAT5 pathway and Ras/MAP kinase pathways. STAT5 is a transcription factor and when activated it is translocated from the cytoplasm to the nucleus where it modulates the expression of several genes involved in the control of cell proliferation, differentiation and apoptosis. Epo signalling also activates and induces other pathways, including the phosphatidylinositol 3-kinase (PI3K) and AKT kinase pathways. The overall effect is that secondary to a hypoxia-driven rise in Epo, a population of erythroid progenitors normally destined for apoptosis during steady-state erythropoiesis receives anti-apoptotic signals, survives and expands the erythroid precursor pool. While the most important effect of Epo is to increase the number of progenitor cells, which rapidly respond by proliferating and differentiating into viable proerythroblasts, it has been suggested that Epo is also able to speed up the rate of terminal differentiation by shortening the cell cycle and maturation times of erythroblasts.

Erythropoiesis is also influenced by pathways other than Epo–EpoR. Erythroid progenitors express receptors for SCF (Stem Cell Factor), IGF-1, insulin, activin and angiotensin II. After Epo, the second most important signalling system for erythropoiesis involves SCF (also termed Kit ligand) and its receptor (c-Kit, a receptor tyrosine kinase). SCF was originally identified by its ability to stimulate proliferation of multipotent haemopoietic progenitors, but it is also effective in supporting growth of committed erythroid progenitors, acting synergistically with Epo. In addition to SCF and Epo, stimulation of the nuclear hormone receptors for dexamethasone (glucocorticoid receptor) and oestrogen (oestrogen receptor) produces sustained proliferation of erythroid progenitors. Furthermore, the nuclear hormone receptors for thyroid hormone (c-ErbA/thyroid hormone receptor), all-*trans* retinoic acid (retinoic acid receptor) and 9-*cis*-retinoic acid (RXR) can promote erythroid differentiation. Such observations are consistent with reports showing that many endocrine disorders (hypothyroidism, hypopituitarism, Addison's disease and male hypogonadism) can be associated with normochromic normocytic anaemia.

Some signalling factors including inflammatory cytokines such as tumour necrosis factor have negative effects on erythropoiesis. Recent studies have shown that a member of the transforming growth factor β superfamily (growth and differentiation factor 11, Gdf11) when bound to activin type IIB (ActRIIB) receptors, activates Smad2/3 dependent signalling to promote expansion of the committed erythroid progenitor pool, while preventing terminal maturation via an autocrine signalling loop. This pathway may be potentiated by oxidative stress but can be inhibited by activin receptor IIA ligand traps (ActIIA) such as Sotatercept or Luspatercept, which are thought to sequester Gdf11 and allow differentiation to proceed both in the steady state and under conditions of erythroid stress. Other explanations for the effects of these two drugs are also being explored. In normal erythropoiesis, Gdf11 may be transiently activated under conditions requiring an acute demand for RBCs. Gdf11 acts to rapidly expand the erythroid progenitor pool, and shortly after may become degraded or downregulated to allow for terminal maturation in response to another, as yet unidentified signal. Gdf11 appears to play an important role in the abnormal ineffective erythropoiesis seen in patients with thalassaemia and myelodysplasia where the associated anaemia may be ameliorated by administration of activin receptor ligand traps (Figure 3.5).

The regulation of apoptosis in erythropoiesis

Normal erythropoiesis requires an appropriate balance between the rate of production of erythroid cells and the rate at which immature erythroid cells undergo programmed cell death (apoptosis). Despite the efficiency of erythropoiesis, a small but significant number of early erythroid cells undergo premature intramedullary death even under normal physiological conditions. Immature erythroid precursors are sensitive to apoptotic triggering mediated by activation of both the intrinsic and extrinsic apoptotic pathways. The major extrinsic pathway controlling apoptosis of immature erythroid cells is activated by the Epo-EpoR pathway.

As discussed above, Epo signalling activates STAT5, a transcription factor that directly binds the promoters of many erythroid genes including a gene encoding the anti-apoptotic protein Bcl-XL. Bcl-XL is also regulated by the master erythroid transcription factor GATA-1 which is itself activated by Epo signalling. Bcl-XL is a key regulator of apoptosis in erythroid cells. This protein normally lies within the outer membrane of mitochondria maintaining their viability under conditions of cellular stress, thereby preventing apoptosis. In addition to increasing expression of the *Bcl-XL* gene, via the Stat5 pathway and via GATA-1, Epo may also protect erythroid cells from apoptosis by blocking caspase-dependent cleavage of Bcl-XL protein (Figure 3.6). In addition to the Epo-EpoR pathway, other cytokines such as stem cell factor (SCF) and its receptor c-Kit, also play an important role in maintaining the balance between proliferation and apoptosis during erythropoiesis (Figure 3.5).

The juxtaposition of immature and maturing erythroblasts within the erythroid niche facilitates an additional mechanism for the regulation of apoptosis. In addition to the Epo-Bcl-XL pathway, apoptosis of erythroid precursors can be regulated via the death domain receptors of the TNF superfamily such as the Fas receptor (FasR). FasR is present on the membranes of both early and late erythroid precursors. However, its activating ligand (FasL) appears only on the membranes of mature erythroblasts. Binding of FasL (on mature erythroblasts) to FasR (on immature erythroid cells)

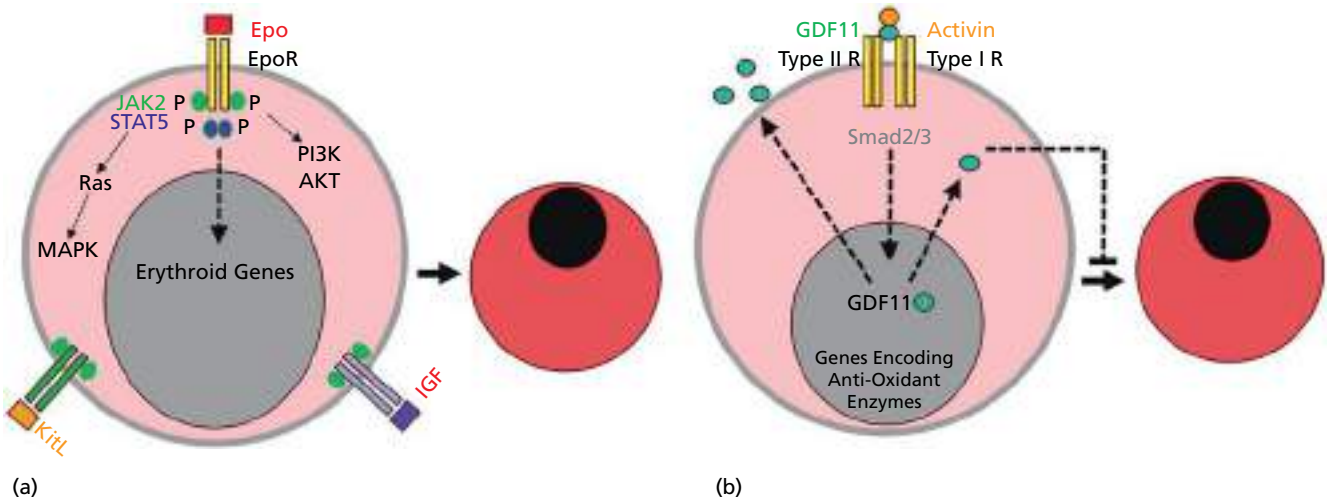

Figure 3.5 Positive and negative cytokines acting on erythroid cells. (a) positive signalling via the Epo-EpoR pathway. (b) Negative regulation of differentiation with expansion of immature erythroid cells via expression of Gdf11.

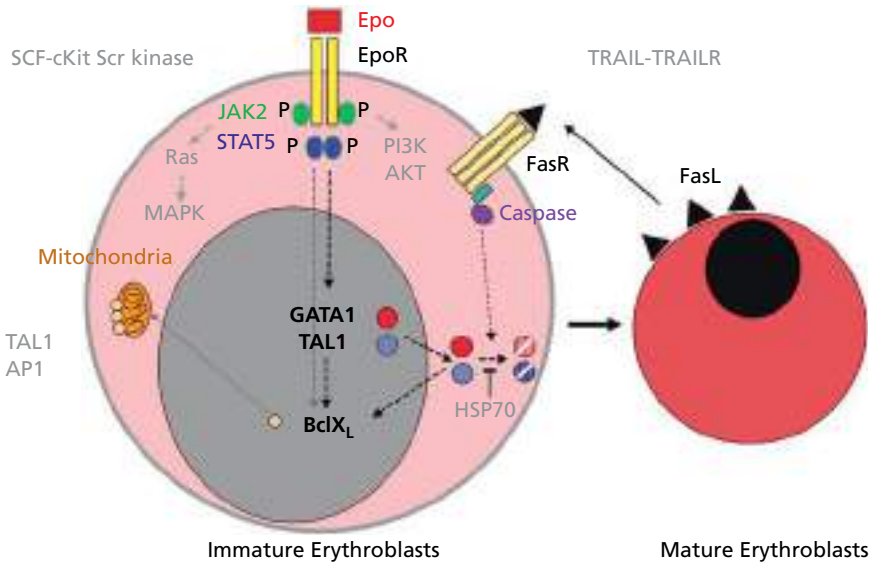

Figure 3.6 A negative feedback loop controlling the numbers of mature erythroid cells. Regulating apoptosis of immature erythroid cells and progression through terminal erythroid differentiation involves signalling via the Epo-EpoR pathway and signalling via death receptors, in this case FasR. A small beige spot in the nucleus represents Bcl-XL. Modifiers (in grey) point to pathways in addition to Epo and Fas that play important roles in regulating erythropoiesis.

activates proteolytic caspases that cleave intracellular proteins, including GATA-1. Cleavage and inactivation of GATA-1 reduces expression of Bcl-XL and promotes apoptosis in immature cells. Therefore, apoptosis only occurs in the context of adequate numbers of mature erythroid cells, in close contact, within the erythroid niche (Figure 3.4). Importantly, Fas-mediated cytotoxicity against immature Fas-positive erythroblasts is in part abrogated by high concentrations of Epo and/or SCF.

Degradation of GATA-1 appears to underlie the Fas-mediated blockade of erythroid cell maturation. However, normally, a Heat Shock Protein (HSP70) protects GATA1 from caspase cleavage during human erythroid maturation. In committed erythroid progenitors and early-stage erythroblasts, HSP70 colocalises with GATA1 and protects it from cleavage. HSP70 decreases when the FasR pathway is activated and consequently, the balance between differentiation and apoptosis of erythroblasts depends at least partly on the abundance and nuclear localisation of HSP70. In addition to FasR, other death receptors, such as TRAIL-R1 and TRAIL-R2 are also expressed on erythroid cells. Again, the expression of these two membrane receptors is higher in immature than in mature erythroblasts. Therefore, the role of the TRAIL/TRAIL-R system may be comparable to that observed for the Fas/FasL system.

Together these observations indicate that the apoptotic effects and inhibitory actions on cell differentiation elicited by Epo deprivation and/or by triggering of death receptors, direct the caspase-mediated cleavage of GATA-1, whose integrity and activity are essential for normal erythroid maturation and survival. These pathways underlie negative feedback loops in which mature erythroid cells control the numbers of earlier precursors by regulating the extent to which they undergo proliferation, differentiation or apoptosis thereby controlling the production of mature erythroid cells. These apoptotic mechanisms are frequently inappropriately activated in some pathological conditions associated with ineffective erythropoiesis and anaemia, including the thalassaemias, myelodysplasia and aplastic anaemia. In summary, erythropoiesis is driven by a balance between positive and negative feedback mechanisms operating within the erythroid niche, involving both cell–cell interactions and soluble factors.

The coordination of erythropoiesis and iron metabolism

The terminal stages of erythropoiesis are dedicated to producing 1–2 billion red cells containing 7–8 g of haemoglobin each day and this process requires ~2–3 × 10^{15} iron atoms every second. Therefore, the production of red blood cells requires balanced crosstalk with iron metabolism. The pathways that maintain appropriate levels of iron affect erythropoiesis and *vice-versa*. While the early stages of erythropoiesis are predominantly controlled by the Epo-EpoR pathway, the later stages of erythropoiesis are regulated by the availability of iron. Iron metabolism is primarily regulated by the hormones hepcidin and erythroferrone. Within erythroid cells a second system involving iron regulatory proteins and

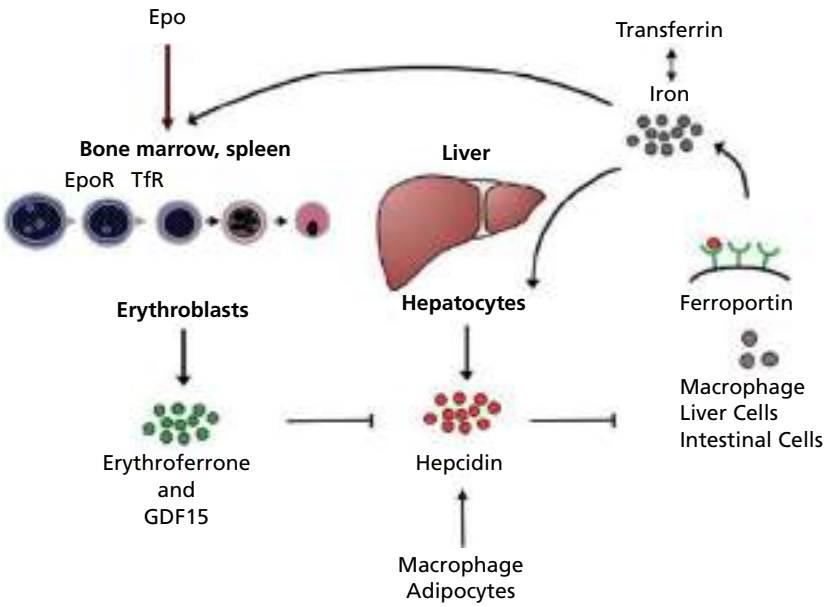

Figure 3.7 Regulation of erythropoiesis and iron metabolism. The major hormones controlling iron metabolism are hepcidin and erythroferrone. These hormones link the process of erythropoiesis and the availability of iron.

iron regulatory elements (IRP/IRE) responds to fluctuating iron concentrations, affecting translation of key iron import and export genes. The details of iron metabolism are discussed in Chapter 11 (Figure 3.7).

Hepatocytes directly sense transferrin-bound iron, which in turn stimulates production of hepcidin to limit the release of iron when it is readily available in the circulation. Under iron-replete conditions, hepcidin levels in the blood are high, which signals to iron-storing organs to suppress the release of iron to the plasma. Hepcidin directly binds and induces the endocytosis and proteolysis of ferroportin, a transmembrane exporter of iron found mainly in intestinal cells, macrophages and hepatocytes; the main reservoirs of iron in the body. By contrast, when more iron is required as a result of increased erythropoiesis, differentiating erythroblasts produce the hormone erythroferrone (an Epo-responsive gene), which suppresses hepcidin production. In turn, ferroportin accumulates on iron reservoir cells leading to increased plasma iron concentrations to support haem synthesis for the production of haemoglobin. An additional and important level of control occurs via translation of mRNAs encoding the globin chains and proteins involved in iron metabolism via iron regulatory proteins (IRPs) which bind iron regulatory elements present in mRNA (IREs) and, haem-regulated eIF2α kinase (HRI) which controls translation by phosphorylating eIF2α (e.g. see Figure 3.3).

In many human diseases, the crosstalk between erythropoiesis and iron metabolism goes awry, particularly in the presence of ineffective erythropoiesis when iron may accumulate in a wide variety of tissues causing associated morbidity. This is particularly seen in patients with chronic haemolytic anaemias and thalassaemia. In chronic inflammatory disorders, cytokines drive over-production of hepcidin that in turn limits iron supply for erythropoiesis, contributing to the anaemia of chronic disease.

The control of erythropoiesis via the oxygen-sensing system

Erythropoiesis must be sensitive to changes in the levels of oxygen and varying physiological demands. This regulation hinges on sensing hypoxia and control over the number of erythroblasts and red cells. The most important mediator of this response is the transcription factor HIF (hypoxia-inducible factor). HIF acts as a dimer consisting of HIF-1α and HIF-1β which activates genes influencing adaptive responses to hypoxia (Figure 3.8) in a wide variety of tissues. In the context of normal oxygenation, HIF-1α is modified by prolyl and asparaginyl hydroxylases, providing a binding site for vHL (the von Hippel Lindau factor – see Figure 3.8), which ubiquitinates HIF thereby targeting it for degradation by the proteasome. At low oxygen tension, hydroxylation of HIF-1α cannot occur and as a consequence, vHL cannot bind and ubiquitinate HIF-1α, the level of which is thereby greatly increased. Stabilised HIF-1αβ then activates genes encoding Epo in the kidney, enzymes of the glycolytic pathway, TfR and VEGF. In rare cases of inherited polycythaemia, constitutive mutations in HIF or vHL result in deregulated oxygen sensing and an erythropoietic drive in the absence of hypoxia (Chapter 35).

Increased expression of Epo is accomplished through a hypoxia-response element (HRE) at the 3′-end of the Epo gene,

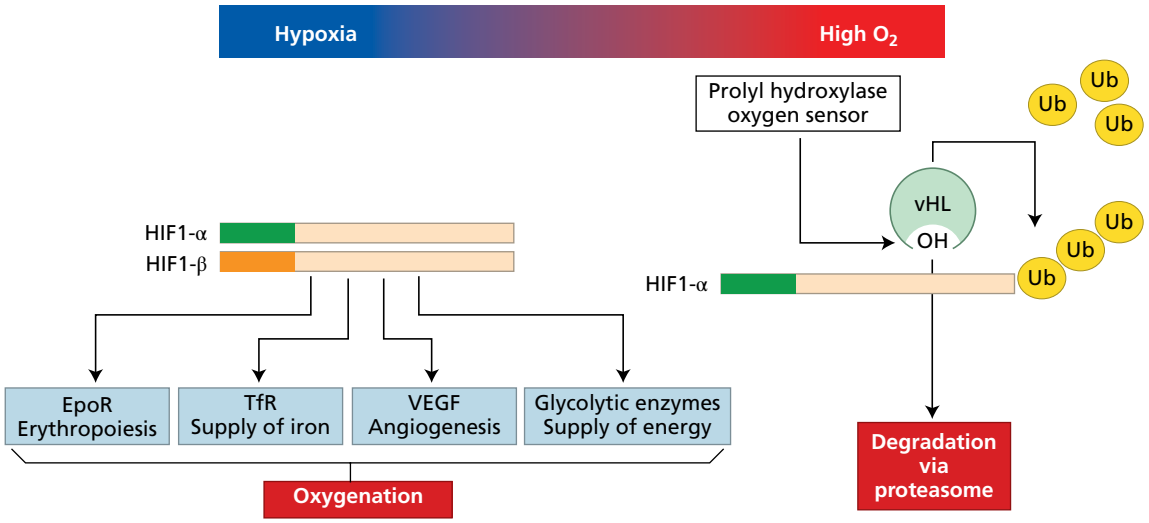

Figure 3.8 The oxygen-sensing system. Under normoxic conditions, HIF-1α is hydroxylated and is thereby targeted by vHL for ubiquitination and degradation by the proteosome. Under hypoxic conditions, this no longer occurs and the level of HIF-1α rises and dimerises with HIF-1β to form a transcription factor that activates oxygen-responsive genes in the pathways indicated. Although this response is present in all cell types, upregulation of Epo, erythroferrone, genes controlling iron metabolism and the glycolytic pathway are of particular importance in erythropoiesis. Ub, ubiquitination; vHL, von Hippel–Lindau protein; HIF, hypoxia-inducible factor. vHL is an E3 ubiquitin ligase.

which increases its expression. Under hypoxic conditions, HIF1-αβ is stabilised and can bind to the HRE of the *Epo* gene (and other hypoxia-sensitive genes), to increase transcription and therefore increase serum Epo levels. Linking Epo production to tissue oxygenation ensures that when there is reduced ambient oxygen tension, blood loss, or shortened red cell survival, the level of Epo and other hypoxia-responsive genes increase, stimulating red cell production and ultimately increasing oxygen delivery.

The mature red cell, senescence and clearance

After 2–3 days in circulation, the red cell lacks the machinery for protein synthesis and the organelles for complex cellular processes. In essence, it becomes a highly concentrated solution of haemoglobin enclosed within a complex membrane that maintains the shape and integrity of the biconcave disc (7–8 μm), which we recognise as the mature red blood cell. In adults, such cells survive for approximately 120 days, travelling 250 km throughout the circulation whilst exposed to repeated membrane deformation and mechanical stress. In addition, while transporting high concentrations of oxygen, red cells experience chemical damage from oxidative species and free radicals. Since mature red cells lack the capacity to synthesise new cellular components, their ability to maintain cellular integrity in the face of these stresses becomes compromised with age. Although ageing red cells cannot be distinguished morphologically, characteristic biochemical features include a reduction in sialic acid, cholesterol, phospholipids and a variety of membrane proteins and a reduction in enzymatic activity, including enzymes of the glycolytic pathway. There is a loss of haemoglobin and an increase in its glycation (measured as HbA1C). Another feature of ageing red cells is microvesiculation; although this provides an effective means of removing damaged or ineffective red cell components, it results in the continual loss of small fragments of the red cell. Together, loss of haemoglobin and red cell membrane ultimately produces cells that are denser, with a higher mean corpuscular haemoglobin concentration (MCHC) and less deformable than their younger counterparts. Such aged red cells are also compromised with respect to their ability to efficiently perform ion transport.

As well as these changes, specific cues to clearance of the aged red cells from the circulation are thought to exist. Phosphatidylserine and phosphatidylethanolamine are key constituents of the red cell membrane that are normally confined to the inner aspect of the lipid bilayer. This asymmetry is maintained by an ATP-dependent aminophospholipid translocase. In aged red cells, phosphatidylserine is found in the outer membrane where it is able to bind to macrophages in the liver and spleen and prompt erythrophagocytosis. Once directed to

macrophages, these effete red blood cells undergo phagocytosis and the red cell components, including the iron from its haem groups, are recycled for subsequent red cell synthesis.

Assessing erythropoiesis

Erythropoiesis is disturbed in a wide range of primary haematological conditions and, to some extent, in almost all multisystem diseases. Initial assessment can be logically based on the successive stages of erythropoiesis set out above. In current clinical practice, erythropoiesis can be most simply assessed by examination of the full blood count and red cell indices, the reticulocyte count and examination of the peripheral blood film and bone marrow morphology. The specific tests used to diagnose the inherited or acquired disorders that may perturb each phase of erythropoiesis are highlighted in the relevant chapters as each anaemia is discussed in detail.

Initial assessment of erythropoiesis can be made from the red cell indices included in the full blood count. Anaemia is said to occur when the level of haemoglobin (g/L) and haematocrit fall below the normal ranges which vary depending on age and sex. The level of haemoglobin reflects the number of red cells/mL of blood (RBC) and their mean corpuscular haemoglobin content (MCH pg). It should be noted that individuals with a low MCH may be anaemic despite a raised red blood cell count. The MCH is largely dependent on the synthesis of haemoglobin and is commonly reduced in iron deficiency, defects of the haem synthesis pathway (e.g. sideroblastic anaemias) or in disorders of globin chain synthesis (haemoglobinopathies). The size of the red cells depends to some extent on the number of cell divisions in the terminal stages of differentiation. Thus, the mean corpuscular volume (MCV fl) is reduced when cells go through an extra division in terminal erythropoiesis (iron deficiency and thalassaemia) and increased when cells go through fewer cell divisions, often associated with dyserythropoiesis (e.g. B12 and folate deficiency, myelodysplasia, congenital dyserythropoietic anaemia). Additional clues to the pathogenesis of the anaemia can be derived from inspection of the red cell morphology on a peripheral blood film (Chapters 11, 13 and 56).

A second critical assessment of erythroid activity can be obtained (when appropriate) from an examination of the bone marrow. The number and ratio of erythroid compared to myeloid precursors in the marrow is normally about 1:4 but may vary within a very broad normal range. When erythropoiesis is stimulated, the ratio of erythroid to myeloid precursors will increase and this may be represented by normal precursors or dyserythropoietic precursors identified via asynchrony between haemoglobinisation and nuclear maturity. In addition, dyserythropoiesis may be accompanied by abnormal nuclei and sometimes binuclearity in erythroid cells. These changes in erythropoiesis are also reflected in the reticulocyte count. When erythropoiesis responds appropriately to anaemia (e.g. caused by bleeding or haemolysis) in the presence of adequate iron stores, the reticulocyte count (normally 0.5–2.0% or $25–75 \times 10^9$/L) increases in proportion to the degree of anaemia. By contrast, in the presence of bone marrow failure or significant dyserythropoiesis, the reticulocyte count is inappropriately low for the associated degree of anaemia. More recently, it has become possible to specifically measure the haemoglobin content of reticulocytes. This provides an indirect measurement of the functional iron available for new red blood cell production over the previous 3–4 days, providing a guide to the quality of erythropoiesis with respect to available iron.

In addition, when iron stores are adequate and available, measuring the level of soluble TfR (normal range 5.0 ± 1.0 mg/mL) also provides a good guide to the total level of erythropoiesis. Soluble TfR is a truncated form of the receptor that circulates in a complex with transferrin. Erythroblasts rather than reticulocytes are the main source of soluble TfR, and the levels of TfR are increased when erythropoiesis is stimulated and decreased when erythropoiesis is diminished. The interpretation of soluble TfR levels is complicated in iron deficiency as this condition independently raises the level of soluble TfR (Figure 3.9).

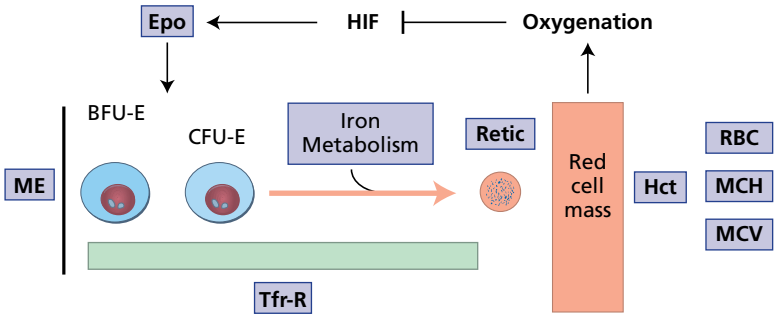

Figure 3.9 Summary of the regulation of erythropoiesis. Note the key points for assessment boxed in grey. ME denotes assessment of the myeloid/erythroid ratio in the bone marrow. Epo, erythropoietin; Hct, haematocrit; MCH, the mean cell haemoglobin; MCV, the mean cell volume; RBC, red blood cell count; Retic, Reticulocyte count; Tfr-R, soluble transferrin receptor.

If the red cell mass is appropriate to meet the demands for oxygenation, then Epo production will be suppressed and the serum level will be in the normal range (~10–30 mU/mL in adults). If there is inadequate oxygenation, the level of Epo will generally be raised in proportion to the degree of anaemia (e.g. up to 3–10 U/mL after severe blood loss) unless there is impairment of Epo production (e.g. chronic kidney disease, anaemia of chronic disease). For any given degree of anaemia, the level of Epo in the blood varies depending on the underlying pathology. For example, levels tend to be very high in aplastic anaemia and less than anticipated in thalassaemia. This may reflect the different numbers of precursors in the marrow that are able to bind available Epo molecules, thus altering the number of free Epo molecules that are measured.

The close crosstalk between iron metabolism and erythropoiesis means that erythropoiesis may also be affected by disorders primarily affecting iron metabolism, most often iron deficiency or the anaemia of chronic inflammatory diseases. Therefore, any assessment of erythropoiesis also needs to take into account the availability of iron. The assessment of iron status and metabolism by measuring serum iron, transferrin, iron saturation, ferritin, hepcidin and erythroferrone, is set out in Chapter 11.

Concluding remarks

The process of erythropoiesis needs to be tightly controlled to ensure adequate oxygen delivery to the tissues across a range of physiological and pathological conditions. An appreciation of the mechanisms of erythroid specification, maturation and feedback has already led to an improved understanding of the pathophysiology of many inherited and acquired anaemias, and provides a framework for the logical investigation and treatment of anaemia in the clinical setting.

CHAPTER 4

Lymphocyte development and function

4

Sean Hua Lim

Centre for Cancer Immunology, School of Cancer Sciences, University of Southampton, United Kingdom

Introduction

The immune system protects against infection and cell changes that can lead to the development of malignancies or autoimmune diseases. It can be broadly divided into two functional arms, also known as the *innate* and *adaptive* immune arms. In reality, these two arms overlap and there are extensive interactions between the two. The innate immune system is largely responsible for the initial rapid response to infection and is mediated by cells such as neutrophils, macrophages and natural killer (NK) cells. The adaptive immunity arm comprises of T and B cells, which responds upon recognition of specific molecules (antigen, for B cells) or when the molecules are processed and short regions of the antigen (peptide) are presented by antigen-presenting cells such as dendritic cells (DC) to T cells.

Cells of the immune system are derived from self-renewing haematopoietic stem cells in the bone marrow. There are exceptions, such as tissue-resident macrophages which are formed during early fetal development in the yolk sac. The haematopoietic stem cell gives rise to common lymphoid or myeloid progenitors. Differentiation of the common lymphoid progenitor gives rise to B cells, T cells, NK cells, NKT cells and DC. The latter can also be derived from a myeloid progenitor.

Most *B cells* are generated from within the bone marrow, the 'B' in their name referring to an obscure avian structure called the bursa of Fabricius in which the B cells of birds develop. Naive mature B cells enter the lymphoid circulation, but, if triggered by antigen in the periphery, a proportion of cells will return to the bone marrow as long-lived plasma cells that secrete immunoglobulin. B lymphocytes are the precursors of antibody-producing cells. Each B cell produces, and expresses on its surface, immunoglobulin with a distinct specificity for antigen. The specificity of the immunoglobulin is determined by the way the immunoglobulin variable-region genes are rearranged during B lymphopoiesis. B cells that bind antigen through their surface immunoglobulin have to obtain accessory signals if they are to proliferate and differentiate into antibody-secreting cells. These can be provided by helper T cells, which recognise antigen that has been taken up and presented by the B cell.

T cells are generated in the thymus following the migration of prothymocytes from bone marrow to thymus followed by selection of thymocyte precursors. Over 95% of thymocytes die in the thymus, but the minority population emerges from the thymus as single-positive $CD4^+$ or $CD8^+$ T cells and enters the lymphoid system as naive precursors that can survive for many years. T cells have extremely diverse functions including: (i) providing signals that help induce T cells and B cells to proliferate and differentiate, (ii) specifically deleting virally infected cells or foreign cells, (iii) activating macrophages to enhance cellular cytotoxicity and (iv) regulation of established immune responses.

NK cells similarly appear to develop from within the environment of the bone marrow. They are able to kill cells that fail to express major histocompatibility complex (MHC) class I molecules on their surface or that express molecules associated with cellular stress.

The bone marrow and thymus are therefore the sites of lymphocyte development and are known as the *primary lymphoid organs*. However, immune responses are initiated when lymphocytes encounter antigen and this occurs primarily in *secondary lymphoid tissues* such as lymph nodes and the spleen.

Lymphocytes circulate around the body tissues via the blood and lymphatic vasculature. Lymphatic vessels drain extravascular spaces and lymph nodes are collections of lymphoid tissue in

lymphatic vessels, which are organised to optimise encounters between lymphocytes and antigen. Afferent lymph drains into the lymph nodes, bringing circulating lymphocytes and populations of antigen-loaded dendritic cells from regional tissue. Efferent lymph returns lymphocytes to the bloodstream, where naive cells continue this circulatory pattern in a continuing quest for antigenic encounter. Antigen-experienced lymphocytes migrate to a variety of tissues in order to mediate their effector functions. The pattern of homing is largely determined by the chemokine receptor profile on the lymphocyte.

In this chapter, we will discuss the development and function of each of these lymphocyte populations and their relevance in the context of disease and therapy.

B cells

Development

B-cell production starts in the fetal liver at the end of the first trimester of pregnancy and ceases at this site later in pregnancy. Subsequently, B cells are also produced in the bone marrow, and production in this tissue continues throughout life such that approximately 2% of adult marrow mononuclear cells are B-cell progenitors.

The transcription factors paired box protein 5 (Pax5), E box binding protein 2A (E2A) and early B-cell factor (EBF1) are critical in driving the differentiation of *common lymphoid progenitors* into early B cells. Mice lacking any one of these transcription factors have impaired B-cell development.

The development of B cells can be divided into *antigen-independent* and *antigen-dependent* phases (Figure 4.1). In the antigen-independent phase, the transition of early B cells from *pre-pro-B* into *pro-B* and then *pre-B* cells are marked by variable of expression of the following cell surface markers: CD34, CD19, CD10 and deoxynucleotidyltransferase (Tdt), as well as changes in surface immunoglobulin expression and rearrangement. Heavy-chain gene rearrangement precedes light-chain gene arrangement. The first rearrangements to occur are in the joining of one of the J segments to one D segment, with the looping out of the intervening sequences. If this is successful, the rearranged V–D–J sequence will be transcribed together with the genes encoding the μ constant region. These processes are mediated by RAG-1/RAG-2 enzymes, which catalyse double-strand DNA breaks at specific regions. Cleaved DNA ends are rejoined in a non-homologous fashion by DNA protein kinases. Translation of this transcript results in the cell expressing a cytoplasmic μ heavy chain (pre-B-cell receptor, pre-BCR), and transition of the cell from a *pro-B cell* to a *pre-B cell*. Only one functional VDJ rearrangement is made by each B cell and this *allelic exclusion* of antigen receptor genes means that only one functional antigen-binding protein is expressed on the surface of the cell. Cells that fail to make a single functional rearrangement die by apoptosis. The enzyme, TdT, is expressed during variable-region gene rearrangement and catalyses the addition of random nucleotides at the junctions of V–D–J and D–J to further expand the antibody specificity repertoire. The enzyme is expressed both in pro-B cells in the marrow and in cortical thymocytes during *TCR* gene rearrangement.

Each B cell expresses only a single light chain and the ratio of κ-expressing B cells to λ-expressing B cells is close to 60:40. Disturbance of the κ/λ B-cell ratio is a reliable indicator of the presence of a neoplastic clone. Intact heavy chains can be exported to the surface of a B cell only if they are complexed with light chain or surrogate light chain. This does not apply to free light chains, which are able to pass out of B cells and plasma cells. Physiological light chain production is always greater than that required to complex all the available heavy chain, and measurement of serum-free light chain is a useful tool in the management of paraproteinaemia. The heavy chains that are secreted in heavy chain disease are able to leave the cell only because they are truncated heavy chains.

The next step in B-cell development is the maturation of the pre-BCR into a BCR. This requires effective pairing of rearranged light changes with rearranged heavy chains and signifies the transition of a pre-BCR cell into an immature B cell. Here, the BCR consists of an antigen-detecting component (surface immunoglobulin M (IgM)) and a signalling component similar to the pre-BCR (Ig-α and Ig-β). VDJ recombination produces a diverse antibody repertoire, essential for host defence, but a drawback is that the specificity is generated randomly and so some of the Ig will be reactive against self-antigens. As a result, tolerance mechanisms such as *anergy* and *receptor editing* are essential. *Anergy* is a process whereby self-tolerance is generated through reduced BCR expression and signalling, whilst *receptor editing* is a process whereby the RAG enzymes continue to catalyse light chain rearrangement until a non-self-reactive BCR results.

In the *antigen-dependent phase*, the non-autoreactive, naive and *immature B cell* (also known as a *transitional B cell*) then migrates into the peripheral blood and then localises into the follicular regions of the secondary lymphoid organs (marrow, lymph nodes) where they are termed *follicular B cells*. Within the follicles of the spleen or lymph nodes, the naive follicular B cells will encounter cognate antigen complexed on the surface of complement receptors of primary *follicular dendritic cells* (FDC) and then migrate to the T:B cell border. B cells can also be activated by soluble antigen but the affinity of the antigen for the BCR is low. In contrast, membrane-bound antigens are able to tether B cells more strongly and enhance BCR signalling through co-stimulation by other surface receptors.

In the T:B cell border, B cells undergo intense proliferation to generate *centroblasts* and form *germinal centres* (GC). B-cell lymphoma 6 (BCL-6) is vital in driving B-cell proliferation and suppressing differentiation. GC formation is critical for the development of secondary immune responses and immunologic memory. Within the GC, two distinct processes occur at the immunoglobulin loci, *somatic hypermutation* and *class*

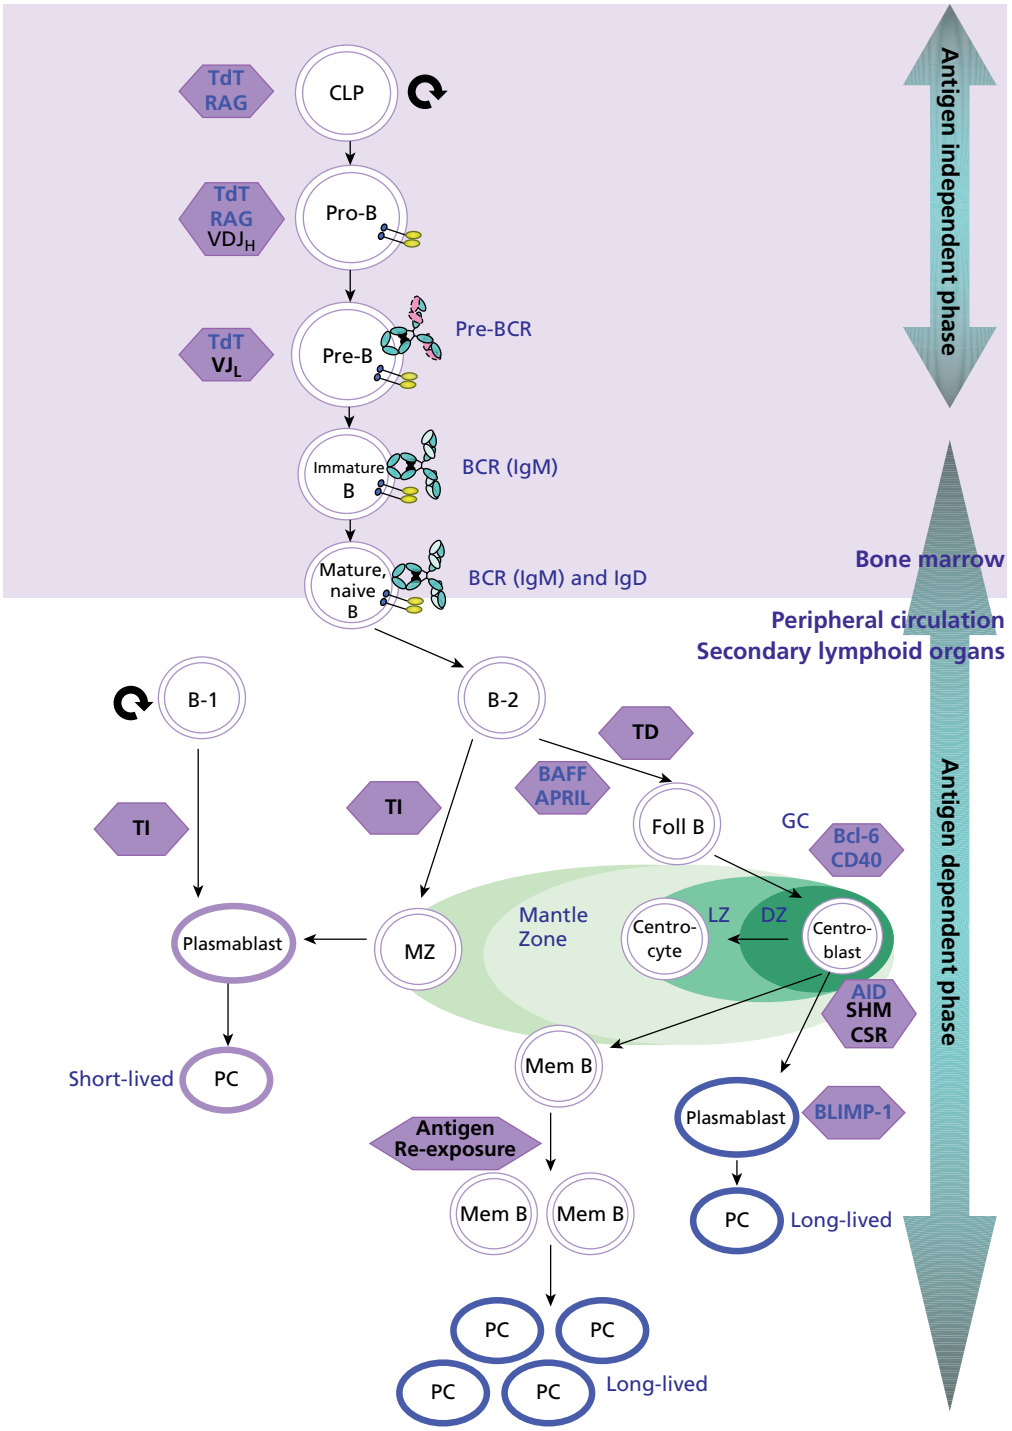

Figure 4.1 The key transcription factors and steps in B-cell development are summarised here. The antigen-independent phase of B-cell development takes place in the bone marrow. During this phase, mature but naïve B cells expressing BCR are produced. The cells then enter the peripheral circulation and upon antigen-encounter, are stimulated via T-cell independent (TI) or T-cell dependent (TD) pathways. TD-stimulated cells migrate to the germinal centre (GC) where somatic hypermutation (SHM) and class switch recombination (CSR) takes place. Proliferating and non-proliferating B-cells are known as centroblasts and centrocytes, respectively. Centrocytes will apoptose, unless they receive rescue signals from CD40-CD40L interaction on T cells, and further differentiate into either plasma cells (under control of Blimp-1) or memory B-cells. Self-renewing B-1 cells and marginal zone (MZ) B cells are stimulated via TI pathways and produce a rapid but transient Ab response. CLP, common lymphoid precursor; mem B, memory B cell; PC, plasma cell.

switch recombination. In somatic hypermutation, activation-induced deaminase (AID) catalyses the deamination of cytidine residues in the Ig variable gene, leading to the introduction of non-random point mutations, thereby increasing the affinity of the antigen-binding domain of the Ig. For class switch recombination, AID also induces double-strand DNA breaks within guanine-rich tandem repeats upstream of each heavy chain constant region leading to recombination in a non-homologous manner. This allows a switch between the variable and constant regions, thereby allowing the Ig to switch from IgM and IgD to IgG, IgA or IgE to vary its function.

Mutated centroblasts then exit cell cycle to become centrocytes and migrate to the edge of the follicle to form the morphologically described light zone. In order to achieve sufficient numbers of high-affinity mutations per B cell, centrocytes enter cell cycle and undergo somatic hypermutation repeatedly. Cells that express high-affinity Ig receptors are selected for survival, in a process called *affinity maturation*. A multitude of interdependent factors are involved in the germinal centre reaction, with the crucial cellular components being the follicular DC and the follicular helper CD4 T cells (Tfh).

Despite the fundamental need for VDJ recombination, somatic hypermutation and class switch recombination, errors during these processes are potentially pathological. Reciprocal chromosomal translocations that juxtapose a proto-oncogene next to an Ig regulatory locus are one of the hallmarks of B-cell lymphomas. Examples of these include c-myc and BCL-6 in aggressive B-cell lymphomas, BCL-2 in follicular lymphoma and BCL-1 which produces cyclin-D1 overexpression in mantle cell lymphoma.

The naive B cells can also be activated on antigen encounter through a T-cell-independent pathway. The T-cell independent pathway is a relatively weak and rapid response that serves to provide a transient protective immune response and results in the production of short-lived, IgM-secreting *plasmablasts*.

Antibodies

Antibodies are immunoglobulins produced by terminally differentiated B cells also known as plasma cells. Each plasma cell produces antibodies of identical specificity for an antigen (*monoclonal antibodies*). However, when B cells are stimulated by an antigen, different B cells recognise and respond to the antigen, and undergo expansion as described above, to produce a diverse antibody repertoire, or *polyclonal antibodies*. This is in contrast to the clonal populations found in B-cell malignancies, where the B cells or plasma cells express or secrete monoclonal antibodies.

The basic structure of a monomeric antibody molecule is a Y-shaped heterodimeric glycoprotein comprising of two large identical polypeptides (heavy chain, ~55 kDa) and two smaller identical polypeptides (light chain, ~22 kDa). (Figure 4.2) The light and heavy chains are held together by disulfide (S–S) bonds. Within each chain are variable and constant regions as defined by the diversity of the amino acid sequence. The antigen-binding surface of each antibody is formed by hypervariable regions called *complementarity-determining regions* (CDR) within the variable regions of the heavy and light chains.

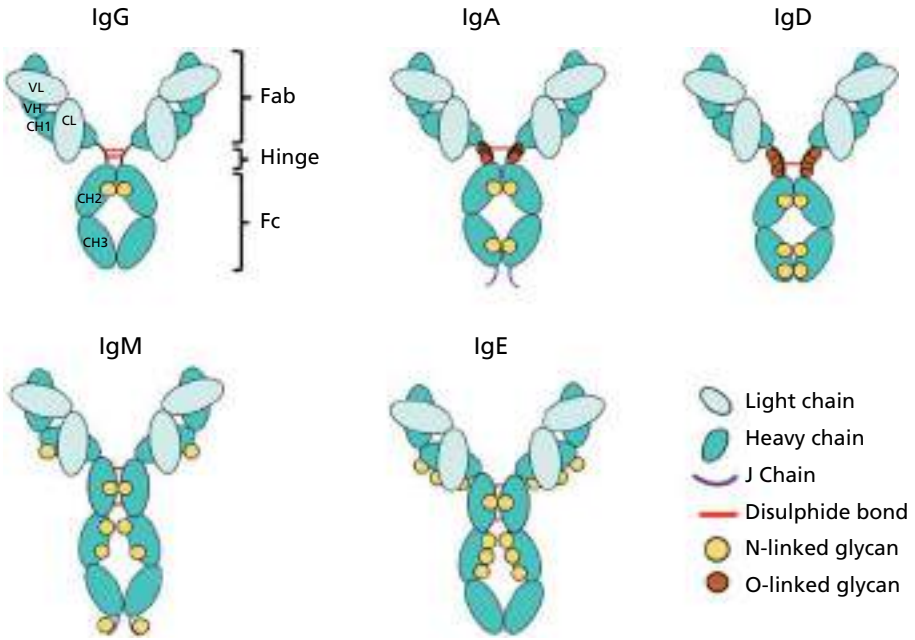

Figure 4.2 Structures of monomeric immunoglobulin molecules are shown. IgA and IgM exist as dimers (10%) and pentamers, respectively via the J chain, a 137 amino acid residue polypeptide.

There are two distinct types of light chain, kappa (κ) and lambda (λ), which are common to all immunoglobulins. Either of these chains may combine with any heavy chain, but in any one immunoglobulin molecule both light chains are identical. κ chains occur in about 65% and λ chains in about 35% of the normal immunoglobulins in each class. There are five types of heavy chains based on the amino acid sequence of the constant region (γ, α, μ, δ and ε), thus producing five classes or isotypes of immunoglobulins: IgM, IgG, IgA, IgD and IgE, respectively. IgG molecules can be further subdivided into IgG1, IgG2, IgG3 and IgG4, and IgA into IgA1 and IgA2 based on subtle amino acid sequence differences. The isotype and subclass variation allow the antibody to mediate different effector functions.

There is preferential active transport of IgG1 relative to the other IgG subclasses. As only IgG passes the placental barrier, only IgG blood group antibodies can cause haemolytic disease of the fetus and newborn (HDFN) and only IgG1 and IgG3 will mediate significant immune red cell destruction. The IgG level in cord blood will be much the same as the level in the mother. Passively transferred maternal IgG gradually disappears from the infant after birth and is almost gone by 3 months of age. The serum of newborn infants contains a small amount of IgM of fetal origin and almost no IgA; the production of IgA and IgG starts at about 1–2 months of age.

Papain can split the basic immunoglobulin molecule into three fragments at a site near the S–S bonds that hold the heavy chains together. One fragment contains the C-termini of the heavy chains and is called the *Fc (Fragment, crystallisable) fragment*. The other two are called *Fab (Fragment, antigen binding) fragments*, each of which consists of the N-terminus of the heavy chain and the whole of the light chain, and contains the antigen-binding site of the molecule.

The Fc mediates the antibodies' effector functions by binding to Fc receptors or complement components such as C1q. Essential to Fc function are sugar (glycan) domains which are linked to the heavy chains. The glycans are important for maintaining the Fc-heavy chains in an open confirmation, required for optimal binding with Fcγ receptors. As such, modification of these sugars, such as through defucosylation leads to improved formation of non-covalent interactions and subsequent increased binding affinity with this activatory Fcγ receptor. The CD20 monoclonal antibody obinutuzumab, used in follicular lymphoma, is an example of a defucosylated antibody.

Antibody function

Antibodies are multifunctional. They perform a variety of functions in addition to binding antigen, depending on their isotype. Most of these additional functions reside in the Fc fragment and will be discussed in turn.

Fc-Fc receptor-mediated interactions

After binding to antigen, the Fc domain of the antibody binds to *Fc receptors* expressed on haematopoietic cells. This is one of the main mechanisms by which the biological activity of antibodies is mediated.

There are multiple classes of Fc receptors to complement antibody isotype, e.g. IgG antibodies bind to FcγR, IgE to FcεR and IgA to FcαR and Fcα/μR, and IgM to Fcα/μR. FcγR can be further subdivided into activatory or inhibitory receptors. FcγRIIb is the sole inhibitory receptor, whilst there are multiple activatory FcγR (FcγRI, FcγRIIa and FcγRIIIa). These receptors are variably expressed in haematopoietic cells and engage the different IgG subclasses with different affinity. As a general rule, activatory FcγR promotes activation of the cell it is expressed on, whereas inhibitory FcγRIIb has the opposite effect. Thus, the balance of engagement between inhibitory and activatory FcγR engagement on a cell determines the eventual response triggered.

Two key mechanisms triggered by Fc-FcγR interaction are *antibody-dependent cellular cytotoxicity* (ADCC) and *antibody-dependent cellular phagocytosis* (ADCP). In ADCC, the antibody forms a bridge between the antigen-expressing cell and the FcγR-expressing NK cell, causing activation of the NK cell and subsequent release of cytotoxic molecules such as perforin and granzyme which lyse the target cell. Similarly, in ADCP, the antibody links the antigen-expressing cell with an FcγR-expression phagocyte such as a macrophage, which leads to cellular activation, phagocytosis and eventually lysis of the target cell. These two are mechanisms, in particular ADCP, underpin the anti-tumour efficacy of monoclonal antibodies such as anti-CD20, rituximab and obinutuzumab.

Complement fixation

The *classical pathway* of the complement system is initiated when antigen-bound antibody of particular isotype binds to the first complement component, C1. (Figure 4.3) IgM, IgG1, IgG2 and IgG3 but not IgG4 or IgA, activate the classical pathway. C1 is a complex of three protein molecules, C1q, C1r and C1s, and activation of this pathway requires multiglobular C1q to bind to at least two juxtaposed Fc regions, thus explaining why pentameric IgG is more effective at activating complement than monomeric IgG1. The C1 complex further activates C4 and C2, generating C4b2b, known as C3 convertase. The cell-bound C4b2b can optimally activate several thousand C3 molecules by splitting them into C3a and C3b. C3b molecules act as an opsonin by binding covalently to the target cell, thereby targeting it for destruction by C3b receptor expressing phagocytes. The active phase of C3 is transient because C3b is rapidly degraded by an enzyme (C3b inactivator or factor I) and its accelerator (βIH or factor H). C4b2b3b will 'trigger' the fixation of C5, C6, C7, C8 and C9, leading to the formation of

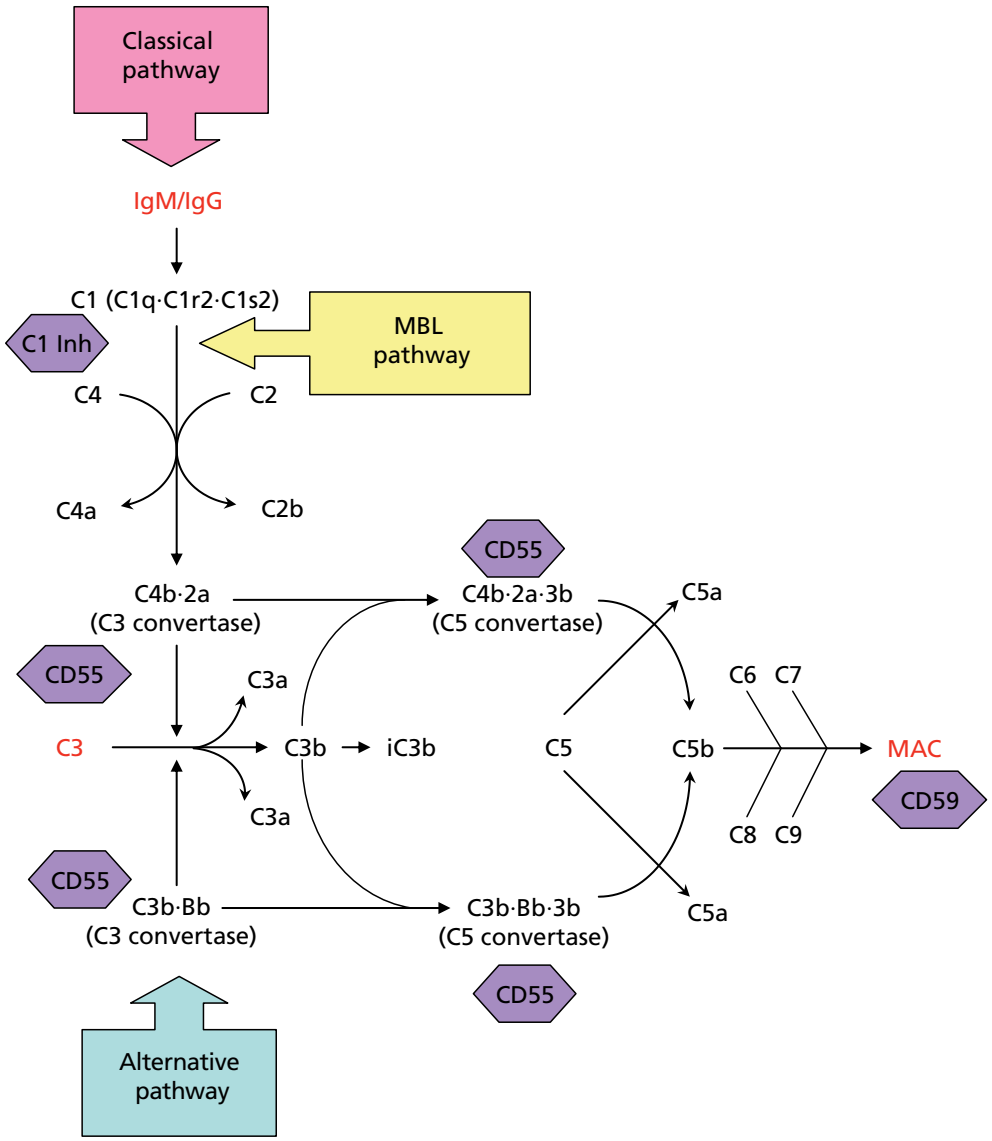

Figure 4.3 The complement cascade comprises three distinct pathways; the classical, mannose-binding lectin (MBL) and alternative pathways. The classical pathway is initiated by the binding of C1q, a component of C1 complex, to the CH2 region of the Fc domain of an antigen-bound antibody. Subsequently, C1s cleaves C4, then C2, resulting in the formation of C3 convertase. The MBL pathway is initiated when host MBL binds to mannose and fucose residues on a suitable surface such as a pathogen. The alternative pathway is constitutively activated at a low rate and is amplified on C3 cleavage. All three pathways converge at C3. C3 is cleaved by C3 convertase into C3a and C3b. C3b is an acceptor site for C5, which initiates formation of MAC. The complement cascade can be inhibited at various points by the C1 esterase inhibitor (C1 Inh), CD55 (decay accelerating factor) and CD59 (membrane inhibitor of reactive lysis).

the membrane attack complex which forms a pore in the membrane of the target cell, bringing about their lysis.

Two other pathways exist, the *alternative* and the *mannose-binding lectin pathways*, which do not necessarily involve antibody and represents non-specific 'innate' immunity. The alternative pathway is constitutively activated at a low rate and is amplified on C3 cleavage. The mannose-binding lectin pathway is initiated when host mannose-binding lectin binds to mannose and fucose residues on pathogen surface. All three pathways converge at C3.

The complement cascade is closely regulated by a number of complement defence molecules. For example, C1 inhibitor is a soluble protein that regulates C1, whilst the membrane protein CD55 inactivates C3 and C5 convertases by binding to C3b and C4b and CD59 binds to C8 and C9 to prevent formation of the membrane attack complex.

Neutralising activity

Antibodies can also mediate effects without effector molecules and immune effector cells by binding to and blocking a receptor, or neutralisation. In infection, protective antibodies bind to an organism's receptor to interfere with its attachment to host tissues. For instance, in COVID-19, caused by the novel coronavirus severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus enters the host cell by attaching its transmembrane spike protein to the angiotensin-converting enzyme 2 (ACE2) receptor. Host antibodies that bind to the viral spike protein, in particular the receptor-binding domain within the spike protein, are able to prevent virus entry. Neutralisation can also occur through other means e.g. multimeric IgA and IgM antibodies are able to bind to and aggregate organisms to inhibit their function and reduce infectivity.

The B cell receptor

The membrane-bound antibody together with Igα (CD79a) and Igβ (CD79b), forms the B cell receptor (BCR), which transmits a low-level basal signal critical for B-cell survival. (Figure 4.4) Upon engaging antigen, BCR aggregation is triggered, leading to phosphorylation of Immunoreceptor Tyrosine-based Activation Motifs (ITAM) within the cytoplasmic tail of CD79a and CD79b. The phosphorylated ITAMs then recruit and activate Syk kinase, which in turn recruit adaptor proteins and kinases such as Bruton's tyrosine kinase (BTK). This further leads to the activation of phosphatidylinositol 3-kinase (PI3K), phospholipase Cγ2 (PLCγ), and mitogen-activated protein kinase (MAPK) pathways, and induction of NF-κB activation to modify B-cell survival, differentiation and proliferation.

As BCR signalling is critical to cell survival, these pathways can be targeted by drugs to treat B-cell malignancies, such as small molecular inhibitors against BTK, ibrutinib, in CLL and mantle cell lymphoma. Conversely, activation of the BCR signalling pathway has been observed in some subtypes of B-cell malignancies e.g. the activated B-cell like (ABC) subtype of diffuse large B-cell lymphoma (DLBCL) as a result of gain-of-function mutations of CD79B and/or MYD88, with the latter mutation also implicated in lymphoplasmacytic lymphoma.

T cells

T-cell development

Although the earliest progenitors of T cells are produced in the bone marrow, the development and selection of the most mature immunologically competent T cells occur in the thymus. Despite the fact that the thymus is largest in neonates and gradually involutes with age, ceasing its activity after the fourth decade of life. The naive T cell pool can be maintained in adults through peripheral division and have a lifespan of 5–10 years.

Similar to B-cell development, the maturation of T cells is marked by rearrangement of *T cell receptor* (*TCR*) genes and expression of a number of key surface antigens. The *TCR* (Figure 4.5) also has certain similarities to immunoglobulin in that it is composed of two non-identical polypeptide chains that have constant and variable regions. There are two types of *TCR*, with αβ T cells expressing a heterodimer of an α-chain and a β-chain, and the minority population of γδ T cells expressing the γδ *TCR* heterodimer. A number of different molecules are associated with the two *TCR* polypeptide chains in order to generate the *TCR* complex. This transmembrane signalling complex of molecules is collectively known as CD3 (Figure 4.5) and is linked to second messenger signalling molecules, whose expression varies between different T-cell subsets and at different stages of T-cell differentiation.

The early T cell progenitors that arrive in the thymus do not express the *TCR* or the signature antigens of T cells (CD3, CD4 and CD8) and are termed *double negative* (CD4–CD8) cells. These cells are identified by expression of CD34 and CD7 and can be further subdivided based on expression of interleukin-2 receptor α chain (CD25) and CD44, an adhesion molecule. Interaction with the thymic stroma is accompanied by expression of CD2 and cytoplasmic expression of CD3 genes. By this stage, the cell is committed to the T-cell lineage and *TCR* gene rearrangement is underway.

Like *BCR* rearrangement, *TCR* β, γ, α and δ gene rearrangement is mediated by RAG-1 and RAG-2 enzymes. Rearrangement of the gene encoding the *TCR* β-chain occurs first with D to J rearrangements followed by V–D–J rearrangements to create a pre-*TCR*, which complexes with CD3 and upregulation of CD4 and CD8 to produce double positive cells. *TCR* α-chain gene rearrangement is then initiated to produce an αβ *TCR*.

During early fetal development, the first cells to leave the thymus as mature T cells have successfully rearranged their γ and δ genes and express the γδ form of the *TCR*. During later stages of human fetal development and throughout the rest of life, 85–98% of T cells that leave the thymus have undergone successful α and β gene rearrangement and express the αβ *TCR*.

Double-positive cells undergo selection to give rise to single-positive ($CD4^+$ or $CD8^+$) thymocytes which then migrate to the periphery as naive T cells ($CD45RA^+$ $CCR7^+$). There are two key thymic selection processes, *positive selection* and *negative selection*. Positive selection is the process whereby thymocytes that express receptors that are able to recognise peptides presented by major histocompatibility complex (MHC) molecules, can proceed through development. Cells that fail positive selection will die by neglect and apoptose within the thymus. In contrast, in negative selection, thymocytes that bind to self-expressing MHC molecules alone with high affinity, or self-antigen complexed with self-MHC, are eliminated. Both processes are critical for the generation of effective but tolerant T cells. It has been estimated that

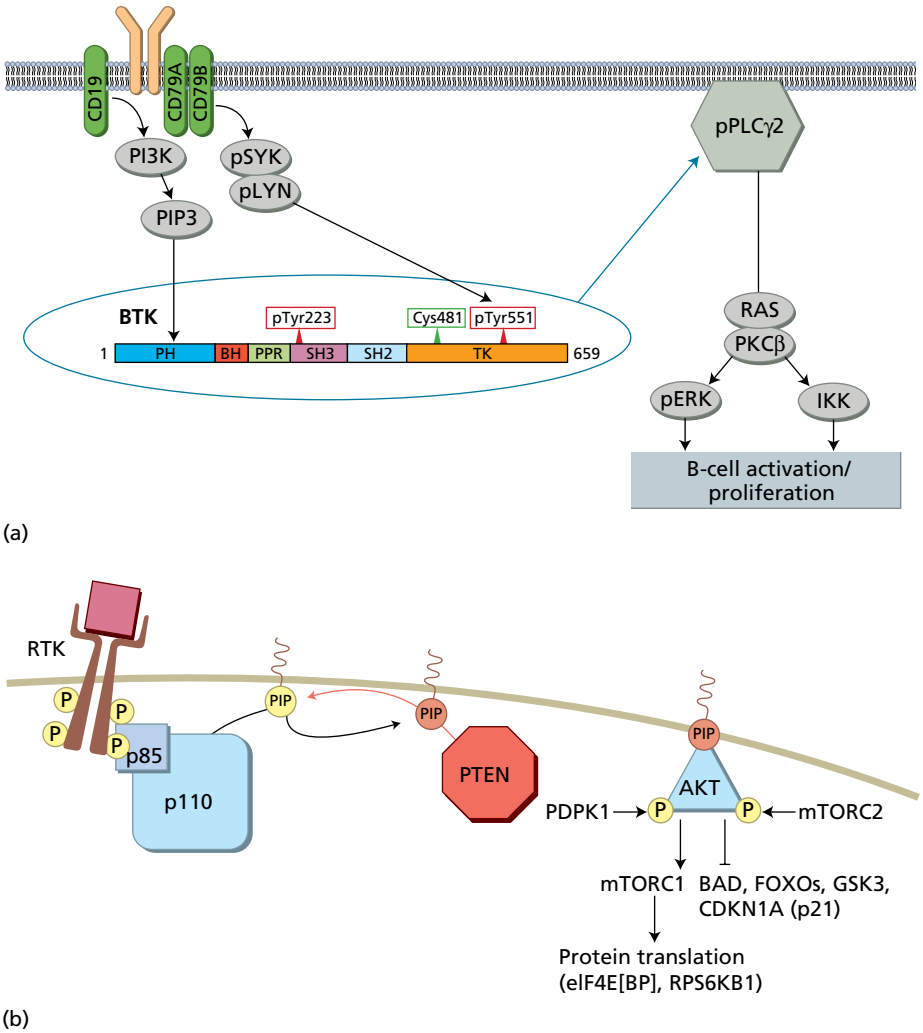

Figure 4.4 (a) BTK and its involvement in BCR signalling. Bruton's tyrosine kinase (BTK) comprises several domains including the: (i) pleckstrin homology (PH) domain, which targets BTK to the plasma membrane, (ii) BTK homology (BH) domain, (iii) polyproline (PPR) domain, (iv) Src homology (SH3 and SH2) domains (SH2 domain of BTK binds to the B cell adapter protein BLNK, which is required for full BTK activation) and (v) tyrosine kinase (TK) domain. Activation of BTK requires phosphorylation and binding of PIP3. Following *BCR* engagement and activation, and following PIP3 binding, BTK translocates to the plasma membrane, where it is phosphorylated at Tyr551 by LYN and SYK, leading to autophosphorylation of Tyr223. Once bound to BLNK, BTK phosphorylates PLCG2 at several sites, leading to calcium mobilisation and activation of the protein kinase C (PKC) family members and other effectors, including RAS, and to NFκB activation and phosphorylation of ERK. Most BTK inhibitors bind irreversibly to Cys481 within the ATP binding site of the BTK kinase domain, thus preventing BTK activation. Apart from its role in BCR signalling, BTK is also implicated in cytokine and Toll receptor signalling pathways. (Source: Hutchinson and Dyer (2014) *Br. J. Haematol.* **166**: 12–22. Reproduced with permission of John Wiley & Sons.) (b) A schematic representation of the phosphoinositol-3 kinase pathways. Extracellular ligands bind receptor tyrosine kinases which are subsequently (auto) phosphorylated. The p85 regulatory subunit of PI3K then binds to one of these phosphates and activates the p110 catalytic subunit. PI3K takes a phosphate from a donor ATP and adds to an acceptor phosphatidylinositol-4,5-bisphosphate (PIP2) to generate phosphatidylinositol-3,4,5-triphosphate (PIP3). This action is opposed by PTEN, which dephosphorylates PIP3. PIP3 can recruit activated (phosphorylated) AKT to the membrane; once PIP3 is bound to the PH domain of activated AKT a variety of downstream substrates are phosphorylated. In the B cell, these targets include BTK. (Source: Blachly and Baiocchi (2014). Reproduced with permission of John Wiley & Sons.)

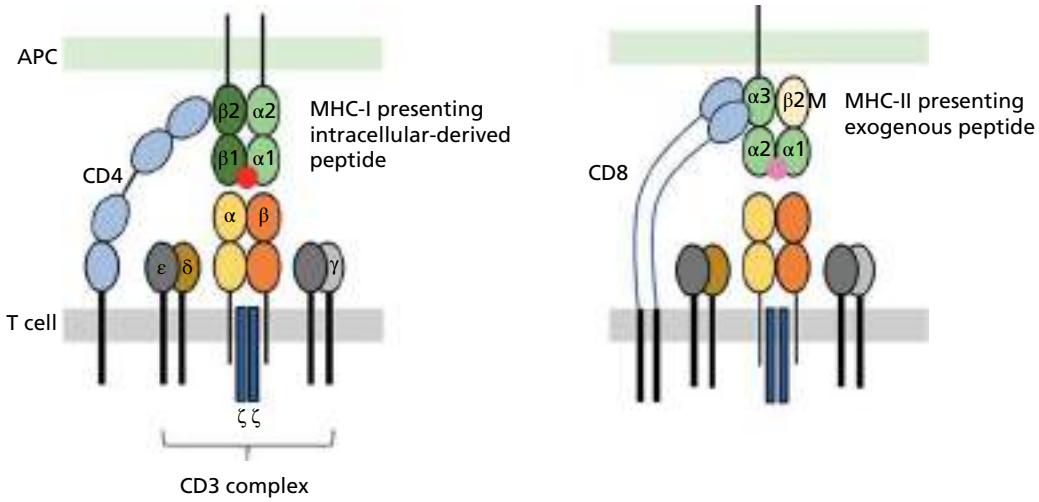

Figure 4.5 T cells recognise peptides held in MHC molecules. A class I MHC molecule is depicted on the left and a class II MHC molecule on the right. Some of the protein produced within each cell is broken down into peptides, which are presented on the cell surface in the peptide-binding groove of MHC molecules, usually class I. Extracellular molecules are taken up by antigen-presenting cells, broken down within the cell and presented on the cell surface in the peptide-binding groove of MHC molecules, usually class II. There are three isotypes of class II molecules, known as DP, DQ and DR, and three main class I isotypes, A, B and C. All of these are encoded within the *MHC* gene complex at 6p21.3. The genes encoding the peptide-binding grooves of each of these isotypes show extraordinary variability within the human population, so-called 'allelic polymorphism'. The range of peptides that can be held by different MHC molecules varies. Consequently, this polymorphism is reflected in differences between individuals in the ability to recognise specific peptides. Any one T-cell receptor (TCR) will only recognise a particular peptide within a particular groove structure. β_2-Microglobulin is a non-polymorphic immunoglobulin-like domain that is non-covalently associated with HLA class I MHC molecules; it stabilises peptide binding and is essential for the expression of class I on the cell surface. The αβ T-cell receptor (TCR) complex. The αβ TCR is composed of two polypeptide chains, each with a variable (open ovoid) and constant (closed ovoid) domain. Peptide plus MHC is recognised by the combined variable regions. The TCR is surrounded by the CD3 complex of transmembrane signalling molecules. This is composed of four types of polypeptide chain, γ, δ, ε and ζ. Most peripheral T cells express CD4 *or* CD8 with their TCR.

95% of all thymocytes die within the thymus either as a result of failure to rearrange their TCR genes in an expressible form or as a consequence of elimination during the T-cell selection process.

Thymic epithelial cells in the cortex are critical in the positive selection of thymocytes that have moderate affinity for MHC–peptide complexes. The boundary of the cortex and medulla is populated by macrophages (often called sentinel macrophages) that phagocytose cells undergoing apoptosis. The medulla contains medullary thymic epithelial cells (mTEC) which mediate the process of negative selection. Interestingly, these cells express the autoimmune regulator (Aire) protein which leads to transcriptional expression of a wide range of cellular genes, therefore ensuring that tolerance is achieved to proteins expressed in a range of peripheral organs. Structures known as Hassall corpuscles, which are whorled aggregates of epithelial cells, can also be seen in the medulla though their function is uncertain.

Antigen recognition by the TCR

T cells recognise peptides presented in association with MHC molecules. In humans, the MHC molecules are also known as human leucocyte antigens (HLA) and there are two classes of MHC molecules. MHC class I molecules are expressed by all nucleated cells except germ cells. They are not expressed by erythrocytes but are found on the surface of erythroblasts. The peptides recognised by T cells in association with class I MHC molecules are, in most circumstances, derived from proteins produced within the cell. This places MHC class I molecules in an excellent position to present peptides derived from viral proteins following intracellular viral infection (Figure 4.6). It is now clear that antigen-presenting cells are also able to take up proteins from outside the cell and process them such that peptides gain access to the MHC class I presentation. This process is called *cross-presentation* and

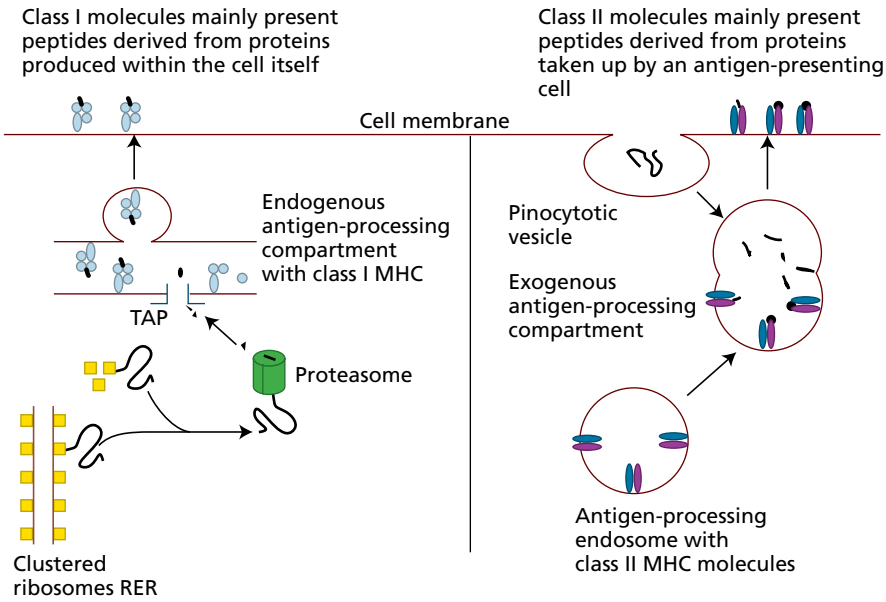

Figure 4.6 Antigen processing and presentation in association with MHC molecules. (Left): Antigen presentation of proteins produced within cells is mainly the property of class I MHC molecules. A proportion of proteins (black ribbons) produced within a cell on ribosomes (yellow) are broken down to peptides (black fragments) within a cytoplasmic molecular complex known as a proteasome. The resulting peptides are actively transported by TAP proteins (blue) through the wall of specialised endoplasmic reticulum (ER) that has MHC class I molecules in its wall. The peptides and β_2-microglobulin associate with class I molecules and are then expressed on the cell surface. (Right): Antigen presentation in association with class II MHC molecules involves pinocytosis of antigen (black ribbon) and fusion with an antigen-processing endosome, which has class II MHC molecules (magenta and blue) inserted in its wall. The antigen-presenting grooves of the class II MHC molecules are kept empty by the association with invariant chain (CD74). Fusion of the pinosome with the endosome heralds the activation of proteolytic enzymes; the invariant chain and the ingested proteins are broken down to peptides. The resulting peptides (black fragments) are assembled into the antigen-presenting groove of class II MHC molecules that are held in the endosomal wall. The HLA class II molecules with bound peptides are then carried to the cell surface.

may be particularly important in generating $CD8^+$ T cell responses to tumour-associated proteins.

MHC class I antigen presentation starts with the intracellular breakdown of proteins by a multimolecular proteolytic complex known as a *proteasome*. These peptides are actively transported by TAP (transporter associated with antigen processing) proteins into the endoplasmic reticulum, where empty MHC class I molecules are being assembled. The nascent MHC molecules are able to 'fold' around the peptides, which make non-covalent interactions with the peptide-binding groove at the top of the molecule. This complex is then stabilised by the association of β_2-microglobulin before being transported to the cell surface. In this way, the cells are continuously advertising the peptide composition of the proteins that they are producing.

T cells that recognise peptide presented by MHC class I molecules express a molecule, CD8, that binds to the α3 domain of the MHC class I molecule. When any cell in the body presents immunogenic peptides, these may be recognised by a cytotoxic CD8 T lymphocyte that can then kill the target cell. This is most likely to occur as the result of virus infection when virus-encoded proteins are produced; it may also occur following the acquisition of a genetic mutation within a cell.

The other class of MHC molecule, MHC class II, is less widely expressed. The only cells that constitutively express large amounts of this class of MHC molecule are specialised antigen-presenting cells e.g. dendritic cells, B lymphocytes and thymic epithelial cells. Dendritic cells share a pattern of haematopoietic differentiation with monocytes and in the laboratory, they can be derived from blood mononuclear preparations by culture with granulocyte/macrophage colony-stimulating factor (GM-CSF) and interleukin (IL)-4. They migrate to many tissues, particularly epithelia, where they remain until activated by local tissue injury. On activation, they take up fluid and particles from their surrounding environment and digest proteins, which they present as MHC class II–peptide complexes at the cell surface.

The scrutiny of antigen-presenting cells by T cells starts when dendritic cells move from peripheral tissues to the T-cell-rich areas of adjacent secondary lymphoid organs. In this site, they are known as interdigitating dendritic cells (IDC), which express

molecules associated with T-cell activation such as CD40, CD80 and CD86. In the T zones of secondary lymphoid organs, recirculating T cells are constantly migrating to the surface of IDC, which they scrutinise for the presence of an MHC–peptide complex to which they can bind with their TCR. In this way, the T cells continually screen for the presence of peptides derived from both extracellular and intracellular antigens.

CD4⁺ and CD8⁺ T cells and their functions

$CD4^+$ T cells are multifunctional. Their major role is in the provision of signals that induce proliferation or differentiation of T or B cells, generally known as *T-cell help*. They can also activate macrophages and may mediate HLA class-II-restricted cytotoxic activity. Increasing attention is being given to their regulatory role in T-cell immune responses and this is mediated through a Forkhead transcription factor (FoxP3)-positive subset of T regulatory cells.

$CD8^+$ T cells have a predominant role in the recognition of virally infected cells and recognise antigen in association with HLA class I. Antigen recognition is followed by lysis of the target cell and secretion of cytokines such as interferon (IFN)-γ. There are two main killing mechanisms, which both induce apoptosis in the target cell. Firstly, enzymes known as *granzymes* and pore-forming molecules termed *perforins* are transferred from the T cell to the target cell. Granzymes and perforins are present in granules that stain crimson and are easily seen against the featureless pale cytoplasm of cytotoxic T cells and NK cells in Jenner–Giemsa preparations. These features have given rise to the term *large granular lymphocyte*. The second cytotoxic mechanism involves the expression of the Fas ligand (FasL, CD95L) by the effector cell. The resulting engagement of Fas (CD95) on the target cell induces the target to undergo apoptosis. Fas is a member of the TNF receptor family and FasL is an analogue of TNF-α and TNF-β.

Differentiation of primed T cells into effector cells

Following the first recognition of antigen or *T-cell priming*, naive $CD8^+$ T cells enter an *expansion phase* whereby they differentiate and proliferate into effector $CD8^+$ T cells which then clear the infection or antigen-expressing cells. This is followed by a *contraction phase* whereupon most of the effector $CD8^+$ T cells apoptose to leave behind a *memory phase*. During this phase, the cells differentiate into memory cells which can react rapidly to reinfection. Memory cells can be subdivided into *central memory*, *effector memory* or *stem cell memory* cells. The central and effector memory cells both produce effector cytokines but only the central memory cells have high proliferative capacity. Stem central memory cells are rare and have no effector function but have high self-renewal and proliferative capacity. After the contraction phase, small numbers of terminal effector $CD8^+$ T cells ($CD45RA^+CCR7^-$) can persist especially in the context of a chronic and persistent insult. These cells have low proliferative capacity but produce high levels of interferon γ (IFNγ).

$CD4^+$ T cells are critical for the development of an effective host immune response. The consequences of low numbers of $CD4^+$ T cells are clearly demonstrated in HIV-infected individuals, who develop malignancies and opportunistic infections. Differentiation of primed $CD4^+$ cells is directed into one of five major pathways depending on the nature of the antigen, associated inflammatory stimuli and the affinity of T-cell engagement. In general, $CD4^+$ cells are highly plastic and can switch from one phenotype to another. For instance, $CD4^+$ T cells stimulated in the presence of IL-12, which is produced by macrophages and dendritic cells, are more likely to differentiate into Th1 cells. But if subsequently stimulated with IL-10, it can change into a regulatory phenotype, especially in chronic inflammation.

Similar to $CD8^+$ T cells, $CD4^+$ T cells undergo expansion, contraction and memory phases to generate effector and memory subsets. In addition, they can be subdivided into five major $CD4^+$ T cell subsets:

1. *Th1 cells*
   As above, release of IL-12 by macrophages and dendritic cells activate the transcription factor Tbet, in naive $CD4^+$ T cells to drive IFNγ release, and differentiation of the cell into a Th1 phenotype. This inflammatory subset is important for the clearance of intracellular pathogens such as viruses and bacteria. The cells are cytolytic and can kill infected macrophages through granzyme/perforin or Fas ligand. This subset is also conventionally regarded as characteristic indicative of an anti-tumour response.
2. *Th2 cells*
   IL-4, produced by activated Th2 cells itself, drives the transcription factors GATA3 and STAT5 to induce Th2 differentiation. Th2 cells produce cytokines associated with antibody production, particularly IL-4, IL-10 and, in some instances, IL-6, although the last of these is mainly produced by macrophages and osteoclasts. The balance between Th1 and Th2 cells can be an important determinant of immunopathology. Tuberculoid leprosy exemplifies apparent dominance of a Th1 response, while atopic disease seems to reflect an imbalance towards Th2. Nevertheless, manipulation of these cytokine networks provides a potential means of modifying established immune responses to avoid the complications associated with over activity of either Th1 or Th2 cells.
3. *Th17 cells*
   The immunosuppressive cytokines TGF-β, IL-6 and/or IL-23, activates the transcription factor retinoic-acid receptor-related orphan receptor γt (RORγt), which is a master regulator for Th17 differentiation. As implied by its name, these cells produce large amounts of the cytokine IL-17, a pro-inflammatory cytokine. These cells play an important role in

the control of fungal disease and defence against extracellular pathogens, but are also implicated in autoimmune disease.

4 *TFH cells*

Follicular helper T cells (TFH) are crucial in providing B-cell help. Differentiation of naive CD4⁺ T cells in TFH is driven by BCL-6, which is also vital in promoting B-cell proliferation in the germinal centre and suppression of B-cell differentiation. TFH cells are attracted into the follicles via CXCR5-CXCL13 interaction. The co-localisation of Tfh and B cells provides CD40L-CD40 costimulation, required for germinal centre maintenance. The inducible costimulatory molecule (ICOS) upregulated on TFH cells, is also necessary for maintenance of CD40L expression on TFH cells.

Regulatory CD4⁺ T cells

Regulatory T (Treg) cells are most abundant in childhood where they keep the immune system in check during this period of recurrent, new antigen exposure. However, they also play an important role in the control of inflammation, allergy and tissue repair and regeneration. *Foxp3* is the master regulator of Treg cells. Mutation or deficiency of Foxp3 in both human and mice are associated with profound and lethal autoimmunity. Phenotypically, these cells express CD4, CD25 (IL-2 receptor α-chain) and low levels of CD127 (a component of the IL-17 receptor).

Broadly, there are two types of Treg cells, *thymic* or *central Treg* cells, which comprise the majority of Treg cells, and *peripheral* or *inducible Treg* cells. As discussed in the section on *T-cell Development*, maturing thymic T cells that react with self-MHC/peptide are deleted by negative selection. Inevitably, some self-reactive T cells will escape and these will be diverted into Treg differentiation. The exact developmental pathway of these cells is likely to depend on the signal strength between the TCR and presented self-peptide as well as availability of co-stimulatory signals.

In the periphery, mature CD4⁺ T cells are polarised to Treg cells by TGF-β, a critical cytokine required for Foxp3 induction. The subsequent survival and proliferation of these cells relies on IL-2, itself produced by activated CD4⁺ T cells, thus producing a negative feedback loop to control T-cell stimulation.

There are multiple ways in which Treg cells can suppress CD4⁺ and CD8⁺ T cells activation, proliferation and function, and activation of antigen-presenting cells. These include secretion of immunosuppressive cytokines (TGF-β and IL-10), compete for growth factors and engagement of MHC class II molecules, and cell–cell dependent suppression. As an example, upon antigen exposure, antigen-specific Treg cells are recruited to the site via chemokines, where they out-compete antigen-specific naive T cells. These Treg cells then downregulate dendritic cell function by directly reducing the expression of co-stimulatory molecules (CD80/CD86).

The role of co-stimulatory and inhibitory molecules

Whenever an immune effector cell recognises a potential antigen on a target cell, the decision as to whether or not the effector cell is activated to kill the target cell depends on the balance of activatory and inhibitory signals received by the immune effector cell. For B cells, this may be the balance between activatory and inhibitory FcγRIIb receptors. For T cells, the immunoglobulin superfamily and *tumour necrosis factor receptor superfamily* (*TNFRS*) are the two major classes that encode such molecules. Conventionally, T-cell activation is viewed in a stepwise manner. *Signal one* is triggered when a naive T cell recognises MHC-bound antigen on the surface of an antigen-presenting cell. CD4 or CD8 will bind MHC simultaneously to stabilise this interaction. To fully activate a naive T cell and initiate its differentiation and proliferation into effector cells, a second signal is required. *Signal two* can be provided by CD28 on T cells, which interacts with either CD80 or CD86 on the antigen-presenting cell to induce T-cell proliferation. To avoid uncontrolled cell proliferation, T-cell activation is accompanied by upregulation of the *cytotoxic T-lymphocyte-associated antigen 4* molecule (*CTLA-4*, CD152) on T cells, which is an inhibitory molecule that competes with CD28 for ligand binding.

Apart from CD28, which belongs the immunoglobulin superfamily, TNFRS members (e.g. OX40, 4-1BB, CD27) can replace CD28 as co-stimulatory molecules. Cytotoxic T cells are less dependent on CD28 but require signals from CD27 or 4-1BB (CD137). Similarly, there are a number of co-inhibitory molecules which contribute to control of T-cell activation such as programmed cell death protein 1 (PD-1), lymphocyte activation gene 3 (LAG-3) and T cell immunoglobulin and mucin-domain containing-3 (TIM-3).

A *third signal* is important for the differentiation of T cells into the defined subsets described in *Differentiation of primed T cells into effector cells*, to enable them to carry out specific tasks. As an example, exposure IL-17 will skew the antigen-experienced, activated T cell into a Th17 phenotype for tissue repair.

Natural killer cells

Unlike T and B cells, NK cells are able to kill infected or malignant cells without prior sensitisation. NK cell-killing is induced when a 'stressed cell' downregulates receptors that are normally expressed on its surface. Under a normal state, these receptors prevent NK cell-killing by binding to inhibitory NK receptors. As an example, MHC class I molecules on nucleated cells bind to inhibitory killer-cell immunoglobulin-like receptors (KIR) on NK cells to keep them in an inhibitory state. Downregulation of class I molecules, e.g. in tumour cells, leads

to loss of NK cell-inhibitory signalling and subsequent killing of the target cell. This is known as '*missing self*' recognition. Similar to cytotoxic T cells, NK cells trigger cell death through release of cytotoxic granules (granzymes and perforin) and death receptor pathways (Fas ligand/Fas receptor). NK cells are also able to modulate T- and B-cell responses through release of cytokines (IFNγ, TNFα) and chemokines (CCL3, CCL4).

NK cells can also be activated through other pathways. Stressed cells often upregulate new molecules on their surface e.g. MHC class I polypeptide-related sequence A or B (MICA/B), which are ligands for activatory receptors on NK cell (e.g. natural-killer group 2, member D [NKG2D]). Activation of the NK cell triggers cytotoxicity.

NK cells are conventionally recognised as $CD3^-$ $CD56^+$ cells. They can be further divided into cells that express low ($CD56^{dim}$) or high levels ($CD56^{bright}$) of CD56. The $CD3^-$ $CD56^{dim}$ population form the majority of peripheral blood NK cells whereas the $CD3^-$ $CD56^{bright}$ cells primarily reside in tissues and are more cytotoxic. As discussed, NK cells express a range of inhibitory and activating receptors and it is the balance of signals received through these molecules that determines whether the target cell will be recognised. Specifically, inhibitory signals include: (i) killer inhibitory receptors (KIRs) that bind to HLA-C or HLA-B alleles on the surface of the target cell and (ii) CD94–NKG2 heterodimers that bind to HLA-E. Activating receptors include: (i) activating forms of KIR molecules, whose ligands are uncertain at present, (ii) NKG2D, which binds to proteins such as MICA and ULBP expressed on cells under physiological stress and (iii) the activatory FcγR, FcγRIII (CD16).

HLA class I expression is often downregulated on the surface of cells following viral infection and is also a common feature of malignant cells. This provides some protection from recognition by $CD8^+$ T cells but renders the cell susceptible to lysis by NK cells. Thus, $CD8^+$ T cells and NK cells can be viewed as having complementary recognition systems based on the level of HLA class I on the target cell.

Natural killer T cells

Natural killer T (NKT) cells represent a small (<1%) population of peripheral blood T cells and appear to be positioned somewhere between conventional T cells and NK cells in that they express a TCR, but also a range of receptors typically associated with NK cells. Moreover, the TCR is invariant, with the same Vβ11Vα24 heterodimer being expressed on all cells. NKT cells recognise glycolipid antigens presented on the surface of non-polymorphic, MHC class I-like CD1d molecules. NKT cells can be subdivided into type 1 or type 2 NKT cells. Type 1 NKT cells recognise a prototypic glycolipid, α-galactosylceramide (α-GalCer), thought to originate from microbes found on marine sponges. In contrast, type 2 NKT cells have a broader lipid antigen profile and do not recognise α-GalCer.

NKT cells are similar to NK cells in that they are activated very early in an immune response. *In vitro* studies show that these cells can be polarised to produced cytotoxic or immunoregulatory cytokines, and contribute to anti-microbial and anti-tumour immunity.

The immune response in cancer and its therapy

The concept that the immune system is able to participate in the control and growth of cancer or '*immunosurveillance*', was suggested by Burnet and Thomas in 1957. However, it was not until the 1990s that incontrovertible evidence of immunosurveillance was demonstrated. A crucial piece of evidence arose with the generation of RAG-2 mice which lack T, B and NKT cells. Without a functioning adaptive immune system, these mice were more susceptible to development of carcinogen-induced sarcomas and epithelial tumours compared to animals with normal immune system. Immunosurveillance can be described in three different stages. The first is the *elimination* stage, where the immune system is ability to kill the tumour. However, if tumour cells survive this phase they enter into an *equilibrium* with the host, where the immune system is able to control but not fully eliminate the tumour. During this stage, the immune system inadvertently selects for resistant tumours capable of surviving continued immune attack. Finally, during the *escape* phase, the evolved tumour overcomes host immunity and grows in an uncontrolled tumour. As cancer arises as a result of failure of the host immune system, cancer immunotherapy rationalises that the immune system can be 'reawakened' to control the tumour.

Allogeneic stem cell transplantation, which relies on the anti-tumour effect from donor lymphocytes is the oldest form of immunotherapy and is discussed in more detail in Chapter 37. However, cancer immunotherapy did not really come of age until 1997, when the CD20 monoclonal antibody, rituximab, was approved for use in treatment of B-cell lymphoma. Rituximab provided the proof-of-concept that monoclonal antibodies can be used to reawaken the immune system. Here, rituximab binds to CD20 via its Fab domains and macrophages via Fc-FcγR interaction to kill lymphoma cells through ADCP (*Fc–Fc receptor-mediated interactions*). NK cell-mediated ADCC and complement-dependent killing have also been proposed, but as none of these mechanisms directly engage normal B or T cells, a memory response is rarely observed, and relapses occur in a significant proportion of patients. This in part, prompted researchers to focus on monoclonal antibodies which are T-cell antigens, in particular, those binding to co-stimulatory or co-inhibitory molecules (*The role of co-stimulatory and inhibitory molecules*). Of these, monoclonal antibodies targeting the T-cell co-inhibitory pathway or, PD-1/PD-L1 (*checkpoint inhibitors*)

have shown the most clinical efficacy. These antibodies either bind to 'exhausted' PD-1 expressing T cells or PD-L1 on macrophages or tumour, in the case of Hodgkin and primary mediastinal B-cell lymphoma, to disrupt negative feedback signalling into tumour-specific cytotoxic T cells, thereby allowing them to kill the tumour cells (see Chapter 6 for more detail). However, akin to CD20 monoclonal antibodies, the effects of PD-1 blockade are thought to be relatively short-lived as the exhausted T cells are transcriptionally hardwired into a distinct exhausted lineage and do not acquire a memory phenotype with treatment.

Significant advances in the TCR, its co-stimulatory receptors and genetic engineering have led to the development of artificial *chimeric antigen receptors* (CAR). This involves grafting the genetic sequence of antigen-binding domains of a monoclonal antibody (e.g. CD19) onto intracellular signalling domains (e.g. ζ chain of TCR molecule and 4-1BB signalling domains), and then transfecting this gene into lymphocytes (commonly T or NK cells) using a viral or non-viral vector. This redirects the specificity of the lymphocyte such that it is now able to kill target cells that express the target for the monoclonal antibody. The greatest success so far has been in the use of CD19-targeted CAR which is used in the treatment of B cell malignancy (see Chapter 6).

With the same purpose of redirecting T-cell specificity, bispecific antibodies can perform the same function. These are essentially monoclonal antibodies engineered to bind to two different targets e.g. CD20 on B cells and CD3 on T cells. In doing so, the bispecific antibodies direct T-cell cytotoxicity towards the CD20-expressing B cell.

Interpretation of blood lymphocyte counts

Blood provides the most accessible view of the lymphoid system, but it must be remembered that peripheral blood contains only around 2% of total body lymphocytes. The cells present in the blood are in transit and many are recirculating T and B lymphocytes that will pass rapidly into secondary lymphoid organs in less than 30 minutes.

The numbers of different lymphocyte subsets normally found in the blood of different age groups are given in Table 4.1. These numbers are derived from studies in which whole blood was labelled by fluorescent dye/monoclonal antibody conjugates, followed by red cell lysis and flow cytometry. When this method is used to measure the proportion of lymphocytes that belong to different subsets, much of the inter-laboratory variation that is observed in calculating absolute numbers of subsets can be attributed to the method of measuring the total white cell count and the percentage of lymphocytes. A wide range of results is to be expected between different individuals. The most consistent variation is seen in childhood, but from adolescence onwards age-related changes are small and there is also little difference in relation to ethnicity or gender.

Alteration of the lymphocyte count can result from an absolute change in the number of cells or alteration in the distribution of lymphocytes within tissues. Redistribution of lymphocytes accounts for much of the variation in lymphocyte subset numbers found in serial measurements within a healthy individual. Some of these changes in lymphocyte number follow a diurnal pattern, with peak levels at night and nadir in the morning; accordingly, time of sampling should be taken into account.

Table 4.1 Normal ranges for lymphocyte subsets in the blood.*

	0–2 months		2–3 months		4–8 months		1–2 years		2–5 years		5–12 years		Adults	
Percentile	*5*	*95*	*5*	*95*	*5*	*95*	*5*	*95*	*5*	*95*	*5*	*95*	*5*	*95*
Total lymphocytes	3.2	8.5	2.9	8.8	3.6	8.8	2.2	8.3	2.4	5.8	1.8	5.8	1.0	3.4
$CD3^+$ (all αβ and γδ T cells)			2.1	6.5	2.3	6.5	1.5	5.4	1.6	4.2	0.9	2.6	0.6	2.5
$CD4^+$ (class II MHC-restricted αβ T cells)	1.2	5.3	1.4	5.6	1.4	5.7	1.0	3.6	0.9	2.9	0.5	1.4	0.35	1.5
$CD8^+$ (class I MHC-restricted αβ T cells, some γδ T cells and NK cells)			0.7	2.5	0.7	2.5	0.6	2.2	0.6	1.9	0.4	1.2	0.23	1.1
CD4/CD8 ratio	1.1	4.5	1.1	4.4	1.1	4.2	1.0	3.0	0.9	2.7			0.66	3.5
$CD3^-$ $CD57^+$ or $CD56^+$ NK cells					0.3	0.7			0.2	0.6			0.2	0.7
$CD19^+$ or $s\kappa^+$ or $s\lambda^+$ total B cells					0.5	1.5			0.5	1.3			0.04	0.7

There is considerable variation in the normal ranges reported from different studies and this table is only intended to be illustrative.
* All values (except CD4/CD8 ratio) are $\times 10^9$/L.

Increased number of effector cells in the blood usually reflects an active immune response. Analysis of the phenotype of these effector cells provides some information on the type of immune response, especially in differentiating between cytotoxic and inflammatory $CD4^+$ T cells. Particularly in viral infections, this response may be of sufficient magnitude to cause a lymphocytosis. Some non-malignant causes of lymphocytosis are given in Table 4.2.

Redistribution of lymphocytes is probably the cause of the lymphocytosis seen in *Bordetella pertussis* infection. Although lymphocytosis is uncommon in bacterial infections, in children over the age of 6 months the second and third weeks of infection with pertussis are usually associated with a lymphocytosis in excess of 10×10^9/L (in some cases $>50 \times 10^9$/L). The lymphocytosis consists of small lymphocytes and is believed to be caused by a protein toxin from *B. pertussis* that prevents migration of lymphocytes across endothelium into tissue.

Acute infectious lymphocytosis is a benign disease, usually in children. In most cases, there are no symptoms, but in some there is fever and in a small proportion gastrointestinal symptoms. Increase in the size of secondary lymphoid organs, anaemia and thrombocytopenia are rare. There is an increased number of small lymphocytes, persisting for 3–7 weeks, with an average peak level of $30–40 \times 10^9$/L. This is usually associated with an eosinophilia (average 2×10^9/L), but the aetiology of the condition is unknown.

Some *lymphopenias* predominantly reflect redistribution rather than a depletion of total body lymphocyte numbers. A dramatic short-term lymphopenia is induced by corticosteroids. This causes the retention of lymphocytes in secondary lymphoid organs but these are released again after about 2 days and the blood lymphocyte count returns to near-normal levels. Endogenous secretion of corticosteroids during acute illnesses may be partly responsible for the lymphopenias often seen in conditions such as heart failure or pneumonia. In many other conditions, lymphopenia reflects an increased rate of death of lymphocytes and/or a reduction in their rate of formation. A normal absolute lymphocyte count can belie an underlying deficit of one or more lymphocyte subsets. This is often seen in HIV infection, when a severe deficit of $CD4^+$ T cells may be disguised by expansion of $CD8^+$ T cells.

Table 4.2 Non-malignant causes of lymphocytosis.

Viral infections
Infectious lymphocytosis, infectious mononucleosis, cytomegalovirus infection; occasionally rubella, hepatitis, adenoviruses, varicella, HIV, human herpesvirus 6, mumps, chickenpox, dengue
Bacterial infections
Pertussis; occasionally healing tuberculosis, brucellosis, secondary and congenital syphilis, cat scratch fever, typhoid fever, diphtheria
Protozoal infections
Toxoplasmosis; occasionally malaria
Other conditions
Serum sickness, allergic drug reactions, splenectomy, dermatitis herpetiformis, metastatic melanoma, hyperthyroidism, congenital adrenal hyperplasia

CHAPTER 5

The spleen

5

Catherine Hildyard[1] and Daniel Royston[2]

[1] Department of Haematology, Buckinghamshire Healthcare NHS Trust, UK
[2] Department of Haematopathology, Oxford University Hospitals NHS Foundation Trust, UK

The spleen is the largest secondary lymphoid organ, with diverse immunological functions in addition to its homeostatic role in the clearance of red blood cells. Splenic function and splenic tissue architecture are intimately related. Symptoms associated with splenic disorders may dominate the clinical picture, for example abdominal discomfort due to gross enlargement. This chapter will therefore review the basic structure and function of the spleen with emphasis on clinical considerations, before considering the spectrum of splenic disorders.

Structure and function of the spleen

The spleen lies in the left hypochondrium, with its long axis beneath the proximal half of the tenth rib. Its convex surface rests under the diaphragm, whereas the visceral surface is in contact with the stomach and left kidney, with the tail of the pancreas reaching the hilum on the medial side. The normal spleen weighs about 150–250 g, but there is considerable variation between normal individuals and at various ages in the same individual. At puberty, it weighs about 200–300 g but after the age of 65 years, this decreases to 100–150 g or less. In adults, its length is 8–13 cm, width 4.5–7.0 cm, surface area 45–80 cm^2 and volume less than 275 cm^3. Of note, up to 10% of people have accessory spleens, normally as a single piece of tissue that can be found in a variety of sites, either locally or more distantly in the abdomen. A spleen greater than 14 cm in cranio-caudal length is usually palpable (see below). It enlarges in a wide range of diseases and has been measured at more than 2 kg in some blood disorders.

The major functions of the spleen are: (i) filtration and quality control of red cells within the circulation, (ii) capture and destruction of blood-borne pathogens and (iii) generation of adaptive immune responses. In order to achieve these functions, the spleen has evolved a unique anatomical structure in which blood is filtered through two main systems. These consist of the white pulp (WP), concerned mainly with adaptive immunological function, and a red pulp (RP) which regulates the selection of red cells for re-entry into the circulation but also serves distinct immunological functions, particularly those of innate immune effector cells such as neutrophils, dendritic cells (DCs), monocytes/macrophages and gamma delta (γδ) T-cells. A major feature is the presence of both 'open' and 'closed' circulatory systems (see below).

The spleen is enclosed by a connective tissue framework that extends inwards to form a fibrous network. Blood enters the pelvis and the majority of terminal arterioles release their contents into an open network without traditional endothelial linings within the RP, before reentering the closed venous system (see below). There is no afferent lymphatic to the spleen and the efferent lymphatic system leaves along the route of the splenic vein. The spleen contains a large amount of lymphoid tissue that is mostly concentrated in concentric rings around the arterioles of the WP. This WP does not contain a capsule to separate it from the RP but instead there is a cellular border (perifollicular zone) largely comprising innate immune cells.

Splenic blood flow and the red pulp

The circulation within the spleen is illustrated in Figure 5.1. Blood is carried to the spleen via the splenic artery, which branches into the trabecular arteries and then arborises in a pattern that lacks

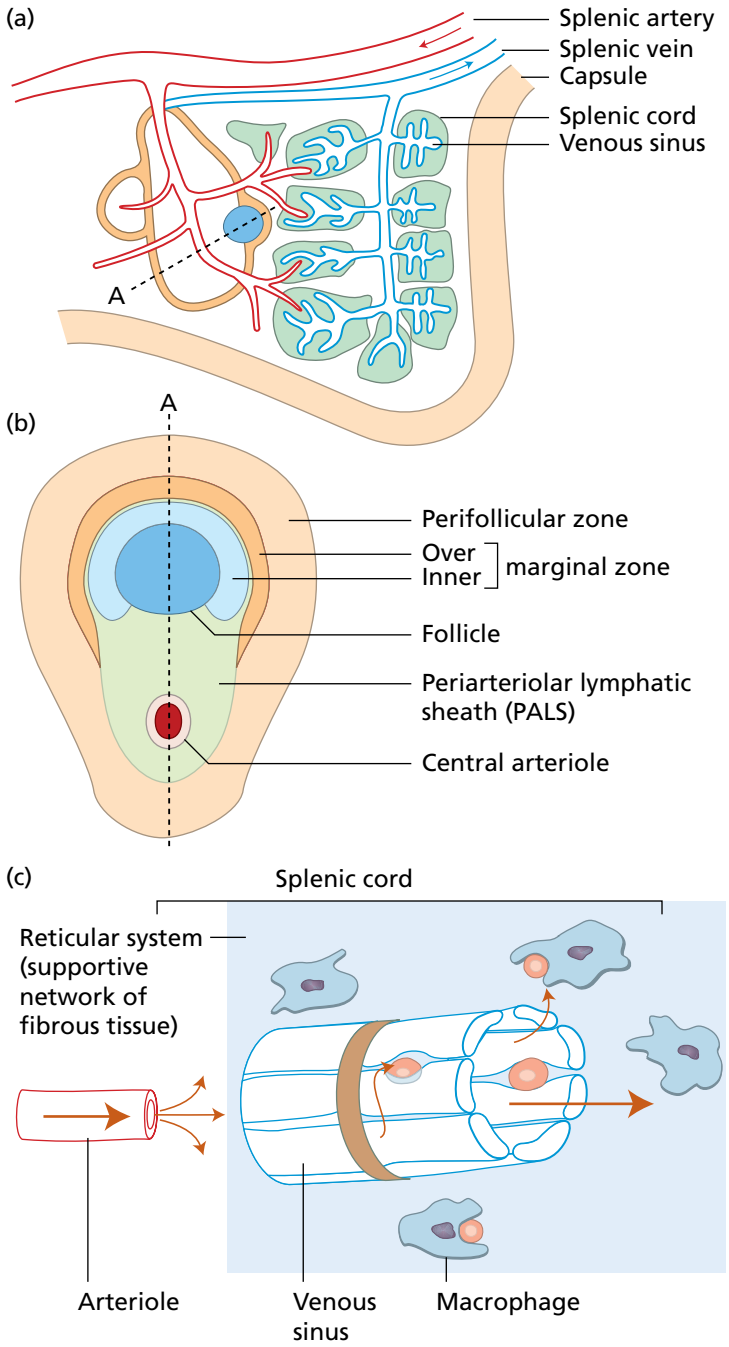

Figure 5.1 The vascular and lymphatic organisation of the spleen. (a) Schematic representation of blood flow in the spleen. Blood enters through the splenic artery and then breaks up into splenic arterioles. The white pulp is an aggregation of lymphoid tissue around these vessels. The arterioles then open into splenic cords lined with macrophages. Blood must then reenter the circulation by passing into a venous sinus. (b) Cross-section of white pulp at section A in (a). The central arteriole is surrounded by a periarteriolar lymphoid sheath of T-lymphocytes and occasional follicles that are rich in B-cells. The marginal zone is divided into an inner and outer zone around which there is a large perifollicular zone. (c) Schematic representation of the organisation of the red pulp. Blood cells are released by a splenic arteriole into a reticulum-lined splenic cord. Red cells that have flexible membranes are able to enter the venous sinus by passing through gaps in the endothelial lining. Cells that are unable to achieve this are 'filtered' from the blood through ingestion by macrophages (Source: Mebius and Kraal (2005). Reproduced with permission of Nature Publishing.)

interarterial connections and thus effectively generates end arteries. The terminal arteries acquire a coaxial sheath of lymphocytes containing lymphoid follicles and this together constitutes the WP (see below). These terminal arteries then split into many arterioles and capillaries, some of which terminate in the WP (perifollicular zone), while others go on to enter the RP.

In the RP, there are two major forms of blood circulation: a closed system, typical of the rest of the vascular system, in which arteries and veins communicate through endothelial-lined vessels, and an open circulation, in which arterioles terminate in free endings on splenic cords (also known as the cords of Billroth) and from which cells must subsequently cross a sinusoidal endothelial layer to reenter the circulation. The cords consist of a fibroblast-like reticular meshwork containing numerous macrophages and monocytes and they are critical to the filtration function of the spleen. Red cells transiting the cords must gain entry to a venous sinus if they are to reenter the systemic circulation. The sinuses are lined by endothelial and adventitial cells with a basement membrane and possess narrow interendothelial spaces through which flexible red cells

may pass. The passage of cells into the sinuses is controlled by their ability to squeeze through the interendothelial spaces, assisted by contraction of the reticular cells. Red cells with inflexible membranes, mostly elderly, are not able to pass through these gaps and are ingested by macrophages in the cords. The great majority of blood flows in this unique open system and only a minority of arteries connect directly to the trabecular vein in a typical closed vascular system.

There is thus both a rapid and a slow transit component in the splenic circulation. The rapid transit (closed circulation) is of the order of 1–2 min, whereas the slow transit (open circulation) has a circulation time of 30–60 min or even longer. In normal subjects, the blood flows through the spleen at a rate of about 5% of blood volume per minute, so that each day the blood has repeated passages through the spleen. During the flow, by a process called plasma skimming, the plasma and leukocytes pass preferentially to the white pulp, while the red cells remain in the axial stream of the central artery.

Blood pooling within the spleen

The normal red cell content of the spleen is 30–70 mL, which represents less than 5% of the total red cell mass. When the spleen is enlarged, there is expansion of the vascular bed. This results in a considerable pool with a high haematocrit and only a slow exchange of red cells with the general circulation. In states of massive hypersplenism, such as myelofibrosis, as much as 40% of the red cell mass may be pooled in the spleen. This pooling will functionally exclude a relatively large volume of red cells from the main arteriovenous circulation, and thus be an important cause of anaemia.

The normal spleen contains a reservoir of granulocytes that is in dynamic equilibrium with the circulating population. It represents 30–50% of the total marginating pool, with a mean transit time of about 10 min. Splenic sequestration of granulocytes is thought to be responsible for the neutropenia that often occurs in patients with splenomegaly. Platelets have also been shown to be significantly reservoired in the spleen and are rapidly interchangeable with the circulation. In normal subjects, 20–40% of the total platelet mass is pooled in the spleen, where they will typically spend up to one-third of their lifespan. The pooling and temporary sequestration that increase when the spleen is enlarged should be distinguished from the destruction of platelets in the spleen that occurs in many cases of thrombocytopenia.

Role of the spleen in ensuring quality control of red cells

The spleen is the body's largest filter of blood and a major function of the spleen is the quality control of red cells. Red cells are normally flexible and capable of transiting the splenic cords and entering the venous circulation, whereas cells with abnormal membranes, or those with inclusions that render them relatively inflexible, remain in the cords where they are repaired or destroyed. Sequestration is a reversible process whereby cells are temporarily trapped by adhesion to the reticular meshwork of the cords on their passage through the spleen. Phagocytosis is the irreversible uptake by macrophages of particulate matter, non-viable cells and viable cells that have been damaged by prolonged sequestration, antibody opsonisation or loss/alteration of surface CD47. In the presence of metabolically active macrophages, the densely packed red cells are deprived of oxygen and glucose. This stress increases membrane rigidity and reduces the natural deformability of the biconcave cell. This effect is particularly marked if there is an underlying abnormality of the red cell metabolic system, if cells are coated with antibodies or if they are fragmented or misshapen in other ways. In these situations, they remain trapped in the cord space and undergo phagocytosis. Siderotic granules, Howell–Jolly (DNA) bodies, nuclear remnants and Heinz bodies are removed by culling or pitting during temporary sequestration. After removal of the inclusions, the red cells return to the circulation. Reticulocytes may be retained in the splenic cords for a considerable proportion of the 2–3 days of their maturation period and during this time they lose their intracellular inclusions, alter the lipid composition of their surface and become smaller in size. It is not clear whether the spleen has any special role in the removal of normal aged red cells, and it seems more likely that such cells are removed by the general reticuloendothelial system, which includes both the spleen and the bone marrow.

Immunological function of the spleen

The spleen is the largest single accumulation of lymphoid tissue in the body and is estimated to contain 25% of the T-lymphocyte pool and 10–15% of the B-lymphocyte pool. T-cells, mainly of the $CD4^+$ subtype, are found predominantly in the periarteriolar lymphatic sheath, whereas B-cells are located in the follicles and marginal zones of the white pulp. There is also an abundance of macrophages and dendritic cells and the architecture is maintained through a complex anatomical organisation that includes a tubular conduit system that transports a range of chemokines and other molecules. The spleen has a unique role in acting as an immunological filter for the bloodstream. Lymphocytes and dendritic cells enter the splenic tissue by initial entry into the marginal zone and from there they can pass into the periarteriolar lymphatic sheath by crossing a lining of sinus cells. There is a constant flow of both T- and B-cells through the spleen, with T-cells typically staying in the spleen for a few hours, whereas B-cells stay in the follicle and marginal zone for prolonged periods. It remains unclear how lymphocytes exit the white pulp.

Of interest is the ability of the spleen to engage in both innate and adaptive immune responses. The marginal zone acts as a site for both of these processes, whereas the WP and RP are

largely restricted to adaptive and innate immune responses, respectively. Blood is filtered directly into the perifollicular zone, where the predominant cell populations are macrophages and marginal-zone B-cells. The macrophages express a range of pattern-recognition receptors that recognise bacterial molecules such as lipopolysaccharide. These cells thus act as an important filter for the clearance of blood-borne pathogens. The marginal-zone B-cells are a unique B-cell subset that bridges the innate and adaptive immune responses. They are able to recognise bacterial pathogens without the help of T-cells. This T-cell-independent antibody response consists largely of low-affinity IgM and can play an important role in limiting bacterial replication. In addition, these B-cells can act as antigen-presenting cells capable of migrating to the periarteriolar lymphatic sheath, where they present antigen to T-cells and facilitate the production of high-affinity IgG antibodies. B-cell maturation and clonal expansion occur in the follicles, with plasmablasts maturing into plasma cells that subsequently migrate to the RP, where they are retained through CXCR4/CXCL12 interactions.

The T-cell-independent antibody response outlined above produces a spectrum of low-affinity IgM antibody clones that provide a first line of immune defence against bacterial sepsis, especially from *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis*. The spleen also appears to act as a defence against viral infections and intraerythrocytic parasitic infections such as *Plasmodium* and *Babesia*. The important role of the spleen in this regard is revealed by immunisation of splenectomised individuals with T-independent antigens, where antibody titres are typically only 10% of those seen in control subjects. Given these unique features, it is no surprise that splenectomy is associated with a degree of relative immunosuppression to encapsulated bacterial species.

Splenomegaly and hypersplenism

While splenomegaly refers to an anatomical increase in spleen size, hypersplenism refers to a functional syndrome characterised by an enlarged spleen; reduction of one or more cell lines in the peripheral blood; and hyperplastic cellularity of the bone marrow. Unsurprisingly, therefore, many of the underlying pathologies are common to both splenomegaly and hypersplenism.

Spleen size

The spleen is palpated in the supine or right lateral decubitus position. Light fingertip pressure is applied below the left costal margin during deep inspiration. A palpable spleen usually implies splenomegaly, although a normal-sized spleen may sometimes be palpable in children, adolescents and occasionally thin adults. In most adults, the spleen becomes palpable when its size is increased by around 40%. While it is an important clinical sign, identification of splenomegaly by means of a physical examination of the abdomen may be unreliable for a number of reasons. A mildly enlarged spleen may not extend far beyond the rib cage. Conversely, a massively enlarged spleen may extend so far into the pelvis that it is difficult to palpate its lower edge. Abdominal obesity or tense musculature may also make the spleen more difficult to palpate.

More reliable assessment for the extent of splenomegaly, and assessment for focal lesions is obtained by radiology through ultrasound, magnetic resonance imaging (MRI) and computed tomography (CT). The choice of imaging modality will depend on the reason for assessment and patient characteristics, with the calculated spleen size varying somewhat between methods. A deviation of 10–20% from the normal range is not considered significant unless there is a trend over time.

Causes of splenomegaly

Pathological enlargement of the spleen can occur in a wide range of conditions. The mechanism of enlargement varies according to the underlying aetiology, for example; reactive increase in WP in inflammation and infection; congestive expansion of RP with increased blood pool, cellular infiltration or extramedullary haemopoiesis. The relative incidence of each cause of splenomegaly is subject to geographical variation. In Western countries, leukaemia and lymphomas, myeloproliferative disorders, haemolytic anaemias, infectious mononucleosis and portal hypertension account for most cases. In tropical countries, the major causes are parasitic infections such as malaria, leishmaniasis and schistosomiasis. The more important haematological and non-haematological (systemic) causes of splenomegaly are provided in Table 5.1, some of which are discussed in more detail below.

Extramedullary haemopoiesis

Together with the liver, the spleen has a transient role in haemopoiesis *in utero* from the third month, continuing until birth (Chapter 31). From about 20 weeks gestation, the bone marrow becomes a site of haemopoiesis and this increases rapidly during the last trimester of pregnancy, whereas haemopoietic activity in the spleen disappears. There is no evidence for a specific inhibitor of splenic haemopoiesis and the spleen remains a potential site for blood production in the adult, particularly for the maintenance of erythropoiesis. This occurs during pathological states and the development of such extramedullary haemopoiesis after birth can occur as a compensatory erythroblastic hyperplasia in disorders of severe anaemia such as chronic haemolysis, megaloblastic anaemia, transfusion-dependent thalassaemias and some haemoglobinopathies e.g. HbC, HbE, HbSC and HbS/beta thalassaemia (HbSS is usually associated with splenic atrophy in adults although the spleen may be enlarged in children).

Table 5.1 Causes of splenomegaly.

Haematological
Acute leukaemia
Chronic myeloid leukaemia*
Chronic lymphocytic leukaemia*
Malignant lymphomas*
Myelofibrosis*
Polycythaemia vera*
Essential thrombocythaemia (some cases)
Hairy cell leukaemia*
Gaucher disease*, Niemann–Pick disease, Langerhans cell histiocytosis X
Primary splenic hyperplasia (i.e. unknown cause)
Thalassaemia
Sickle-cell disease, HbSC disease and other haemoglobinopathies**
Haemolytic anaemias*
Megaloblastic anaemia (rare)
Systemic
Acute infections: septicaemia, typhoid, infectious mononucleosis, cytomegalovirus
Subacute and chronic infections: tuberculosis, syphilis, brucellosis, subacute bacterial endocarditis, HIV
Tropical parasitic infections (tropical splenomegaly*): malaria*, leishmaniasis*, schistosomiasis*, trypanosomiasis
Collagen diseases: systemic lupus erythematosus, rheumatoid arthritis (Felty)
Sarcoidosis
Amyloidosis
Cysts
Haemangiomas
Carcinoma (rare)
Congestive splenomegaly
Portal hypertension*
Splenic/portal/hepatic vein obstruction
Congestive cardiac failure

* Splenomegaly is a frequent finding with these conditions.
** Sickle cell disease often causes an atrophic spleen later in life due to infarction.

Alternatively, extramedullary haemopoiesis may arise as a more generalised haemopoiesis often seen in primary myelofibrosis or other malignant disorders in the bone marrow, particularly those inducing significant marrow fibrosis. The mechanisms involved in this myelofibrosis-related extramedullary haemopoiesis are poorly understood; it is unclear if pluripotent stem cells are present in the spleen or migrate from the bone marrow. It is even conceivable that changes in the stroma or clonal haemopoietic stem cells driving the underlying pathological process are involved in favouring initiation of the extramedullary haemopoietic process.

Haemolytic anaemia and immune cytopenias

Haemolytic anaemias can be either predominantly intravascular or extravascular. In extravascular haemolytic anaemias such as warm autoimmune haemolytic anaemias, haemolytic transfusion reactions and red cell membrane defects such as hereditary spherocytosis and hereditary elliptocytosis, there is excess removal of red cells by the spleen and rest of the reticularendothelial system. This drives splenic enlargement through increased macrophage and cytotoxic T-cell proliferation and trapping of spherocytes within splenic sinusoids. Enhanced opsonisation of neutrophils or platelets, due to autoantibody production in immune thrombocytopenia purpura (ITP) and autoimmune neutropenia, also drives immune cell expansion of the red pulp.

Infections

Splenomegaly driven by infectious aetiologies (see Table 5.1) occurs due to a variety of factors including direct infiltration by the infective organism, reactive lymphoid change, and expanded phagocytic activity.

Infiltration by haematological malignancies

A comprehensive description of the various haematological malignancies that can infiltrate the spleen is beyond the scope of this chapter. However, some of the more commonly encountered and clinically important entities will be briefly considered.

Non-Hodgkin lymphoma

Non-Hodgkin lymphoma (NHL) infiltration of the spleen most commonly occurs in the setting of systemic lymphomatous spread. While NHL of various types can involve the spleen, it is particularly frequent in low-grade B-cell lymphomas. True primary splenic lymphoma in which disease is restricted to the spleen or splenic hilar lymph nodes is rare (accounting for less than 1% of all lymphomas). Dominant, although usually not isolated, splenic involvement is most frequently seen with splenic marginal zone lymphoma (SMZL). Small B-cell lymphomas including CLL/SLL, PLL, SMZL, LPL, HCL, FL and MCL typically cause fairly uniform nodular expansion of the WP with variable RP infiltration, while the formation of single or multiple discrete masses is more typical of DLBCL. The specific features of splenic involvement by T-cell and NK-cell malignancies are not well described, partly reflecting their rarity. However splenic involvement is characteristic of certain T-cell lymphomas with distinct clinicopathological characteristics. Hepatosplenic T-cell lymphoma and T-PLL both result in significant splenomegaly with diffuse infiltration of the RP but relative preservation of the cord and sinus architecture. In hepatosplenic T cell lymphoma (HSTL), there is marked reduction or near complete loss of the WP with variable WP involvement in T-PLL. T-LGL is also characterised by splenic involvement with

RP infiltration, but the WP is typically spared and patients often have less significant splenomegaly.

Hodgkin lymphoma

Although splenic involvement by classical Hodgkin lymphoma (cHL) is fairly common, primary disease is extremely rare. Splenic infiltrates are typically nodular and frequently present as distinct masses that may be multiple or solitary. As at other nodal sites, cHL in the spleen may be associated with prominent sarcoid-like granulomas and careful histological and immunophenotypic investigations is essential when cHL is suspected. Of note, granulomas in the absence of detectable cHL may be found in patients with an established cHL diagnosis.

Myeloid stem cell disorders

Although leukaemic disorders invariably involve the spleen, with neoplastic cells typically confined to the RP cords with secondary involvement of the sinuses, the extent of splenic involvement depends upon the type and duration of disease. Some chronic stem cell disorders frequently result in hypersplenism secondary to significant splenomegaly, but this is less commonly seen in de novo or rapidly emerging acute leukaemia. Splenomegaly in myeloproliferative neoplasm (MPN) is particularly well recognised with sudden changes in splenic size often a sign of acute transformation, classically blast crisis in chronic myeloid leukaemia (CML). Splenomegaly in PV reflects the stage and severity of disease, with intense RP congestion and cordal macrophage proliferation in the erythrocytotic phase of disease, followed by variable amounts of extramedullary haemopoiesis in the spent phase which is characterised by significant bone marrow fibrosis. Splenomegaly is most striking in primary myelofibrosis (PMF), driven by extramedullary haematopoiesis and may be a dominant presenting clinical feature at diagnosis. The splenic changes in ET are less well described and typically less pronounced than PV or PMF, with sudden or progressive enlargement suggestive of fibrotic progression or acute/blast transformation.

Infiltration by non-haematological malignancies and tumour-like lesions

The most common neoplasms of the spleen are vascular tumours. Splenic haemangiomas are relatively common benign vascular proliferation forming single or multiple tumour nodules; they are typically asymptomatic and discovered as incidental findings with only a minority resulting in splenomegaly or pain. Littoral cell angiomas are unique to the spleen and result in mild to moderate splenomegaly; they are regarded as benign with most cases successfully treated by splenectomy. Splenic angiosarcomas are aggressive, high-grade malignant neoplasms that typically present with splenomegaly, abdominal pain or splenic rupture. The prognosis is generally very poor, particularly when widely disseminated, with only rare cases of cure reported following splenectomy. Other splenic vascular proliferations or lesions with a prominent vascular component include lymphangioma, sclerosing angiomatoid nodular transformation of the spleen (SANT), peliosis and splenic hamartoma. Perhaps surprisingly, carcinoma of the spleen from metastasis is relatively rare although reports of microscopic tumour cell metastasis suggest their frequency may be underestimated by imaging studies. Carcinomas of the breast, stomach, lung and ovary are amongst the most common primary tumours to involve the spleen. Primary sarcomas of the spleen, with the exception of angiosarcoma, are extremely uncommon. Inflammatory pseudotumour-like dendritic cell sarcoma is peculiar to the spleen and liver, presenting with fever and abdominal pain and sometimes associated with other malignancies. This spindle cell tumour is positive for Epstein-Barr Virus (EBV) and expresses follicular dendritic cell markers; splenectomy is typically curative.

Though rare, patients with lysosomal storage diseases often demonstrate evidence of splenic involvement. Gaucher's and Niemann-Pick diseases are the most common storage diseases encountered in the spleen with hypersplenism sometimes resulting from significant splenomegaly. The pattern of RP expansion by numerous histiocytes is not specific for any lysosomal storage disorder. Other non-malignant causes of focal splenic lesions include abscesses, typically resulting from infective endocarditis or haematogenous seeding from other sites such as the respiratory or gastrointestinal tract or splenic infarcts. Splenic thromboemboli may be associated with atrial fibrillation; valvular heart disease or atrial septal defect; microvascular thrombi in sickle cell disease; or prothrombotic states such as antiphospholipid syndrome.

Vascular congestion

The spleen can become engorged with blood when there is increased vascular pressure secondary to parenchymal liver disease or congestive cardiac failure. The pathological mechanisms driving vascular congestion in parenchymal liver disease are multi-factorial and include portal congestion, altered haemodynamics and inflammatory mediators. Vascular obstruction due to portal, hepatic or splanchnic vein thrombosis can also cause splenic enlargement due to increased pressure. Vaso-occlusion in children with sickle cell disease can cause such rapid and profound engorgement of the spleen as to induce haemodynamic compromise. This is typically not seen in adults with sickle cell disease as the spleen is more frequently atrophic.

Diagnostic evaluation of splenomegaly and splenic lesions

Radiological or clinical evidence of splenomegaly should prompt careful evaluation of patients and consideration of the pathological processes/disorders summarised above. Clinical assessment for symptoms and risk factors along with appropriate laboratory

investigations (peripheral blood smear, viral serology, autoimmune serology, enzyme analysis, genetic studies, etc.) should be determined and prioritised based upon the initial differential diagnosis. Further imaging may be helpful, particularly for focal lesions. Abscesses, infarcts and cysts, can often be accurately characterised on CT and/or MRI. Contrast-enhanced CT/MRI is useful for suspected vascular lesions. PET-CT may be used to predict the likelihood of malignancy for solid lesions; PET avid lesions are more likely malignant or contain granulomas.

Biopsy of the spleen is now rarely performed due to the organ's extensive vascularity and the consequent high risk of bleeding. Even for those patients with suspected malignant infiltration of the spleen, alternative sites for tissue biopsy are preferable. In cases of suspected haematological malignancy, bone marrow aspirate and trephine, lymph node biopsy or flow cytometry of peripheral blood are often sufficient for diagnosis. Where other alternative modalities have failed or there is no other potential site for tissue diagnosis, CT-guided biopsy of focal lesions may be indicated. Diagnostic splenectomy is usually reserved as a last resort for patients in whom a diagnosis cannot be reached in any other way, malignancy is suspected, and tissue diagnosis is essential to guide management. In some cases, where there is diagnostic uncertainty and the patient does not need urgent treatment, such as for suspected asymptomatic low-grade lymphoproliferative disorder, expectant management potentially with serial imaging may be appropriate.

Management of splenomegaly

Appropriate management of splenic enlargement depends on the underlying cause, with treatment potentially reducing spleen size and leading to symptomatic improvement.

Splenectomy

Splenectomy is rarely performed for symptomatic splenomegaly as other measures are often effective, and it is associated with an increased risk of infection and thrombosis, as well as entailing perioperative risk. However, it may be appropriate in some specific cases where other interventions have been unsuccessful or are inappropriate, such as hereditary spherocytosis or immune thrombocytopenia or even occasionally in malignant conditions such as SMZL where the bulk of the tumour population is located in the spleen. It may also sometimes be used for diagnosis of unexplained splenomegaly, as described above. The role of splenectomy in the individual diseases described above is discussed in the relevant chapters. For elective splenectomy, a laparoscopic approach is preferred where possible because of reduced morbidity and mortality.

Splenectomy is now most commonly performed in the emergency setting following splenic rupture. Splenic injury is common after blunt abdominal trauma and must be assessed in order to consider the need for emergency splenectomy. Focused abdominal sonography for trauma (FAST) is a form of ultrasound that is rapid and particularly useful in patients who are haemodynamically unstable. Abdominal CT remains the investigation of choice when the pulse and blood pressure remain stable. Low-grade injury may be managed conservatively, and angioembolisation can be very useful for controlling haemorrhage while preserving splenic function (Figure 5.2). Atraumatic splenic rupture may also occur but is rare, most commonly resulting from neoplastic haematological infiltration, infection (especially EBV) or drug/treatment-related (e.g. granulocyte colony-stimulating factor).

Where splenectomy is contemplated in a planned capacity, the preoperative evaluation of the patient requires close co-operation between surgeon and haematologist. Vaccinations should be performed and it is valuable to check liver function, obtain appropriate imaging and potentially evaluate the hepatic and portal blood flow by Doppler ultrasound examination. Haemoglobin and platelet counts should be optimised which may be particularly challenging in cases of autoimmune cytopenias and may require pre-operative interventions such as intravenous immunoglobulin.

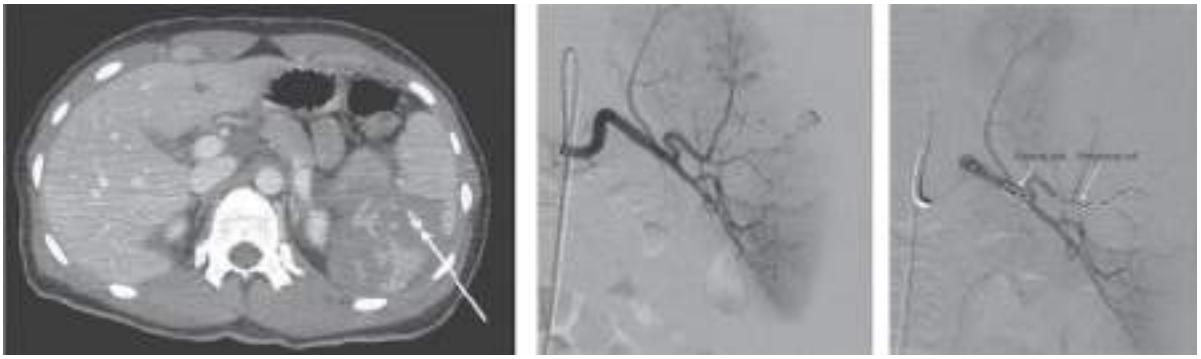

Figure 5.2 (a) Computed tomogram showing splenic injury (Organ Injury Scale grade 4) with contrast extravasation (white arrow). (b) Angiography (i) with signs of ongoing bleeding before embolisation and (ii) after distal and proximal embolisation (Source: Skattum *et al.* (2012)/Reproduced with permission of John Wiley & Sons.)

In some cases, simultaneous cholecystectomy may be performed if there is a history of gallstones which can develop as a complication of chronic haemolysis.

Complications of splenectomy

Bleeding can be a complication after surgery and usually comes from the peritoneal and diaphragmatic surfaces rather than from identifiable blood vessels. Frequently, no specific bleeding source is found at re-operation. Venous thromboembolism (VTE) risk is increased post splenectomy and is likely to be multifactorial, including thrombocytosis, which peaks at round 7–12 days post splenectomy and persists indefinitely due to alterations in the vascular anatomy and changes in coagulation parameters. The risk of VTE is particularly high in patients with hereditary stomatocytosis and splenectomy is avoided for this reason. Close attention should be paid to VTE prophylaxis, evaluation of signs and symptoms suggestive of VTE, and patient education on discharge.

There is some evidence of an association between cardiovascular events and pulmonary hypertension and splenectomy. However, convincing evidence for a causal relationship is lacking. Indeed, pulmonary hypertension may in fact be secondary to chronic haemolysis for which the splenectomy was originally performed. Some case series have reported an increased risk of cancer following splenectomy, although such an association has not been consistently reproduced. Accessory splenic tissue, an anatomically separate collection of splenic tissues thought to arise following failed tissue fusion during embryogenesis, may be overlooked at operation; after splenectomy, it may enlarge and cause a recurrence of the symptoms for which the original operation was performed.

Post splenectomy sepsis

Splenectomy increases the risk of developing an overwhelming bacterial infection, (sometimes termed *overwhelming post splenectomy sepsis*; OPSS), which in historical cohorts can be fatal in up to 50% of patients. The onset is often acute and fulminant with a non-specific presentation that may include fever, muscle ache, chills, sore throat, diarrhoea or vomiting. Septicaemia or meningitis can be seen, and features such as disseminated intravascular coagulation and hypoglycaemia may develop rapidly. *S. pneumoniae* is the most common cause and bacteraemia can be so severe that cocci are seen directly in stained blood films. *H. influenzae*, *N. meningitidis* and *Escherichia coli* may also be implicated. The underlying cause is a defective reticuloendothelial clearance of encapsulated organisms, combined with delayed and impaired development of the IgM antibody response. Infection by encapsulated bacteria is therefore the greatest concern, although infections are not limited to encapsulated organisms. The risk of infection is partially correlated with the underlying disease for which splenectomy was performed (see Figure 5.3).

Infection may occur at any age, but children are at increased risk, particularly within the first few years of life. Splenectomy should therefore be postponed until after the age of 5 years of age wherever possible. The prevention of fatal post splenectomy sepsis has four components:

- Patient education
- Vaccination
- Antibiotic prophylaxis
- Early empirical use of antibiotics for febrile episodes.

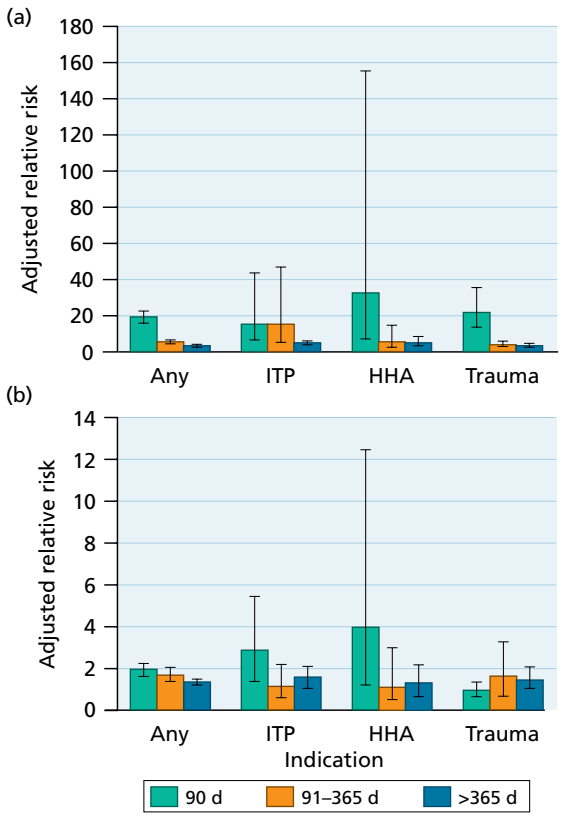

Figure 5.3 Relative risk of hospital contact for any infection in splenectomised patients according to the time since splenectomy. Data is based on a Danish population-based study (Thomsen *et al.* 2009). Results are shown for: any indication of splenectomy, immune thrombocytopenia, hereditary haemolytic anaemias and trauma, in comparison with age- and sex-matched subjects from the general population (a) and up to five matched-indication non-splenectomised patients (b) (Source: Rodeghiero and Ruggeri (2012). Reproduced with permission of John Wiley & Sons.)

Patient education

Education of patients or parents is perhaps the most important aspect of management, to ensure that they are aware of the possibility of infection and know how to react appropriately. Patients should be advised to carry a card or bracelet to alert health professionals to the potential risk of overwhelming infection. When travelling to tropical areas, asplenic patients are at

increased risk of severe *Plasmodium* infection and must adhere scrupulously to antimalarial prophylaxis. Patients should also be advised that severe infection can occur after animal bites, typically due to *Capnocytophaga canimorsus* which is a commensal bacterium of cats and dogs.

Vaccination

When splenectomy is being planned the patient should be considered for immunisation against pneumococcus, *H. influenzae* type B (Hib) and meningococcal infection. To obtain the maximum immune response, patients should be immunised at least 2 weeks and ideally 10–12 weeks before splenectomy. Vaccines, including live inoculations, can be given safely after splenectomy and appropriate vaccines that were not administered before splenectomy should be given 14 days post splenectomy. One approach to vaccine policy for hyposplenic patients is shown in Table 5.2.

S. pneumoniae is the major concern and there are two major forms of vaccine available. Polyvalent polysaccharide pneumococcal vaccines (PPV) include a wide range of different serotypes, typically at least 23, but their efficacy in hyposplenic individuals is poor. Conjugated vaccines consist of a bacterial polysaccharide linked (conjugated) to a carrier protein and thereby enlist a T-cell immune response. The 13-valent pneumococcal conjugate vaccine (PCV13) is more effective than PPV in hyposplenic and asplenic patients, although the breadth of serotype coverage is not as great. The optimal schedule of vaccination with both subtypes is not yet known and, in some countries, PCV vaccines are not recommended, whereas others suggest a schedule such as PCV13 followed 2 months later by PPV23. The recommendations for vaccination in children under 5 years will depend on the prior vaccination history (Table 5.2). Annual influenza vaccine is also recommended for asplenic or hyposplenic patients, primarily as influenza may predispose patients to secondary bacterial infection.

Antibiotics

Long-term antibiotic prophylaxis should also be taken into consideration but there are some concerns about antibiotic resistance especially if there is poor compliance. There is a

Table 5.2 Suggested schedule for vaccine immunisation in individuals with asplenia or splenic hypofunction.

Age at which asplenia or splenic dysfunction acquired	Vaccination schedule*		
	Month 0	**Month 1**	**Later**
Under 2 years	Complete according to national routine childhood schedule, including booster doses of Hib/MenC and PCV13	A dose of MenACWY conjugate vaccine should be given at least 1 month after the Hib/MenC and PCV13 booster doses	After the second birthday, one additional dose of Hib/MenC and a dose of PPV should be given
Over 2 years and under 5 years (previously completed routine childhood vaccinations with PCV7)	HibMenC booster PCV13	MenACWY conjugate vaccine	PPV (at least 2 months after PCV13)
Over 2 years and under 5 years (previously completed routine childhood vaccinations with PCV13)	HibMenC booster PPV	MenACWY conjugate vaccine	
Over 2 years and under 5 years (unvaccinated or previously partially vaccinated with PCV7)	HibMenC vaccine First dose of PCV13	MenACWY conjugate vaccine	Second dose of PCV13 and then PPV (at least 2 months after PCV13)
Over 5 years (regardless of vaccination history)	HibMenC vaccine PVV	MenACWY conjugate vaccine (boosters every 5 years)	

* Where possible, vaccination course should ideally be started at least 2 weeks before surgery or commencement of immunosuppressive treatment PCV, pneumococcal conjugate vaccine; PPV, pneumococcal polysaccharide vaccine.
(*Source:* Davies *et al.* (2011) *Br. J. Haem.* **155**: 308–17. Reproduced with permission of John Wiley & Sons.)

relatively poor evidence base for this approach in the era of pneumococcal vaccination and different regimens are sometimes advised. The British Society for Haematology advises prophylaxis for patients at high risk of infection. These are defined as:

- Age less than 16 years *or* greater than 50 years
- Inadequate serological response to pneumococcal vaccination
- History of previous invasive pneumococcal disease
- Splenectomy for underlying haematological malignancy, particularly in the context of ongoing immunosuppression.
- The immediate postoperative period is when risks are highest.

Those at lower risk should be advised about the risks and benefits of lifelong antibiotics and may wish to discontinue them. Oral penicillin 250 mg b.d. is usually recommended, and patients who are allergic to penicillin should be offered erythromycin 250 mg b.d. Pre-emptive antibiotics should be given to patients so that they may start them if they develop a fever or infective symptoms such as pyrexia, malaise or shivering and cannot get to hospital within 2 hours. In all such cases, the patient should also seek immediate medical help. Signs of systemic infection in an asplenic individual should be considered a medical emergency and most patients should be admitted to hospital and started on broad-spectrum antibiotics after cultures have been taken, pending specific antibiotic sensitivity results.

Changes in peripheral blood following splenectomy

Red cell changes

The changes in red cell morphology include the presence of Howell–Jolly bodies, siderotic granules and target cells. In a proportion of subjects, irregularly contracted or crenated acanthocytic forms are also a feature (Figure 5.4). There is usually an increase in the number of reticulocytes in the circulation and occasionally isolated erythroblasts are seen. However, there is no alteration in red cell survival.

Leucocyte changes

After splenectomy, there is a rise in the total leucocyte count. A neutrophil leucocytosis in the immediate postoperative period is later replaced by a significant and permanent increase in both lymphocytes and monocytes. Usually, the total white cell count stabilises at between 10 and 15×10^9/L, but occasionally it may rise to twice this level. Minor increases in blood eosinophils and basophils have been noted after splenectomy, but this is not a regular feature. In response to infection, splenectomised subjects produce a much greater leucocytosis than people with intact spleens. Often, there is a marked left shift in the differential leucocyte count, with myelocytes and occasionally more primitive cells.

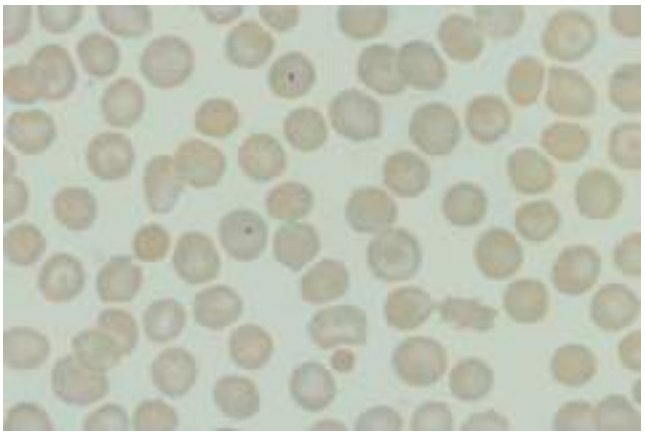

Figure 5.4 Blood film showing features of hyposplenism: Howell–Jolly bodies, target cells and contracted cells.

Platelet changes

As indicated above, the thrombocytosis after splenectomy is usually transitory and falls to normal or near-normal values over the following 1–2 months. However, even if the platelet count has returned to normal values, occasional large and bizarre platelets can be seen in the blood films of many splenectomised subjects. Their presence suggests that the spleen normally removes these particular platelets.

Hyposplenism

Absent or reduced splenic function occurs in a range of medical conditions, as well as following surgical splenectomy or therapeutic splenic embolisation. In some disorders such as sickle cell disease, severe gluten-induced enteropathy and untreated human immunodeficiency virus (HIV) infection it is a fairly frequent complication. It may also be seen less frequently in a variety of other conditions (see Table 5.3). In sickle cell anaemia, there is functional asplenia by 1 year of age, and autoinfarction leads to a state of anatomical asplenia after 6–8 years of age. Congenital absence of the spleen is rare and may be associated with organ transposition and severe malformations of the heart and lungs. At the other extreme of life, atrophy of the spleen is seen after around 65 years of age, with a rapid decrease in weight in older age. Patients with functional hyposplenism have impaired immunity to blood-borne bacterial and protozoal infections and persistent thrombocytosis. Management is similar to that required after splenectomy, including prophylactic antibiotics and vaccines (see above) and advice to seek medical attention immediately in the event of illness or fever.

Table 5.3 Causes of hyposplenism.

Congenital aplasia syndrome

Introduction

A relationship between the immune system and cancer was first hypothesised in the late nineteenth century. Anton Chekhov, a famous playwright, reported on the association between infection and cancer remission, writing 'It has long been noted that the growth of malignant tumours halts for a time when this disease [(erysipelas)] is present'. William Coley, a surgeon in New York, re-enforced this concept by demonstrating that an immune response induced through injection of *Streptococcus pyogenes* bacilli could improve cancer patient outcomes, cementing a relationship between the immune system and cancer.

At the beginning of the 20th century, the concept of 'cancer immunosurveillance' was formed. This hypothesis, mainly curated by Lewis Thomas and Sir Frank Macfarlane Burnet, stated that the immune system can detect and target tumour-associated neoantigens (Oiseth and Aziz 2017). Extensive data supported their hypothesis, with immune-deficient knockout murine models demonstrating the relationship between an immune deficiency and unfavourable cancer outcomes (Waldman *et al.* 2020). In 2011, Hanahan and Weinberg revised their hallmarks of cancer to include loss of immune surveillance.

Our knowledge of the interactions between the immune system and cancer has since grown exponentially. This has culminated in the development of the field of immunotherapy, where the immune system is utilised to survey, target and fight cancer, being recognised as the fifth pillar of cancer treatment.

Cancer immunotherapy is a broad term encompassing a wide range of various technologies from antibody and cytokine-based drugs, through to cellular therapies (see Figure 6.1). One of the key paradigm-changing developments has been in the field of checkpoint inhibitors (CPI); monoclonal antibodies (mAbs) that disrupt inhibitory signals allowing restoration of robust immune surveillance in the presence of established cancer (Robert 2020). The discovery of cluster of differentiation antigen-152 (CD152)/cytotoxic T-lymphocyte associated protein-4 (CTLA4) and the CD279/programmed cell death protein-1 (PD-1), CD274/programmed death ligand-1 (PD-L1) co-inhibitory biology earned James P. Allison and Tasuku Honjo the Nobel Prize in Physiology or Medicine in 2018. Blockade of these receptors for clinical development has led to remarkable responses with durable survival for a subset of haematological and non-haematological cancer patients.

Immunotherapy is key to the treatment of an ever-increasing list of malignancies. However, it does not come without its disadvantages. Loss of peripheral tolerance and triggering of auto-inflammation complicates the use of CPIs and potentially fatal complications of cellular therapies remain relatively common (Waldman *et al.* 2020). In addition, they are not always effective, and the results of treatment with CPIs in myeloid malignancies, for instance, were not encouraging. Therefore, selecting the right type of therapy and optimum timing for each individual cancer type/patient is crucial.

This chapter will describe the immune evasion and subversion in cancer, immunotherapeutic strategies to counteract this

subversion and immunotherapy limitations. We will finish with an outlook on the future of immunotherapy with its progression towards centre stage in cancer treatment. Immunotherapy strategies in specific haematological malignancies are discussed separately in relevant chapters.

Immune evasion and subversion in cancer

The immune system and tumour microenvironment

The human immune system is comprised of two systems, the innate and the adaptive. The innate system encompasses physical barriers and cells that are the first responders to invading antigen, including dendritic cells, macrophages, eosinophils, basophils, neutrophils, mast cells and natural killer cells. The adaptive immune system responds more specifically and forms immunological memory. It comprises B cells, $CD4^+$ and $CD8^+$ T cells, unconventional T cells (γδ T cells, NKT cells and MAIT cells) and innate lymphoid cells.

The environment in which a tumour resides is known as the tumour microenvironment (TME) (Anderson and Simon 2020) (see Figure 6.2). It is where most of the cancer cell and immune system interactions happen and is composed of a complex collection of blood vessels, immune cells (innate and adaptive), stromal cells and extracellular matrix. The composition of the TME depends in part on the type of tissue the tumour grows in (Anderson and Simon 2020).

The adaptive immune system utilises different cell types to continuously balance its fight against threat whilst sustaining self-tolerance and suppressing excessive inflammation. This is exemplified by the juxtaposition of cytotoxic $CD8^+$ T cells that detect and destroy transformed cells and T regulatory cells (Tregs) which are the immune system's most suppressive cells.

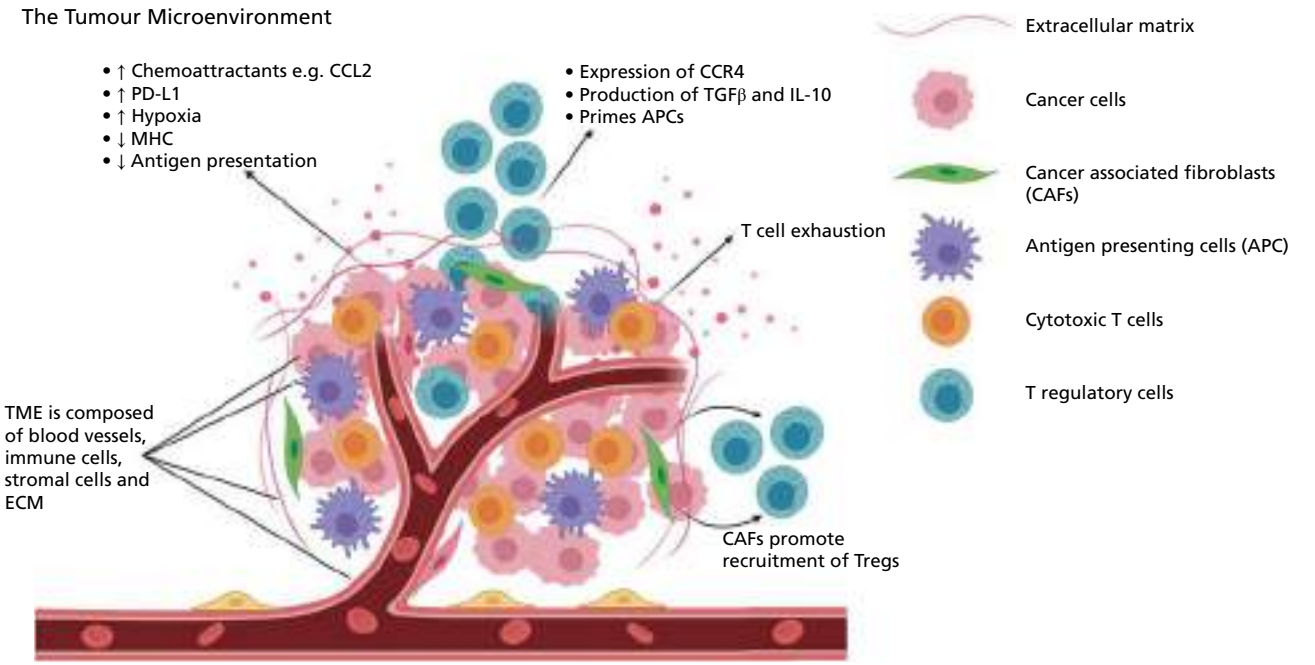

Figure 6.2 The Solid Tumour Microenvironment (TME) is a highly immunosuppressive environment composed of a large array of immune cells, stromal cells, cancer cells, extracellular matrix and blood vessels. Arrow pointing up, Upregulation; Arrow pointing down, Downregulation; APC, Antigen Presenting Cell; CCL2, Chemokine Ligand 2; CCR4, Chemokine Receptor 4; IL-10, Interleukin-10; MHC, Major Histocompatibility Complex; PDL1, Programme Death Receptor 1; TGFb, Transforming Growth Factor beta.

Within the TME, Tregs are unfavourable as they can promote tumour growth and reduce anti-tumour response. Indeed, the TMEs can demonstrate multiple mechanisms used to escape $CD8^+$ T cell cytotoxicity and enhance the suppressive activity of Tregs (Vinay *et al.* 2015). One primary mechanism is the secretion of Treg-attractant chemokines such as C-C Motif Chemokine Ligand 22 (CCL22) by cancer cells, such as ovarian cancer cells. CCL22 is recognised by C-C Chemokine Receptor Type 4 (CCR4) which is expressed on Tregs. When CCL22 is secreted by the cancer cells, it induces the migration of Tregs to the TME, resulting in the suppression of immune response against the cancer. Cancer cells can additionally secrete factors that induce the proliferation of Tregs, such as transforming growth factor β (TGFβ) and interleukin 10 (IL-10). Once attracted to the TME, Tregs can prime antigen-presenting cells to capture costimulatory molecules CD80/86 in a CTLA4-dependant manner in a process known as trans-endocytosis. After the removal of CD80/86, co-stimulation is inhibited, thus rendering T cells anergic and dysfunctional. Additionally, specific Treg subsets are shown to be able to provide a 'niche' for stem cells in animal model. Whether these Tregs could support a malignant clone in the microenvironment is yet to be determined.

In addition to enhancing the suppressive capabilities of Tregs, cancer cells have been shown to down-regulate the expression of their major histocompatibility complex (MHC); the antigen-displaying molecules. Cancer cells are derived from normal self-cells and therefore most of the peptides that they express are minimally recognised by T cells. However, mutations within the cancer cells lead to the formation of neoantigens. These are highly immunogenic antigens and are not expressed in healthy tissue, making them highly attractive targets for immunotherapy (Zhang *et al.* 2021). However, this can be inhibited by the cancer cell's ability to downregulate their MHC, meaning that the neoantigens are not displayed, thus evading recognition and cytolysis by T cells.

Another mechanism by which cancer cells supress the immune response is by inducing unresponsiveness and dysfunction in T cells, a state known as T cell exhaustion (Wherry and Kurachi 2015). Tumour cells can upregulate ligands that bind to T cells and induce exhaustion, thereby rendering the T cells unable to fight the cancer (Wherry and Kurachi 2015). One such ligand that cancer cells can express is PD-L1. The binding of PD-L1 to PD1 inhibits intracellular T cell signalling which restrains the immune response. The docking of PD-L1 induces the phosphorylation of PD1's two intracellular tyrosines and recruitment of SH2-domain containing tyrosine phosphatase 1 (SHP-1) and SHP-2. These become dephosphorylated thereby preventing the phosphorylation and activation of downstream effectors CD3ζ and Zeta Chain of TCR-Associated Protein 70

(ZAP70) which are important in early T cell activation. PD-L1 is naturally expressed by immune cells including macrophages and dendritic cells and it binds the PD1 receptor on T cells. The binding of PD-L1 to PD1 inhibits intracellular T cell signalling which restrains immune response. This interaction occurs naturally to prevent T cell hyperactivation and to keep the immune response in check. However, when cancerous cells overexpress PD-L1, it prevents T cells from being able to mount a response against the cancer.

There are also physical barriers to the infiltration of T cells into the tumour. As previously mentioned, the TME is a complex interplay of cells and extracellular matrix. It is a highly hypoxic environment that not only leads to increased malignancy, but also inhibits the activity of T cells. The TME is also a 'stiff' environment, which promotes tumour formation and inhibits the migration of T cells to the cancer site. For instance, cancer-associated fibroblasts (CAFs) suppress the immune response by promoting the recruitment of Tregs.

Reviving an effective immune response against malignant cells is the main focus of immunotherapy. This can be achieved through several approaches which are discussed in the next sections.

Types of immunotherapy

Antibody therapy

Immunotherapy aims to reintroduce malignant cell recognition and destruction. Efforts have been made to develop therapies that can home to the cancer and produce a localised response rather than a systemic one. Such therapies include the use of mAbs. These are proteins produced by B cells that are used to neutralise foreign antigens such as an invading virus or bacteria. They can be engineered to selectively target tumour-associated antigens (TAAs) and elicit an immune response (Reichert and Valge-Archer 2007).

For instance, Rituximab, an anti-CD20 antibody, that induces antibody-dependent cellular cytotoxicity (ADCC) towards B cells, is now routinely used in the treatment of lymphomas. They can also be engineered to target factors such as PD1 without engaging cellular cytotoxicity to overcome T cell exhaustion, allowing T cell activation and reintroduction of an immune response against the cancer (Reichert and Valge-Archer 2007).

Three signals are required to activate T cells antigen recognition, co-stimulation and cytokine signals (see Figures 6.3 and 6.4).

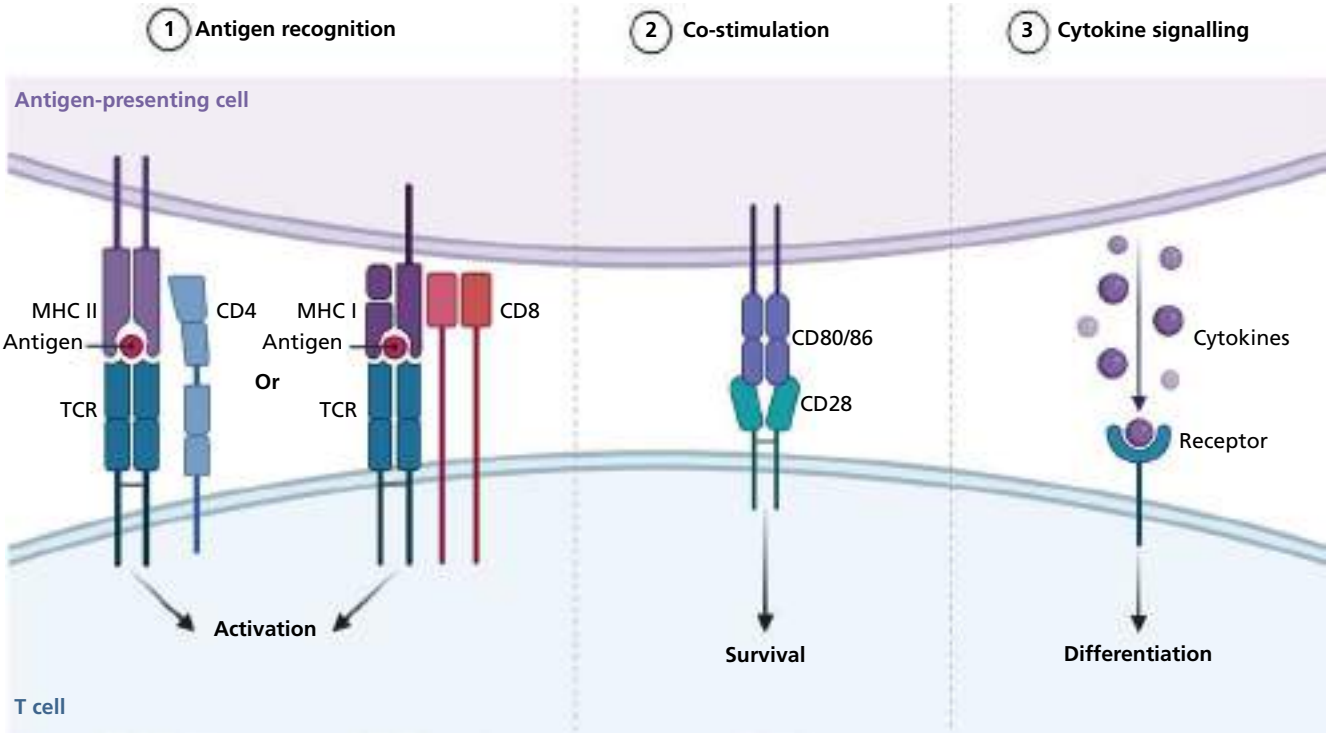

Figure 6.3 Three Signals of T cells activation. 1. Antigen recognition occurs when the APC presents an antigen via either MHC I or II to the TCR of the T cell, this is known as signal one. 2. Co-stimulation is known as signal two and involves the binding of molecules on the APC such as CD80/86 to the CD28 receptor on the T cell, this activity aids T cell activation. 3. Cytokine signalling induces the differentiation of the T cell into either effector or regulatory phenotypes and is known as signal three. APC, Antigen Presenting Cell; MHC, Major Histocompatibility Complex; TCR, T Cell Receptor.

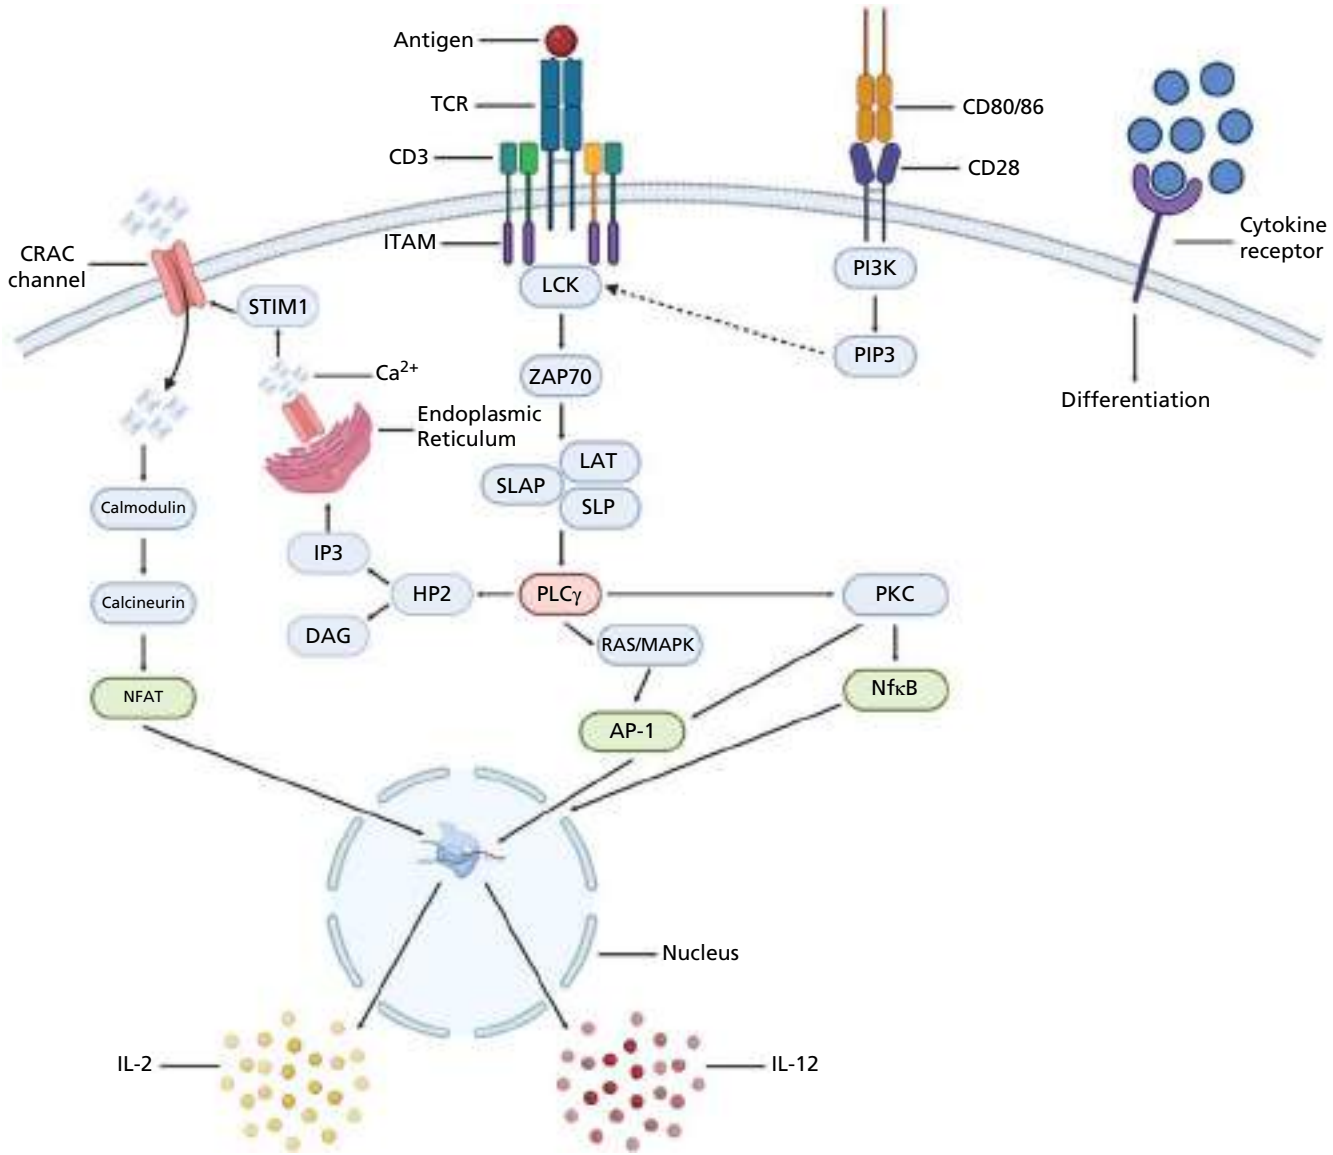

Figure 6.4 T cell activation: The first signal of T cell activation is TCR engagement with antigen. This initiated a signal which is transmitted by co-receptor CD3 via ITAMS which are phosphorylated by LCK. This phosphorylation provides a binding site for ZAP70 which phosphorylates adaptor proteins SLAP, SLP and LAT, resulting in the recruitment and activation of PLC-g. This has three different effects; the release of calcium, the activation of the RAS/MAPK pathway and the activation of PKC, all of which lead to the activation of different transcription factors involved in the activation of the T cell. The release of calcium begins with PLC-g cleaving PIP2 into IP3 and DAG. IP3 binds to calcium receptors in the ER membrane which releases calcium this stimulating STIM1 to open the CRAC channels allowing calcium flow into the rest of the cell. The increased intracellular calcium causes a conformational change in calmodulin which activates calcineurin. Calcineurin dephosphorylates NFAT which moves to the nucleus and acts as a transcription factor, inducing the production of IL-2. PLC- g also activates the RAS/MAPK pathway which activates AP-1 and subsequence genes similar to NFAT, inducing IL-12. Finally, PLC- g activates PKC which activated transcription factors NfkB and AP-1. The second signal of T cell activation, co-stimulation, occurs when CD28 comes in to contact with one of two molecules on the APC, CD80 or CD86. Engagement of CD28 induces tyrosine phosphorylation which activated PI3K with subsequent production of PIP3. This results in the recruitment of enzymes such as LCK which are needed for the activation of PLC-g. Stimulation from cytokines such as IL-12 act as the third signal and instruct how the T cell differentiates. AP-1, Activator Protein 1; CRAC, Ca^{2+}release-activated Ca^{2+}; DAG, diacylglycerol; IP3, Inositol triphosphate; ITAMS, Immunoreceptor Tyrosine-Based Activation Motifs; LAT, Linker for Activation of T cells; LCK, Lymphocyte-Specific Protein Tyrosine Kinase; NFAT, nuclear factor of activated T cells; NFkB, Nuclear Factor kappa-light-chain-enhancer of activated B cells; PIP2, Phosphatidylinositol 4,5-bisphosphate; PIP3, Phosphatidylinositol (3,4,5)-trisphosphate; PI3K, PI-3 kinase; PKC, Protein Kinase C; PLC-g, phospholipase C gamma; RAS, a small GTPase; MAPK, Mitogen-activated protein kinase; TCR, T Cell Receptor; ZAP70, Zeta Chain of TCR-Associated Protein 70; SLAP, Src-like adaptor protein; SLP, Src homology 2 (SH2) domain-containing leukocyte protein.

The immune system has several mechanisms in place to prevent T cell hyperactivation and autoimmunity. After T cell activation, a protein receptor called CTLA4 is expressed on the surface of the T cell. It competes with CD28 for CD80 and CD86, thereby preventing co-stimulation and inhibiting further T cell activation. Similarly, when an APC is presenting an antigen to a T cell, it simultaneously expresses PD-L1/2, which binds to PD1/2 receptor on the T cell. PD1 was identified as a mediator of apoptosis in 1992 by Honjo and colleagues. The docking of PD-L1 or PD-L2 inhibits intracellular cytokine signalling, which in turn restrains T cell activity.

The discovery that CTLA4 and PD1 negatively regulate T cell activation led to the idea that blocking these receptors could be used as a therapeutic against cancer. This idea was first tested by James Allison and colleagues in 1996 and since, mAbs that target immune checkpoints, termed checkpoint inhibitors, have been widely developed and have revolutionised cancer therapy. These act by directly binding to and neutralising the checkpoint molecules, preventing them from inducing T cell exhaustion.

Anti-CTLA4

The CTLA4-based therapy ipilimumab was the first checkpoint immunotherapy (CPI) to receive FDA approval for unresectable stage III/IV melanoma in 2011. This came after a trial demonstrated ipilimumab treatment to confer a 3.6-month short-term survival benefit in metastatic melanoma patients when combined with glycoprotein 100 (gp100) peptide vaccine, compared to patients receiving gp100 alone (hazard ratio for death, 0.68; $P < 0.001$). More impressive still, the long-term survival meta-analysis data showed that 22% of melanoma patients treated with ipilimumab gained an additional 3 years of life compared to treatment-naïve patients.

It is thought that anti-CTLA4 works not only by preventing the inactivation of cytotoxic T cells, but also by inducing the death of immunosuppressive Treg cells. CTLA4 is highly expressed in Treg cells. When bound to the Fcγ receptor on APCs, anti-CTLA4 can induce ADCC against the Tregs that it binds. This would be disadvantageous against cytotoxic T cells, however, it is useful when directed at Treg cells.

Anti-PD1

As previously discussed, the PD-L1-PD1 interaction is a key mechanism used by the immune system to prevent T cell hyperactivation, keeping the immune response in check. Preclinical studies showed that blockade of PD-L1 or PD1 not only enhances anti-tumour response but limits metastasis in mouse models. The first anti-PD1 mAbs, pembrolizumab and nivolumab, were FDA-approved for the treatment of refractory and unresectable melanomas in 2014. Nivolumab showed in one phase III-controlled study to yield an overall rate of survival of 72.9% in the nivolumab-treated group compared to 42.1% in patients treated with chemotherapeutic dacarbazine (hazard ratio for death, 0.42; 99.79% CI, 0.25–0.73; $P < 0.001$).

Pembrolizumab also demonstrated significant results. One trial investigating anti-PD1 treatment in non-small cell lung cancer, showed Pembrolizumab treatment to provide 10.3 months of cancer-progression-free survival compared to 6 months in the chemotherapy-treated patient group (hazard ratio for disease progression or death, 0.50; 95% CI, 0.37–0.68; $P < 0.001$).

Since 2014, Nivolumab and Pembrolizumab have been FDA-approved for the treatment of multiple forms of cancer.

Recently, other checkpoint inhibitors/negative regulators of T cell activation have been investigated as new targets for checkpoint blockade, including Lymphocyte-Activating Protein 3 (LAG3), T cell Immunoglobulin (TIM3), V-Domain Ig Suppressor of T cell Activation (VISTA), B7 Homolog three protein (B7-H3/CD276) and T cell Immunoreceptor with Ig and ITIM Domains (TIGIT). In particular, Relatlimab, an anti-LAG3 therapy, in combination with anti-PD1 mAb Nivolumab, has recently shown to confer a significant progression-free survival benefit compared to Nivolumab monotherapy in patients with advanced melanoma.

Combination therapies

Due to the success of CPI therapy, investigations have taken place in combining them to yield even more favourable responses. In 2017, data from a phase III trial showed metastatic melanoma and renal cell carcinoma patients to have increased survival when administered with ipilimumab in combination with nivolumab compared with ipilimumab alone (hazard ratio for death with nivolumab plus ipilimumab vs. ipilimumab, 0.55 [$P < 0.001$]; hazard ratio for death with nivolumab vs. ipilimumab, 0.65 [$P < 0.001$]) (Wolchok *et al.* 2017). However, adverse events were experienced in 96% of patients treated with the combination therapy, compared to 86% in the monotherapy treatment group. In addition, these adverse events were reported to be severe or life-threatening (grade 3 or 4) in 59% of combination therapy-treated patients compared to 21% in the nivolumab-only group and 28% in the ipilimumab-only group. Despite these toxicities, stable to complete response was reported in 70% of combination-treated patients, compared to 54% in nivolumab and 41% in ipilimumab-treated patients. These results have delivered practice-changing progress in survival for melanoma patients over the past decade. Further work to develop novel combinations and to 'de-risk' toxicity is ongoing.

Similarly, a combination of radiotherapy and both anti-PD1 and anti-CTLA4 have shown promising preclinical results and await further investigation in clinical trials. In addition, radiotherapy in

combination with checkpoint blockade has been shown to enhance the abscopal effect when treatment at one site leads to metastatic regression at another site.

Adverse effects of checkpoint inhibition

Despite the successes of Ipilimumab, Nivolumab and Pembrolizumab, these therapies do not come without adverse effects. Blockade of inhibitory checkpoints can lead to auto-inflammation and auto-immune reactions. This professes itself through the accumulation of hyperactive memory T cells which travel to peripheral organs and cause inflammation. The most common immune-related adverse events (irAEs) include fatigue, skin manifestations such as pruritis, gastrointestinal inflammation, hepatic toxicity and endocrine dysregulation. Targeting CTLA4 is associated with higher rates of irAEs and combination therapy with both anti-CLTA4 and anti-PD1 therapy further increasing the risk of toxicity. Less commonly arthritis, nephritis, uveitis and pneumonitis can occur. In fact, any organ can be affected, and occasionally, toxicity can be life-threatening. The management of irAEs requires immune suppression to dampen down an out-of-control auto-reactive immune state.

In addition to the adverse effects of checkpoint inhibition, one-quarter to one-third of metastatic melanoma patients become resistant to therapy and relapse over time, despite initially having objective responses and receiving continuous therapy. This is due to a combination of intrinsic and extrinsic factors including T cell exhaustion and the downregulation of tumour antigen presentation. Studies are currently investigating whether combinatorial therapies can overcome these resistance mechanisms.

Whilst checkpoint inhibition does not guarantee complete remission and can yield adverse effects, it has proven revolutionary in the treatment of cancer, with those treated gaining significant extensions of life. Future work is needed to reduce associated toxicities and elucidate the mechanisms of tumour resistance to CPI.

Antibody-drug conjugates

While chemotherapy is still the main approach in the majority of malignancies, the cytotoxic effect is the limiting factor and causes various side effects. Thus, more targeted chemotherapy approaches have long been desired. Antibody-Drug Conjugate (ADC) is one of the approaches, which has been employed to achieve a more targeted drug delivery and less systemic toxicity. ADCs are developed by combining a tumour antigen-specific antibody and cytotoxic agent. Gemtuzumab ozogamicin (Mylotarg) consists of a cytotoxic antibiotic (calicheamicin) and a recombinant monoclonal antibody against the CD33, is an example of ADCs, which is used for the treatment of acute myeloid leukaemia (AML).

Bispecific antibodies

mAbs have shown great success in the clinic but are restricted by their monospecific targeting. One type of therapy that has shown promise to circumvent such specificity is the use of small bivalent antibody fragments known as diabodies or bispecific antibodies (bsAbs) (Ahamadi-Fesharaki *et al*. 2019). These antibodies have two antigen binding Fc domains which can simultaneously target two antigens involved in the same cancer or infection. Since 2009, two bsAbs have been approved for clinical use against EpCAM-positive carcinoma and relapsed or refractory acute lymphoblastic leukaemia, and a further 60 diabodies are under investigation in clinical trials (Ahamadi-Fesharaki *et al*. 2019). For instance, Mosunetuzumab is an anti-CD20 -CD3 bispecific antibody (Ab) that redirects T cells to eliminate malignant B cells. This novel treatment has shown in clinical trial to be effective in patients with Relapsed/Refractory Follicular Lymphoma who have received $\geq$2 prior lines of therapy.

Adoptive T cell therapy

In recent years, adoptive T cell (ATC) therapy has shown promising results in cancer patients. This form of immunotherapy involves modifying autologous or allogenic T cells and infusing them into cancer patients. A study demonstrating tumour regression after leukocyte transfer first appeared in 1966 by Southam and colleagues. Later, and initially unintentional, donor lymphocyte infusions appeared as one of the first forms of ATC. Kolb and Colleagues demonstrated that lymphocytes administered to patients with acute or chronic leukaemia in relapse after bone marrow transplantation mediated a graft-versus-tumour effect against leukaemic cells, reducing tumour burden. Since these early studies, three main types of ATC therapies have emerged including *T cell receptor* (*TCR*) gene therapy, ATC therapy with tumour-infiltrating lymphocytes (TILs) and ATC with synthetic Chimeric Antigen Receptors (CARs).

Tumour-infiltrating lymphocyte therapy

ATC therapy using TILs first appeared in the late 1980s (Rosenberg *et al*. 1979) and involves isolating TILs from a patient tumour biopsy, expanding the cells with IL-2 and reinfusing the cells into the patient where they can produce a potent immunological response against the tumour. Studies have shown this therapy to work more efficiently when the patient is depleted of lymphocytes (lymphodepletion) prior to

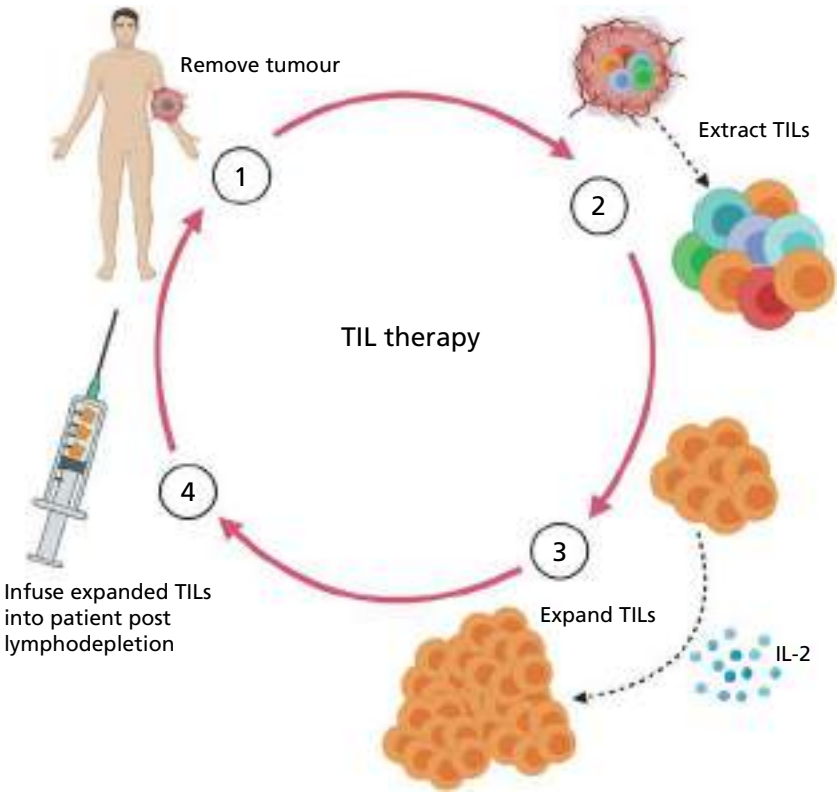

Figure 6.5 TIL therapy: 1. Tumour is removed from the patient. 2. TILs are extracted from the tumour. 3. TILs are expanded with IL-2. 4. Expanded TILs are re-infused into patients post lymphodepletion conditioning. TIL, Tumour Infiltrating Lymphocyte; IL-2, Interleukin-2.

the infusion, with studies showing complete objective response rates of up to 72% and tumour regression in up to 24% of treated metastatic melanoma patients. Recently, TIL therapy in combination with up to six doses of IL-2 has shown promise in patients with advanced melanoma who have progressed after checkpoint inhibition and targeted therapies. A phase II trial involving lymphodepleted patients who had received a mean of 3.3 prior treatments demonstrated objective response rates of up to 81% after receiving TIL infusions. However, melanomas are one of the only cancer types to reliably give rise to TILs with anti-tumour activity. Furthermore, TILs must be grown *in vivo* for this therapy to work and produce a long-lasting response (see Figure 6.5), ensuing a long production process when time is not always available.

T cell receptor gene therapy

Studies using TILs spawned the idea of modifying the T cell receptor (TCR) in order to increase the specificity of response against the tumour. This form of therapy is called *TCR* gene therapy and involves genetically modifying the *TCR* to recognise specific cancer antigens, eliminating the need to extract/produce and expand TILs. When the modified *TCR* binds the antigen plus MHC of interest, such as NY-ESO-1, it induces T cell activation and anti-tumour activity. Recently, the first CRISPR-edited *TCR* gene therapy showed safety in a phase I clinical trial, presenting *TCR* gene therapy as a promising technology (Stadtmauer *et al.* 1979). However, the downside to this type of therapy is that the T cells require antigen presentation from APCs in order to become activated. The reliance on other cell types has prompted research into bypassing MHC antigen presentation, leading to the creation of CAR T cells.

CAR T cell therapy

CARs are synthetic structures that consist of four main components, an antigen-binding domain, a hinge region, a

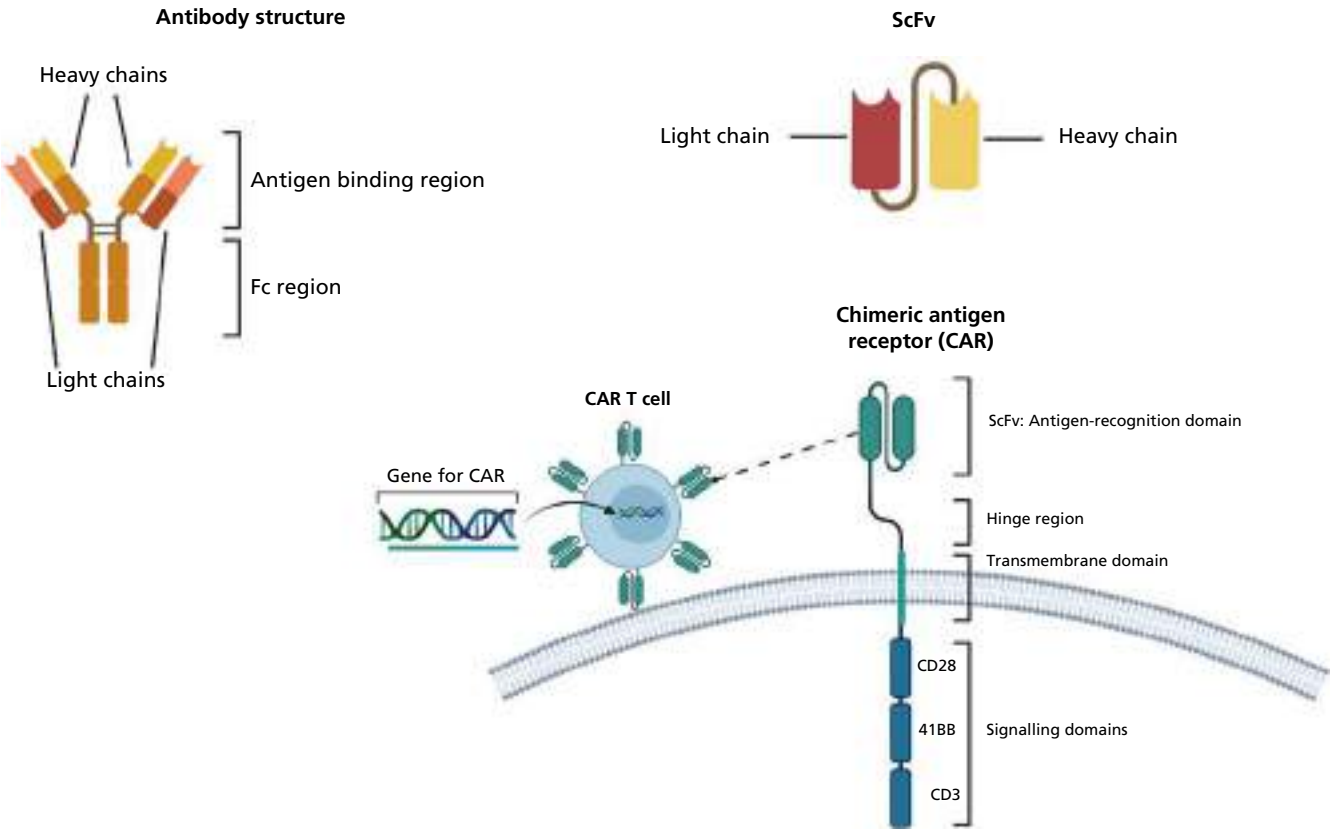

Figure 6.6 Antibody structure: Composed of a light and heavy chain forming the antigen binding region. The Fc region interacts with Fc receptors on the surface of immune cells and elicits signalling. Scfv are engineered structures originating from antibodies and used to generate CAR T cells. CARs consist of four main components, an antigen-binding domain, a hinge region, a transmembrane domain, and an intracellular signalling domain. CAR, chimeric antigen receptor; Fc, fragment crystallisation; ScFv, single chain variable fragment.

transmembrane domain and an intracellular signalling domain (see Figure 6.6).

The antigen binding domain is commonly composed of a variable heavy (Vh) and light (Vl) chain derived from a monoclonal antibody, connected via a linker, forming what is known as a single chain variable fragment (ScFv) (Sterner and Sterner 2021). It is the ScFv that is coupled to a CD3-singalling domain which targets extracellular cancer antigens and provides signal 1 of T cell activation. The hinge connects the ScFv to the transmembrane domain which anchors the CAR to the T cell membrane. Below this is the intracellular domain, where co-stimulatory molecules such as CD28 or 4-1BB are inserted and used to initiate intracellular signalling within the T cell, providing signal 2 of T cell activation. Fourth-generation CARs have additional domains including chimeric cytokine receptor 4αβ which when docked by IL-4, induces the production of IL-2 and further T cell proliferation, providing signal 3 of T cell activation.

The generation of CAR T cell therapies is an extremely precise science and is largely due to the combined efforts of immunologists, bioengineers and geneticists. It is thanks to this multidisciplinary research that five CAR T cell therapies have been brought to clinic since 2017. The first FDA-approved CAR was directed at CD19, an antigen expressed on B cells, for the treatment of relapsed/refractory acute lymphoblastic leukaemia (ALL). CD19 CARs have shown great success, with initial studies showing complete remission in relapsed B-acute lymphoblastic leukaemia patients and a 5-year follow up again showing complete remission in 83% of patients. The largest impact to date for CD19-directed CAR T cells however has been in relapsed/refractory diffuse large B-cell lymphoma where three products have now received an FDA license. The latest CAR, Idecabtagene vicleucel, was approved for use against relapsed or refractory multiple myeloma in March 2021. As CD123, an IL-3 receptor subunit, is expressed on CD34+CD38- AML blasts, it is considered a potential target for CAR therapy in AML as well as other surface proteins such as CD33.

Limitations and adverse effects of ATC therapy

A limitation of CAR T cell therapy is the reliance on finding TAAs for the CARs to target. The CD19 antigen, for instance, is not a TAA, it is an expendable antigen. Normal B cells expressing CD19 are also killed by the CAR T therapy, something that can be managed with supportive therapies.

Whilst CAR T cell therapy has proven effective in the treatment of haematological malignancies, its use against solid tumours has proven less successful to date. This is primarily due to the lack of cancer-specific antigens which allow for the migration of CAR T cells to the tumour site (Sterner and Sterner 2021). Current CAR T cell therapy research is therefore highly focused on the discovery of neo-antigen cancer targets. The most promising targets under investigation include Glutamate Carboxypeptidase 2, also known as Prostate-Specific Membrane Antigen (PSMA) and Fibroblast Activation Protein Alpha (FAP). Antigen heterogeneity in tumours is another barrier to effective CAR T cell therapy. Tumour cells display a large array of antigens, facilitating escape from the CAR T cell response. Efforts have been made to increase CAR specificity to multiple antigens, however, this can lead to an increase in off-target toxicity. As previously mentioned, the TME is a hypoxic and 'stiff' environment where collagen-rich stroma can prevent T cell infiltration. This is especially enhanced in solid tumours. In addition, the TME is highly immunosuppressive, partially due to the presence of Tregs and expression of antigens such as PD-L1, which can impair the function of T effector cells and enhance T cell exhaustion (Sterner and Sterner 2021). With more than 90% of cancer-related deaths in America being due to epithelial solid tumours, combating these barriers could prove revolutionary in the treatment of cancer.

It is important to consider that like checkpoint inhibition therapy, the use of TILs and CAR T cell therapy can yield severe adverse effects, the most common being cytokine release syndrome (CRS). CRS occurs when the T cell becomes activated and releases inflammatory cytokines. This is a natural reaction by the T cell but is amplified in ATC therapy due to the amount of T cells being activated. Clinical features of CRS include fever, myalgias, malaise, loss of appetite and muscle pain. Another adverse event of ATC therapy is neurotoxicity, including Immune Effector Cell-Associated Neurotoxicity Syndrome (ICANS) and CAR T cell-related encephalopathy, manifestations of which can include seizures, cerebral oedema, headaches, confusion, ataxia, delirium and aparaxia. In addition, lymphodepletion and the use of IL-2 in TIL therapy are associated with additional toxicities. IL-2 treatment can lead to capillary leak syndrome which can present itself as oedemas, hypotension reduced urination, myalgia, fever and nausea. Toxicities associated with lymphodepletion consist largely of pancytopenia and neutropenia, as well as thrombocytopenia and lymphopenia.

ATC therapy has opened many doors to treat a wide range of cancers. To date, the most successful CARs have targeted specific antigens. The future of CAR T cell therapy will likely involve focusing on solid tumour cancers and myeloid malignancies such as myelodysplastic syndrome (MDS) and AML, increasing the specificity to multiple tumour-specific antigens (TSAs) without increasing toxicities, as well as engineering the CARs to survive better within the immunosuppressive TME. Associated toxicities remain the biggest barrier to the widespread implementation of CAR T cell therapy.

Cancer vaccines

Cancer vaccines are employed to prompt the immune system to respond and fight the malignant cells. Two main types exist, prophylactic and therapeutic vaccines. These vaccines are largely in the form of synthetic peptides or messenger RNA (mRNA) that are loaded into a DNA or viral plasmids. These plasmids are injected into the patient to yield an immune response against the injected peptide or mRNA.

Prophylactic

Prophylactic vaccines are generally administered to healthy individuals to prevent cancer. They can be used, for instance, to prevent infection from oncogenic viruses. It is estimated that globally, 13% of cancers are due to chronic viral, bacterial or parasitic infections. Therefore, targeting these infections can lead to reduced incidence of cancer.

Hepatitis B (HBV) is the leading cause of global liver cancer incidence. Prophylactic HBV vaccines have shown great success in reducing the incidence of hepatocellular carcinoma (HCC), especially when administered early in childhood. One study in Taiwan, showed an 80% decline in HCC incidence in cohorts born after the country's HBV vaccination programme began.

Like HBV, human papillomavirus (HPV) is oncogenic. It is causatively associated with head and neck cancer and cervical cancer. A study in Sweden demonstrated that administration of HPV vaccines, especially before the age of 17, can substantially reduce the risk of cervical cancer (Lei *et al.* 2020). Of the over 1.5 million girls and women who took part in the study, only 19 women who had received a HPV vaccine were diagnosed with cervical cancer, as opposed to 538 women who had not received the vaccine (Lei *et al.* 2020).

Prophylactic vaccines against oncogenic viruses have, therefore, proven successful in the prevention of cancer. There is a great demand for worldwide vaccination programmes against HPV and HBV, with studies such as the one in Taiwan playing a vital role in this implementation. However, there remain other viruses that require attention, including Epstein-Barr Virus (EBV). This is another virus aetiologically linked with

the onset of various cancers. First discovered in cells cultured from Burkitt Lymphoma, EBV is widespread in all human populations, but infection is largely asymptomatic. EBV infection can, in rare cases, become activated in immunodeficient patients and transform B cells into fast-growing lymphoblastoid cell lines (LCLs). It is thought that EBV is associated with 200,000 cases of cancer annually, yet no vaccine is currently available against EBV. Few vaccines are in phase I clinical trials, including a multiplication-incompetent-attenuated pox viral vector of modified vaccinia virus Ankara (MVA) encoding EBV antigens EBNA1 and LMP2. This vaccine has been shown to be well tolerated, however, the efficacy is yet to be shown. Considering the strong association between EBV infections and cancer, the development of an EBV vaccine is a high priority.

Therapeutic

Cancer vaccines can also be therapeutic, meaning they are administered to directly trigger anti-tumour immunity. Historically, these types of vaccines involved administering patients with their own tumour cells together with a virus to activate the immune response against the TAAs (Waldman *et al*. 2020). This method has seen the rise of vaccines such as Provenge; a vaccine formulated to target prostate acid phosphatase (PAP) for the treatment of metastatic castration-resistant prostate cancer, FDA-approved for clinical use in 2010. However, targeting TAAs such as PAP can elicit auto-immune and off-target responses. There has therefore been a push to discover TSAs that can produce a more effective and localised response to the tumour. As described in Section 6.2, cancerous cells often undergo mutations that lead to the production of novel self-antigens called neoantigens. These are not expressed in healthy tissue and can be recognised by T cells. Thanks to the development of next-generation sequencing, these tumour-specific mutations can be identified. For instance, Sahin and colleagues found over 1680 mutations in murine colon carcinoma cells, 48 of which were taken forward for further investigation due to their specificity and immunogenicity. Of these 48, 16 were made into mRNA vaccines and were found to generate an immune response in the vaccinated individuals, producing a strong anti-tumour response. Therapeutic vaccines are now largely based on targeting these neoantigens forming what is now called personalised recombinant cancer vaccines. *Wilms tumor 1* (*WT1*) gene product peptide vaccination has also been tried in MDS and AML with some encouraging results and could elicit antigen-specific $CD8^+$ T cell response in these patients.

Rapid advances in genomics and data science are likely to push this novel form of immunotherapy forward. However, there are time delays and high costs associated with the manufacturing of personalised vaccines that target an individual's specific TSAs. Efforts to reduce these barriers have so far involved improving vaccine delivery platforms. There is also research taking place on when best to administer other therapies in conjunction with cancer vaccines to improve clinical outcomes.

Cytokine therapy

Cytokines are a group of peptides, proteins or glycoproteins that are produced by immune cells. They act as signalling molecules that modulate and regulate immune cells and the immune response. Due to their ability to potentiate immune responses, they have been investigated as a form of immunotherapy, where administration could induce immune responses against cancer. Indeed, pro-inflammatory cytokines were found to increase the number of effector T cells within the TME as well as enhance T cell cytolytic activity (Berraondo *et al*. 2019). Two cytokines, IL-2 and Interferon α (IFNα), have proven particularly successful.

IL-2 is a key cytokine in the proliferation and survival of T cells and is used to expand T cells for ATC therapy. The first metastatic melanoma patient to be administration IL-2 had a complete response and was disease-free for 29 years. Further trials showed IL-2 administration to yield objective response rates of up to 20% in patients with metastatic renal cell carcinomas. The other successful cytokines are interferons (IFN). These are some of the most potent initiators of signalling cascades within the immune system, utilisation of which has shown tumour regression in over a dozen types of cancer, including myeloma, Karposi's sarcoma, melanoma, lymphoma and renal cell and bladder carcinoma.

The efficacy of IL-2 and IFN treatment led to their approval by the FDA for clinical use in the late 1990's against a wide range of cancers such as advanced renal cell carcinoma, metastatic melanoma, hairy cell leukaemia, follicular non-Hodgkin lymphoma and AIDS-related Kaposi's sarcoma (Berraondo *et al*. 2019). Despite this success, cytokine therapy has several limitations. The first being the severe toxicities that they can cause. Considering the vast effects that cytokines have on the immune system, namely their ability to induce pro-inflammatory activity, administration of potent cytokines can cause a range of haematologic, pulmonary, endocrine, neurologic, dermatological and autoimmune adverse events. Another limitation is the short half-life of cytokines and their sub-optimal localisation to the tumour (Berraondo *et al*. 2019). However, alterations to the cytokine structure can be made to increase the half-life. For instance, IFNα can be pegylated to protect it from proteolytic breakdown, thereby increasing the cytokine's half-life. Additionally, IFNα can be fused to apolipoproteins to increase the cytokine's anti-tumour activity and pharmacokinetics.

Although recombinant cytokine therapy has largely been superseded by CPIs, there is potential for future development through further engineering. Approaches in development include immune-cytokine design where a cytokine is linked to an antibody to deliver tumour specificity and engineering approaches to extend cytokine half-life (Berraondo *et al*. 2019).

Emerging types of immunotherapy

Oncolytic viruses

When a myelogenous leukaemia patient experienced tumour remission after an influenza virus infection, it hatched the idea of using viruses as a therapy against cancer. This discovery, in the early 1900's, led to the concept of oncolytic viruses (OV). OVs are viruses engineered to either lyse tumour cells whilst sparing healthy cells or to incite the immune system to raise an anti-cancer immune response (Zheng *et al*. 2019). In October 2015, the first herpes-derived OV, talimogene laherparepvec (T-Vec), was approved by the FDA for the treatment of advanced melanoma.

Recently, a novel combination therapy has emerged where patients are treated with both OVs and checkpoint inhibition. Several trials are underway, namely involving the combination of OVs such as T-Vec, HF-10, ONCOS-102, Pexa-Vec and a form of checkpoint inhibition. Results have been promising, with one phase I study showing objective response rates of 50% in T-Vec + ipilimumab-treated melanoma patients, with limited toxicity. Another trial of T-Vec + pembrolizumab for the treatment of melanoma has shown similar results, with objective response rates of up to 62%, again maintaining tolerable and limited toxicities. OVs can also be combined with CAR T cell therapy and cancer vaccines.

One of the main barriers to this therapy is the effective delivery of the OVs to the tumour site, as systemic administration of the OVs can result in premature degradation of the viral construct by the immune system. Future work will focus on editing the capsid of the virus to make it 'unrecognisable' to the immune system, and to develop novel carriers, such as transformed cells and tumour cell-derived microparticles to deliver the OV to the tumour.

Allogeneic cell therapies

NK cells

Natural Killer (NK) cells are immuno-surveillant, cytolytic cells belonging to the innate lymphoid cell family. They are activated through a set of stimulatory and inhibitory receptors; therefore, their activation depends on the balance of activating and inhibitory signals present. Once activated, they detect whether the adjacent cells are targeted for killing and induce cytolysis through the release of degradation granules (Shimasaki *et al*. 2020). As well as degrading target cells, NK cells can release multiple effector molecules including IFNγ, Tumour Necrosis Factor (TNF) and CC-chemokine ligand 4 (CCL4) which can modulate and magnify the immune response from other cells (Shimasaki *et al*. 2020). Their ability to modulate the immune response has been investigated as a form of therapy. Studies have shown NK cells to attract effector T cells to the tumour site and enhance the inflammatory response against the tumour. They have also been shown to eliminate circulating tumour cells and prevent the formation of metastasis.

NK CAR therapy

The development of CAR T cell therapy and its clinical success has paved the way for the development of other forms of CAR therapy. In particular, NK cells have been investigated as potential cells with which to express CARs. Studies utilising NK CARs have presented encouraging results, with one, in particular, showing that 64% of treated patients with either non-Hodgkin lymphoma or chronic lymphocytic leukaemia, had a complete remission, without the development of toxicities. There are multiple advantages for using NK cells over traditional T cells for CAR therapy. As hinted in the above study, the primary advantage is the reduced toxicities experienced with NK CARS, as NK cells release cytokines that are less likely to cause CRS and neurotoxicity compared to those released by T cells. By inhibiting the cytokine-inducible Src homology 2–containing (CIS) protein, it is also possible to further enhance the fitness of CAR-NK cells and their tumour cell-killing function. In addition to the engineered CAR-directed tumour killing, NK cells are naturally primed to direct cytolysis against tumour cells through the process of immunosurveillance (Xie *et al*. 2020). Finally, NK CARs have reduced risk of causing graft versus host disease. Therefore, they could represent an 'off the shelf' allogeneic cell therapy, rather than the personalised and costly traditional autologous CAR T cell therapy.

Other cells under current investigation for use as CAR therapies include NKT cells, macrophages and gamma delta T cells.

Future of immunotherapy

Now a standard pillar of cancer treatment, immunotherapy has proven to be specific, durable and effective. Checkpoint inhibition, adoptive T cell therapy, cancer vaccines, cytokine therapy and emerging forms of immunotherapy have all shown encouraging preclinical results with most having been FDA-approved for clinical use.

Despite the high enthusiasm for these forms of cancer treatment in some haematological malignancies, there remain barriers in the treatment of solid tumours, owing to the complexities of the solid TME. Another issue requiring attention is the varying patient response to immunotherapy and the development of resistance to treatment (Sharma *et al*. 2017). This can be explained by the continuously changing TME and interaction between the immune system and cancer cells. Tumour cells are genomically unstable and can produce tumour-cell intrinsic factors that prevent immune-mediated eradicaton (Sharma *et al*. 2017). Due to their instability, cancer cells may not always express the same antigens, thereby facilitating the escape from immune recognition and response (Sharma *et al*. 2017). In addition, extrinsic factors are also at play such as the presence of immunosuppressive cells (Sharma *et al*. 2017).

Advances are currently underway in improving patient selection for treatment (Iivanainen and Koivunen 2020) and in determining the intrinsic and extrinsic factors involved in resistance. Unveiling these mechanisms will not only be vital in overcoming resistance, but also in improving the prediction of treatment efficacy. Biomarkers may also provide a useful tool in predicting how resistant a patient is prior to treatment. Currently, the best markers in solid tumours include total tumour mutational load and density and distribution of $CD8^+$ T lymphocytes (Sharma *et al*. 2017), which may not be directly applicable to many haematological malignancies. Therefore, there is an unmet need to identify predictive biomarkers for response to immunotherapy in the majority of haematological malignancies (Sharma *et al*. 2017). Further to better understanding the TME, it is also necessary to research the molecular and cellular interactions that regulate the immune response in order to optimise efficacy and reduce toxicity.

The future of immunotherapy will also involve reevaluating the costs of these treatments with an aim to decrease the per-patient expense. This is necessary as CAR T cell therapies such as tisagenlecleucel can cost up to US$475,000 per patient, not including the adverse effects of treatment costs. Checkpoint inhibition is similar, reaching up to US$12,500 per month. These costs are due in part to the lack of laboratories that produce the therapies and a lack of standard production procedures which leads to variable outcomes and costs. Broadening the set of laboratories capable of producing immunotherapies as well as standardising the production methodology will be crucial to the widespread and accessible implementation of immunotherapy.

Despite these areas in need of improvement, immunotherapy remains an exciting and promising field of medicine. Novel types of immunotherapy come to surface each year, offering hope to many cancer patients.

CHAPTER 7

Clinical applications of gene editing and therapy

Introduction

The development of targeted gene therapies for patients with genetic disorders has been a goal for medical researchers for nearly five decades (Friedmann and Roblin 1972). Haematological diseases have been at the forefront of this endeavour and genetic therapies are rapidly becoming available as an important treatment modality for many haematological disorders.

Gene therapy in its broadest definition involves the introduction of exogenous genetic material into cells. This is usually but not exclusively achieved using viral vectors or nanoparticles. Cells can be modified with gene therapy approaches either *ex-vivo* by taking cells out of the patient, manipulating them and transplanting them back in, or *in-vivo* by directly introducing the genetic cargo to the target organs.

Genome editing is a relatively new technology that involves specifically modifying the sequence of the host genome to treat disease by precisely altering individual bases or disrupting particular sequences in their native genomic location. In some ways, this is distinct from conventional gene therapy, in which exogenous genetic material is added to cells, but there is considerable overlap because genome editing can also be used to insert sequences into the genome. The first cell therapy product based on genome editing technology obtained regulatory approval for the treatment of thalassaemia and sickle cell in December 2023 and this is likely to become an extremely important treatment modality in the future.

There are many potential applications for gene therapy and genome editing in haematology (Figure 7.1). Many are directed at correcting inherited genetic diseases such as haemoglobinopathies, immunodeficiencies and haemophilias. The other major application is to use exogenous genetic material to reprogram cells to treat disease. This is exemplified by the targeting of immune cells with gene therapy constructs to introduce chimeric antigen receptors, which target these cells to kill malignant cells. A third, important use of gene therapy approaches is to introduce genetic material to create an immune response in the context of vaccination.

In this chapter, we will largely focus on the principles behind genetic therapies and illustrate these using the paradigms of gene therapy and genome editing to treat inherited haematological disorders.

General principles of gene therapy

As early as 1961, it was shown that it was possible to make normal haemoglobin by adding free DNA to cultured cells from bone marrow taken from a patient with sickle cell disease (SCD). This was at levels well below that required for a clinical effect but established that in principle it is possible to correct genetic disorders by introducing exogenous DNA. In the 1980s, it was realised that genetic material could be much more efficiently delivered into haemopoietic cells, which undergo many rounds of cell division, using viruses that integrate into the host genome. Over the last 30 years several different types of viral vectors,

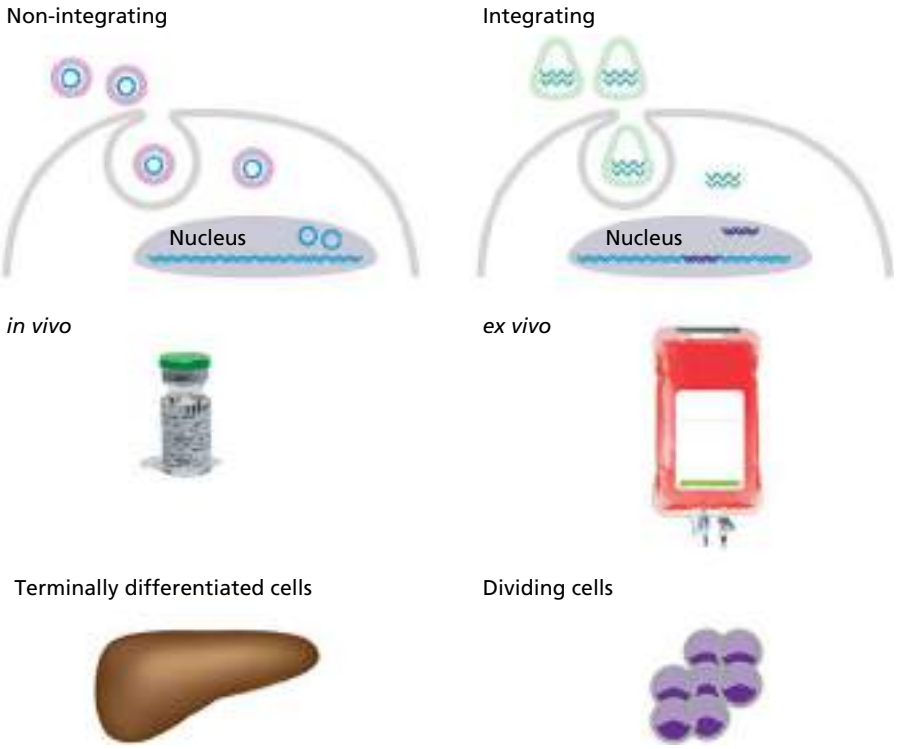

Figure 7.2 Integrating versus non-integrating viral vectors.

vehicles for delivering genetic material derived from viruses, have been used for gene therapy. These broadly fall into two categories depending on whether the DNA becomes integrated into the genome or not (Figure 7.2).

Vectors based on retroviruses (lentivirus, γ-retrovirus) integrate the viral genome into the host genome. This results in long-term retention of the genetic material from the vector because the DNA is replicated every time that the cell divides and all progeny therefore contain the viral construct. However, the viral vector integrates into the host genome in a random or semi-random manner. This can lead to disruption of genes or alterations in the way that genes within the host are controlled, which has the potential to cause malignant transformation.

Non-integrating viral vectors based on adenoviruses or adeno-associated viruses (AAV) deliver genetic material to cells effectively and only rarely integrate into the host genome. The risk of insertional mutagenesis is therefore much lower. However, over time the genetic material has the potential to be lost, particularly

from dividing cells. This is because the episomal viral genome is not replicated along with the host DNA during cell division and is therefore progressively diluted. Therefore, non-integrating viral vectors are only transiently effective in cells with rapid turnover, but they can generate effective levels of expression in terminally differentiated cell types. The age of the patient can make a significant difference to this effect, and it may prevent the use of non-integrating vectors in paediatric patients due to higher levels of cell proliferation compared to adults.

The vectors used for gene therapy have a differential ability to infect different cell types but they do not have perfect cell type specificity. For *ex-vivo* editing, this is not a significant problem because the target cell populations can be purified. However, for *in-vivo* gene therapy approaches, this is extremely important and there are limited numbers of cell types for which there are specific viral vectors available. Some degree of tissue specificity can be introduced into gene therapy approaches by engineering constructs with regulatory elements that encourage gene expression in that particular cell type. However, it is difficult to mimic the endogenous regulation of many genes accurately with a viral construct because many genes are controlled by multiple regulatory elements that act over large distances in the genome. This can be a problem when high levels of gene expression are required. Gene therapy approaches for haemoglobinopathies are particularly challenging because the gene requires expression at extremely high levels. This is an inherent limitation of gene therapy approaches compared to genome editing in which the endogenous gene can be repaired in its native locus with all its regulatory elements nearby.

Another important factor is that many viruses have a limited cargo size. AAV vectors in particular are unable to carry large genes as the wild-type genome is 4.7 kb in size, and this hampers gene therapy approaches for several indications (Wang *et al*. 2019).

Immunogenicity is a key consideration for *in-vivo* viral gene therapy approaches. Since many of the viral vectors used are naturally occurring, prior exposure to the virus or another closely related subtype can commonly occur and if this leads to an immune response with neutralising antibodies it will potentially lead to substantial reduction in the efficacy of treatment. The viral capsid proteins can be engineered to circumvent this problem, but immunogenicity will still be highly likely to prevent repeat dosing with the same therapeutic product.

Genetic material can also be packaged into synthetic nanoparticles which can be used to target entry into cells. There are a large variety of different approaches and this area is likely to expand very significantly in the future.

Gene therapy in haemopoietic stem cells

Although the earliest haemopoietic stem and progenitor cells (HSPCs) are generally quiescent, haemopoietic progenitors and precursors have extremely high rates of cell division and this means that integrating viruses are required for gene therapy approaches for immunodeficiency syndromes and haemoglobinopathies. As the haemoglobinopathies are encountered more frequently in haematology, we will focus on these in this chapter, but readers can be directed to reviews on gene therapy in immunodeficiency syndromes elsewhere (Ferrari *et al*. 2021; Houghton and Booth 2021).

Initially, Moloney leukaemia virus-derived γ-retroviral vectors were used in the first successful gene-therapy cure of an individual with a genetic disease; a 4-year-old girl with adenosine deaminase severe combined immunodeficiency (SCID). Whilst these approaches were efficacious, viral gene therapy has been beset by safety concerns. Notably, there were catastrophic outcomes in some early trials using γ-retroviruses, in which five patients with X-SCID and six with Wiskott-Aldrich Syndrome (WAS) developed T cell acute lymphoblastic leukaemia (T-ALL), with a further patient in the WAS trial developing acute myeloid leukaemia (AML). Furthermore, three of four patients with chronic granulomatous disease developed myelodysplastic syndrome following gene therapy. These transformations to leukaemia were found to be due to insertional mutagenesis at the regulatory elements of transcriptionally active oncogenes; integration into the host genome occurred in a non-random manner.

HIV-derived lentiviral vectors were developed to circumvent the problems associated with γ-retroviruses. Self-inactivating lentiviral vectors were developed with several important safety features. These included removal of the viral promoter from the U3 region of long-terminal repeats (LTRs) and modifications to the manufacturing process to prevent viral replication. Viral replication proteins were placed on different plasmids to those containing the genetic cargo for insertion. These steps have reduced the risk of transcriptional activation of nearby genes and viral-particle replication generating a safer integration profile. Most modern gene therapy approaches use self-inactivating lentiviral vectors.

Gene therapy for thalassaemia

The first individual with a haemoglobinopathy to be successfully treated with gene therapy had HbE/β-thalassaemia. The patient's cells were removed as in an autologous bone marrow harvest, transduced with a lentiviral vector known as HV569 containing a modified β-globin gene and reinfused after myeloablative chemotherapy. The modified version of β-globin involved an amino acid substitution at position 87 (T87Q), making it easy to track the globin produced by the gene therapy product compared to that produced by untreated cells. The patient was transfusion independent at 33 months (Cavazzana-Calvo *et al*. 2010). HbA^{T87Q} made up approximately a third of total haemoglobin in the patient at this time, and the levels stayed similar over the following decade of follow-up, with only occasional transfusions required.

Since then, more than ten phase I and II and two phase III trials have been conducted using lentiviral vectors to treat β-thalassaemia

and SCD using a gene addition or a shRNA knockdown of *BCL11a* approach (Ferrari *et al.* 2021). The BB305 vector (also known as Betibeglogene Autotemcel) was based on HV569, containing HBA^{T87Q}, and was used in phase I/II and III trials involving patients in the US, France, Thailand and Australia who had $\beta^0\beta^0$ and non-$\beta^0\beta^0$ genotypes. In the HBG-04 and HBG-05 studies, patients with a variety of genotypes received an infusion of modified autologous cells (Thompson *et al.* 2018). At a median of 26 months, follow-up 12 of 13 patients with a non-$\beta^0\beta^0$ genotype were transfusion independent, and of the 9 patients with $\beta^0\beta^0$ genotypes, the annualised transfusion requirement went down by 73%. However, only three of these patients became transfusion independent. A longer term follow-up of 4.9 years of patients on the HBG-05 study with transfusion dependent non-$\beta^0\beta^0$ thalassaemia found that all four patients remained transfusion independent. In the HBG-07 phase III study involving patients with non-$\beta^0\beta^0$ thalassaemia, 20 of 23 patients treated were transfusion independent, with a median follow-up of 29.7 months. 12 months after treatment the amount of gene-therapy-derived HBA^{T87Q} haemoglobin was 87 g/L, an improvement from the initial study in 2010. Results from the phase III HBG-212 study of patients with $\beta^0\beta^0$, $\beta^0/\beta^{+IVS\text{-}I\ 110}$, and $\beta^{+IVS\text{-}I\text{-}110}/\beta+^{IVS\text{-}I\ 110}$ genotypes are awaited.

An Italian phase I study utilised an alternative lentiviral vector, named GLOBE. Three adults and six children with $\beta^0\beta^0$ or severe non-$\beta^0\beta^0$ genotypes were treated with the vector. In contrast to the BB305 studies, the stem cell product was delivered intrabone rather than intravenously. At 24 months post-gene therapy all three adults showed a reduction in transfusion requirements, and three of four children achieved transfusion independence.

Finally, a US group utilised the TNS9.3.55 lentiviral vector in their phase I clinical trial. In contrast to the majority of other trials for haemoglobinopathies, reduced intensity conditioning was used prior to product infusion. At 6–8 years follow-up, the longest of the studies discussed here, none of the four patients were transfusion independent. This was felt to be due to the low vector copy number (the number of insertions of the genetic cargo per cell) in the product, 0.15. This was lower than the lowest vector copy numbers found in transfusion independent patients in the GLOBE and HBG trials (0.8 and 0.3 respectively).

Gene therapy for sickle cell disease

The vector used in the HBG trials, BB305 also used HBA^{T87Q}, which in addition to facilitating tracking conferred the β-globin chains with anti-sickling properties as it incorporated the amino acid in the γ-globin chain that is responsible for much of its anti-sickling properties, making the vector suitable for use in gene therapy for SCD. A single patient in France with $\beta^s\beta^s$ was treated with the BB305 vector as part of the HGB-205 trial. At 15 months follow-up approximately 50% of the patient's haemoglobin was comprised of the anti-sickling globin, which is consistent with levels of non-sickle haemoglobin found in patients with asymptomatic sickle-cell trait. There was no recurrence of sickle pain crises, an improvement in iron loading and he was transfusion independent. Longer term follow-up of the HGB-205 trial involved this patient (SCD-1) and two other patients (SCD-2 and SCD–3). The results were mixed, with SCD-2 continuing to suffer pain crises and acute chest syndromes with recommencement of hydroxyurea and exchange transfusions. SCD-1 has had one pain crisis to date since the therapy, but otherwise, he and SCD-3 have remained complication-free and are transfusion independent at 6.7 and 4.3 years post-gene therapy. Subsequent modifications to the protocol included peripheral blood stem cell collection with plerixafor mobilisation to improve the cell dose obtained and an improved manufacturing and transduction process. Results of the phase I/II HGB-206 study were recently published, including 35 patients with median follow-up of 17.3 months (Kanter *et al.* 2022). The mean haemoglobin concentration increased from 85 to 110 g/L or more, with HbA^{T87Q} contributing at least 40% of total haemoglobin. Of 25 patients who were available for evaluation, all had complete resolution of severe vaso-occlusive events. Following this trial lovotibeglogene autotemcel was approved by the FDA for the treatment of patients over the age of 12 with veno-occlusive events.

An orthologous approach has been to use a lentiviral vector to deliver a version of the γ-globin gene instead of β-globin, in order to harness HbF's potent anti-sickling activity. A phase I/II trial using the vector ARU-1801 which contains the modified gamma-globin gene γ^{G16D} delivered using a reduced-intensity conditioning regimen is currently ongoing with promising results (Grimley *et al.* 2021).

Finally, rather than deliver a form of β- or γ-globin, another approach has been to reduce the erythroid-specific expression of the transcription factor BCL11A, which increases γ-globin expression (explained further below). A microRNA-adapted short-hairpin RNA was delivered by a lentiviral vector, which post-transcriptionally silences *BCL11A* expression in erythroid cells through RNA interference. Six patients were initially treated at Boston Childrens' hospital with a median follow-up of 18 months. HbF-induction ranged between 20.4 and 41.3%, and no patient has had an acute pain crisis, chest syndrome or stroke since receiving gene therapy, with two of three patients who were transfusion dependent pre-gene therapy no longer needing red cells.

Safety and efficacy concerns

Given the previous malignant transformations in patients treated with γ-retroviral vectors, patients enrolled on lentiviral vector trials have been monitored closely. In the initial lentiviral trial, approximately 45% of vector-bearing nucleated red blood cells were found to contain a clonally expanded insertion of the

construct within the third intron of the gene *HMGA2*. To date, these clones have not progressed into a malignant disorder. More concerningly, 5.5 years after treatment, a female with SCD in HBG-206 Group A developed AML (Goyal *et al*. 2022). 86.7% of CD34+ bone marrow cells at AML diagnosis were lentiviral vector positive, and the relative frequency of insertions at a particular gene, *VAMP4*, was 98.6% at this time. However, as there was low transgene expression in blast cells, no perturbation of *VAMP4* expression or that of surrounding genes and the presence of known molecular and cytogenetic AML-driver mutations, it was felt that the AML was unlikely to be related to the vector insertion. A similar conclusion was reached in the case of another patient with SCD in HBG-206 Group A who developed MDS and then AML, though in this case vector insertion in blast cells was not detected. Notably, SCD is known to be a chronic inflammatory disorder, with an excess risk of developing malignant haematologic disease. Clearly longer term follow-up is needed to fully assess the safety profile of patients with haemoglobinopathies receiving viral-vector-based gene therapy.

Gene therapy for haemophilia

Gene therapy is becoming an important treatment modality for haemophilia and the first gene therapy products have recently received authorisation by regulatory agencies in the UK, Europe and the United States. Here *in-vivo* gene therapy approaches have been used with non-integrating viruses. Hepatocytes are readily infected by non-integrating AAV vectors and because these cells do not undergo rapid turnover, in contrast to HPSCs, persistent expression from AAV vector constructs has been seen several years after treatment. In children, hepatocyte proliferation is greater than adults and it is likely that gene therapy in children will lead to gradual loss in factor production as they progress into adulthood.

Immunogenicity is a major concern with current AAV vector gene therapy approaches. Around 30–80% of the population have neutralising antibodies to AAVs depending on the serotype of the virus and the geographical location of the study. Generally, the presence of neutralising antibodies is an exclusion criterion for treatment at present. Following administration of AAV vectors there is a very potent immune response probably making repeat dosing ineffective.

AAV vector approaches have been developed for both Factor VIII (FVIII) and Factor IX (FIX). Development of gene therapy for haemophilia B has been more straightforward than for haemophilia A for a number of reasons. First, the gene is smaller and can easily be packaged into AAV vectors, whereas the FVIII gene is too large (cDNA ~9 kb) and so all current transgene approaches have used truncated forms of the gene, generally with the B domain removed. Secondly, FIX is synthesised natively by hepatocytes whereas FVIII is largely synthesised in endothelial cells. Finally, there is a gain of function variant for FIX (FIX Padua), which allows therapeutic FIX activity with lower protein levels.

Therefore, the first successful gene therapy trials were for haemophilia B but in the last few years gene therapy for FVIII has caught up and fully licenced products became available for haemophilia B (etranacogene dezaparvovec) in late 2022 and haemophilia A (valoctocogene roxaparvovec) in 2023.

The main side effect of AAV gene therapy approaches for haemophilia is hepatic toxicity, which usually occurs 1–3 months following treatment. The pathogenesis is not completely understood but it likely relates in part to the immune response to the AAV vector and partly due to direct hepatocyte toxicity caused by high levels of clotting factor protein expression, which is a particular problem with FVIII therapy. This is treated empirically with corticosteroids (e.g. prednisolone 1 mg/kg) with addition of other immunosuppressants in a subgroup of patients who fail to respond.

The longer term safety of gene therapy for haemophilia will not fully be known for several decades. Long-term follow-up of these patients is important and the international haemophilia gene therapy registry is being developed to facilitate vigilance.

The duration of responses following AAV therapy can be excellent. From the initial haemophilia B study, only a minimal decline in FIX levels was seen at 8 years post-treatment. However, this may not hold true for all cases. In the longest duration FVIII study, levels have been seen to decline substantially at 4 years post-treatment down to 0.2 IU/mL; a level which provides substantial bleed protection but it is unclear whether this will continue to fall. Predicting the clotting factor levels post-therapy has proven to be difficult. In human trials to date, there has been a 10-fold range in variability between different subjects (0.2 to >2.0 IU/mL). This variability likely results from a number of factors including how well the virus enters hepatocytes, the process by which the transgene remains episomal, the complexity of production of the protein by hepatocytes and differences in secretion and clearance of the proteins, which is also highly variable for FVIII and FIX in the normal population.

Genome editing

Within the last decade, huge advances have been made in genome editing technologies. These allow the genome of human cells to be altered precisely. This is the beginning of a new era for us as a species because we are now not only able to read our own genetic code but also edit it at will. It is worthwhile thinking about the scale of what this technology allows us to do. The human genome is made up of 3 billion base pairs and we are now able to change the sequence of the genome precisely in millions of cells simultaneously at nearly any site we choose, with high efficiency. It is an incredible feat which will almost certainly lead to huge advances in therapeutics and not simply for inherited genetic disorders, whilst at the same time raising

important ethical concerns. Regulatory approval for the first genome edited product for treatment of thalassaemia and SCD (exagamglogene autotemcel) was obtained in late 2023.

Genome editing relies on the use of proteins known as endonucleases, which can be programmed to bind to specific DNA sequences. These endonucleases have an intrinsic ability to cut DNA at their binding site but they can be attached to other proteins to confer a variety of different effects at the target site. Several different types of programmable nucleases have been developed including meganucleases, zinc finger nucleases (ZFNs) and transcription activator-like effector nucleases (TALENs) but the discovery that the clustered regularly interspersed short palindromic repeat (CRISPR)/CRISPR associated proteins (Cas) system could be used for genome engineering transformed the field (Kim and Kim 2014).

The CRISPR/Cas system evolved in bacteria as a defence against infection by viruses. First described in 1993, it was found to utilise *cas* endonucleases that could cut and neutralise viral phage DNA but only when the virus had previously been encountered. We now know that during viral infection in bacteria, part of the viral DNA becomes incorporated into the CRISPR sequences in the bacterial genome and this directs the *cas* proteins to cut and neutralise that sequence in subsequent infections. In 2012, two groups used recombinant Cas9 and *in-vitro* transcribed RNA to show that the CRISPR/Cas9 system could be reprogrammed to cut DNA *in-vitro*. This RNA, known as a guide RNA (sgRNA) is complementary to a target genomic sequence and guides the Cas9 endonuclease to theoretically any sequence in the genome. This is hugely powerful because it can be used to cut any DNA sequence and this work earned Jennifer Doudna and Emmanuelle Charpentier the Nobel prize for chemistry in 2020. The potential bioengineering and therapeutic applications were very rapidly exploited and the following year the system was adapted for use in mammalian cells.

General principles of genome editing

Several different types of genome editing have been developed (Figure 7.3). Initial approaches used endonucleases to create a double-stranded break (DSB) in the DNA at the target site. This is usually repaired by the non-homologous end joining (NHEJ) pathway, which usually causes a small deletion at the target site although occasionally insertion of small sequences can occur. This process can have very high editing efficiencies (even as high as >95% of alleles) and several approaches have been developed to utilise these small deletions for therapeutic effect but generally, it is not ideal for repairing mutations precisely because a mixture of different editing outcomes are seen leaving a 'scar' at the target site.

Alternatively, the homology-directed repair (HDR) pathway can seamlessly repair the DSB and this can be used to change the

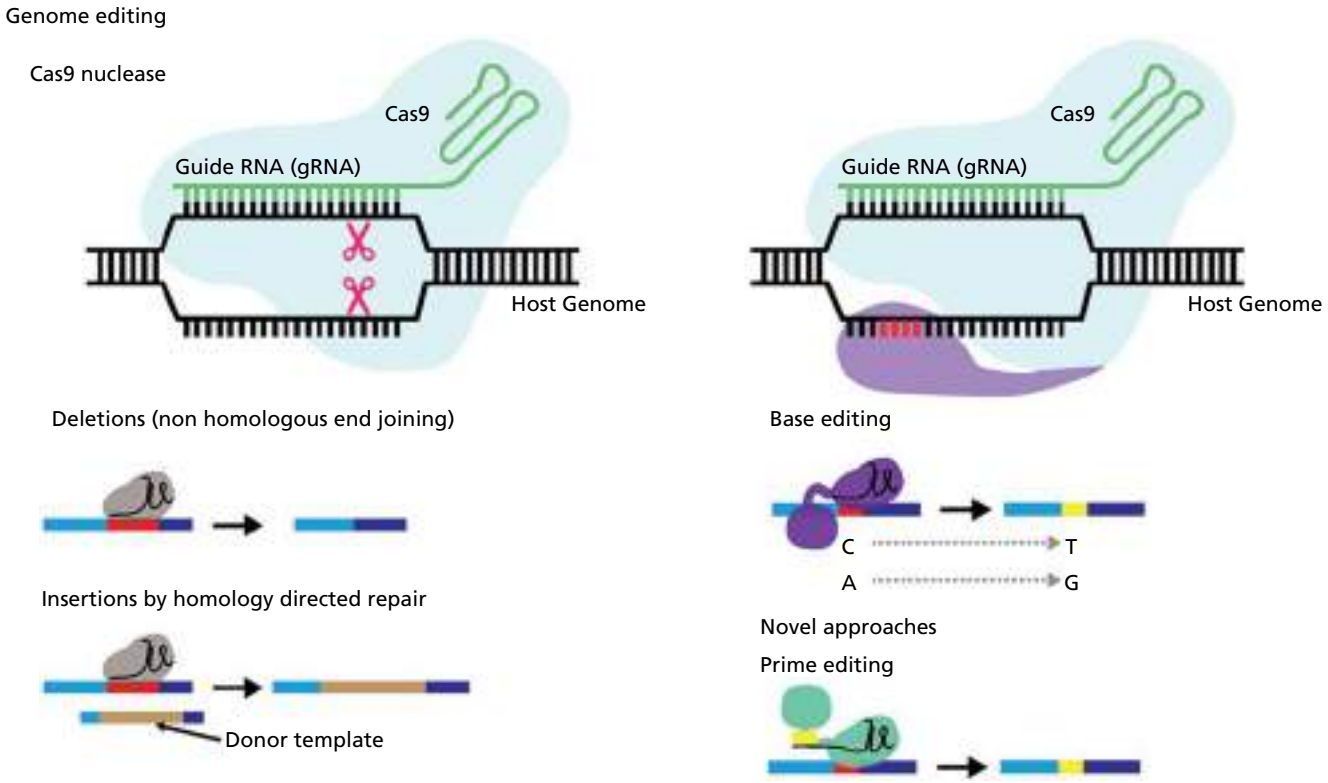

Figure 7.3 General principles of genome editing.

DNA sequence by supplying a DNA template with the desired repair sequence. Whilst this can potentially repair genetic mutations, such as the SCD mutation, the process is not as efficient as NHEJ. Furthermore, HDR preferentially occurs in actively dividing cells and quiescent HSPCs are therefore more challenging to edit with HDR.

A third alternative is the use of base editors. Base editors are naturally occurring deaminases that are able to irreversibly change one DNA base to another *in-situ* without the need for DSBs.

These systems allow transitions of A–G and C–T but not transversions from purine to pyrimidine or vice-versa (A–C or G–T). Recently glycosylase base editors have been reported which allow conversion of purine to pyrimidine but these have lower editing efficiencies. Base editors have the potential to make highly specific edits and the off-target effects may be lower than with conventional genome editing.

Further experimental approaches have been developed that further extend the scope of genome editing. For example, prime editing uses a reverse transcriptase to convert part of the guide RNA into a template to alter the DNA sequence. This has the potential to allow highly efficient repair of small deletions or sequence changes that cannot be achieved with base editors. Finally, another area with therapeutic potential is termed epigenome editing. Here the genetic code is left unchanged but the epigenetic annotation of the DNA and histones is altered and this can be used to both turn on genes and inactivate them. This can result in changes in gene expression that persist despite many rounds of cell division.

Delivery of genome editing technology

In contrast to conventional gene therapy, the editing proteins and RNAs only need to be expressed by cells for a short period of time because once the DNA sequence has been edited it will remain altered indefinitely in the cell and its progeny. Editing machinery can be delivered into the cell in one of three broad ways: electroporation, lipofection and viral transduction (Stewart *et al*. 2016).

Electroporation is a membrane-disruption-based approach first used in 1982. Cells and the material to be electroporated are held in suspension, between two electrodes and electrical pulses are used to transiently disrupt the membrane. Whilst there is some cytotoxicity, partly depending on the biomolecules being transferred, electroporation is commonly used as it is rapid, is applicable to a diverse set of primary cells, has a defined period of transfection, is straightforward to perform and is not immunogenic. For human clinical uses, electroporation is only used *ex-vivo*.

As with gene therapy, gene editing components can be delivered into the cell via viral vectors, with similar strengths and weaknesses as described above. Non-viral carrier-based techniques involve the use of lipoparticles, polymers or other non-organic nanoparticles to enclose editing machinery and deliver it to the cell through fusion with the cell membrane. These techniques are attractive as they potentially circumvent cellular toxicity of electroporation and the genotoxicity of viruses. In addition, they could lend themselves to *in-vivo* therapy.

CRISPR/Cas9 components are delivered into the cell in several different forms: as DNA, mRNA or pre-formed ribonucleoproteins (RNPs). If DNA is delivered, the cell's machinery must transcribe the DNA into mRNA and translate this into Cas9 protein before editing can occur. Nucleic acid and viruses often induce type I interferon responses in the host cells. Alternatively, the editing machinery can be delivered as mRNA. This results in more rapid, transient editing because it only requires the protein to be translated by the host cells. Finally, very high editing efficiencies can be achieved by manufacturing Cas9 protein, incubating it with the sgRNA and delivering this as an RNP. Current clinical trials using CRISPR/Cas9 for patients with SCD and β-thalassaemia have used RNPs combined with *ex-vivo* electroporation of CD34+ HSPCs. However, *in-vivo* approaches with viruses are beginning to come into the clinic for other indications.

Genome editing for the β-thalassaemias and sickle cell disease

The β-haemoglobinopathies are an attractive candidate for the use of CRISPR/Cas9-based gene editing. Decades of research means that the α- and β-globin loci are amongst the most well studied and best-understood genes in the genome in terms of their regulation. In addition, the technology for harvesting and transplanting HSPC has been optimised over the last 50 years and it is well understood how to perform haemopoietic stem cell transplantation for patients with haemoglobinopathies. This allows *ex-vivo* editing to be used to correct these defects. Combined with the huge burden of disease this has made correction of haemoglobinopathies one of the first targets to enter the clinic and multiple approaches have been developed, which demonstrate many of the key principles of genome editing (Figure 7.4).

Approaches for treating haemoglobinopathies through elevation of fetal haemoglobin levels

One of the tragedies in SCD and β-thalassaemia is that the vast majority of patients have a completely normal fetal haemoglobin gene, and they only develop disease because this gene becomes repressed during the first few months of life. Understanding this switching process has been the focus of huge research effort. A key advance came in 2007 when Swee Lay Thein's group at King's College London discovered that the *BCL11A* gene plays a critical role in determining HbF levels (Menzel *et al*. 2007). *BCL11A* has subsequently been shown to be a developmental-stage specific repressor of γ-globin expression and it can be targeted for

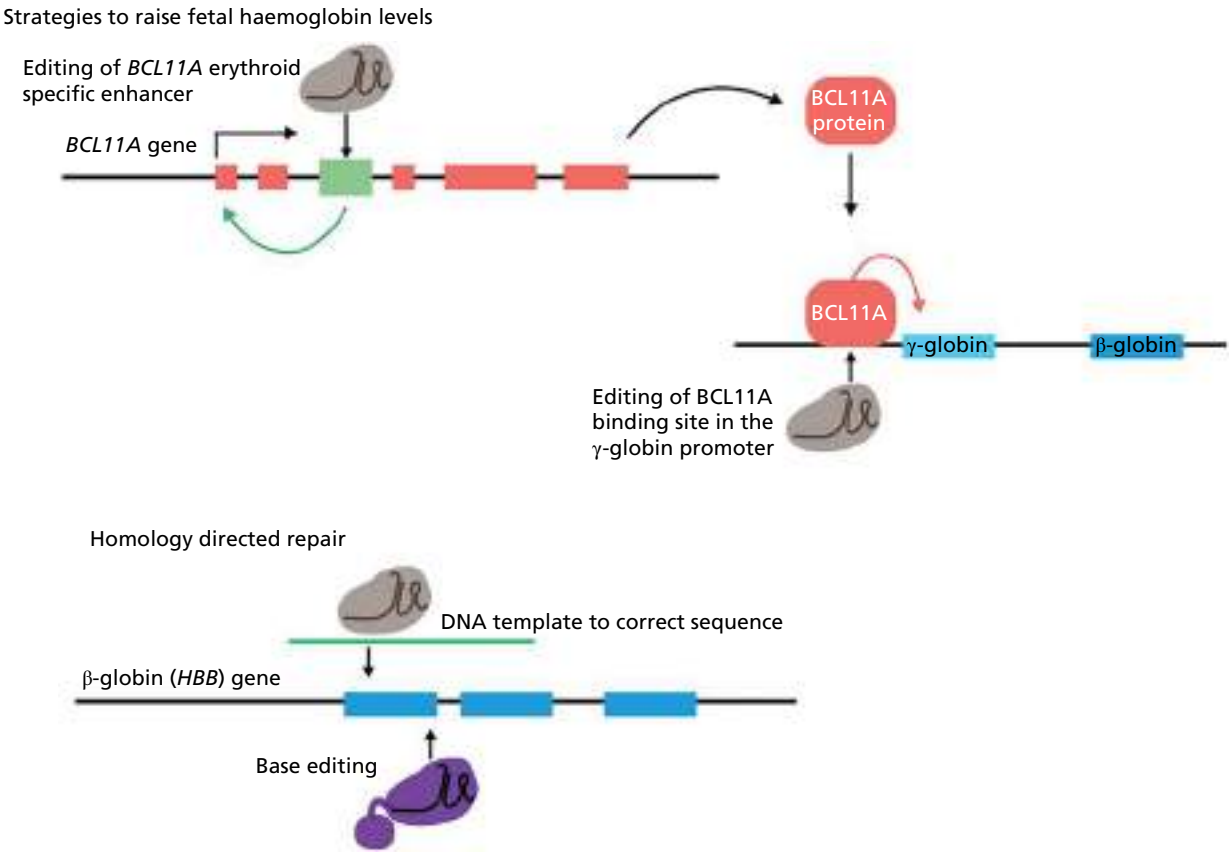

Figure 7.4 Different approaches for using genome editing to treat haemoglobinopathies.

therapeutic reactivation of HbF. A significant advantage of this approach is that it can be used to treat nearly all β-haemoglobinopathies irrespective of the mutation.

Reducing expression of *BCL11A* results in increased HbF levels but the gene is also important in lymphoid development so targeting of the gene itself is not possible without causing immunodeficiency. However, the expression of *BCL11A* can be reduced specifically in erythroid cells through editing of the sequences that control when the gene is turned on (known as enhancers). *BCL11A* and other repressors are known to bind to the promoter of the *γ-globin* gene. These binding sites are known to occur in hereditary mutations causing hereditary persistence of fetal haemoglobin (HPFH).

The first phase 3 studies in patients with β-thalassaemia and SCD using the *BCL11A* enhancer-editing approach have been undertaken and are promising (Frangoul *et al.* 2024; Locatelli *et al.* 2024). It is possible to manufacture edited CD34+ cell products with editing efficiencies of >70%. 32 of 35 patients treated for β-thalassaemia became independent of blood transfusion with a mean Hb level of 131 g/L, with a median follow up of 20.4 months post-transplant. For SCD HbF levels of 43.9% were achieved and 29 out of 30 patients with sufficient follow up were free from vaso-occlusive crises for at least 12 consecutive months although 6 of 43 patients had a crisis at some point post transplant. These patients had significant adverse events because the approach requires full-intensity conditioning. The most serious events were associated with prolonged neutropenia (median neutrophil engraftment occurred on day +27 (range 15-40)). The long-term safety of these approaches is likely to be favourable compared to gene therapy approaches, but the full safety will not be known for many years.

Approaches for treating haemoglobinopathies through direct correction of the gene

It is possible to repair mutations using a repair template through homology-directed repair (HDR) pathway. Unfortunately, HDR is less efficient than NHEJ and HDR preferentially occurs during cell division and this particularly makes it challenging to edit haematopoietic stem cells, which are largely quiescent.

Despite these problems, HDR approaches have been optimised in HSPCs, and reasonably high editing efficiencies are possible. In particular, an approach which combines Cas9 in ribonuclear protein format with an AAV viral vector to deliver

the HDR template can achieve editing efficiencies in the order of 60%. These approaches are likely to enter into clinical trials in the near future.

Base editors, which directly modify the DNA at the target site can also be used to correct mutations but with significantly higher editing efficiencies than HDR. The potential disadvantage of this approach is that a specific editing strategy has to be developed for every mutation and these enzymes are only able to convert C–T or A–G, meaning that not all variants can be corrected. However, the two most important variants of β-globin in terms of disease burden (HbS and HbE) can be corrected with base editors. Interestingly HbS is an A to T transversion which is difficult to correct with a base editor, however, it can be corrected to a non-pathogenic variant (Hb Makassar), which does not cause a sickling phenotype. Similarly, HbE can be corrected to a variant haemoglobin (Hb Aubenas), which also has a normal phenotype.

Safety of genome editing

Whilst genome editing offers an attractive alternative to random/semi-random viral integration-based therapies, there are still safety concerns surrounding adverse editing outcomes. Characterisation of these events is complex because mutations and other forms of cellular toxicity can occur at any point during the manufacturing process. In addition, HSPCs from patients may carry higher rates of underlying mutations and pathology may only occur after additional mutations accrue *in-vivo* after cells have been transplanted, which means that it will take many years for the toxicities of cellular therapies to be fully known. However, it is important to weigh the potential toxicity against the toxicity of the underlying disease process and the toxicity of other treatment options. For many conditions which severely limit life expectancy and quality of life, this means that substantial levels of off-target effects are acceptable but clearly patients will need to be counselled carefully until the safety is fully known.

Unintended consequences from genome editing can occur at the site of editing. When an editor is used to make a deletion the majority of editing outcomes will be mediated by NHEJ and most of these outcomes are deletions that are under 50 bp. However, it has been observed that large deletions spanning many kilobases can also be generated. These have even been shown to extend to megabase scale, and involve chromosomal losses in human embryos.

Cells can develop chromosomal translocations at the editing sites, particularly if more than one site is being targeted simultaneously. Providing oncogenes are avoided, these are unlikely to be pathogenic but deliberate cutting of the genome at sites associated with recurrent translocations in haematological malignancy will cause pathogenic translocations. Beyond simple deletions and translocations, more complex local and large-scale rearrangements have been observed, ranging from small inversions to chromothripsis (chromosome shattering). DSB formation following Cas9 editing has been shown to activate the cellular p53 DNA damage response, with potential to confer a selective advantage to cells carrying a *p53* mutation.

A second major adverse consequence of editing is 'off-target effects'; editing at sites that have sequence similarity to the guide RNA directing the editor to the target site. This off-target editing could potentially cause disruption to genes and sequences anywhere in the genome. Potential off-target sites can be profiled with computational and molecular biology approaches and targeted sequencing approaches allow rare mutations at these sites to be detected. It is possible to profile the consequences of these types of off-target effects and redesign unfavourable targeting guide RNAs. Thus far trials using conventional Cas9 off-target events have not been problematic, with the caveat that current sequencing approaches do not have sufficient sensitivity to readily detect sporadically occurring mutations in populations of cells.

Conclusion

Haematological diseases and the manipulation of haematopoietic cells have been at the forefront of genetic therapies, from the inception of the field in the 1970s and 1980s. Recent technological advances have seen a rapid expansion in this area in recent years, with high-profile trials yielding very promising results. With the development of CRISPR/Cas9-based strategies the promise of meaningful long-term cures for many inherited blood disorders is closer than ever. However, the permanent and irrevocable nature of these treatments, combined with the lack of long-term safety data and the rapid pace of developments both in genetic therapies but also in alternative conventional therapeutics, presents a major challenge for clinicians and patients. The decision whether to go ahead with a therapy that will last the duration of the patient's lifetime and is likely to be superseded by safer alternatives will have to be carefully balanced with the patient's symptoms and prognosis. Given the uncertainties and the lack of a straightforward approach to patient selection, these patients will need to be carefully advised prior to treatment. Translating these early successes into accessible and affordable therapeutics for patients with both common and rare disease will be a major challenge for the field. However, it is likely that gene editing will become a major treatment avenue for patients with haematological disease in the decades to come.

Introduction

Since the discovery of the Philadelphia chromosome in chronic myeloid leukaemia and the *HBB* p.(Glu6Val) amino acid substitution in sickle cell disease, it has been clear that genomic investigation has a key role to play in the diagnosis and management of a broad range of both malignant and non-malignant haematological disorders. Although the use of genomic techniques in haematology is not new, over the last decade there has been widespread adoption of Next-Generation Sequencing [NGS] technologies allowing the rapid acquisition of much larger quantities of genomic data than previously achievable.

NGS, also referred to as massively parallel sequencing, relates to technologies which permit multiple nucleic acid fragments to be sequenced simultaneously, allowing many regions from numerous individuals' genomes to be analysed in a single reaction. An NGS assay can vary from sequencing a few hundred bases of an individual's genome to the entire genome (Whole-Genome Sequencing [WGS]). In addition to the speed and data breadth advantages this brings over conventional Sanger sequencing, the ability to analyse multiple fragments of nucleic acid covering any single region of the genome means the depth of sequencing and, therefore, sensitivity is much higher. Consequently, mutations with lower allele frequency changes can be detected, which is often highly relevant in the acquired disease setting. The massively parallel nature of the technologies also significantly reduces the cost of sequencing improving its affordability for routine implementation in appropriate clinical scenarios.

NGS technology

A summary of some of the technologies underpinning NGS is shown in Figure 8.1 and discussed in greater detail below. These can be divided into short-read technologies which typically sequence 50–300 base pairs [bp] in each read (nucleic acid fragment) and long-read technologies which can sequence over 10,000 bp (i.e. 10 kb) in a single read. Currently, short-read technologies constitute the bulk of clinical NGS services but long-read technologies are being explored for possible implementation. Whichever technology is used, there are some pre-sequencing steps which are common to most and are encompassed in the process of 'library preparation', with the library being what will ultimately be sequenced. Differences in library preparation relate to the nature of the input substrate (i.e. DNA, RNA or cDNA), the scope of the assay (breadth of genome to be sequenced and variant type to be detected), and in the case of a targeted panel whether amplicon or hybridization technology is being employed.

Choice of input substrate

The choice of assay substrate will depend on the combination of the type of genomic information required and the technology being used. Typically, with short-read technologies DNA is used

for small variants (often classified as single nucleotide variants [SNV] and small insertions or deletions up to 50 bp) and copy number variant (CNV) detection, while cDNA reverse transcribed from RNA is used to identify structural variants (SV) (i.e. inversions and balanced translocations) and measure gene expression (i.e. to what degree a gene is being transcribed to RNA allowing its protein product to be produced). However, it is possible to detect structural variants using DNA, particularly if extensive intronic and intergenic regions are sequenced in the assay. Where a translocation brings a promoter/enhancer from one gene in proximity to the coding region of another gene (e.g. *IGH* translocations with *MYC*, *CCND1* and others), it is preferable to use DNA as the substrate as promoter/enhancer regions do not undergo mRNA transcription and therefore such translocations will not be detected using cDNA as the substrate.

The tissue of origin of the nucleic acid substrate (and its preservation) can also have implications for the choice of downstream assay. Typically, peripheral blood can be used for the detection of germline variants in non-malignant haematological disorders; this is usually a bountiful source of high-quality fresh DNA and RNA. Many haematological malignancies are present in either peripheral blood and/or bone marrow aspirate samples, similarly providing an excellent source of nucleic acids. Some haematological malignancies, however, are only found in tissue biopsies (often from lymph nodes) or bone marrow trephines both of which usually undergo formalin fixation followed by paraffin embedding (FFPE) in order to aid morphological assessment.

Formalin fixation can cause hydrolytic deamination of cytosine to uracil which can result in artefactual C:G>T:A substitutions upon sequencing. Extraction of nucleic acid from paraffin often involves the use of sufficient heat to cause significant fragmentation of the DNA resulting in very short molecules; this precludes nucleic acids obtained from FFPE material being used in long-read sequencing and can limit the ability of short-read sequencing to detect more complex genomic abnormalities from this sample type. An additional consideration with using bone marrow trephine samples as a source of nucleic acid is the decalcification method employed with EDTA (i.e. E hylenediaminetetraacetic acid – a weak acid) allowing

extraction of much higher quality DNA compared to more traditional decalcifying agents such as hydrochloric acid.

In certain circumstances, it is desirable to undertake testing of a germline sample in haematological malignancies: This may be to confirm that an abnormality detected in a tumour sample was constitutional in origin rather than somatic. Alternatively, it may be in the context of a broad assay like WGS where the availability of the germline sequence will allow, through a tumour:normal subtraction, the determination of which variants are acquired and therefore associated with the development of the malignancy. In the event, the malignancy is known or suspected to be in the peripheral blood this cannot be used as the germline source as the presence of tumour in the germline sample will result in the removal of the tumour variants at the time of the tumour:normal subtraction. Many alternative samples have been investigated as potential germline samples in haematological malignancies. Although saliva and uncultured skin samples are usually an adequate germline for lymphoid malignancies, they are often relatively heavily contaminated with myeloid lineage cells (usually neutrophils) which can harbour the 'tumour' mutations. DNA obtained from nails is often of poor quality and although usually uncontaminated; DNA from hair follicle cells can be limited in quantity. It can also be challenging to sort CD3+ cells to sufficient purity and in sufficient quantity for NSG assays with higher DNA input requirements and these may contain any mutations which arose at the level of the haematopoietic stem cell. Therefore, the gold standard germline sample is cultured fibroblasts although it is noted that this both involves the patient undergoing a skin biopsy and the requirement for this to undergo *in vitro* culture which may not be routinely available.

Choice of assay breadth and depth

The breadth of an assay or footprint (i.e. region of the genome to be sequenced) will depend on what genomic information is desired. In both malignant and non-malignant haematology, there is often a defined list of variants to be demonstrated or excluded which can be appropriately accommodated on a targeted panel. If information about CNVs is required, a single nucleotide polymorphism (SNP) backbone can be deployed across a DNA-based panel. Through the even distribution of these regions containing polymorphisms across the genome, deletions/amplifications and regions of loss of heterozygosity (LOH) (i.e. where one allele is lost either due to deletion or in the case of copy neutral LOH replacement with the other allele) can be inferred without the need to sequence the entire genome.

The depth of sequencing (i.e. number of reads covering a region of the genome) required for a DNA-based assay will depend on the expected variant allele frequency of the genomic abnormalities (i.e. percentage of analysed DNA at that position having the abnormality): In non-malignant haematology, the inherited i.e. germline variants under investigation would be expected to have allele frequencies of ~50% or ~100% (providing there is no germline mosaicism). Panels designed to detect only germline variants usually have a minimum coverage of ~30× (i.e. at least 30 sequencing reads cover each nucleotide in the target regions). In contrast, acquired variants would be expected to have highly variable allele frequencies depending on whether they are fully clonal or sub-clonal and the proportion of mutated cells in the blood, bone marrow or tissue. Most assays designed to test for acquired variants have a minimum coverage of ~250× (although many often sequence deeper) in order to be able to detect variants with an allele frequency of at least ~5–10%.

An alternative to a targeted panel, particularly if there is any ambiguity surrounding the diagnosis, is to perform Whole-Exome Sequencing (WES) and then apply virtual panels to the data bioinformatically. This DNA-based technique sequences all the protein-coding regions (i.e. exons) of the genes in a genome (~1% of the whole genome) so is ideal for detecting SNVs and CNVs involving exons. Target sequencing depth is typically 30–100× depending on its application. Although used by some in malignant haematology diagnosis, it will not detect many translocations owing to the absence of sequencing covering intronic and intergenic regions. It is, however, increasingly used in non-malignant haematology to identify germline variants and allows sequential panels of gene targets to be applied to data, particularly useful if a phenotype evolves or new data becomes available relating to causative mutations for any specific disease. This approach removes the need for laboratories to continually validate new targeted panels as genomic knowledge increases.

For an unbiased approach for SV detection or gene expression quantification, whole transcriptome analysis/whole RNA-seq can be used. The former analyses coding and non-coding RNAs while the latter concentrates on mRNA. Although such comprehensive RNA analyses are currently more typically employed for research purposes, whole transcriptomic analysis is being used by some in clinical practice in combination with either WES or WGS to provide the most comprehensive analysis of the genome. Aside from the additional gene expression data (which for a genome-wide analysis would normally require a microarray), when combined with WES it provides the 'missing' SV data, and when used in conjunction with WGS it provides information as to whether SVs at the DNA level result in altered mRNA expression, therefore suggesting they are functional.

WGS is a DNA-based assay which aims to sequence the entire genome and therefore can detect all variant types, including translocations. If being used for germline variant detection sequencing at a depth of ~30× is usually considered adequate whereas if discovery of acquired variants is required, depths of ~70–100× are usually aimed for.

Amplicon versus hybridization panel

Broadly, two different approaches exist for the enrichment step of library generation for targeted panels as shown in Figure 8.2. The amplicon-based approach first involves a multiplex

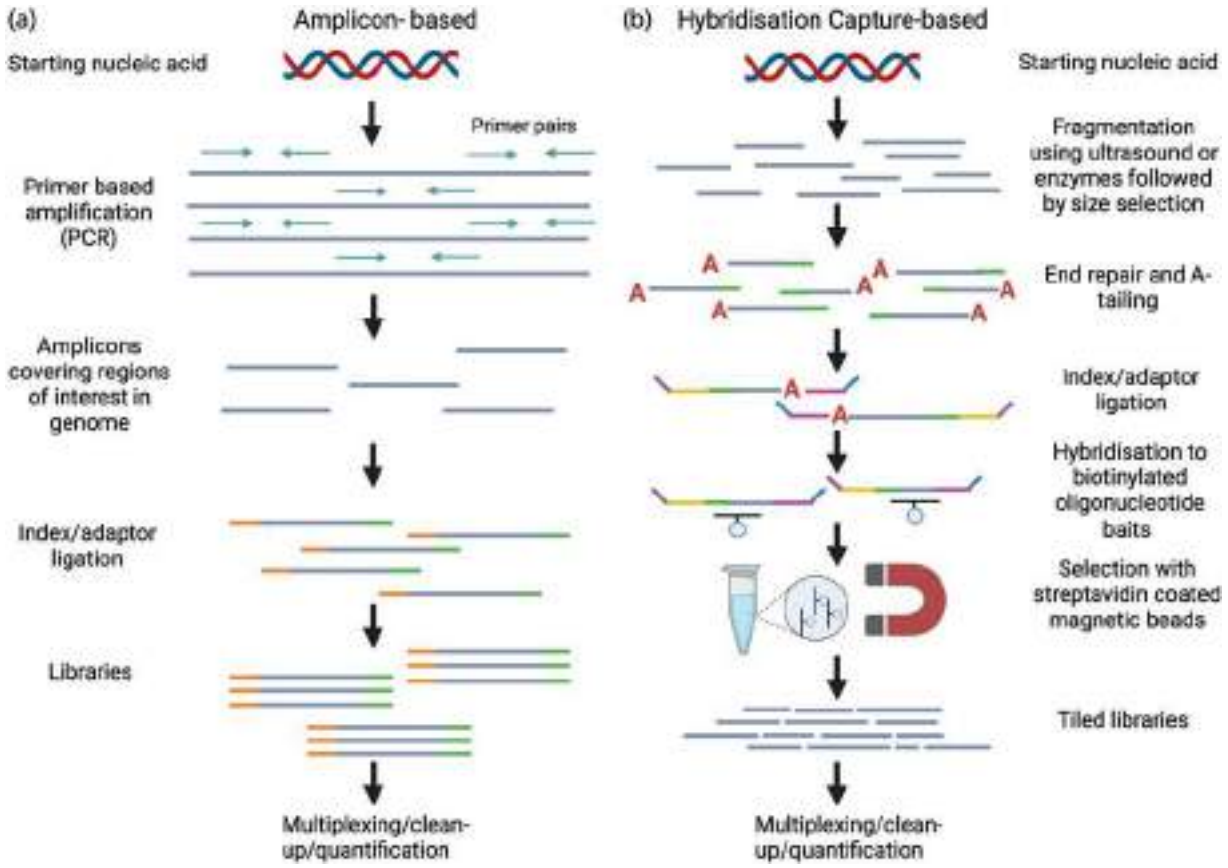

Figure 8.2 Outlines the main steps in Amplicon-based and Hybridization Capture-based library preparation. (a) amplicon-based, (b) hybridization capture-based. Created with BioRender.com.

Polymerase Chain Reaction (PCR) which uses oligonucleotides flanking the regions of interest in the genome, allowing their amplification. The hybridization capture-based approach involves first fragmenting the genome (most commonly performed ultrasonically or enzymatically), before incubating with biotinylated oligonucleotide probes which are complementary to regions of interest. Nucleic acid fragments hybridised to the probes are then selected using streptavidin-coated magnetic beads. Each approach has advantages and disadvantages as outlined in Table 8.1.

The fragmentation step of hybridization panels means nucleic acid molecules sequenced covering any particular target will have a large range of combinations of first and last nucleotides. Therefore, it is much easier to identify families of identical reads likely to have been generated from a single starting molecule which can then be collapsed (i.e. PCR repeats removed), allowing only one read in the family to contribute to the final sequencing result. In contrast, all reads derived from an amplicon-based approach covering any particular target will have the same first and last nucleotides as these have been determined by the oligonucleotide primers used. In this situation without the use of Unique Molecular Identifiers/Indexes ([UMIs] – described below), it is not possible to remove PCR duplicates meaning it is not possible to exclude a variant being a sequencing artefact.

Library preparation

Figure 8.2 outlines the specifics of library preparation for the two targeted panel approaches but there are additional steps which are common to both. In order that DNA from more than one individual can be sequenced in a single reaction (i.e. multiplexed), it is necessary to 'label' the DNA from each individual with an index (or indexes); these are short sequences of DNA which are ligated to one or both ends of the DNA molecules originating from an individual which ultimately allow each sequencing read to be assigned to the correct person's genome.

In addition to the ligation of indexes, various platform-specific adaptors are used, particularly in sequencing by synthesis methods which allow DNA molecules to adhere to surfaces (e.g. beads or flow cells) where sequencing steps are taking place. Other common steps include size selection/clean-up steps (where DNA molecules of inappropriate length and excess indexes and adaptors can be removed) and DNA quantification steps (can be fluorescence or amplification-based) to ensure

Table 8.1 Comparison of advantages and disadvantages of hybridsation-based versus amplicon-based library preparation.

	Hybridization-based library preparation	Amplicon-based library preparation
Workflow	More complex (typically 1–2 days)	Less complex (typically <1 day)
Cost	Varies*	Generally considered to be cheaper*
Input nucleic acid	>10 ng**	<10 ng**
Capture size	Virtually unlimited	Usually <10,000 amplicons
Assay characteristics	More even coverage of targets owing to less differential annealing of oligonucleotide probe More off-target reads owing to probes annealing to non-target regions	Less even coverage of targets owing to differential annealing of oligonucleotides leading to amplification bias Fewer off-target reads
Sensitivity	~1% with removal of PCR repeats without the need for UMIs	~5% in the absence of UMIs
Variant detection	SNVs/small indels CNVs	SNVs / small indels

* Cost will vary depending on the specific design of the assay but for smaller footprints amplicon panels are generally considered to be cheaper than hybridization panels overall.
** The required nucleic acid input will vary depending on the specific assay but amplicon panels generally can tolerate lower inputs than hybridization panels.

that when libraries from different individuals are combined the desired sequencing depth for each sample can be obtained.

In order to improve the overall accuracy of sequencing, particularly if quantification of a variant is required, UMIs can be used. These are short 'unique' nucleic acid sequences which are ligated to each individual DNA molecule prior to any amplification during library preparation such that every input DNA molecule has its own UMI sequence and can be separately identified. UMIs are particularly useful if very little input nucleic acid is available and the likelihood of large numbers of PCR repeats is high, or if very high-depth sequencing (e.g. tens or hundreds of thousands of reads) is occurring to look for rare variants e.g. in measurable residual disease (MRD) monitoring, where an early error may falsely bias the detection of MRD.

Short-read technologies

As discussed above, short-read technologies relate to those which sequence nucleic acid fragments typically up to 300 bp in length. A number of different proprietary technologies exist with those used by Illumina (see Figure 8.1a) and Thermo Fisher Scientific (see Figure 8.1b) currently most commonly deployed for clinical use. Both these technologies use a form of sequencing by synthesis, Illumina utilises the incorporation of fluorescently labelled complementary nucleotides, whereas Thermo Fisher Scientific exploits the release of hydrogen ions upon incorporation of (a) complementary nucleotide(s).

Figure 8.1a outlines Illumina's technology: The DNA molecules for sequencing, generated during library preparation, contain adaptors at both ends which allow them to bind to complementary primers adhered to channels on a flow cell. Each bound DNA molecule forms a template allowing synthesis of a new DNA molecule, contiguous with the adapter adhered to the flow cell. This newly synthesised DNA molecule can then bend so the end not adhered to the flow cell can interact with another primer, forming a bridge. Synthesis of a new DNA strand, again contiguous with the primer, results in a forward and reverse strand derived from each DNA molecule bound to the flow cell. These DNA molecules then undergo clonal amplification to form a cluster where there are ~1000 identical DNA molecules which originated from a single starting DNA molecule.

To determine the sequence of the bases in the DNA strands, a new strand is synthesised nucleotide by nucleotide by adding fluorescently labelled reversible terminator deoxynucleotide triphosphate molecules (RT-dNTPs), primers and polymerase. Owing to the nucleotides being terminator dNTPs only a single nucleotide can bind to a single fluorescence colour (different RT-dNTPs are labelled with a different colour) which is captured by a camera and correlates with a specific nucleotide. After each synthesis cycle, the fluorescent dye and blocking group (which is responsible for limiting nucleotide incorporation to one at a time) are enzymatically cleaved off allowing another RT-dNTP to be incorporated during the next cycle. This process is repeated until the desired length of the DNA molecule is sequenced with the order of bases being determined by the order of the different wavelengths of light emitted. Typically for clinical applications 'paired-end' sequencing is undertaken during which DNA molecules are sequenced in both forward and reverse directions; this allows improved accuracy of sequencing, particularly of repetitive regions and insertion/deletion variants. Illumina sequencers vary in the amount of sequencing data a single chip can produce from an iSeq to a NovaSeq with a NovaSeq able to analyse multiple whole genomes simultaneously.

Figure 8.1b outlines Thermo Fisher Scientific's technology: The DNA molecules for sequencing, generated during library preparation, include an adaptor that contains biotin. Biotin-containing DNA molecules are mixed with streptavidin-coated magnetic beads at a ratio such that ~one DNA molecule will bind to each bead (the streptavidin:biotin interaction is one of the strongest non-covalent interactions in nature). The DNA molecule is then clonally amplified via an emulsion PCR (emPCR) resulting in multiple copies of identical DNA molecules attached to each bead; emPCR allows each DNA molecule to be amplified separately in a water-in-oil droplet, preventing interaction between the different starting template DNA molecules and formation of chimeric reads. Beads covered with clonally amplified DNA molecules are then applied to a semiconductor chip covered with millions of microwells, at a concentration which means ~one DNA molecule is in each microwell.

To determine the sequence of the bases in the template DNA molecules, a new complementary DNA strand is synthesised. Different types of dNTP (i.e. dATP, dCTP, dGTP, dTTP) are sequentially flooded across the microwells in the chip. If a dNTP is complementary to the nucleotide on the DNA template molecule it will be incorporated into the new DNA strand which results in the release of a hydrogen ion and a decrease in the pH. The semiconductor chip is able to detect this pH change in the microwell and record which nucleotide it occurred in response to exposure. The release of hydrogen ions and change in pH is proportional to the number of consecutive identical nucleotides; i.e. two adjacent identical nucleotides will result in a doubling of the decrease in pH when their complementary nucleotide is incorporated into the growing DNA strand. Unattached dNTPs are washed out of the microwells and sequential exposure of the DNA template molecule to dNTPs continues until the desired length of the DNA molecule is sequenced. Thermo Fisher Scientific sequencers include the GeneStudio S5 and Genexus.

Long-read technologies

Long-read sequencing technologies usually refer to those that are able to sequence nucleic acid fragments 10 kb or longer. Using short-read technologies, it is difficult to accurately sequence highly repetitive regions of the genome as are seen in telomeres, centromeres and acrocentric genomic regions (i.e. where the centromere is located near the end of a chromosome rather than in the middle) which can make calling of structural variants troublesome owing to difficulties mapping (i.e. matching) short reads against a reference genome (see bioinformatics section for more information). Longer sequencing reads to reduce the possibilities of where a fragment of nucleic acid could match in the reference genome making mapping easier. Similarly with short-read sequencing if there is more than one variant in a gene, unless they are covered by the same read it is not possible to determine whether they are occurring in cis (i.e. are in the same allele) or in trans (i.e. are in different alleles); ability to accurately phase variants is relevant when the clinical implications of mono- or biallelic disruption of a gene differ (e.g. *TP53* mutations).

At the time of writing, long-read sequencing technologies are less mature in standard clinical practice but are under active investigation as to how and when they could be more routinely utilised. As with short-read technologies, a number of different long-read proprietary technologies exist with those used by Oxford Nanopore Technologies (ONT) (see Figure 8.1c) and Pacific Biosciences (PacBio) (see Figure 8.1d) being the most dominant.

Bioinformatic processing and interpretation of data

Bioinformatics pipeline

Once the sequencing itself has been performed, significant manipulation of the resulting raw output signal is required in order to have usable data that can influence patient care (see Figure 8.3). The initial stage is to convert the raw sequencing signal into corresponding nucleotide calls with each nucleotide usually accompanied by a quality score reflecting the likelihood it has been incorrectly called. This data is represented in the FASTQ file.

Following nucleotide calling, it is possible to decode the indexes applied to the reads and data can be demultiplexed and assigned to separate individuals. Adaptor and other 'added' sequences can also be computationally 'trimmed' i.e. removed at this point. Given in clinical practice the purpose of NGS is usually to identify 'differences from normal', data is normally aligned against a reference human sequence. It should be noted that a number of different human genome builds exist; as sequencing technologies improve and more human genomes are sequenced, sequentially 'more accurate' versions of the reference sequence have been produced. Care must be taken as to which build alignment is taking place against.

A number of different algorithms exist for performing this alignment each of which may perform better in different contexts (e.g. lower depth of coverage, frequent repetitive regions or sections with very high or low GC content). Depending on the nature of the sequencing and variant detection required, more than one alignment tool may be applied (see Figure 8.3). For example, owing to their repetitive similarity to the reference genome, FLT3 internal tandem duplications [ITDs] are often difficult to align using standard alignment tools with short-read sequencing; Specialist programmes such as PINDEL are able to take unaligned reads and perform a local re-alignment in order to detect this variant type. The output of the alignment process is a BAM file (or closely related SAM or CRAM file).

After sequencing data has been aligned to a reference genome, variant calling can be undertaken which seeks to identify 'differences from normal'. As with aligners, a number of

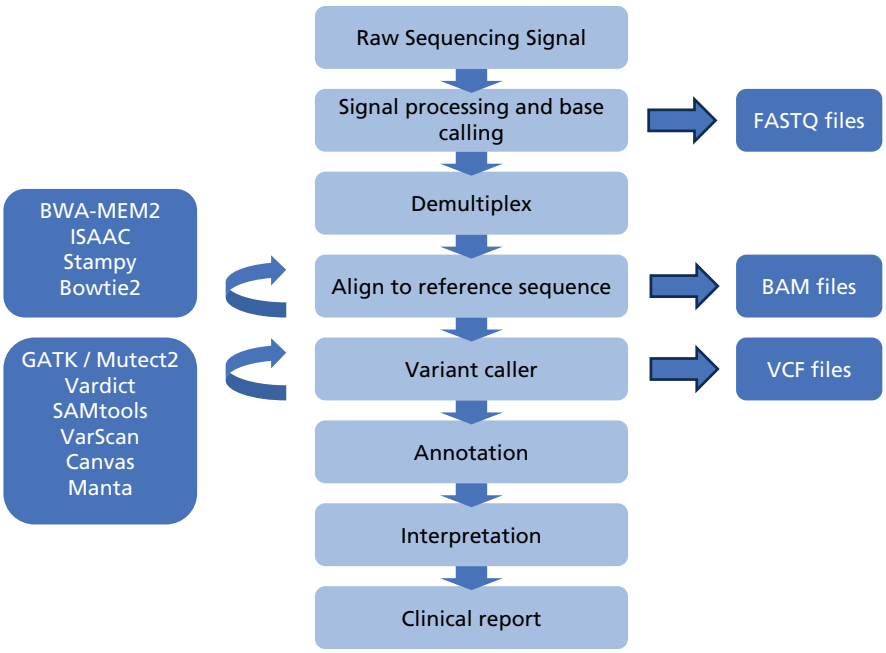

Figure 8.3 Flow chart demonstrating the different processing steps raw sequencing data needs to undergo before reaching a clinically useful output. Indicative examples of alignment tools and variant callers have been given but it should be noted that many alternative tools, not listed, are also available.

different variant calling algorithms are available which may perform better in specific sequence contexts (as discussed above) and with the detection of particular variant types (e.g. SNVs, CNVs, SVs). In clinical practice, it is advised to use a combination of variant callers in order to increase the sensitivity of variant detection. The output of the variant calling process is the VCF file.

Having identified variants, it is necessary to annotate them in order to understand what contribution, if any, they may be having to a presenting phenotype. A number of different annotation tools exist (e.g. ANNOVAR, Variant Effect Predictor [VEP]) which seek to describe the effect a variant is having. This includes where the variant occurs relative to a gene (e.g. exonic, intronic, splice site) and, assuming a variant is in a coding region, these include information about the transcript involved (multiple mRNA transcripts can be produced from a single gene). Annotation describes the effect the variant is expected to have (e.g. amino acid substitution, introduction of a premature termination codon, in-frame deletion, balanced translocation) and can include information from computational algorithms as to the likely predicted effect of the variant i.e. deleterious/tolerated (e.g. SIFT, PolyPhen2).

It also provides information about the number of reads supporting the presence of a variant from which the variant allele frequency can be derived. This information can attempt to assign germline or somatic status although it should be noted that if there is a high tumour content in a sample, acquired variants can have an allele frequency similar to that of a germline variant. Variant annotation can be more extensive and provide information on its frequency in germline population databases (e.g. gnomAD/1000 Genomes), as well as databases listing variants associated with specific diseases (e.g. Human Gene Mutation Database [HGMD] for inherited i.e. germline diseases and Catalogue of Somatic Mutations in Cancer [COSMIC] for malignant diseases).

Interpretation of variants

Once a variant has been confidently identified, investigation is required to assign pathogenicity or otherwise. Increasingly this is being automated at the end of the bioinformatics pipeline by the utilization of highly curated databases (e.g. HGMD in inherited disease and OncoKB in malignant disease), but in the creation of these databases, extensive manual assessment has typically taken place. In order to ensure consistent interpretation of variants between different operators, a number of variant classification systems have emerged. The first was developed by the American College of Medical Genetics (ACMG) and Association for Molecular Pathology (AMP) and considered variants in the context of their likely causation of Mendelian disorders. Variants were therefore classified as pathogenic, likely pathogenic, uncertain significance, likely benign and benign based on the available evidence (e.g. population frequency, functional studies, segregation data) as to their contribution to a specific phenotype.

Although this initial classification system is well suited to inherited disease, it works less well with malignant conditions as in this context, frequently the detection of genomic abnormalities is not utilised to make the diagnosis (which can be done morphologically or immunophenotypically), but rather to inform prognosis and treatment (see utility section below). Therefore, a classification system based on actionability was developed by the AMP, American Society of Clinical Oncology (ASCO) and College of American Pathologists (CAP) which divided variants into four tiers (i): Strong clinical significance, (ii): Potential clinical significance, (iii): Unknown clinical significance, IV: Benign or likely benign.

While the AMP/ASCO/CAP framework provided a mechanism for accurately assigning clinical actionability to a somatic variant, it did not provide a fully comprehensive system for determining the oncogenicity of an acquired variant. Therefore, the Clinical Genome Resource (ClinGen), Cancer Genomics Consortium (CGC) and Variant Interpretation for Cancer Consortium (VICC) adapted the ACMG/AMP guidelines specifically for somatic variants and developed a similar five-category classification system: oncogenic, likely oncogenic, uncertain significance, likely benign and benign. Using a combination of population, functional, predictive, cancer hotspot and computational data, a numerical score is generated which assigns a variant to one of the five categories. This variant classification system is increasingly being adopted across laboratories at the time of writing with the hoped effect of more consistent variant interpretation throughout the world.

Utility

The potential utility of NGS can be categorised in a similar way to that of any other genomic testing methodology i.e. performed for diagnostic, prognostic, therapeutic (including the selection of targeted inhibitors), MRD and genetic predisposition identification purposes. Although individual chapters elsewhere in this book cover the genomics of specific haematological diseases, below is a summary of examples in each of these utility categories.

Diagnostic

In the context of inherited non-malignant haematological disorders, the availability of NGS has enhanced the ability to reach a diagnosis in a timely fashion owing to being able to sequence multiple genes pertaining to the spectrum of differential diagnoses raised by the presenting phenotype. Whereas previously sequential rounds of Sanger sequencing +/− Multiplex Ligation-dependent Probe Amplification (MLPA) could be required to reach (or eliminate) the suspected diagnoses, a single NGS panel or WES with virtual panel application can provide similar information in a single assay. Table 8.2 lists the different panels (of 3 or more genes) currently (in 2023) commissioned for inherited haematological disorders, by the Genomic Medicine Service (GMS) in England's National Health Service (NHS).

Accepting that acquired haematological disorders (usually malignancies) are often diagnosed through a combination of clinical presentation, morphology and immunophenotyping, genomic information can still be critical for making diagnoses in both acute (e.g. acute promyelocytic leukaemia [APL]) and chronic presentations (e.g. myeloproliferative neoplasms). Although to date, the urgency of diagnosis in acute leukaemias and usual turnaround times (TATs) of NGS have meant Fluorescence *In Situ* Hybridization (FISH) testing is a more practical approach (e.g. to detect *PML::RARA*). In less urgent presentations (e.g. most suspected myeloproliferative neoplasms) NGS has utility in reaching or eliminating a diagnosis in an efficient manner without the need for sequential rounds of testing.

The recently published 5th edition of the World Health Organization (WHO) Classification of Haematolymphoid Tumours and International Consensus Classification (ICC) of Myeloid and Lymphoid Neoplasms (Chapters 20 & 23–26) both demonstrate the need for comprehensive genomic information to reach accurate diagnoses in haematological malignancies. It should also be noted that NGS is key to the diagnosis of acquired pre-malignant disorders such as Clonal Haematopoiesis of Indeterminate Potential (CHIP) and Clonal Cytopenia(s) of Undetermined Significance (CCUS) (Chapter 38) as well as acquired non-malignant disorders which can present with haematological phenotypes such as VEXAS syndrome (associated with mutations in the *UBA1* gene and presenting with similarities to myelodysplasia). Table 8.3 part A provides examples of the role of NGS in the diagnosis of haematological malignancies.

Prognostic

Although NGS is primarily undertaken in suspected inherited non-malignant haematological disorders for diagnostic purposes, associations are increasingly being demonstrated between genotype and prognosis. For example, the specific mutation in the *F8* gene contributes to an individual's risk of acquiring FVIII inhibitors in haemophilia A, whereas the genotype in Fanconi anaemia has implications for both phenotype and the risk of bone marrow failure. In contrast, in haematological malignancies, much of the NGS undertaken is primarily for prognostic purposes and genomically-defined diagnoses in the WHO and ICC have often been selected because of a specific associated prognosis; e.g. acute myeloid leukaemia (AML) with *NPM1* mutation and AML with myelodysplasia-related gene mutations are associated with favourable and adverse prognoses respectively. Furthermore, refinement of morphological diseases into multiple genomic subtypes with particularly associated prognoses has only become possible with the widespread implementation of NGS and subsequent correlation of genotype with clinical outcomes.

Table 8.2 List of gene panels (with 3 or more target genes) currently commissioned with the NHS in England for inherited haematological disorders. The panels, although correct at the time of writing, are regularly updated with the most up-to-date panel content available at https://nhsgms-panelapp.genomicsengland.co.uk/panels.

Panel	Gene content
Bleeding and platelet disorders	*ABCG5, ABCG8, ACTB, ACTN1, ACVRL1, ANKRD26, ANO6, AP3B1, AP3D1, ARPC1B, BLOC1S3, BLOC1S6, CDC42, CHST14, COL3A1, CYCS, DIAPH1, DTNBP1, ENG, ETV6, F10, F11, F12, F13A1, F13B, F2, F5, F7, F8, F9, FERMT3, FGA, FGB, FGG, FLI1, FLNA, FYB1, GATA1, GBA, GFI1B, GGCX, GNE, GP1BA, GP1BB, GP6, GP9, HPS1, HPS3, HPS4, HPS5, HPS6, IKZF5, ITGA2B, ITGB3, KDSR, KLKB1, KNG1, LMAN1, LYST, MCFD2, MECOM, MPIG6B, MPL, MYH9, NBEAL2, P2RY12, PLA2G4A, PLAU, PTGS1, RASGRP2, RBM8A, RUNX1, SERPINE1, SERPINF2, SLFN14, SRC, STIM1, STXBP2, TBXA2R, TBXAS1, THBD, THPO, TNXB, TPM4, TUBB1, VIPAS39, VKORC1, VPS33B, VWF, WAS*
Fanconi anaemia or bloom syndrome	*BLM, BRCA1, BRCA2, BRIP1, ERCC4, FANCA, FANCB, FANCC, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCL, PALB2, RAD51, SLX4, TOP3A, UBE2T*
Cytopenia – not Fanconi anaemia	*ACD, ADA2, AK2, ANKRD26, CLPB, CSF3R, CTC1, CXCR4, CYCS, DDX41, DKC1, DNAJC21, EFL1, ELANE, ERCC6L2, ETV6, FYB1, G6PC3, GATA1, GATA2, GFI1, HAX1, JAGN1, KLF1, MECOM, MPL, MYSM1, NHP2, PARN, RMRP, RPA1, RPL11, RPL15, RPL35A, RPL5, RPS10, RPS17, RPS19, RPS24, RPS26, RPS29, RPS7, RTEL1, SAMD9, SAMD9L, SBDS, SRC, SRP54, STN, TAZ, TERC, TERT, THPO, TINF2, USB1, VPS45, WAS, WIPF1, WRAP53*
Hereditary Erythrocytosis	*BPGM, EGLN1, EPAS1, EPO, EPOR, HBA1, HBA2, HBB, SLC30A10, VHL*
Inherited predisposition to acute myeloid leukaemia	*ANKRD26, CEBPA, DDX41, ETV6, GATA2, MBD4, RUNX1, SAMD9L, TERC, TERT, TP53*
Iron metabolism disorders – NOT common HFE mutations	*ABCB7, ALAS2, ATP7B, BMP6, CP, CYBRD1, FTL, GBA, GLRX5, HAMP, HFE, HFE2, SLC11A2, SLC25A38, SLC40A1, TF, TFR2, TMPRSS6*
Rare anaemia	*ABCB7, ABCG5, ABCG8, ADA2, AK1, ALAS2, ALDOA, AMN, ANK1, C15orf41, CD59, CDAN1, CUBN, CYB5R3, DHFR, EPB41, EPB42, G6PD, GATA1, GCLC, GIF, GLRX5, GPI, GSR, GSS, HBA1, HBA2, HBB, HBD, HBG1, HBG2, HEATR3, HK1, HSPA9, KCNN4, KIF23, KLF1, LARS2, LPIN2, MTR, MTRR, NT5C3A, PFKM, PIEZO1, PKLR, PUS1, RHAG, RPL11, RPL15, RPL31, RPL35A, RPL5, RPL9, RPS10, RPS17, RPS19, RPS24, RPS26, RPS29, RPS7, SBDS, SEC23B, SLC11A2, SLC19A2, SLC25A38, SLC2A1, SLC4A1, SPTA1, SPTB. TCN2, TF, TMPRSS6, TPI1, TRNT1, UMPS, VPS4A, XK, YARS2*
Thrombocythaemia	*JAK2, MPL, THPO*
Thrombophilia with a likely monogenic cause	*ADAMTS13, F2, F5, FGA, FGB, FGG, HRG, PIGA, PLG, PROC, PROS1, SERPINC1, SERPIND1, SERPINE1, THBD*

The broad deployment of NGS in clinical trials has allowed the addition of molecular (i.e. gene level) genomic data to prognostic scoring systems. Such comprehensive risk calculators include the molecular international prognostic scoring system (IPSS-m) and the mutation-enhanced international prognostic scoring system for transplant-age patients (MIPSS70) in myelodysplasia and primary myelofibrosis respectively. Internationally, there is ongoing work in the development of similar genomically-driven prognostic scoring systems in lymphomas (e.g. LymphGen in diffuse large B cell lymphoma which uses CNV and SNV data): However, the requirement to date for high-quality DNA derived from fresh rather than FFPE tissue for these NGS assays has limited the widespread use of NGS in this context. Table 8.3 part B provides examples of the role of NGS in the prognostication of haematological malignancies.

Therapeutic

NGS data can be considered to inform treatment strategies in a range of scenarios in haematological malignancies. If NGS has been used to make or subtype a diagnosis e.g. assist in the differentiation of a morphologically unusual hairy cell leukaemia from lymphoplasmacytic lymphoma or another mature B cell neoplasm (via the detection or not of *BRAF* p.[Val600Glu] or *MYD88* [Leu265Pro] variants), each of which will have its own treatment

Table 8.3 Gives illustrative examples of where NGS is used in clinical practice. It is acknowledged that not all laboratories will be delivering testing for all of these targets using NGS approaches. It is recognised that many targets can be delivered using different NGS assays e.g. DNA or RNA panels or WGS and that the preferred approach as well as the spectrum of targets is likely to evolve over time. It should be noted that the RNA panels referred in Figure 8.3 all used cDNA rather than native RNA as their substrate.

(A) Examples of how NGS is used to assist in the diagnosis of haematological malignancies. In general the target lists are not exhausted and should be supplemented by reference to the most recent malignancy-specific diagnostic guidance.

PART A: DIAGNOSTIC TESTING

Clinical indication	NGS assay	Targets
Acute myeloid leukaemia	RNA panel	*BCR::ABL1* *CBFB::MYH11, RUNX1::RUNX1T1* *DEK::NUP214* *GATA2::MECOM(EVI1)* and other *MECOM* rearrangements *MLLT3::KMT2A* and other *KMT2A* rearrangements *NUP98* rearrangements *PML::RARA* and other *RARA* rearrangements *RBM15::MRTFA*
	DNA panel	*ASXL1, BCOR, CEBPA, EZH2, NPM1, RUNX1, SF3B1, SRSF2, STAG2, TP53, U2AF1, ZRSR2* del(5q)/add(5q), −7/del(7q), +8, del(12p)/add(12p), −17/add(17p) or del(17p), del(20q)
	WGS	All of the above and complex karyotype, t(5q), t(12p), i(17q), idic(X)(q13)
Acute lymphoblastic leukaemia	RNA panel	*BCR::ABL1* *KMT2A* rearrangements *ETV6::RUNX1* *IL3::IGH* *TCF3::PBX1* ABL-class rearranged *MYC* rearrangement *MEF2D* rearrangement *ZNF384* rearrangement *NUTM1* rearrangement *HLF* rearrangement *UBTF::ATXN7L3/PAN3,CDX2* *BCL11B* rearrangement
	DNA panel	*IKZF1, PAX5* iAMP21, hyperdiploid, hypodiploid, near haploid
	WGS	All of the above and *DUX4* rearrangement
Suspected myeloproliferative neoplasm (not chronic myeloid leukaemia)	DNA panel	*CALR, JAK2, MPL* *CSF3R* *ASXL1, EZH2, IDH1, IDH2, SF3B1, SRSF2, TET2* and others*
Mature B cell neoplasms (e.g. hairy cell leukaemia, hairy cell leukaemia variant, lymphoplasmacytic lymphoma)	DNA panel	*BRAF, MAP2K1, MYD88*

* Other myeloid-malignancy related genes can be added to the list of genes where the presence of mutations can be used to indicate clonal haematopoiesis in the context of a suspected diagnosis of a myeloproliferative neoplasm.

(*Continued*)

Table 8.3 (*Continued*)

(B) Examples of how NGS is used to inform prognosis in haematological malignancies. It should be noted that many other genomically-informed prognostication algorithms exist beyond those listed in the following table and it is expected that the contents of these will evolve over time and additional data becomes available and treatments change.		
PART B: PROGNOSTIC TESTING		
Clinical indication	**NGS assay**	**Targets**
Acute myeloid leukaemia	RNA panel	*BCR::ABL1* *CBFB::MYH11, RUNX1::RUNX1T1* *DEK::NUP214* *GATA2::MECOM(EVI1)* and other *MECOM* rearrangements *KAT6A::CREBBP* *MLLT3::KMT2A* and other *KMT2A* rearrangements
	DNA panel	*ASXL1, BCOR, CEBPA, EZH2, FLT3, NPM1, RUNX1, SF3B1, SRSF2, STAG2, TP53, U2AF1, ZRSR2* −5/del(5q), −7, −17/abn(17p)
	WGS	All of the above and complex karyotype
Myelodysplasia	DNA panel	*ASXL1, BCOR, BCORL1, CBL, CEBPA, DNMT3A, ETNK1, ETV6, EZH2, FLT3, GATA2, GNB1, IDH1, IDH2, KRAS, KMT2A* (PTD), *NPM1, NF1, NRAS, PHF6, PPM1D, PRPF8, PTPN11, RUNX1, SETBP1, SF3B1, SRSF2, STAG2, TP53, U2AF1, WT1* del(5q), −7/del(7q), +8, del(11q), del(12p), +19, del(20q), −Y
	RNA panel	*GATA2::MECOM(EVI1)* and other *MECOM* rearrangements
	WGS	All of the above and complex karyotype, i(17q),
Primary myelofibrosis	DNA panel	*ASXL1, CALR, CBL, EZH2, IDH1, IDH2, JAK2, KRAS, NRAS, SRSF2, TP53, U2AF1*
	WGS	All of the above and prognostic cytogenetic abnormalities
(C) Examples of how NGS is used to inform therapy haematological malignancies. This table has been limited to targeted inhibitors but it should be noted that genomic data is also used to decide on the choice of non-targeted treatments, as well as the intensity of treatment and whether an allogeneic HSCT is required.		
PART C: THERAPEUTIC TESTING		
Clinical indication	**NGS assay**	**Targets**
Acute myeloid leukaemia	RNA panel	*KMT2A* rearrangements – patient may respond to menin inhibitors
	DNA panel	*FLT3* – patients with an activating mutation may respond to a FLT3-inhibitor *NPM1* – patients with a 4 bp insertion in exon 11 may respond to a menin inhibitor *IDH1* – patients with a codon 132 mutation may respond to an IDH1-inhibitor *IDH2* – patients with a codon 140 or 172 mutation may respond to an IDH2-inhibitor
	WGS	All of the above
Chronic myeloid leukaemia	DNA panel	*BCR::ABL1* TKD – identity of any mutations in the TKD or the *BCR::ABL1* fusion genes informs tyrosine kinase inhibitor choice

Table 8.3 (*Continued*)

Myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions	RNA panel	*FIP1L1::PDGFRA* and other *PDGFRA* rearrangements – patient may respond to tyrosine kinase inhibitor *ETV6::PDGFRB* and other *PDGFRB* rearrangements – patient may respond to tyrosine kinase inhibitor *ZMYM2::FGFR1* and other *FGFR1* rearrangements – patient may respond to FGFR inhibitor *PCM1::JAK2* and other *JAK2* rearrangements – patient may respond to JAK inhibitor *ETV6::FLT3* and other FLT3 rearrangements – patient may respond to FLT3 inhibitor *ETV6::ABL1* – patient may respond to second generation tyrosine kinase inhibitor
	WGS	All of the above
Follicular lymphoma	DNA panel	*EZH2* – patients with an activating mutation may respond to an EZH2-inhibitor
(D) Examples of how NGS can be used in both MRD target identification and MRD quantification assays.		
PART D: MEASURABLE RESIDUAL DISEASE TESTING		
Target identification		
Clinical indication	**NGS assay**	**Targets**
Acute myeloid leukaemia	RNA panel	*PML::RARA* *CBFB::MYH11, RUNX1::RUNX1T1* *KMT2A* rearrangements
	DNA panel	*KMT2A* rearrangements *NPM1* 4 bp insertion in exon 11
	WGS	All of the above
Acute lymphoblastic leukaemia	DNA panel	*IGH, IGK, TCRB, TCRD, TCRG*
	WGS	All of the above
Measurable residual disease detection		
Lymphoid malignancies	DNA panel	*IGH, IGK, TCRB, TCRD, TCRG*
(E) Examples of how NGS can be used for the detection of germline predisposition to haematological malignancies.		
PART E: GERMLINE PREDISPOSITION TESTING		
Clinical indication	**NGS assay**	**Targets**
Myeloid malignancies	DNA panel	*ANKRD26, CBL, CEBPA, DDX41, ETV6, GATA2, KRAS, NRAS, PTPN11, RUNX1, SAMD9, SAMD9L, TP53* Genes associated with bone marrow failure syndromes see table 2
	WGS	All of the above
Lymphoid malignancies	DNA panel	*DDX41, ETV6, IKZF1, PAX5, RUNX1, TP53*
	WGS	All of the above

approaches, it has indirectly directed therapy. Similarly, if NGS has been used to refine a diagnosis of acute myeloid leukaemia and demonstrate a likely genomic background of myelodysplasia this will influence the choice of front-line therapy (e.g. eligible for CPX-351). Furthermore, the use of genomic data by the 2022 ELN risk classification by genetics at initial diagnosis is routinely used in AML to help inform the decision around an allogeneic haematopoietic stem cell transplant (HSCT) in otherwise suitable patients in complete remission 1 (CR1).

The demonstration of a specific genomic abnormality using NGS may lead to the use of a targeted inhibitor e.g. *FLT3*, *EZH2* and menin inhibitors in the context of activating *FLT3*

mutations, activating *EZH2* mutations and *NPM1* exon 11 4 bp insertions or *KMT2A* disruptions (rearrangements or partial tandem duplications [PTD]) respectively. NGS assays can also be used to investigate for secondary resistance mutations as seen in the tyrosine kinase (TK) domain of the *BCR::ABL1* fusion gene in the context of TK inhibitor usage in CML. Table 8.3 part C provides examples of the role of NGS in therapy decisions in haematological malignancies.

Measurable residual disease

When considering MRD, NGS is currently primarily used for target identification. In myeloid malignancies, much current MRD monitoring involves the detection of translocations e.g. *BCR::ABL1* in CML and *RUNX1::RUNX1T1* in AML using reverse transcriptase quantitative PCR (RT-qPCR) or digital droplet PCR (ddPCR) assays. In order to use such a test, it is necessary to know where the respective breakpoints are, something which can be determined by both DNA and cDNA assays as described above. Other MRD targets include the 4 bp insertion in exon 11 of the *NPM1* gene, the identity of which (as there are multiple different reported 4 bp insertions) is usually determined using NGS. In lymphoid malignancies, the basis of MRD assays is usually immunoglobulin (IG) (*IGH*, *IGK*) or T cell receptor (TCR) (*TCRB*, *TCRD*, *TCRG*) VDJ or VJ rearrangements. NGS is increasingly being used as the preferred method for this target identification as opposed to Sanger sequencing-based approaches.

In addition to using NGS for the identification of MRD targets, the technology can also be used for the detection of MRD itself providing the sequencing is of high enough depth (i.e. up to hundreds of thousands of reads) and methodology is in place to remove PCR repeats e.g. the use of UMIs. Commercial NGS assays exist for the detection of IG and TCR rearrangement MRD with sensitivities quoted of up to 1×10^{-6} which is 1–2 logs more sensitive than non-NGS MRD assays. More recently, in AML, there has been interest in using UMI-assisted NGS-based MRD assays to look at the clinical significance of the detection of a range of other SNVs. Currently, this remains largely a research tool as it is unclear which SNVs in which genes represent MRD associated with a poor prognosis. MRD is usually predicated on detecting the initial driver mutation(s) which are stable throughout the lifecycle of the malignant clone (as opposed to latterly acquired sub-clonal mutation[s]), yet there is some evidence that persistence of variants associated with CHIP does not confer an inferior prognosis. Table 8.3 part D provides examples of the role of NGS in MRD monitoring in haematological malignancies.

Germline predisposition

Wider use of NGS in haematological malignancies in both the research and clinical settings has led to the discovery of an increasing number of genomic abnormalities which are associated with a predisposition to haematological malignancies, currently best characterised for acute leukaemias. It follows, therefore, that NGS is an efficient way of detecting germline variants conferring a predisposition to haematological malignancies. The caveat to this is that most clinical NGS is performed using tumour samples without a comparative germline sample meaning it is not possible to definitively determine the origin of a variant (something that would require the testing of separate germline sample). This topic will be further discussed below. Table 8.3 part E provides examples of the role of NGS in the detection of germline predisposition to haematological malignancies.

Discovery

The categories of utility listed above all relate to the deployment of NGS in the routine clinical setting. However, as discussed, much of our knowledge which has precipitated this utility has arisen from the use of NGS in the research setting. Therefore, the use of NGS, particularly those assays with a broader footprint such as WGS, WES and whole RNA-seq, retains an important discovery purpose to enhance our understanding of the genomics of haematological diseases, both malignant and non-malignant. Efforts should, therefore, be made to try and enable the required ethical governance and logistical frameworks to be in place to facilitate appropriate anonymised sharing of NGS results and associated clinical phenotype to create datasets which can inform our knowledge and treatment of these diseases.

Practical considerations

As with any diagnostic technology, its utilization in the clinical setting depends on its ability to deliver the required information in the required timescale at the right price. The following section discusses these and other considerations which help inform how and when this technology is deployed.

Cost

The cost of any individual NGS assay will depend on the size of its footprint, the depth of sequencing required, the specific NGS technology being used and the number of samples being multiplexed. Typically, the larger the footprint, deeper the sequencing and lower the number of samples that can be multiplexed, the higher the cost of the assay on a per-patient basis. As discussed above, the footprint and depth of an assay will be related to the questions the assay is trying to answer and the expected allele frequency of an abnormality. In addition to the size of assay footprint and required depth, the number of samples that can be multiplexed is influenced by the sequencer choice, size of the

sequencing flow cell or chip being used and available sample numbers. Generally, the larger the flow cell the cheaper the per base cost of sequencing, but filling the largest available requires availability of sufficient numbers of samples from a single or compatible assays. In high throughput laboratories, this does not usually present a problem, but in smaller laboratories, the requirement for batching to ensure the economic viability of an assay can compromise the turn-around time such that a result is not available in a clinically meaningful timescale.

Other costs to consider are the technician's hands-on time during library preparation and scientist analysis and interpretation of the resulting sequencing data. Automation of both assay setup and data interpretation can result in cost savings. A number of commercial interpretation and decision support programmes exist for some types of genomic data to try and streamline the reporting process. It should be noted that the general direction of costs for NGS assays on a per-base basis is downwards.

Turn-around-times

The TAT of any NGS depends on the technology, degree of automation and complexity of the library preparation, bioinformatics pipeline and analysis process. ONT technologies have examples of assays returning results in minutes to hours, while most NGS assay workflows can return results in hours to 3 days (including WGS). It is notable that most clinical services have longer TATs which reflects the need for economic batching of samples, availability of technicians in non-automated workflows, access to sequencers and the time often taken to perform analysis of the data and clinical interpretation. Greater degrees of consolidation of services, automation of laboratory workflows and the greater use of machine learning in interpretation are likely to reduce the TATs.

Interpretation complexities

Prior to the advent and introduction of NGS, most clinical molecular genomic testing was limited to investigating the presence or absence of well-known genomic abnormalities which resulted in reporting being a binary exercise i.e. abnormality detected or not detected. The increasing breadth of footprints of NGS assays means large amounts of data can be generated, for much of which the clinical significance is unclear. One approach is to apply restrictive bioinformatics filters to the data to limit at least the initial analysis to only the most well-characterised regions, particularly if a targeted panel assay is designed to answer different questions in different haematological phenotypes. As discussed above variant interpretation frameworks in both the germline and acquired settings exist to assist with this interpretation but both inevitably result in the classification of many variants as of uncertain significance (VUS). There still remains some inter and even intra-laboratory variability as to which VUSs, if any, should be reported back to a clinician. In the context of a suspected haematological malignancy, the reporting of a VUS with an allele frequency suggestive of an acquired variant (e.g. <30%) can be useful as an indication of clonality. The observation that NGS assays relatively frequently demonstrate such clonality in the blood particularly of ageing individuals, has helped contribute to the coining of the pre-malignant diagnoses of CHIP and CCUS. Detecting such an abnormality without knowing the full implications can cause anxiety for patient and healthcare professionals alike (see clonal haematopoiesis Chapter 38 for more details).

Other examples of where the availability of NGS data can create challenges for the patient and healthcare team are in the MRD setting (as discussed above) and the germline predisposition setting. Comprehensive data collection on the long-term outcomes of individuals with variants in different genes persisting post-treatment (e.g. for AML) is needed in order to know when this should precipitate an intervention; e.g. in the setting of residual low-risk CHIP following AML therapy. How to manage the detection of likely germline variants in certain haematological predisposition genes e.g. *DDX41* has also created a management dilemma. Although offering, and if accepted, consenting the patient for confirmatory testing using an appropriate germline sample is straightforward, how and when to cascade testing in the wider family and how to manage the detection of a pathogenic variant in any family members in terms of ongoing surveillance remains an evolving field that will require additional data.

Finally, how to retrofit high-resolution NGS data (particularly that including structural abnormalities) to prognostic classifications developed using less sensitive technologies such as karyotyping and FISH is currently unclear. Definitions such as a complex karyotype in AML, critical for prognostication, relate to the low-resolution technique of karyotyping (resolution 5–10 Mb). That equates to a complex karyotype with NGS techniques with individual base-level resolution remains a research question and is only likely to be answered by considerable genotype:phenotype and clinical outcome correlation.

Ethical considerations

Although healthcare systems have developed systems of up-front informed consent for all research genomic testing and designated germline testing in the clinical setting, there is much less uniformity around clinical practice in the acquired setting. When genomic testing was confined to a limited set of well-characterised mutations, the probability of detecting an abnormality with unexpected implications was low. As the footprint of even targeted assays has grown, the probability of detecting a

variant which could be germline in origin has increased with the subsequent uncertainties of how this should be optimally managed in the wider family setting as discussed above. Whether patients should be consented up-front for this possibility remains a controversial subject.

As laboratories move towards larger and larger NGS panels (and even routine WGS) which are designed to be used for both haematological and non-haematological malignancies, increasingly the footprint contains genes in which germline variants confer a predisposition to non-haematological malignancies. How to deal with the presence of such variants remains controversial; one approach is to apply virtual filters such that only those predisposition genes relevant to haematological malignancies are analysed, another approach is to obtain up-front patient consent for the presence of additional findings in such off-target genes. As NGS testing progresses over the next decade it is envisioned that a more consistent framework around how to deal with these challenges will evolve.

The future

The introduction of NGS into clinical haematological practice has been a game-changer. The ability to routinely undertake extensive genomic analysis has developed our ability to diagnose haematological diseases as well as highlighted a spectrum of pre-malignant disorders hitherto undiscovered. It has enhanced our ability to prognosticate, demonstrated targets for therapeutic intervention, improved monitoring of response to therapy and paved the way for potential earlier diagnosis through the detection of individuals with a genetic predisposition. However, as with any new technology, there are challenges and for NGS these include how to interpret the breadth of data and manage the associated uncertainty, and how to deploy clinically in an economical and timely fashion.

If the current trajectories continue, it would be envisioned that the cost of NGS will decrease and the time required for any assay will shorten. It would also be expected that with appropriate correlation of genomic data with clinical phenotype, our understanding of what the genomic data means on an individual patient level will improve, potentially assisted by artificial intelligence and machine learning.

Introduction

Cellular growth and differentiation are carefully controlled processes that are regulated by several interconnected pathways in order to facilitate diverse biological phenomena ranging from development, responses to normal and abnormal stimuli and the replacement of dying cells. In this context, the growth of individual cells is restrained in the interest of their cognate tissue and by extension of the organism as a whole. Oncogenesis represents the progressive corruption of this order and the stepwise escape of an individual cell and its progeny from checks on their growth. This corruption occurs in the form of the serial acquisition of genetic mutations, which disrupt the genome of the fateful cell and morph it into a *cancer genome* (Table 9.1). In turn, the ontogeny of the cell of origin and the nature of the mutations are the primary determinants of the cancer phenotype, including its histological type, biological behaviour, clinical characteristics and responsiveness to therapies.

Over the last few years, we have witnessed unprecedented progress in our understanding of cancer genomes, driven primarily by extraordinary advances in DNA sequencing technologies. The impact of cancer genomics on the study of haematological malignancies has been particularly dramatic, in large part because of our deep prior acquaintance with normal blood cell development and hierarchy, as well as our detailed characterisation and classification of haematological cancers. Importantly, these developments are not only enhancing our understanding of blood cancer biology but are already having an impact on the way we diagnose and treat patients.

This chapter will describe important advances in genomics and review key themes and paradigms relating to the pathogenesis and evolution of haematological cancers.

The cancer genome

The identification of the Philadelphia chromosome in patients with chronic myeloid leukaemia (CML) by Nowell and Hungerford in 1960 was the first report of a genetic lesion associated with a human malignancy and forms a landmark in cancer studies. It has since become clear that cancer is a genetic disease, which develops through a process of Darwinian-like clonal evolution involving the stepwise acquisition of somatic mutations in individual cells subject to natural selection on the basis of their ability to outgrow their peers through increased proliferation and survival. Within a healthy adult human, there are many small clones, most of which have limited abnormal growth potential and are invisible or manifest as common benign growths such as skin moles. Occasionally, however, a single cell acquires a set of mutations that allows it to proliferate to the extent that it generates a malignant phenotype. The nature of such mutations and the way in which they collaborate to produce the malignant phenotype can only be fully understood through the integrated study of the large set of variants within a tumour.

Table 9.1 Glossary.

Acquired mutation: see 'somatic mutation'

Allele burden: The fraction of alleles with a specific sequence in relation to the total number of alleles for the same region of the genome. For example, a heterozygous mutation in a pure population of leukaemia cells has an allele burden of 0.5. If 70% of cells are leukaemic and 30% of cells are normal, the mutant allele burden of the heterozygous mutation would be $0.7 \times 0.5 = 0.35$.

Amplification: A genetic modification producing an increased number of copies of a genomic region

Autosomal dominant: Inherited mutation affecting one allele on a non-sex chromosome is sufficient to confer the disease.

Autosomal recessive: Inherited mutation must affect both alleles on the respective non-sex chromosomes to confer the disease.

Branching evolution (of cancer): A form of clonal evolution of cancer which leads to the generation of more than one clone of cells characterised by distinct somatic mutations, but which share at least one mutation traceable back to a single ancestral cell.

Cancer genome: The genome of a cancer cell, which differs from the germline genome as a result of somatic mutations.

Chromosomal translocation: see 'genomic rearrangements'.

Chromothripsis: a single catastrophic event by which hundreds to thousands of chromosomal rearrangements occur in confined genomic regions of one or a few chromosomes (from Greek θρύΨις = shattering into small pieces).

Clonal evolution (of cancer): The stepwise acquisition of mutations in a founder cell and its progeny leading towards the development of a cancer.

Clonal mutation: A mutation present in a population of related cells derived from a single cell.

Constraint hypothesis: A hypothesis about clonal evolution proposing that the observed order of acquisition of somatic mutations during cancer evolution reflects a requirement for a specific mutation to occur before another for a growth advantage to be gained by the host cell(s).

Co-occurrence (of cancer mutations): The occurrence of two or more mutations in the same type of cancer more often than would be expected by chance.

Convergent evolution (of cancer): A pattern of cancer evolution during which independent clones expand after acquiring the same or very similar mutation. This is likely to reflect the fact that such a mutation is particularly advantageous to the specific cancer cell, giving a marked growth advantage when acquired by chance.

Deletion: A genetic modification leading to the loss of a genomic region.

Dominant negative mutation: A heterozygous mutation that leads to marked or complete loss of function of the coded protein and of the normal protein coded by the other (wild-type) copy of the gene.

Driver gene or driver mutation: A mutated gene that confers a selective growth advantage to a cancer cell

Epigenetics: The study of changes to DNA and chromatin, other than those that alter the DNA nucleotide sequence, that alter the transcriptional potential of a cell and are usually heritable

Exome: The collection of all exons in a genome.

Exome sequencing: Sequencing of all exons in a genome. This has referred to exons of protein-coding genes, but increasingly non-protein-coding genes are included (e.g. long non-coding RNAs).

Gain-of-function mutation: A mutation that gives the coded protein a novel or markedly enhanced function

Genome-wide association studies (GWAS): studies of many common and uncommon genetic variants in different individuals to determine if any variant is associated with a disease or trait. The primary outcome of these studies is the identification of variants such as SNPs which are *associated* with, but do not necessarily cause the disease in question.

Genomic instability: Increased frequency of mutations in the genome caused by either increased DNA damage or deficient DNA repair.

Genomic rearrangement: A mutation that juxtaposes nucleotides that are normally distant from each other, such as a chromosomal translocation, inversion or deletion.

Genotoxin: Chemical or other agent that modifies DNA and generates mutations.

Germline genome: An individual's genome as formed at the time of conception (fertilised oocyte). This genome is shared by all cells in the body.

Germline mutation: Mutations present in the germline genome. Sporadic mutations acquired in the germ cells of parents are also included in this category.

Germline variants: Variations in sequences or copy number of DNA segments observed between different individuals that are responsible for the phenotypic variation between people. Two unrelated individuals differ by approximately 3 million such variants.

Haplotype: A contiguous region of the genome containing a set of tightly linked genes that are usually inherited as a block.

Indel: A mutation that results in insertion or deletion of one or a few nucleotides to DNA.

Kataegis: Localised hypermutation of a region of the genome, thought to be mediated by APOBEC enzymes (from Greek καταιγίς = storm).

Linear evolution (of cancer): A form of clonal evolution of cancer that generates a single final clone of cancer cells which harbours all mutations that ever arose during its evolution.

Loss-of-function mutation: A mutation that leads to marked or complete loss of function of the coded protein.

Table 9.1 (*Continued*)

Loss-of-heterozygosity (LOH): A genetic modification leading to the loss of the maternally- or paternally-derived copy of a genomic region. This can happen as a result of deletion or uniparental disomy (uPD).

Methylation: Covalent addition of a methyl group to a DNA, RNA, protein or other molecule.

Missense mutation: A nucleotide substitution (e.g. G–T) that results in an amino acid change (e.g. valine to phenylalanine).

Mutational signature: A recurrent pattern of DNA mutations attributable to a particular type of mutagen or mutational process, characterised by certain nucleotide mutations in a specific 5′ and 3′ nucleotidic context.

Mutual exclusivity: The occurrence of two or more mutations in the same cancer type less often than would be expected by chance.

Next-generation sequencing (NGS): DNA sequencing using one of the methodologies developed since 2005 and which allow massively parallel sequencing of thousands or millions of fragments of DNA simultaneously.

Nonsense mutation: A nucleotide substitution that results in the generation of a stop codon (i.e. TAA, TGA or TAG).

Non-synonymous mutation: A mutation that alters the encoded amino acid sequence of a protein. These include missense, nonsense, splice site, gain of translation start, loss of translation stop and indel mutations.

Oncogene: A gene that confers growth advantage to a cell and contributes to its progression/transformation to cancer.

Opportunity hypothesis: A hypothesis proposing that the observed order of acquisition of somatic mutations during cancer evolution reflects the statistical likelihood that mutations are acquired in this order. This likelihood is determined by the earlier mutation influencing the opportunity for acquiring the next. Implicit in this hypothesis is that the reverse order can also be observed, albeit less often.

Passenger mutation: A mutation that does not give a selective growth advantage to its host cell.

Proto-oncogene: A gene that when activated by mutations, becomes an **oncogene** and imparts a growth advantage of its host cell.

Single nucleotide polymorphism (SNP): A DNA sequence variation occurring commonly within a population (e.g. 1%) in which a single nucleotide in the genome differs between individuals.

Somatic mutation: A mutation that occurs in any cell of the body after conception. Sometimes called *acquired mutation*.

Substitution (or nucleotide substitution): A DNA mutation leading to the replacement of a native nucleotide with another.

Splice sites: DNA sequences flanking exons which are important for mRNA splicing.

Subclonal mutation: A mutation that exists in only a subset of the neoplastic cells within a tumour.

Transition (mutation): Change of a nucleotide to another of the same group such as C > T (both pyrimidines) or G > A (both purines).

Transversion (mutation): Change of a nucleotide to another of the opposite group such as A > C (purine to pyrimidine).

Tumour suppressor gene: A gene that inhibits the development of cancer, commonly by limiting cell proliferation. These genes are frequently inactivated in cancer cells.

Uniparental disomy (uPD): A genetic modification leading to the loss of the maternally or paternally derived copy of a genomic region as a result of replacement of this sequence with the equivalent sequence derived from the other parent.

Untranslated region (UTR): An exonic region located before the start (5′ UTR) or after the stop (3′ UTR) codon of a gene and which does not code for any amino acids.

Whole genome sequencing: Sequencing of the entire sequence of an individual genome using germline DNA, tumour-derived DNA or DNA from another cellular source such as cell lines, single cells etc.

Whole exome sequencing: Sequencing of all the exons of all the genes in an individual genome (there are approximately 30,000 coding genes in a mammalian genome). As with whole genome sequencing this could be done using germline DNA, tumour-derived DNA or DNA from another cellular source.

X-linked gene: Any gene located on the X chromosome.

Next generation sequencing (NGS) technologies allow such analysis through parallel sequencing of thousands to millions of DNA molecules in a relatively short period of time. Compared to classical Sanger methodology this represents an increase in speed and capacity in excess of 1 billion-fold and a dramatic reduction in costs. NGS output is in a digital form, where each sequencing read, corresponding to an individual genomic DNA fragment, is captured separately. Reads are then mapped back to the reference genome using computational aligning algorithms, allowing the sequence of the *whole genome* to be analysed in one sequencing run. Alternatively, genomic regions of interest can be enriched for prior to sequencing, allowing the investigator to limit analysis to the coding portion of the genome (*whole exome sequencing*), or to specific parts of the genome such as the exons of a selected set of genes. Importantly, NGS is quantitative and can be used to discriminate between homozygous, heterozygous and subclonal events based on the number of DNA molecules supporting each variant (*allele burden*), see Chapter 8 for more details on next-generation sequencing and its application in this context.

The accumulation of somatic mutations is an inevitable consequence of the passage of time and this is true for any cell,

including the germ cells through which acquired mutations are passed to the offspring, generating diversity in the human and any other living species. However, mammalian genomes are afforded an extraordinary level of protection from mutations such that each nucleotide has only a 1 in 10^{10} chance of mutation per generation. Nevertheless, mutations do accumulate with time at a rate that is influenced by the abundance and nature of mutagens acting on cellular DNA and its proof-reading machinery.

A cancer cell, just like all the other cells in the body, is a direct descendant of the fertilised egg through a lineage of mitotic cell divisions. However, the genome of a cancer cell and indeed that of a normal cell harbour a set of somatic mutations acquired during the cell's own life and the life of its ancestors back to the fertilised egg (Figure 9.1). These are collectively termed **somatic mutations** to distinguish them from **germline mutations.** In the following paragraphs, we will describe examples of germline as well as somatic variants associated with cancer and discuss the processes leading to acquisition of somatic variants.

Classes of DNA mutations

The structure and sequence of genomic DNA can be altered in several ways by mutagens. The resulting changes belong broadly to one of two categories: those that change the nucleotide sequence at a local scale and those that affect large genomic regions such as parts of chromosomes or entire chromosomes (Figure 9.2). Mutations that change the nucleotide sequence of DNA are broadly classified as *substitutions* and *indels* (insertions or deletions). When substitutions affect coding exons, they can be *synonymous* (no change in the coded amino acid), *missense* (change of the coded amino acid to another amino acid) or *nonsense* (change of the coded amino acid to a stop codon). When indels affect coding exons, they can have similar effects. However, if the size of an indel is not a multiple of three nucleotides the resulting change is a *frameshift* mutation. Frameshift mutations lead to the translation of a novel aberrant sequence of amino acids terminating at an endogenous stop codon sequence.

Both substitutions and indels do occur outside coding exons where their effects are more difficult to decipher. When they affect splice junctions of exons, they can lead to reduced usage or complete exclusion of an exon from the final mRNA. When they occur elsewhere in the genome, they may not have a significant functional effect, but in some cases, they can affect gene regulatory sequences. Examples of such mutations having an oncogenic effect were recently described.

Mutations altering the copy number of regions of the genome are referred to as *amplifications* and *deletions*. They can affect part of a gene, several genes, large chromosome segments or whole chromosomes. With these mutations, the net gain or loss of genes has an oncogenic effect, although for large amplifications or deletions, it is often difficult to pinpoint which of the several genes involved are most important. *Chromosomal translocations* and *inversions* are a recurrent type of structural genomic rearrangement in haematological and other cancers. With these mutations, two regions of the genome situated far away from each other are juxtaposed as a result of breakages in their host chromosomes, followed by illegitimate fusions between them. These events can result in the formation of a fusion oncogene, such as *BCR::ABL* in the t(9;22) in CML (see Chapter 33) or lead to marked over-expression of a gene such as *CCND1* or *MYC* in the t(11;14) and t(8;14), respectively (Figure 9.3). In each of the latter two cases, the target gene is over-expressed as a result of coming under the control of the strong IGH promoter in mantle and Burkitt lymphomas, respectively. *Chromothripsis* is a very dramatic type of structural change affecting the genomes of some cancers. In chromothripsis, tens to hundreds of chromosomal rearrangements

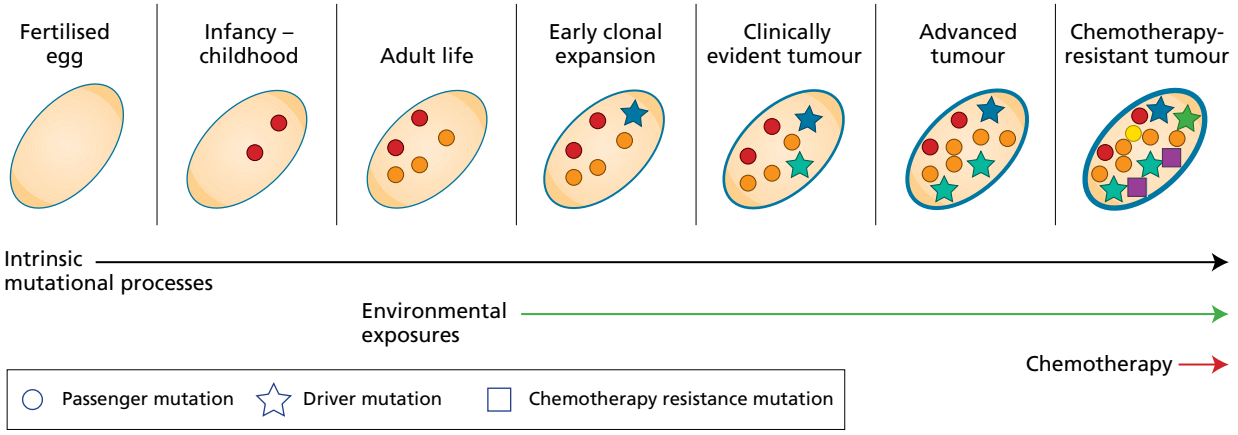

Figure 9.1 The sequence of somatic mutations acquired during cell divisions from the fertilised egg to a single chemoresistant cancer cell. The mutational processes causing these mutations are also highlighted. (Source: Modified from Stratton *et al.* 2009).

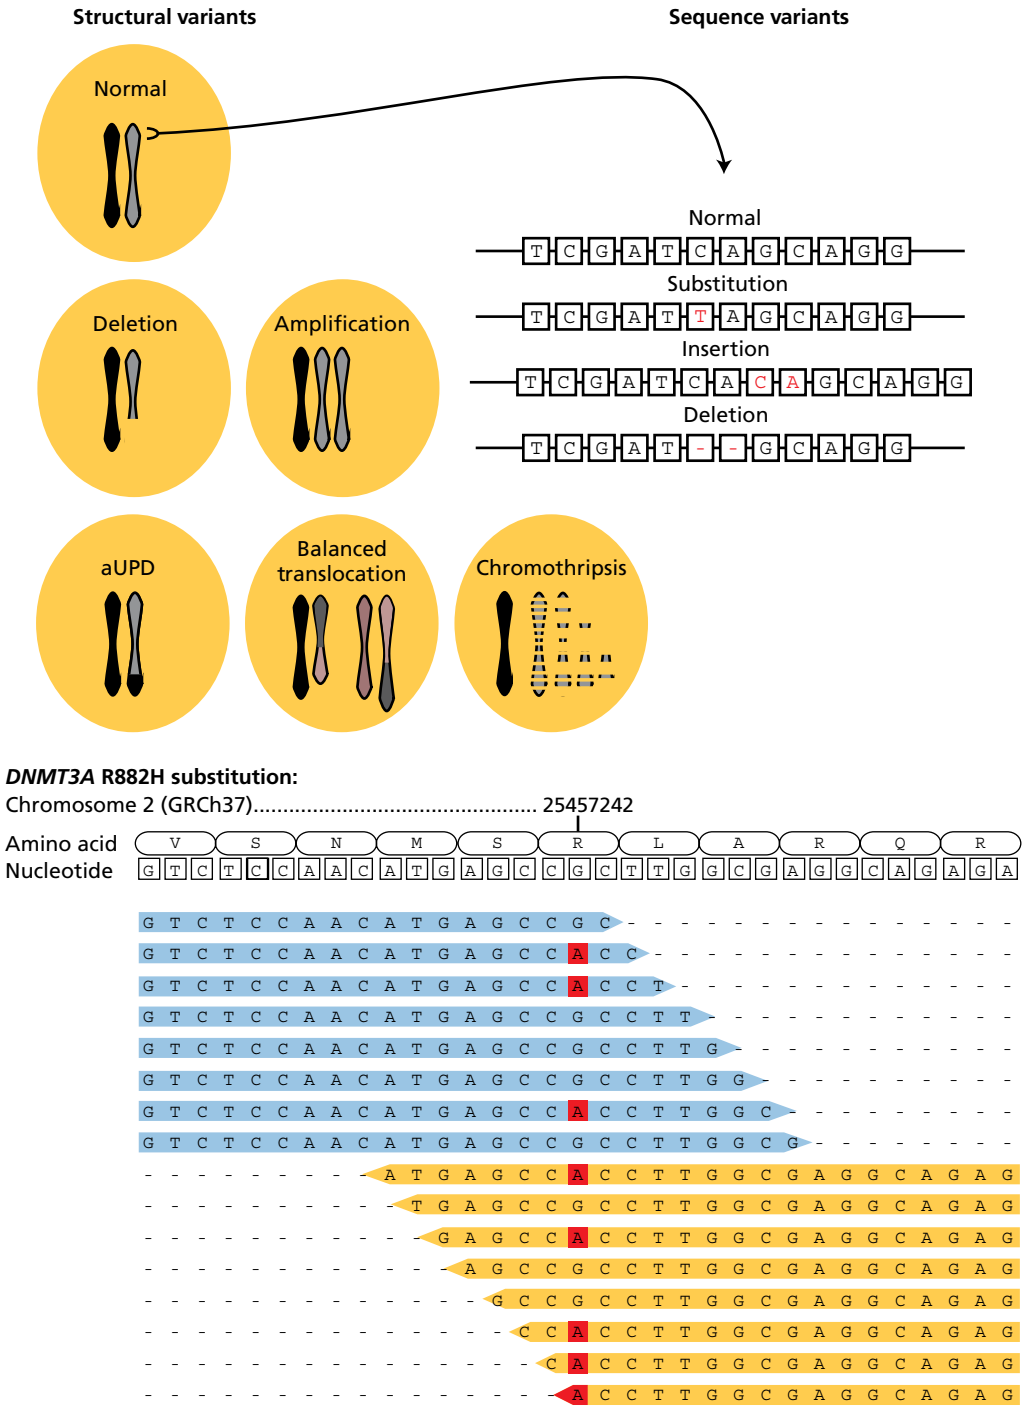

Figure 9.2 Different types of mutations and chromosomal rearrangements.

involving localised genomic regions can be acquired in an apparently single catastrophic event.

Finally, an important concept in cancer genomics is that of *loss-of-heterozygosity (LOH)*. As each of us inherits a maternal and a paternal allele for every gene or genomic region, we are heterozygous throughout our genome. Our heterozygosity can be verified using polymorphisms that distinguish the maternal and paternal alleles. In cancer, it is common to find that areas of the genome have 'lost their heterozygosity', as they only display one of the two alleles and this happens if one of the two alleles is lost. This can be due either to a deletion of that allele or its replacement by the other allele (which is now duplicated).

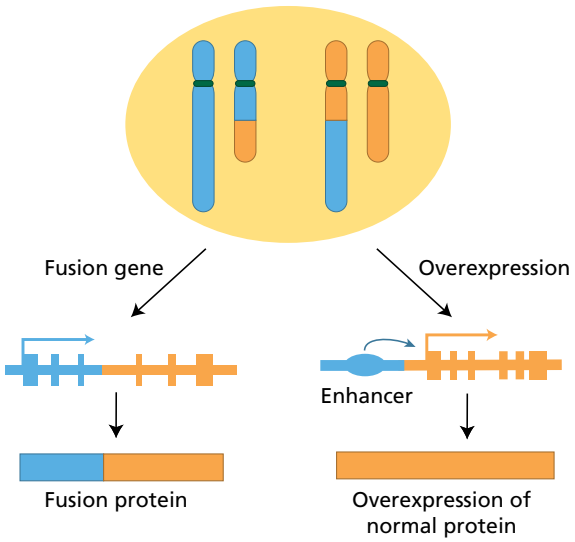

Figure 9.3 Common mechanisms of gene activation by chromosomal translocations: (i) formation of a chimaeric gene by fusion of the two genes spanning the chromosomal breakpoints and (ii) over-expression of an intact gene through the action of a potent enhancer translocated upstream.

The duplication of one allele and associated loss of the other is known as acquired *uniparental disomy (aUPD)* and is the result of mitotic recombination (or mitotic cross-over) between two homologous chromosomes. As there is no net loss of genetic material, aUPD is also known as *copy-neutral LOH*. Mitotic recombination occurs at a very low rate and the reason it appears a lot more frequently in cancer is because just like any other mutation, aUPD can give an additional growth advantage to the host cell, often by duplicating a previously acquired oncogenic mutation. For example, *FLT3* internal tandem duplications and the *JAK2V617F* mutation are commonly duplicated by aUPD.

Inherited predisposition to haematological cancers

Most haematological malignancies are sporadic and not attributable to identifiable heritable or environmental risk factors, with some important exceptions (Table 9.2). For example, the risk of developing blood neoplasms is higher in individuals with certain uncommon inherited syndromes. In most instances, what is inherited is a genetic predisposition to develop cancer(s) through transmission of genetic variants that are either oncogenic themselves or accelerate the acquisition of somatic mutations that cause overt cancer. As cancer is a multistep process, acquiring the first oncogenic variant through germline transmission significantly increases the chances of acquiring the full set of variants that generate a cancer during the person's lifetime, hence the increased risk of cancer in these individuals.

Table 9.2 Examples of risk factors for the development of leukaemia and lymphoma.

Germline syndromes
- Oncogenic variants
  - *RUNX1* (familial platelet disorder with propensity to myeloid malignancy)
  - *CEBPA* (rare cases of familial AML)
  - *DDX41* (Familial predisposition to myeloid neoplasms)
  - *NF1* (Type I neurofibromatosis)
  - *PTPN11* (Noonan's syndrome)
  - *CBL* (rare cases of JMML)
- Variants that increase genome instability
  - *BLM (Bloom's syndrome)*
  - *ATM (Ataxia Telangiectasia)*
  - *FA genes (Fanconi anaemia)*
  - *ALDH2 and ADH5 coinheritance (Aldehyde degradation deficiency syndrome)*
  - *ERCC6L2 (familial MDS and AML in children and young adults)*
- Predisposition alleles/haplotypes
  - *46/1 haplotype in PV/ET*
  - *Several alleles in multiple myeloma, e.g. rs603965 in t(11;14)*
  - *Several alleles in chronic lymphocytic leukaemia, e.g. rs13397985*

Endogenous mutagenic processes
- Spontaneous deamination of methylated cytosines at CpG islands
- Cytidine deaminases (AID, APOBEC)
- RAG-driven chromosomal breaks and translocations, e.g. in B-ALL carrying t(12;21)

Exogenous mutagenic processes
- Biological
  - *EBV infection (EBV-driven lymphoproliferative disorder)*
  - *HTLV-1 infection (adult T-cell leukaemia/lymphoma)*
  - *HHV-6 (Castleman's disease and lymphomas of serous cavities)*
- Chemical
  - *Benzene*
  - *Chemotherapeutic agents*
- Physical
  - *Ionising* radiation

Also, as germline mutations are present in all cells of the body, they can have developmental effects in several organs and tissues. For this reason, many of the common mutations acquired somatically in cancer are never seen as heritable mutations. For example, the acute myeloid leukaemia (AML)–associated *NPM1* mutations lead to early embryonic lethality in mice and unsurprisingly are never seen as germline mutations in humans.

In familial platelet disorder with propensity to myeloid malignancy (FPD/AML), heterozygous inheritance of a *RUNX1* oncogenic variant causes an autosomal dominant syndrome

characterised by mild to moderate thrombocytopenia, abnormalities of platelet function and a propensity to develop myelodysplasia (MDS) and/or AML. *RUNX1* is a transcription factor critical for the establishment of definitive haemopoiesis and a target of somatic mutations including *deletions*, *translocations*, *substitutions* and *indels* in leukaemia. Most familial *RUNX1* mutations in FPD/AML lead to premature stop codons or affect the Runt domain of the gene involved in DNA binding. The median incidence of myeloid malignancy in FPD/AML ranges between 20 and 65% between families, but even within the same family affected individuals may present with variable clinical severity and at varying ages. This highlights how *RUNX1* mutations are insufficient for carcinogenesis in isolation but require co-operating somatic mutations for cancer development. In fact, mutations affecting the other copy of *RUNX1* as well as unrelated chromosomal deletions and translocations are commonly seen at the time of leukaemia progression.

An increased risk of malignancy can also arise from inheritance of variants in genes that increase the acquisition of mutations required to transform a normal cell to a cancer cell. One such example is Bloom's syndrome, an autosomal recessive disorder characterised by predisposition to the development of haematological and solid cancers, along with a constellation of physical findings. In this disorder, biallelic mutations in the gene for the DNA helicase *BLM,* result in a widespread *genomic instability* and a highly increased rate of mitotic recombination leading to aUPD. This can lead to rapid homozygosity of oncogenic mutations and an increased growth advantage to the host cell. Fanconi anaemia is another autosomal recessive genetic disorder characterised by early onset bone marrow failure, leukaemia and solid cancers. Children with this disease inherit inactivating mutations in at least 23 genes in the Fanconi anaemia DNA repair pathway, leading to hypersensitivity to DNA crosslinking agents such as cisplatin. Reactive aldehydes, by-products of cellular metabolism, are a major endogenous source of DNA damage in Fanconi anaemia. Aldehydes are well known to cause DNA crosslinks, and cells deficient in the FA pathway are unable to repair aldehyde-induced DNA damage, ultimately leading to genomic instability and/or cell death. Interestingly, a bone marrow failure and leukaemia syndrome similar to Fanconi anaemia was discovered in several Japanese families with children who inherited inactivating mutations in two enzymes that detoxify aldehydes (ALDH2 and ADH5). Mouse models of this disease show that the loss of ALDH2 and ADH5 results in accumulation of endogenous formaldehyde, which acts as a potent *genotoxin* that disrupts haemopoiesis, and increases cancer risk.

As well as genetically well-defined syndromes such as the ones described above, a predisposition to cancer is also seen in some families with haematological malignancies, including CLL, myeloma, myeloproliferative neoplasms and lymphoma. The increase in risk is generally small and the genetic basis unclear, however *genome-wide association studies* (GWAS) have identified areas of the genome within which the genetic risk 'resides'.

An intriguing example of inherited risk comes from the observation that *JAK2* mutations, found in most cases of polycythaemia vera (PV) and also in other myeloproliferative neoplasms, are acquired preferentially within a particular *JAK2 haplotype* called 46/1. This haplotype, whose frequency in Europeans is approximately 25%, appears to 'invite' the acquisition of somatic *JAK2 V617F* mutations and gives 3–4 times increased risk of developing *JAK2 V617F*-positive myeloproliferative neoplasm. It is not clear what underlies this phenomenon, but one possibility is that acquisition of *JAK2 V617F* on this haplotype gives a greater growth advantage to the host cell than its acquisition on any other *JAK2* haplotype ('fertile ground hypothesis'). An alternative hypothesis is that the mutation occurs more frequently in this haplotype (hypermutability hypothesis).

Finally, another phenomenon of predisposition to a specific acquired mutation occurs in children with Down syndrome. In the first 3 years of life, up to 10% of these children develop transient myeloproliferative disorder (TMD), a disease that mimics AML, but typically resolves spontaneously within a few months (see Chapter 54). Almost all cases of TMD carry somatic mutations affecting the *X-linked* transcription factor GATA1, which drives the proliferation of leukaemic cells in TMD. The mutations disappear with the resolution of the TMD.

Acquired DNA mutations in haematological cancers

Although a lot can be learned from studying genetic susceptibility to cancer, neoplasms arise as a result of somatically acquired DNA mutations. The accumulation of somatic mutations is an inevitable consequence of the passage of time and this is true for all cells of all living organisms. However, mammalian genomes are afforded an extraordinary level of protection from mutations. Nevertheless, mutations do accumulate with time at a rate which is determined by the very small infidelity of the DNA replication and repair machinery and by the degree of exposure to endogenous or exogenous mutagens. Therefore, each somatic cell and by extension each cancer cell harbours a variable number of somatic mutations, which accrued during its lifetime and that of its ancestors from the fertilised egg onwards (Figure 9.1). This cargo of mutations in the cancer cell genome can be generated through a number of different mutational processes. The number and the nature of the mutations can provide important pathogenic information and in some cases identify the responsible mutagen and the extent of its impact on the genome. For example, it is evident that the total number of mutations identified in the genomes of different forms of cancer varies widely and reflects the type and length of exposure to different

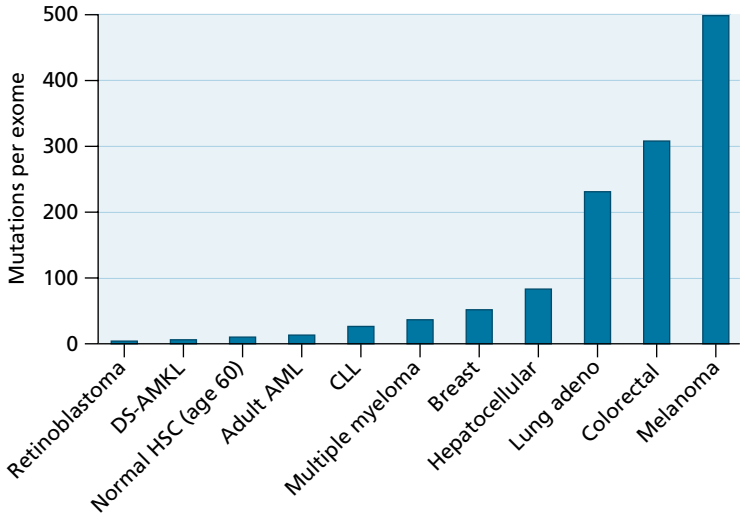

Figure 9.4 Median number of mutations per exome in various haematological and solid cancers.

mutagens (Figure 9.4). In addition, by sequencing multiple pre-cancerous and cancer genomes, we can model the rate of mutation accruing in cells. This has revealed that the earliest cancer-associated mutations can be acquired within the first two decades of life. Also, studies of the particular type of change in DNA sequence can give important information about the mutagens and processes involved. More than 30 such *mutational signatures* have now been described and for many of these, the responsible biological processes or mutagens have been identified. Below we discuss some of these processes.

Endogenous processes

A specific type of DNA mutation that affects all cells is the spontaneous deamination of methylated cytosines primarily at CpG islands which, if not corrected by editing enzymes, leads to a C > T *transition*. This process causes mutations at a very slow, but constant, rate and is thought to account for most of the spontaneous background mutation rate and for the under-representation of CpG dinucleotides in mammalian genomes. It is thought to play a role in the evolution of species and can lead to cancer development if it causes oncogenic mutations. In fact, it is the only recognisable mutational process in most AML genomes.

In addition to spontaneous deamination, enzymatic deamination of cytosines in DNA by the enzyme family APOBECs (apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like) and AID (activation-induced deaminase) can create C > T *transition* and C > G/A *transversion* mutations. APOBECs and AID can deaminate cytosine in both RNA and DNA substrates to play diverse physiological roles. For example, APOBEC1 edits the apolipoprotein B mRNA to introduce a premature stop codon required for the synthesis of shorter forms of apolipoprotein B. The APOBEC3 complex plays a role in anti-viral immunity through the targeted hypermutation of viral DNA genomes such as the cDNA intermediate of the HIV. AID deaminates cytosine in B lymphocyte immunoglobulin genes to initiate secondary antibody diversification via somatic hypermutation and class-switch recombination. Both APOBECs and AID have substrate preference for cytosines flanked by specific nucleotides. In the case of APOBECs, these enzymes preferentially deaminate cytosine in the TpCpN trinucleotide sequence (N represent any nucleotide). For AID, the preferred substrate is RpCpW (where R = A/G, W = A/T). Through the analysis of these mutational signatures, it has been observed that many mutations at cytosines are attributed to the off-target mutational activity of APOBECs/AID in haematological cancers, including B-ALL, CLL, MM and DLBCL. In addition, the AID/APOBEC mutation signatures are often associated with local hypermutation of regions of the genome, a phenomenon known as *kataegis*, representing localised mutation 'storms' at different genomic regions. Ectopic action of AID has been detected at a number of secondary sites, some of which have been implicated in the pathogenesis of CLL and DLBCL (e.g. *BCL-6* mutations and *IGH* translocations).

Another group of DNA editing enzymes, the RAG endonucleases *RAG1* and *RAG2,* mediate the physiological V(D)J recombination process during B-cell development. In cases of B-ALL carrying t(12;21) and expressing the chimeric *ETV6::RUNX1* fusion protein, the RAG enzymes can be aberrantly activated to drive a mutational process characterised by deletions scattered across the genome at regions flanked by recombination signal sequence motifs. These deletions can be oncogenic and collaborate with *ETV6::RUNX1* to drive B-ALL.

There are almost certainly other endogenous processes that have yet to be discovered. For example, through analysis of mutational signatures, we know that signature 5 is prevalent in leukaemia, and in many solid cancers, but the mutagenic process that underpins this signature remains unknown.

Exogenous processes

The best-known mutagen, tobacco smoke, causes mutations with a particular signature which abound in the genomes of lung and some other epithelial cancers from smokers. So far, no evidence of this signature has been described in haematological cancers and the same can be said for UV-induced mutations. However, exposure to a number of exogenous biological, chemical and physical agents can lead to haematological cancers. One of the best-studied examples is the correlation between Epstein–Barr virus (EBV) infection and development of cancers, including lymphomas. Asymptomatic EBV infection can be demonstrated in >90% of the world population, in whom the virus can establish a latent infection in B-lymphocytes. The latent virus expresses a set of genes/antigens to maintain the viral genome and to successfully evade host immune surveillance. The same antigens have the ability to manipulate several cellular pathways and promote B-cell proliferation. This proliferation is normally kept in check by EBV-specific T lymphocytes that continuously survey and suppress infected B cells. However, in some highly immunosuppressed individuals, such as bone marrow or solid organ transplant recipients, this suppression fails and an EBV-driven B-cell lymphoma develops (post-transplant lymphoproliferative disorder). EBV is also implicated in the pathogenesis of Burkitt lymphoma and Hodgkin lymphoma, although the mechanism leading to neoplastic transformation is less understood. Similarly, infection with the human T-lymphotropic virus type 1 can lead to development of adult T-cell leukaemia/lymphoma, whilst HIV infection significantly increases the risk of B-cell lymphomas through reduction of anti-tumour immuno-surveillance, a risk that can be mitigated by combination antiretroviral therapy.

Amongst oncogenic chemical and physical agents in haematology, exposure to benzene, ionising radiation, alkylating agents and other chemotherapeutic agents have been clearly linked to the development of leukaemia and lymphoma with variable latency. A particular example is that of the association between exposure to topoisomerase inhibitors, such as etoposide and anthracyclines, and the development of acute leukaemia associated with chromosomal translocations involving the mixed lineage leukaemia (*MLL*) gene on chromosome 11q23. Topoisomerase II (Topo II) creates double-stranded breaks during execution of its function of relaxing overwound DNA, and it appears that Topo II inhibitors may stabilise complexes that are formed between the enzyme and free DNA ends, thus increasing the likelihood that those ends might participate in a translocation. The possibility has been raised that naturally occurring Topo II inhibitors have a causative role in some cases of leukaemia, but there is no good evidence to support this.

From genotype to phenotype

Regardless of how mutations are generated, most of them will not impart a growth advantage and are deemed to be 'passengers'. In most cancers only a minority of mutations are 'drivers', a term used to signify mutations that impart oncogenic properties to the host cell(s) and drive cancer growth; either by activating *oncogenes* or inactivating *tumour suppressor genes*. While a definitive categorisation of any mutation as a driver would require functional evidence that the variant can actually cause cancer, this is impractical for the ever-increasing number of variants that are identified by NGS studies. Instead, the 'driver' label is commonly given to mutations that are seen in any cancer type more often than would be expected by chance. Implicit in this working definition is the fact that it relies on some statistical calculation of 'chance' and is therefore prone to some error. In other words, some of the less frequently observed true drivers may not make the cut, whilst some passengers may fortuitously do so.

Another important concept to highlight here relates to the fact that each cancer has several driver mutations that work together to endow the cancer cells with their neoplastic phenotype. When studying these mutations, what becomes clear is that certain mutations co-occur regularly in the same cancer (e.g. *NPM1* and *FLT3* mutations in AML), whilst others almost never co-occur (e.g. *JAK2* and *CALR* mutations in MPD). When these observations are combined with what we know about the function of individual mutations, it becomes apparent that mutations that co-occur more often than expected by chance (*co-occurrence*), complement each other in transforming the host cell. By contrast, mutations with similar function do not co-occur or do so less often than expected by chance (*mutual exclusivity*), as only one or the other is sufficient to cause a specific effect or subvert a particular pathway, or in the case of spliceosome mutations, combinations of mutation might result in synthetic lethality.

Below we discuss some important examples of driver mutations from different haematological malignancies and highlight some of the better-understood genetic pathways subverted in these cancers.

NOTCH-signalling and lymphoid malignancies

NOTCH1 is a cell surface receptor with a central role in T-lymphopoiesis. It regulates interactions between adjacent cells and is activated by ligand binding, which triggers heterodimerisation of the receptor and proteolytic cleavage of an intracellular peptide (ICN1 = intracellular domain of NOTCH1) that migrates to the nucleus, where it affects DNA transcription. In the bone marrow, NOTCH1 signalling is required to promote the generation of T-lymphoid precursors from early haemopoietic progenitors, at the expense of B-lymphopoiesis. T-cell precursors subsequently migrate to the thymus, where NOTCH1 signalling is essential for survival and differentiation of T-cells with a successfully rearranged T-cell receptor. Furthermore, NOTCH1 is required for T-cell proliferation in the presence of antigen-presenting cells in peripheral tissues.

Given its physiological roles above, it is not surprising that in the multistep process leading to T-cell lymphoblastic leukaemia (T-ALL), constitutive activation of NOTCH1 signalling is one of the most prominent genetic events. It is present in 60% of T-ALL cases, and it invariably results in constitutive activation of ICN1 and its transcriptional activity. Interestingly, deregulated ICN1 activity can be achieved through different molecular mechanisms, all of which represent subversions of the physiological pathway (Figure 9.5). Point mutations affecting the heterodimerisation domain of NOTCH1 result in ligand-independent activation, while truncating mutations of the C-terminal regulatory PEST domain result in increased half-life of ICN1. Rarely, *NOTCH1* is involved in the chromosomal translocation t(7;9), which results in the expression of a truncated and constitutively active form of the protein. Finally, loss-of-function mutations of *FBXW7*, an E3 ubiquitin protein ligase that targets ICN1 for degradation, similarly result in its constitutive activation. Studies have shown that ICN1 over-expression causes leukaemia by altering the transcriptional profile of the cell and in particular by activating the oncogene *MYC*. Amongst co-operating recurrent events are deletions of the *CDKN2A* tumour suppressor locus, encoding a negative regulator of the cell cycle and a positive regulator of p53, present in up to 70% of T-ALL. In addition, T-ALLs characteristically show translocations and aberrant expression of transcription factor oncogenes, and deletions of other tumour suppressor genes. Clearly, different T-ALL cases will display different arrays of such genetic lesions; however, it appears that T-ALL cells rely on NOTCH1 signalling independent of its mutational status, making the pathway an attractive therapeutic target.

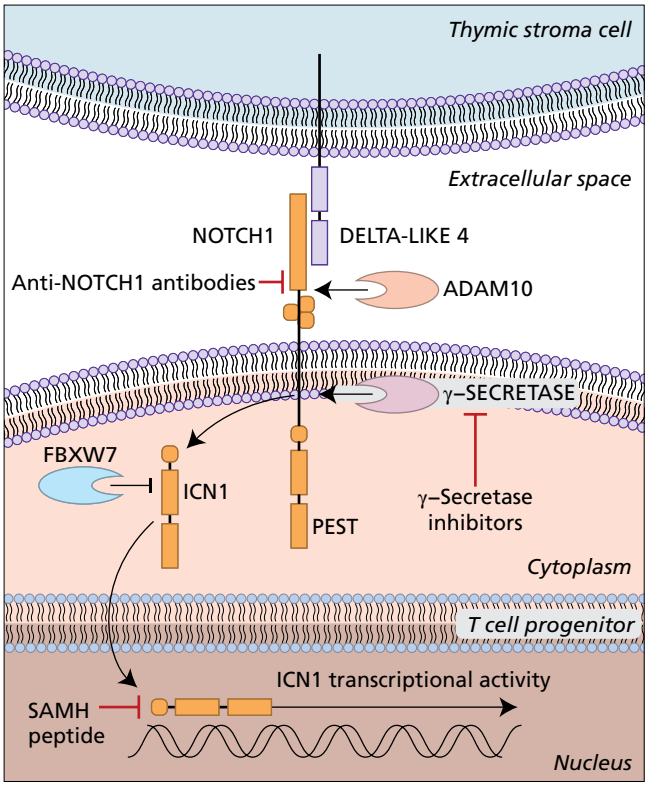

Figure 9.5 Schematic representation of NOTCH1 signalling and possible inhibitory strategies. NOTCH1 undergoes a double proteolytic cleavage upon interaction with the delta-like 4 ligand. The first is by the ADAM10 metalloprotease and can be inhibited by anti-NOTCH antibodies. The second cleavage is by the gamma-secretase complex, which can be targeted by small molecules. This double cleavage results in the release of the intracellular domain of NOTCH1 (ICN1) which activates transcription of target genes in the nucleus. FBXW7 antagonises this activity by targeting activated NOTCH1 to the proteasome. Lastly, small SAMH1 peptides disrupt the NOTCH1 nuclear transcriptional complex.

The well-defined role of NOTCH1 in T-cell development explains the relative specificity of these mutations to T-ALL. However, recently NOTCH1 PEST domain mutations were identified in approximately 10% of CLL, where they constitute a poor prognostic indicator. In most cases, *NOTCH1* mutations occur in the subgroup of CLL with unmutated IGHV genes and in cases with trisomy of chromosome 12 as the sole cytogenetic abnormality. Unlike T-ALL, *NOTCH1* mutations in CLL are almost exclusively frameshift or nonsense events, clustering within a hotspot in exon 34 of the gene and generating a truncated protein. The identification of *NOTCH1* mutations in CLL may be somewhat surprising, given the role of this gene in T-cell development; however, NOTCH1 signalling has a well-defined role in promoting terminal differentiation of mature B-lymphocytes to antibody-secreting cells. The theme of cancer mutations targeting genes involved in physiological pathways important to different types of cells in the body is very common in both haematological and solid tumours.

Epigenetics and leukaemia

The regulation of transcription is the fundamental regulatory node for controlling gene expression. The process requires physical access of specialised proteins to genomic DNA in order to read and transcribe the code into RNA. However, every human cell contains about 2 m of linear genetic information, which is packaged into a nucleus with a 6 µm diameter. This packaging is achieved by 'wrapping' genomic DNA around histones, a family of ultra-highly conserved nuclear proteins. This moulds genomic DNA into a beads-on-string configuration, which is then further folded and tightly compacted into a macromolecular complex known as chromatin. This makes access to DNA by transcriptional machinery very challenging, but also turns histones into the custodians of such access; a role which they conduct primarily through their N-terminal protein 'tails'. The process is controlled by

different post-translational modifications of these histones, including methylation, acetylation and phosphorylation, which can lead to increased or decreased access to DNA and by extension to a higher or lower level of gene transcription, respectively. Additionally, changes to the DNA itself have a further role in controlling gene expression. The area of biology concerned with these phenomena is known as epigenetics and corruption of epigenetic processes is a frequent event in leukaemogenesis.

Amongst the better-understood examples of leukaemogenic mutations operating through their aberrant effects on chromatin are those affecting the *MLL* gene. MLL is a lysine-specific methyltransferase which normally methylates specific lysine residues in histone tails to alter chromatin accessibility and increase gene expression. In the haemopoietic system, the MLL protein activates transcription of posterior *HOXA* genes (*HOXA7-A10*), which promote the self-renewal of HSCs and immature progenitors. In normal haemopoiesis, their expression is maintained by MLL in the HSC/immature progenitor compartments and diminishes as cells differentiate. However, *MLL* is a recurrent target of chromosomal translocations, which lead to an aberrant fusion of this gene to one of more than 80 gene partners. MLL-fusion proteins hijack the function of MLL and misdirect it to histone lysine residues, which are not normally targeted by the wild-type MLL. For example, the *MLL::AF9* fusion protein was shown to be co-recruited with normal MLL (expressed from the intact MLL allele) to the *HOXA9* gene locus, where the two proteins methylate different lysines on local histones to 'open' the chromatin and increase *HOXA9* mRNA expression (Figure 9.6). This results in aberrant self-renewal of haemopoietic progenitors, leading to leukaemia.

Recent developments in this area have identified that BET (bromodomain and extraterminal) proteins are important for recruiting MLL fusion proteins to chromatin. Inhibitors of the interaction between MLL fusion proteins and BRD4, a BET family member, have shown potent antileukaemic activity against MLL-fusion leukaemias and have recently entered clinical trials.

As well as its effects on chromatin, leukaemogenic mutations can alter the normal processes involved in the other important set of epigenetic events, namely modifications of DNA itself. The most important DNA modifications are those affecting cytosine residues, which can be methylated by DNA methyltransferases such as DNMT3A and DNMT3B to form methylcytosine, a residue that is generally inhibitory to gene transcription. Additionally, cytosine methylation is an important process for suppressing the expression of the large numbers of genomic parasites found in mammalian genomes, such as transposons and endogenous retroviruses. However, cytosines at particular parts of the genome rich in cytosine-guanine dinucleotides and known as CpG islands, are not always methylated. CpG islands are frequently located at the promoter regions of genes and methylation of cytosines in these islands is associated with reduced gene expression. In fact, unmethylated CpG cytosines are frequently found in regions of 'open' chromatin where histones allow the transcription machinery access to the genomic DNA.

So how do cytosines become unmethylated? With the exception of germ cells, the process was poorly understood until recently. Instead of demethylation, methylcytosines can undergo hydroxylation to hydroxymethylcytosines by enzymes known as TET dioxygenases; namely TET1, TET2 and TET3. These enzymes can further modify hydroxy-methylcytosine to formyl- and then carboxylcytosine, which can then be converted back to a cytosine. Importantly, the hydroxyl group for the initial hydroxylation by TETs comes from α-ketoglutarate produced by the action of isocitrate dehydrogenase 1 or 2 (IDH1 or IDH2) as an intermediate in the tricarboxylic acid (Krebs) cycle (Figure 9.7).

A number of key genes involved in the above processes are recurrently mutated in myeloid and less often in some lymphoid malignancies. In particular, *DNMT3A* mutations are found in 30%, *TET2* in 10%, whilst *IDH1* and *IDH2* are each mutated in 7–8% of cases of AML. Additionally, all of these genes are mutated in other myeloid neoplasms including MDS, MPN and CMML. Both *DNMT3A* and *TET2* are targeted by nonsense or other loss-of-function mutations that can be homozygous or heterozygous. However, the most frequent *DNMT3A* mutation is a missense mutation leading to substitution of arginine 882 with histidine (R882H) or

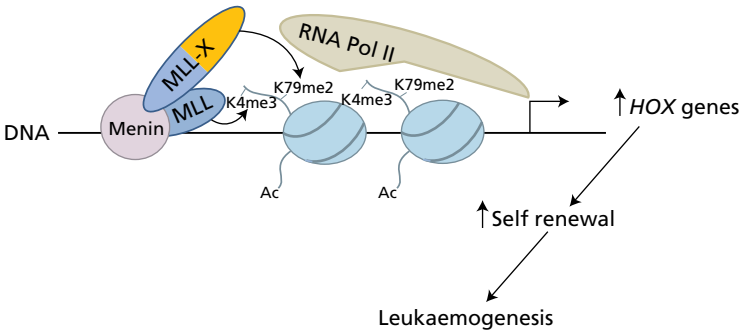

Figure 9.6 Functional consequences of disrupted MLL activity by an MLL fusion protein (MLL-X). The fusion protein acts in a dominant manner recruiting the normal MLL protein to lysine residues (K4 and K79) of histones that are not normally targeted by MLL and whose methylation promotes active and aberrant transcription of the downstream genes (such as *HOXA* genes).

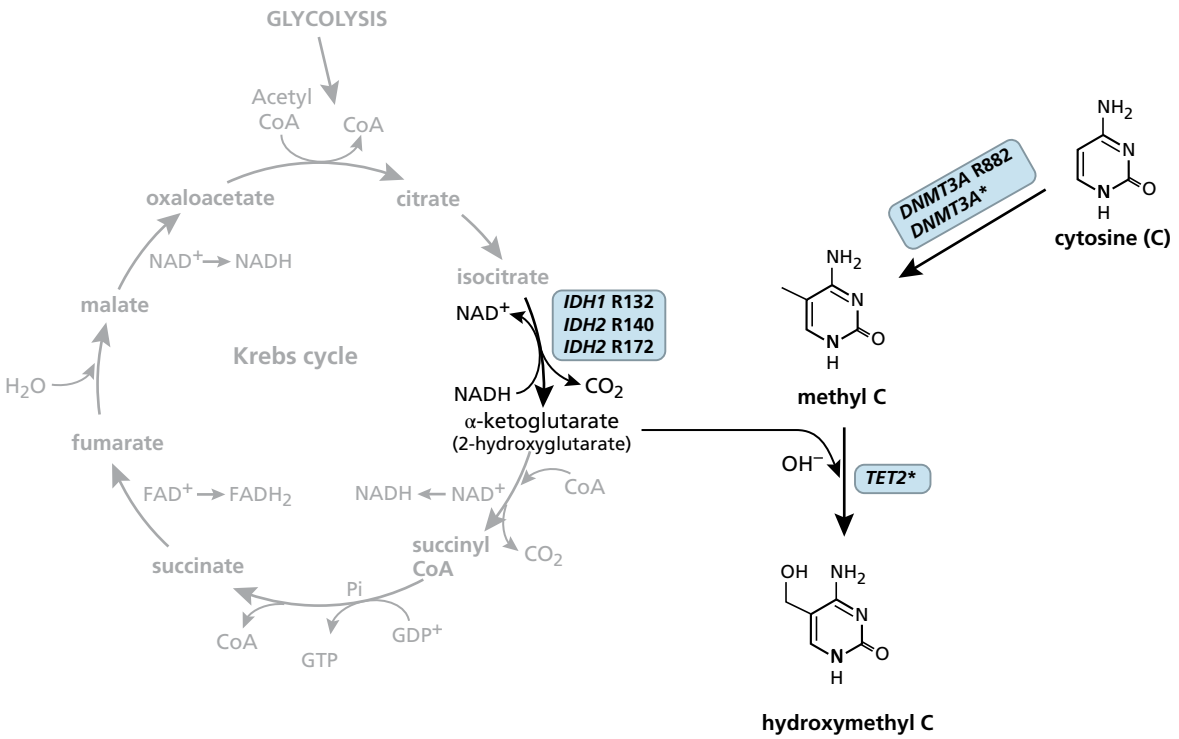

Figure 9.7 Enzymes involved in DNA methylation whose mutations are implicated in myeloid disorders. The metabolic reaction catalysed by each enzyme is indicated along with the most frequent leukaemogenic mutations (blue boxes + see text). The oncometabolite 2-hydroxyglutarate is produced, instead of α-ketoglutarate, by the action of mutant *IDH1* or *IDH2*. 2-hydroxyglutarate inhibits *TET* dioxygenases (including *TET2*) and other epigenetic enzymes.

cysteine (R882C) and less commonly serine (R882S) or phenylalanine (R882P). These substitutions are almost always heterozygous, but they are thought to have a dominant negative effect, i.e. as well as lacking methylase activity themselves, they act to inhibit the methylase function of the remaining normal *DNMT3A* allele, although they may also have other effects. Mutations affecting *IDH1* and *IDH2* have the effect of disrupting the enzymatic function of TET proteins by generating the 'oncometabolite' 2-hydroxyglutarate (2-HG) instead of α-ketoglutarate. There is now good evidence that 2-HG mediates the oncogenic properties of these mutations, by inhibiting the function of TETs and also that of a number of chromatin-modifying enzymes such as histone demethylases. In keeping with this, *IDH1, IDH2* and *TET2* mutations do not occur together in the same AML, supporting the premise that they influence similar genetic pathways (see mutual exclusivity and co-occurrence earlier in this chapter). Studies to understand the molecular consequences of *DNMT3A, TET2* and *IDH* mutations have demonstrated that their effects on DNA methylation are genome-wide rather than being specific to leukaemia genes. In other words, it is probable that they change gene expression of some genes that promote leukaemia and others that do not. However, their net effects are pro-leukaemic.

Mutations affecting *IDH1* and *IDH2* are *gain-of-function* changes, which in contrast to loss-of-function mutations are usually more amenable to targeting by new therapies. The specific mutations affecting codons *IDH1* R132, *IDH2* R140 and *IDH2* R172 (Figure 9.7) are not only seen commonly in myeloid malignancies but also occur in non-haemopoietic cancers such as glioblastoma and cholangiocarcinoma. *IDH1* and *IDH2* inhibitors are now in clinical trials and showing significant promise against AMLs carrying these mutations.

Tyrosine kinases and myeloproliferation

Tyrosine kinases are a large diverse family of enzymes that catalyse the transfer of phosphate groups from ATP onto tyrosine residues on target proteins (see also Chapters 33 and 35). These enzymes can exist within cell surface receptors, known as receptor tyrosine kinases (RTKs) e.g. KIT, PDGFR, FGFR or as free cytoplasmic enzymes e.g. *JAK2* and ABL1. Tyrosine kinases play essential roles in cell signalling, relaying both intracellular and extracellular signals to regulate core functions such as proliferation, transcription, translation, energy metabolism and differentiation. In haematopoiesis, tyrosine kinase signalling pathways underpin the regulation of haemopoietic stem and progenitor cells for proliferation and differentiation. It is thus

not unsurprising that tyrosine kinases and their regulators are targets of leukaemia driver mutations.

Cell signalling via RTK begins with the binding of a ligand to the extracellular surface of the receptor. Ligand binding promotes receptor dimerisation, which in turn stimulates autophosphorylation of specific tyrosine residues within the intracellular part of the protein. The dimerisation and associated increase in kinase activity result in recruitment of effector molecules and activation of downstream signalling pathways. Many cytoplasmic tyrosine kinases are also thought to be activated by phosphorylation and dimerisation. Driver mutations in tyrosine kinases result in constitutive kinase activity without the need for prior activation. Individual myeloproliferative disorders are associated with activation of different tyrosine kinases, with specific correlation between gene mutations and the resulting neoplastic phenotype. For example, the kinase activity of *JAK2* is activated by point mutations (e.g. Val617Phe) in almost all cases of polycythaemia vera and 50% of essential thrombocythaemia. Mutations in the thrombopoietin receptor (MPL) or in Calreticulin (*CALR*) are alternative [mutually exclusive] mutations which can also active *JAK2* signalling) see Chapter 35 for more details on this and other aspects of MPN. Point mutations in *KIT* (Asp816Val) are present in 90% of cases of systemic mastocytosis. As a consequence of these changes, the corresponding signalling pathway is activated and this provides the transformed cell with a proliferative or survival advantage.

Tyrosine kinases can also be activated by translocations, like in CML where the *BCR* gene becomes fused in-frame with the *ABL1* tyrosine kinase gene as a consequence of the Ph translocation (Figure 9.8). This usually results in the formation of a fusion protein of 210 kDa (hence p210 *BCR::ABL*), see Chapter 33 for more details on this and other aspects of CML. For example, activation of the RAS pathway is thought to contribute to the increased cell division and proliferation seen in CML cells, altered interactions with the actin cytoskeleton may underlie the diminished adhesion to inhibitory bone marrow stromal cells and STAT5-dependent upregulation of BCL-XL is implicated in the reduced apoptosis of CML progenitors.

As shown in Figure 9.8, two other versions of the *BCR::ABL* protein exist in which the breakpoint occurs in different introns of the *BCR* gene than those usually seen in CML. The smaller protein, p190 *BCR::ABL*, is found in Ph-positive ALL and has a higher level of constitutive tyrosine kinase activity than the p210 *BCR::ABL* protein. This is thought to contribute to the more aggressive behaviour of the ALL. A p230 *BCR::ABL* isoform is found rarely in patients with CML. In some cases, it is associated with a morphological picture resembling chronic neutrophilic leukaemia and possibly a lower rate of acute transformation. These variants illustrate how small structural differences in a fusion protein can cause significant differences in disease phenotype.

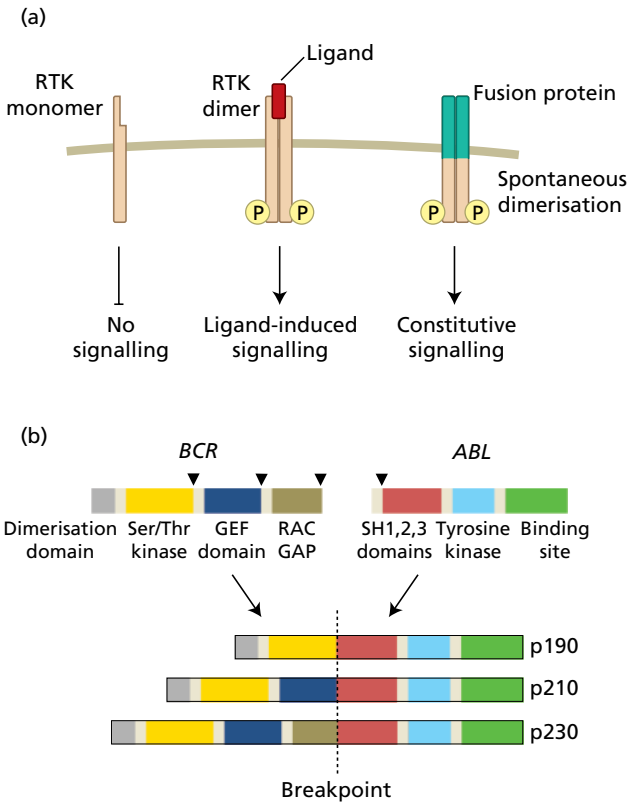

Figure 9.8 Fusion tyrosine kinases. (a) In normal cells, receptor tyrosine kinases (RTKs) exist as inactive monomers which, upon ligand binding, become activated by dimerisation and autophosphorylation. By contrast fusion tyrosine kinases dimerise spontaneously and are constitutively active. (b) Different forms of *BCR::ABL1* fusion genes contain varying lengths of the *BCR* gene and result in different molecular effects (see text). Unlike the examples in (a) that depict transmembrane *RTK*s, *ABL1* and *BCR::ABL1* are intracellular TKs.

Receptor tyrosine kinases such as *PDGFRA*, *PDGFRB* and *FGFR1* can participate in fusion genes found in eosinophilic myeloproliferative disorders. A remarkable feature of these syndromes is the large number of fusion partners described for each of these kinases, with more than 10 partners currently known for *FGFR1*, more than 5 for *PDGFRA* and more than 20 for *PDGFRB*. As with *BCR* in *BCR::ABL*, most of these partners harbour dimerisation domains that facilitate constitutive activation of the tyrosine kinase. However, reflecting their molecular heterogeneity, these disorders exhibit significant clinical diversity. For example, cases associated with the *FIP1L1::PDGFRA* fusion exhibit marked eosinophilia, while those associated with *ETV6::PDGFRB* often show dysplastic features and a lesser degree of eosinophilia. Additionally, cases involving *FGFR1*, collectively known as the *8p 11 myeloproliferative syndrome,* are

usually associated with a co-existing non-Hodgkin lymphoma. Notably, cases associated with rearrangements of the *PDGFR* genes respond well to imatinib, while those associated with *FGFR1* fusions do not. Newly developed FGFR inhibitors are currently being tested against the latter.

GM-CSF and RAS signalling in juvenile myelomonocytic leukaemia

Juvenile myelomonocytic leukaemia (JMML) is a rare disorder of childhood characterised by a marked expansion of both myeloid and monocytic lineages, with varying degrees of dysplasia and exquisite sensitivity to granulocyte–macrophage colony-stimulating factor (GM-CSF) in colony assays. These features reflect the fact that components of the GM-CSF receptor signalling and its key downstream effector, the RAS pathway, are frequently mutated in JMML (Figure 9.9).

The *RAS* genes (*KRAS, NRAS* and *HRAS*) code for small GTPases that operate as molecular switches, which are 'on' when bound to GTP and 'off' when the GTP is hydrolysed to GDP. Ras has only weak GTPase activity and in order to hydrolyse GTP and turn itself 'off' it requires activation by a GTPase activating protein (Ras-GAP). Once GTP is hydrolysed to GDP, Ras re-activation requires that GDP is exchanged for GTP. The latter process is catalysed by guanine nucleotide exchange factors (GEFs), which release GDP and allow Ras to bind the more abundant GTP. Once active, Ras stimulates cell proliferation by activating a number of cellular pathways, including mitogen-activated protein kinase (MAPK), PI3 kinase (PI3K) and phospholipase C epsilon (PLCε).

Mutations in the *NRAS* and *KRAS* genes are seen in many solid cancers, but also in several haematological malignancies, including AML, MDS, chronic myelomonocytic leukaemia (CMML), myeloma and others. Analyses of samples from patients with JMML show point mutations in *NRAS* and *KRAS* in approximately 25% of cases. The point mutations cause single amino acid substitutions, which result in constitutively active forms of the protein and thus mimic markedly amplified signalling from the GM-CSF receptor. The neurofibromin (*NF1*) gene has Ras-GAP activity and is therefore a Ras inhibitor. Interestingly, germline inactivating mutations in the *NF1* gene cause neurofibromatosis type 1, an autosomal dominant disorder characterised by protean clinical features, including increased risk of developing JMML and other tumours. Patients who have both neurofibromatosis type 1 and JMML have a high frequency (60%) of somatic inactivating mutations of the second *NF1* allele in the leukaemic cells. Furthermore, inactivating *NF1* mutations are found in 15% of sporadic cases of JMML without the clinical syndrome of neurofibromatosis. It appears, therefore, that *NF1* acts as a classical tumour suppressor gene, where two-step inactivation of both alleles allows unchecked signalling through the RAS pathway. A similar story holds true for the gene *PTPN11*, which encodes the tyrosine phosphatase SHP2. Germline mutations of this gene can cause the developmental disorder Noonan's syndrome, which is associated with an increased incidence of JMML. Up to 35% of non-syndromic patients with JMML have somatic mutations of *PTPN11* in their leukaemic cells. The mutations all cause amino acid substitutions clustering in the N-terminal SH2 domain of the protein, which is thought to result in enhanced phosphatase activity and activation of the downstream RAS pathway, giving the host cells a growth advantage over their normal counterparts.

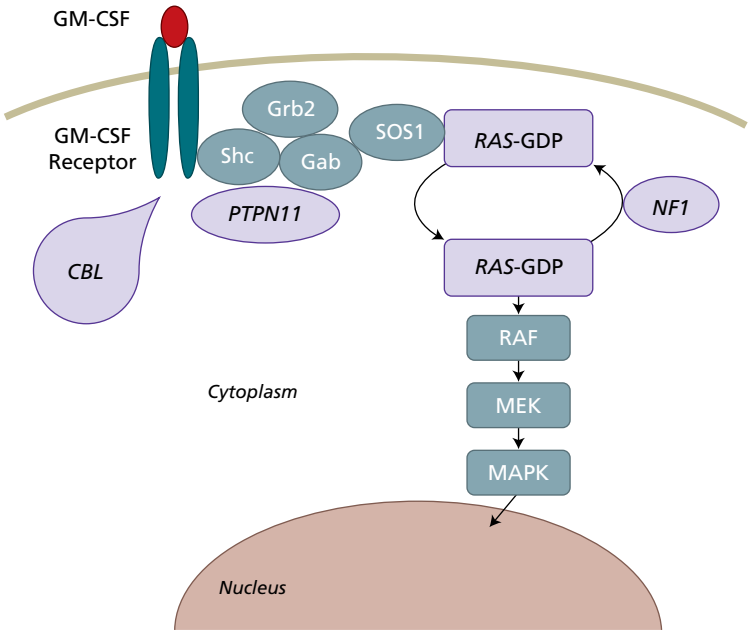

Figure 9.9 The RAS pathway and juvenile myelomonocytic leukaemia (JMML). The Ras pathway mediates many of the downstream effects of cytokine receptor activation. In most cases of JMML, the pathway is activated by mutations in one of four genes depicted in black text, which are involved in signalling downstream of the GM-CSF receptor: *RAS* (25% of cases), *PTPN11* (also known as SHP2, 35% of cases), *NF1* (15% of cases) and *CBL* (10–15% of cases). All of these mutations lead to *RAS* activation, which signals to a number of downstream effectors, including the RAF-MEK-MAPK pathway, to alter gene transcription and promote cell proliferation.

Most recently, mutations in the gene CBL were identified in 10–15% of JMML cases. Their identification followed the observation that some JMML cases exhibited aUPD of the long arm of chromosome 11. Further studies showed that some of these patients were born with germline heterozygous loss-of-function mutations in CBL, which became homozygous by duplicating the part of chromosome 11 carrying the mutation. CBL is an E3 ubiquitin ligase that controls proliferative signalling networks by downregulating the growth factor receptor signalling cascades in various cell types. JMML-associated mutations thus lead to complete loss of E3 ligase activity and increased GM-CSF receptor kinase activity and downstream signalling.

Thus, the common theme underlying most JMML is enhanced GM-CSF receptor pathway signalling, and this can be achieved by activating mutations of a positive regulator (such as *RAS* or *PTPN11*) or inactivating mutations of a negative regulator (*NF1* or *CBL*). Not surprisingly, mutations in *RAS*, *NF1*, *PTPN11* or *CBL* are mutually exclusive, suggesting that mutation of just one component is sufficient to activate the signalling pathway and that additional mutations in the pathway offer little additional advantage. Other mutations that have been reported to occur less frequently in JMML target the genes include *ASXL1, FLT3, SETBP1* and *JAK3*, with the last two conferring a poorer prognosis.

Other Ras pathway mutations in haematological malignancies

The Ras protein superfamily comprises more than 100 related small GTPases with diverse functions, including the Ras, Rho, Rab, Rap and Arf subfamilies. Mutations in *HRAS*, discovered in 1982, were the first example of a human-transforming oncogene. The closely related *KRAS* and *NRAS* were also found to be mutated in a plethora of different solid and haematological cancers. However, mutations in members of some of the other Ras subfamilies and also in genes coding for proteins in their downstream signalling cascades have been identified more recently. Most famous amongst them are mutations in *BRAF*, found frequently in melanoma and colorectal cancer amongst others. Amongst haematological cancers, mutations in *BRAF* were recently found in virtually all cases of hairy cell leukaemia and also in about 10% of cases of myeloma and less frequently in other lymphoid tumours. Also, mutations in the phosphatase *PTPN1* are present in 20–25% of Hodgkin and primary mediastinal B-cell lymphomas; whilst mutations in *RHOA* were recently identified in 25–30% of peripheral T-cell lymphomas including 75% of angioimmunoblastic lymphoma.

The P53 network

TP53 encodes the P53 transcription factor that is activated in response to different types of cellular stress and best characterised in its response to DNA damage. P53 activates a number of transcriptional networks that result in cell cycle arrest and/or activation of apoptosis. This serves to block the transmission of damaged/mutated DNA to daughter cells, preventing the accumulation of mutations that ultimately could lead to cancer. The important tumour suppressor role of P53 is evident in P53-deficient transgenic mice, which display a significantly increased frequency of cancers leading to shortened survival. In humans, *TP53* mutations disrupting one of the two P53 alleles cause the Li Fraumeni syndrome, where afflicted individuals develop cancers at an early age. Somatically acquired mutations in the *TP53* gene are found in more than 50% of human solid organ cancers. *TP53* mutation frequency is lower in haematological malignancies, found in 8–10% of AML and 4–8% of CLL. The majority of *TP53* mutations are missense changes that destroy the DNA binding ability of the P53 protein. *TP53* mutations confer poor prognosis as P53-deficient leukaemic cells can withstand genotoxic chemotherapy through failure to activate the appropriate DNA damage response that triggers apoptosis. Furthermore, the surviving P53 deficient cells have increased genomic instability that facilitates clonal evolution through acquisition of further chemotherapy-resistant mutations. Indeed, pre-leukaemic/leukaemic clones carrying *TP53* mutation can be preferentially selected following chemotherapy due to their resistance to treatment. This is evidenced by higher frequency of *TP53* mutations in leukaemias arising in patients with prior exposure to genotoxic chemotherapy. For example, up to 30% of all cases of therapy-related AML (t-AML) harbour *TP53* mutated.

The P53 protein is regulated by a number of post-translational protein modifications such as phosphorylation and ubiquitination. One such enzyme that regulates the activity of P53 is PPM1D (also known as Wip-1), a phosphatase that dephosphorylates and deactivates P53. PPM1D is itself a transcriptional target of P53, enabling a negative feedback loop upon P53 activation. The frequency of mutations in *PPM1D* follows the pattern observed for *TP53* in leukaemia, with less than 1% in de novo AML and 1–2% in MPN, and 5–10% in t-AML. Altogether, this suggests the loss of P53 pathway in leukaemia plays a greater role in providing resistance to chemotherapy than the initiation of leukaemogenesis.

Splicing factors

The initial transcription of genes produces a pre-mRNA transcript that contains both exons and introns. In order to permit protein translation from the exons, a fundamental process called splicing removes the non-coding introns and joins the remaining exons to produce a mature mRNA. In addition, splicing can also include or exclude specific exons from the mature mRNA to produce proteins with different amino acid sequences. This is known as alternative splicing and serves to expand the diversity of our genome by enabling a single gene to encode multiple protein variants. RNA splicing is coordinated in the nucleus by the

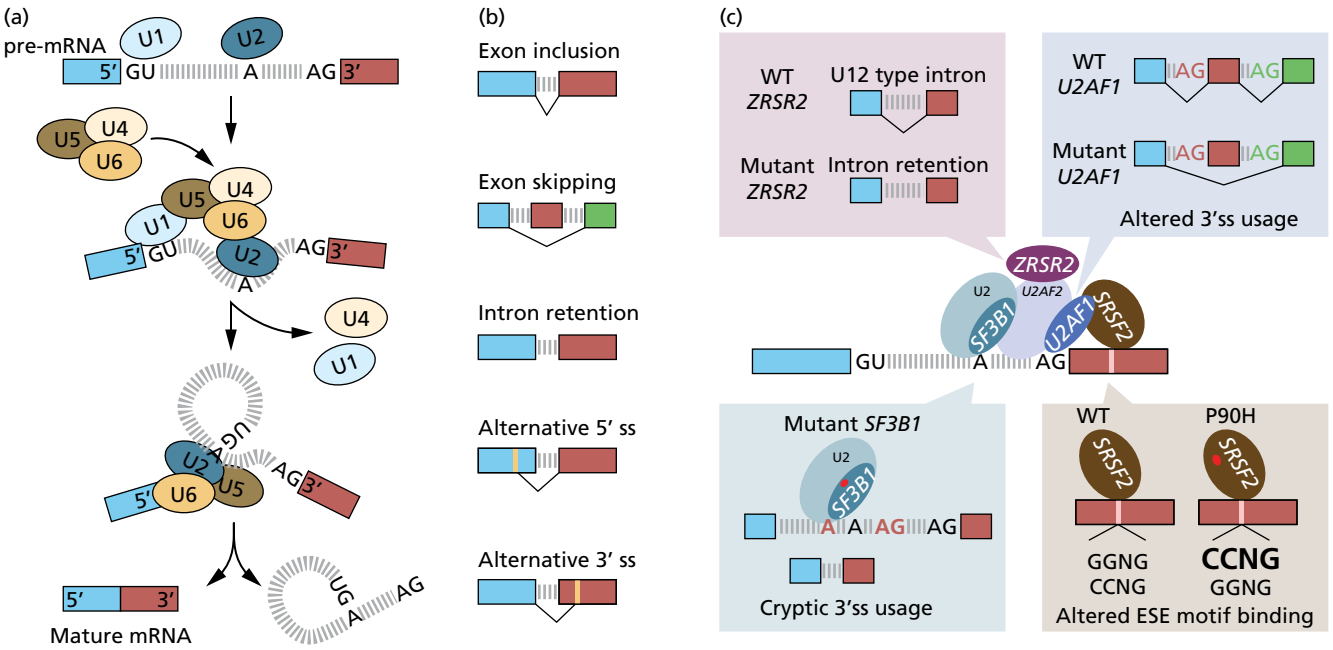

Figure 9.10 Abnormal splicing in haematological malignancies. (a) In normal splicing, the GU dinucleotides at the 5′ donor splice site (ss) of the intron are bound by the U1 small nuclear ribonucleoprotein complex (snRNP), and the A nucleotide at the splice branch site is bound by the U2 snRNP. The U4, U5 and U6 snRNP trimer is recruited and promotes cleavage at the 5′ GU donor site, followed by ligation of the GU to the A branch site to form a lariat structure. Subsequently, the RNA is cleaved at the AG dinucleotides 3′ receptor splice site to release the lariat structure, and the two flanking exons are ligated together. (b) In addition to removal of introns, alternative splicing of the pre-mRNA transcript can lead to skipping of adjacent exons, retaining introns, using alternative 5′ splice donor site (5′ ss) or 3′ splice receptor site. This leads to a diversification in the protein sequences arising from a single gene locus. (c) Mutations in the genes for splicing factors *SF3B1*, *U2AF1*, *SRSF2* and *ZRSR2* and their pathological consequence on splicing.

spliceosome, a complex of small ribonucleoprotein enzymes that catalyse the removal of introns and joining of exons (Figure 9.10).

Aberrant splicing in cancers can originate from somatic mutations in the actual sequences recognised by the splicing reaction. Paired analysis of DNA and RNA sequencing from the TGCA has shown around 1.6% of over 600,000 somatic mutations from 12 cancer types affected these splice sites. Whilst splice site mutations typically only affect the splicing of a single gene, blood cancers are enriched for somatic mutations affecting the core components of the spliceosome complex and resulting in global splicing aberration. The splicing factor genes most often mutated are *SF3B1*, *SRSF2*, *U2AF1* and *ZRSR2* (Figure 9.10c). Collectively, these mutations are most frequently identified in MDS (>65%), secondary AML progressed from MDS (>40%), CLL (10–20%) and de novo AML (5–10%). The clinical impact of spliceosome mutations varies depending on the haematological malignancy. For example, CLL harbouring SF3B1 mutations is generally associated with worse overall survival. In MDS, *SF3B1* mutations confer a more favourable prognosis with improved overall survival, whilst *SRSF2* and *U2AF1* mutations are associated with poorer prognosis. Spliceosome mutations have also been identified as drivers of clonal haematopoiesis, particularly in people aged 70 years or older. This suggests the spliceosome mutations drive clonal expansion in the context of ageing, but the mechanism by which altered splicing improves the fitness/survival of the haematopoietic clone is unknown (see clonal haematopoiesis Chapter 38).

Splicing gene mutations are heterozygous and alter the splicing activity of the affected spliceosome proteins. *SF3B1* mutations, such as K700E and K666N, result in variant SF3B1 proteins that select an upstream cryptic 3′ splice site leading to aberrant inclusion of an additional 10–15 nucleotides into the spliced mRNA transcript. The canonical function of SRSF2 is to recognise and bind the exonic splicing enhancer sequences in the RNA transcript to facilitate splicing. The vast majority of *SRSF2* mutations are non-synonymous substitutions affecting the P95 codon. These mutations produce an SRSF2 variant that alters the affinity to the exonic splicing enhancer sequence to favour the CCNG over the GGNG sequence, leading to changes recurrent splicing changes. *U2AF1* mutations also affect the recognition of the 3′ splice site, leading to usage of alternative 3′ splice sites and in many

cases to skipping of entire exons. Unlike the other three commonly mutated splice factor genes, *ZRSR2* is affected by loss-of-function mutations that are associated with increased intron retention events. The effects of altered splicing on a target gene can vary from gene expression, a shift in the physiological ratio of splice variants and/or the production of a protein with altered activity due to retention or skipping of specific exons.

The identification of the aberrantly spliced target genes that contribute to leukaemogenesis has been challenging and elusive. Spliceosome mutations can affect splicing of hundreds of different genes and it is not clear which of these, are responsible for the associated phenotypic changes. In addition, dissection of the molecular mechanisms of spliceosome mutations in murine models is complicated by the murine spliceosome factors targeting a different set of genes compared to their human counterparts. Nevertheless, the basis of some of the changes associated with splicing gene mutations is better understood. The best example of this is the formation of ring sideroblasts in *SF3B1*-mutant MDS, which is driven by altered slicing of genes involved in haem biosynthesis, namely *ABCB7*, *TMEM14C* and *PPOX*. The failure to produce adequate amounts of haem molecules leads to an excess of free iron in mitochondria, which is morphologically detectable as ring sideroblasts.

Multiple myeloma

Unlike any other somatic cell type, B and T lymphocytes undergo physiological DNA rearrangements during their development. These events are confined to the loci encoding their antigen receptor components and are required to generate the necessary antigen receptor diversity. In the case of B lymphocytes, the antigen receptor specificity is first generated through rearrangement of the V(D)J region mediated by the RAG1 and RAG2 enzymes when the developing B-cell is still in the bone marrow. In the mature circulating B-cell, the activation-induced (DNA-cytosine) deaminase (AID) protein then mediates two further processes, class-switch recombination and somatic hypermutation in the germinal centre of secondary lymphoid organs. While the former is required to change the class of the antibody produced by the B-cell (e.g. IgM to IgG), the latter introduces random point mutations in the antigen-binding site of the immunoglobulin in an attempt to increase its specificity and affinity to the target antigen. V(D)J rearrangements and class-switch recombination are achieved through generation of DNA double-stranded breaks (DSB) at specific consensus sites, deletions of part of the locus, and subsequent non-homologous end joining of the two DNA ends.

Multiple myeloma is a neoplasm of antibody-producing post-germinal centre B-lymphocytes, i.e. plasma cells. As an unwanted side-effect of their development, B-cells can occasionally acquire translocations caused by illegitimate joining of a DSB in the Ig region with a second DSB elsewhere in the genome, both caused by the activity of RAG or AID. In fact, about 40% of multiple myeloma cases show deregulated expression of oncogenes caused by their translocation next to highly active immunoglobulin (Ig) regulatory elements. This is a common theme in lymphoid malignancies in general and underscores the tight link between normal developmental processes and cancer. Notably, Ig translocations in multiple myeloma do not usually result in fusion proteins, but rather in deregulated over-expression of a full-length proto-oncogene under the control of highly active Ig enhancer elements. Deregulation of the G1/S transition is a key early molecular abnormality in myeloma, and frequently a D-group cyclin is deregulated in Ig translocations. This can be either through a direct mechanism, where *CCND1* and *CCND3* expression is driven by Ig enhancers in the t(11;14) and t(6;14), respectively, or it can occur indirectly, such as in t(14;16) where over-expression of *MAF* leads to activation of *CCND2*. The t(4;14), present in 15–20% of multiple myeloma cases, is by contrast a rare example of a translocation resulting in the simultaneous deregulation of two oncogenes, *FGFR3* on der(14) and *MMSET* on der(4). Over-expression of FGFR3 protein occurs in only approximately 70% of patients with the translocation, while *MMSET* is over-expressed in all cases. The *MMSET* gene product is a histone methyltransferase with affinity for H3K36 and H4K240, and its deregulated expression can influence DNA damage repair processes and the overall transcriptional profile of the cell. FGFR3 is a transmembrane tyrosine kinase receptor that is involved in key embryonic and adult processes including regulation of proto-oncogenic pathways such as the mitogen-activated protein kinase (RAS-RAF-MAPK), phosphatidylinositol 3-kinase (PI3K-AKT-mTOR), phospholipase Cg (PLCg), protein kinase C (PKC) and signal transducer and activator of transcription (STAT). Interestingly, activating mutations of FGFR3 and MMSET are also found in multiple myeloma and other malignancies, indicating that they may be more broadly implicated in oncogenesis.

Multiple myeloma shows multistep evolution and is almost invariably preceded by the premalignant condition, monoclonal gammopathy of unknown significance (MGUS). Chromosomal aberrations are regularly present in MGUS, indicating that Ig translocations are early events in the pathogenesis of multiple myeloma, whilst transition towards full-blown myeloma is achieved through the stepwise acquisition of additional mutations. Amongst those are deletions of chromosomes 1p, 13 and 17p, and amplification of chromosomes. Furthermore, mutations of genes involved in the MAPK signalling pathway, including *KRAS*, *NRAS*, *NF1* and the downstream protein BRAF are present in about 50% of cases, and their frequency increases in more advanced cases, again underscoring the broad relevance of this pathway to carcinogenesis.

Clonal evolution and subclonal architecture of haematological cancers

Clonal evolution of cancer

Cancer develops through the serial acquisition of somatic mutations in an individual cell and its progeny. The mutations are usually acquired in a stepwise manner, such that each time a new driver mutation is acquired, this can be seen as a cloning event. In other words, the new mutation en route to neoplasia can be seen as an event that extricates that cell from its peers, such that the onward path towards cancer continues in this individual cell's progeny. The next step in cancer evolution occurs when a new driver mutation arises in this progeny and a new clone is formed and so on. The process continues until a cell acquires a complement of driver mutations for frank malignancy to become manifest (*linear evolution*, Figure 9.11). In reality, the length of time required for this process is long enough for different individual cells within each of the serially appearing clones to acquire different mutations and continue along their own independent paths towards cancer (*branching evolution*), although one clone will usually get there first and represent the bulk of the disease. This process has been very well worked out in AML, ALL and multiple myeloma, where it is clear that although many cases follow a predominantly linear evolution, others follow a branching pattern. Of note, sometimes a very similar or even the same mutation can be acquired independently by two different subclones. This reflects a 'craving' for that mutation by the evolving cancer and the process is often referred to as *convergent evolution*. The subclonal structure of the tumour and the relationship between subclones is also relevant with regard to disease relapse and is discussed below.

Another important conundrum in cancer evolution is the order of acquisition of specific mutations. A number of studies have demonstrated such an order and AML, ALL and myeloma are again amongst the best-studied paradigms for this phenomenon. For example, in myeloma there is good evidence that chromosomal translocations and aneuploidy are usually acquired first, whilst mutations in proliferative pathways are acquired later. Also in AML, mutations affecting genes involved in DNA methylation such as *DNMT3A* and *TET2* are acquired first, whilst mutations in *NPM1* are acquired second and proliferative mutations are again acquired late.

There are two theories proposed for this recurrent order of acquisition: the *constraint theory* argues that a certain mutation has to happen first in order to 're-wire' the cell so that the second can give additional growth advantage, which would not be present in the absence of the first mutation. By contrast, the *opportunity theory* argues that the first mutation imbues features such as increased proliferation or accelerated level of mutagenesis,

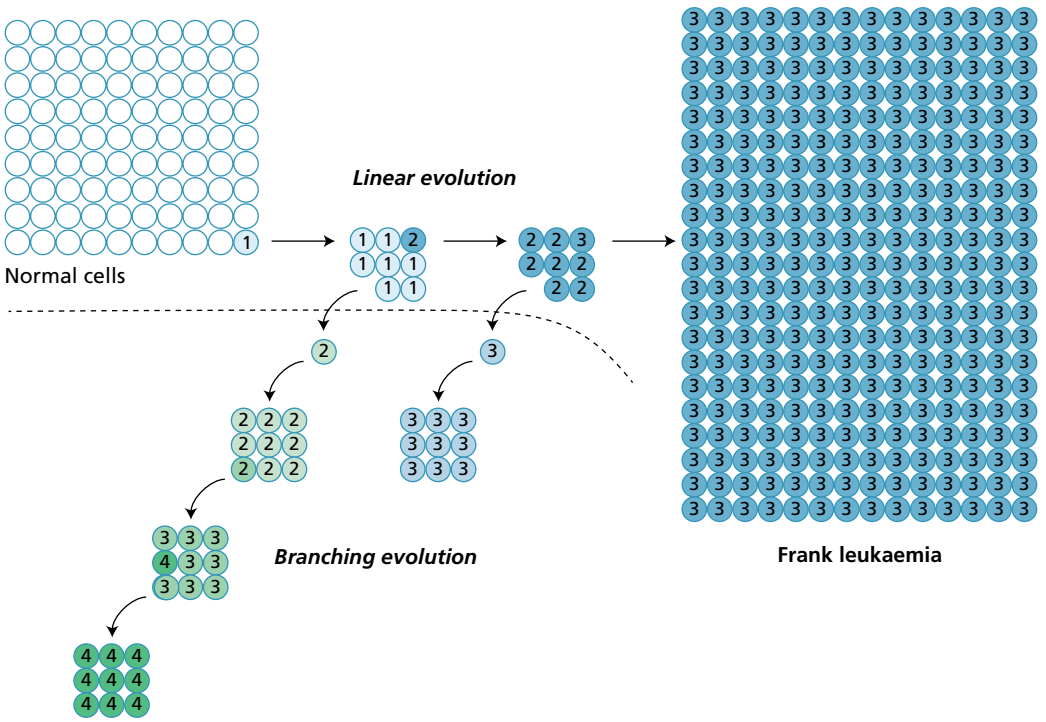

Figure 9.11 Linear and branching evolution.

that confer greater opportunity for the second mutation to be acquired. Additionally, in the latter theory, the order can be reversed, but this will happen a lot less often as there will be less opportunity. It is not yet clear which of the two theories holds true, or if indeed they both do, depending on the type of mutation; however, there is some evidence directly supporting the second. Namely, *DNMT3A* is usually acquired before NPM1c in AML; however, occasional cases of AML may acquire the *NPM1* first and *DNMT3A* mutation second. Another interesting observation about mutations that are usually acquired first in clonal evolution is the fact that they are found frequently in related, but distinct, neoplasms. For example, *TET2* mutations are seen in AML, MDS, PV, ET, CMML, systemic mastocytosis (SM), chronic neutrophilic leukaemia (CNL) and even in B- and T-cell lymphomas. This suggests that these mutations provide a fertile ground for 'second' mutations to be acquired that will eventually dictate the resulting phenotype of the cell. In fact recent studies have revealed that mutations in particular genes, most commonly *DNMT3A*, *TET2*, *ASXL1* and *JAK2*, can establish a detectable clone of haemopoietic cells in healthy individuals lacking any evidence of haematological cancer (see Chapter 38 for more details). This phenomenon of 'clonal haemopoiesis', becomes more frequent with age and can be detected in the majority of people aged 90 years or older. Cells with such clone-founder mutations can then acquire additional mutations, such as those affecting *NPM1* and *FLT3* in the case of mutant *DNMT3A*-driven clones, that can generate an acute leukaemic expansion. Treatment of the acute leukaemia may then result in remission, but original clone harbouring *DNMT3A* mutations only can persist untouched by chemotherapy and may give rise to late disease relapses.

Impact of clonal structure on treatment and relapse

The parallels between the clonal development of cancer and Darwinian evolution by natural selection are particularly instructive when studying anticancer treatment. Having escaped physiological controls, cancer cells effectively take charge of their own destiny, not unlike a species of individuals doing so in nature. The administration of chemotherapy can then be seen as a serious menace that threatens the 'species' with extinction. Species evade such extinction by leveraging their heterogeneity; in other words, they rely on some individuals resisting the onslaught and surviving to regenerate the species. The simultaneous presentation of multiple different hazards to a species increases the likelihood of extinction, as witnessed by the effectiveness of combination antiretroviral therapy against HIV and combination chemotherapy regimens against paediatric ALL.

Nevertheless, only a minority of adult haematological cancers are curable. Clinically, treatment failure can present itself as resistant disease, partial response or relapse, but effectively in all instances, this amounts to variable numbers of cancer cells surviving chemotherapy. Advances in genomics have demonstrated that tumours represent an admixture of competing subclones with distinct genotypes, which have different abilities to resist chemotherapies. The different types of treatment failure reflect the numbers of cells resisting therapy, with resistant disease and partial response indicating that the bulk of cells were resistant or partially resistant to treatment. Relapse after complete remission indicates that only a small number of cells survived and this talks directly to the subclonal architecture of cancers.

As first shown in AML and subsequently in multiple myeloma and CLL, sequencing of serial samples at diagnosis and relapse reveals tumour subclones that are present only in the relapsed sampled, only in the diagnostic sample or in both (Figure 9.12). Despite the fact that treatment can eradicate subclones in some cases, mutations representing the founding clone are invariably presented at relapse, often associated with subclones containing new mutations not apparent at diagnosis. This clearly shows how the same treatment can have a differential effect on tumour subclones. From this perspective, chemotherapy can be seen as an 'evolutionary bottleneck' that either allows low-frequency chemoresistant tumour cells to survive and reconstitute the bulk of disease at relapse, or promotes evolution of clones through acquisition of new mutations associated with chemoresistance.

Usually, novel mutations identified first in chemoresistant clones can be retrospectively identified in the pre-treatment sample when sensitive techniques are used, although in some instances such mutations appear to be unique to the relapsed clone. Arguably this is only of academic significance, as in both instances the disease relapses with mutations associated with chemoresistance. However, there is some evidence that relapsed clones may harbour signatures of mutational processes attributable to chemotherapy, suggesting therefore that if non-mutagenic treatment had been used, relapse may not have ensued. It is not as yet clear if this applies to some or many cases of relapsed haematological cancers.

When trying to optimise treatment against relapsed disease, one can consider that tumours relapsing after a certain latency and without any change in their subclonal structure may be sensitive to the same treatment they responded to previously, whereas samples showing early relapse in association with acquisition of new driver/resistance mutations may require different therapy. Furthermore, the identification of clinically actionable mutations may lead clinicians to favour a particular targeted treatment over another. Finally, large studies correlating the genotype of subclones with treatment response could predict which combination of drugs will be most effective, and thus allow the clinician to deliver a 'tailored' treatment for maximal efficacy to individual patients. Based on its substantial potential for guiding treatment, it is likely that the usage of NGS techniques for diagnosis and prognosis will increase significantly to assist the future management of haematological malignancies.

CHAPTER 10

Laboratory diagnosis of haematological neoplasms

10

Barbara J Bain[1] and Torsten Haferlach[2]

[1] Centre for Haematology, Department of Immunology and Inflammation, St Mary's Hospital, London, UK
[2] MLL Munich Leukemia Laboratory, Munich, Germany

Introduction

The diagnosis of a haematological neoplasm usually starts from a clinical suspicion, although for chronic leukaemias, the diagnosis is sometimes an incidental one. A blood count and blood film are essential first steps whenever a haematological neoplasm is suspected. The next step in the diagnostic process depends on the clinical features and the specific condition that is suspected. In this chapter, we discuss the laboratory techniques that are available and how they are integrated into an efficient diagnostic pathway (Figure 10.1). It is of crucial importance that all laboratory investigations are done with an awareness of the medical history and physical findings. It is also essential that a conclusion as to diagnosis is based on integrating the results of all laboratory investigations and imaging in the context of the clinical features. Achieving this can be a challenge if investigations are done in different laboratories on different sites. One possible solution, if all procedures are not performed in a single laboratory, is that a haematologist/haematopathologist should take the lead in making a final diagnosis when the diagnosis depends primarily on the blood and bone marrow and that a haematopathologist/histopathologist should take the lead when the diagnosis depends primarily on a biopsy of another tissue. Three important factors contribute to accurate diagnosis:

1 The provision of very detailed clinical information to laboratories

2 The correct sample promptly delivered, e.g. blood or bone marrow aspirate specimen (appropriately anticoagulated), blood and bone marrow films, trephine or fine-needle biopsy specimen, should all be sent to the laboratory in the shortest possible time

3 The integration of information technology across different sites dealing with diagnostic samples from a single patient.

Consideration should also be given to the need for centralised diagnosis by a panel of experts when experience has shown that misdiagnosis is common, for example in lymphoma. It is also necessary to ensure that a diagnosis is achieved in a timely manner, particularly when treatment may be urgent, as in acute leukaemias and aggressive lymphomas.

Blood count and blood film

The most important information that must be extracted from the blood count is the white cell count, the haemoglobin concentration and the platelet count. The red cell indices should also be noted since macrocytosis and, less often, microcytosis can occur in haematological neoplasms. The automated instrument will generally provide a differential count and 'flags' indicating the likely presence of blast cells, abnormal lymphocytes or granulocyte precursors. An abnormal total or differential count or a low platelet count should always be verified on a blood film and a blood film should also be examined when there are relevant 'flags'. Even if the blood count is normal, a blood film should be examined for the presence of abnormal cells in any patient with lymphadenopathy, splenomegaly, skin infiltration or any other reason to suspect a haematological neoplasm.

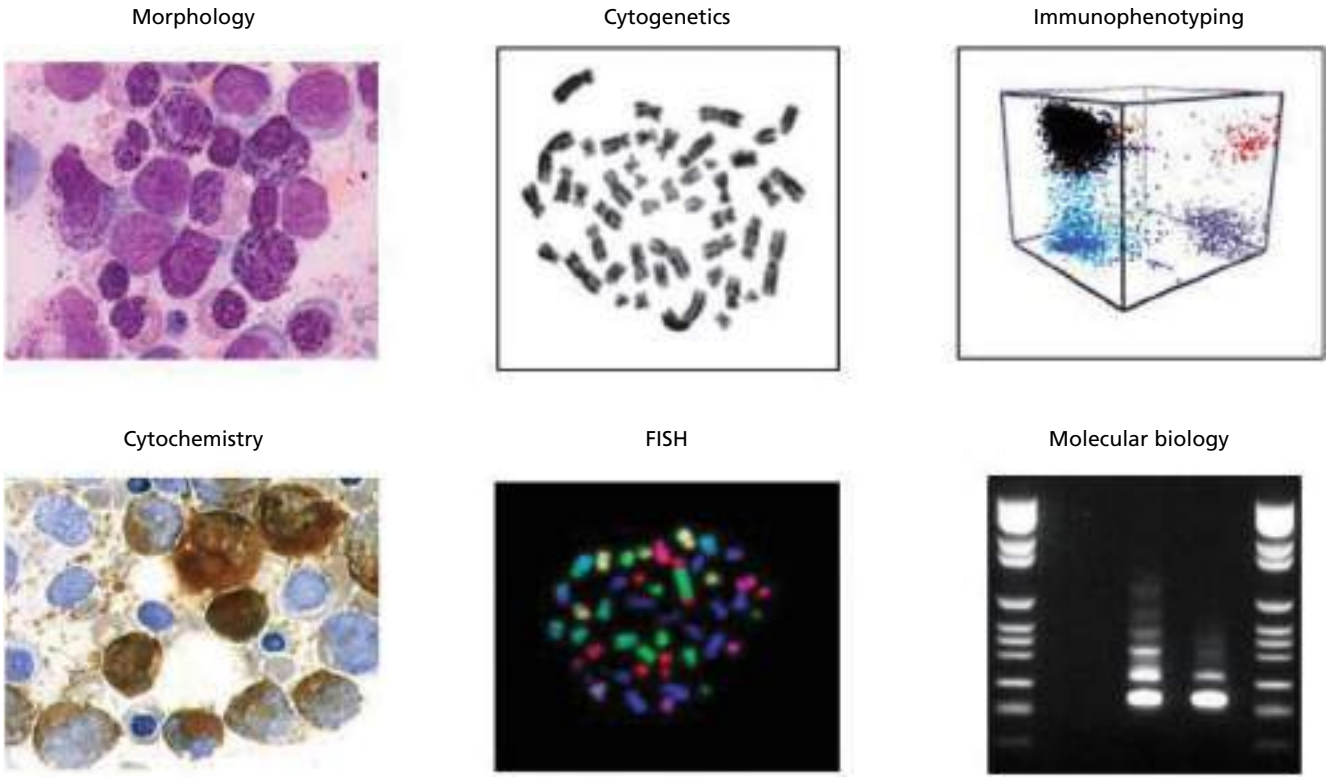

Figure 10.1 The principal laboratory methods employed in haematological diagnosis.

The blood film has two major roles. In some circumstances, it provides strong evidence of a specific diagnosis that can be confirmed on further testing. In others, it suggests a differential diagnosis and indicates the appropriate direction of further tests. A blood film also has the advantage that a rapid provisional diagnosis can be made, something that is important when treatment is urgent. For example, when there are circulating neoplastic cells a rapid provisional diagnosis of Burkitt lymphoma (Figure 10.2) and acute hypergranular promyelocytic leukaemia (Figure 10.3a) can be made. Acute microgranular/hypogranular promyelocytic leukaemia (Figures 10.3b and 10.4) should also be suspected from the blood film. Even very infrequent neoplastic cells can suggest the correct diagnosis, for example in hairy cell leukaemia. Other diagnoses that may be strongly suggested by the blood film include most subtypes of acute myeloid leukaemia (AML), chronic lymphocytic leukaemia (CLL) (Figure 10.5), chronic myeloid leukaemia (CML) (Figure 10.6), follicular lymphoma, splenic marginal zone lymphoma (when villous lymphocytes are present), large granular lymphocytic leukaemia, Sézary syndrome and plasma cell leukaemia.

Sometimes the blood film suggests only a differential diagnosis. Although the cytological features of some cases of acute lymphoblastic leukaemia (ALL) (Figure 10.7) are very likely to indicate that this is the diagnosis, this is not so of other cases (Figure 10.8), which can be cytologically very similar to AML with minimal differentiation or AML without maturation (Figures 10.9 and 10.10). Similarly, acute monoblastic leukaemia (Figure 10.11) can be cytologically indistinguishable from large-cell lymphoma or even plasma cell leukaemia.

In suspected myeloid malignancy, the blood film is important for the detection of myelodysplastic features, particularly

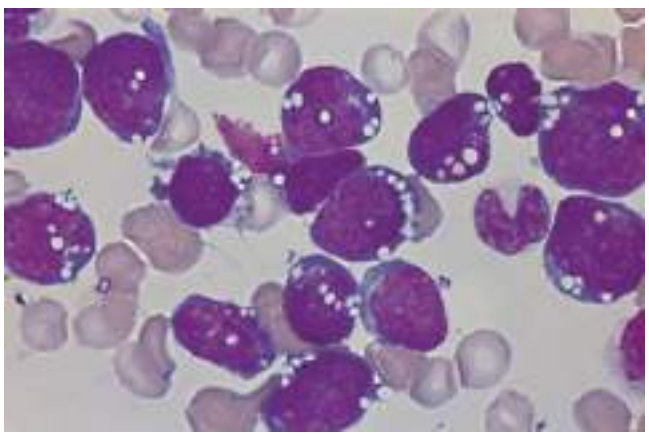

Figure 10.2 Burkitt lymphoma showing blast-like cells with strongly basophilic, heavily vacuolated cytoplasm. The cytological features were once designated 'FAB L3 ALL' but the immunophenotype is that of a mature B cell. Bone marrow film, May–Grünwald–Giemsa (MGG).

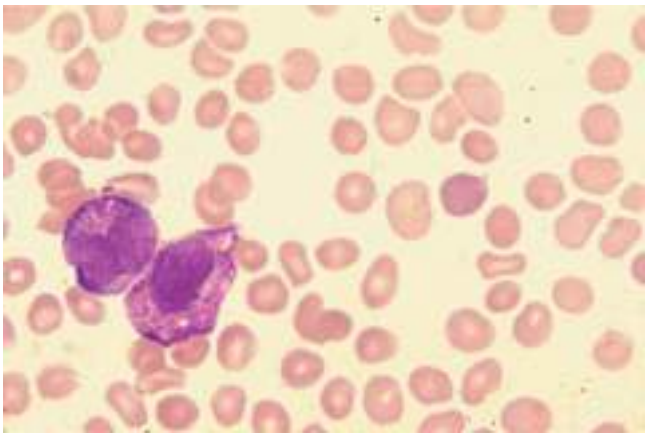
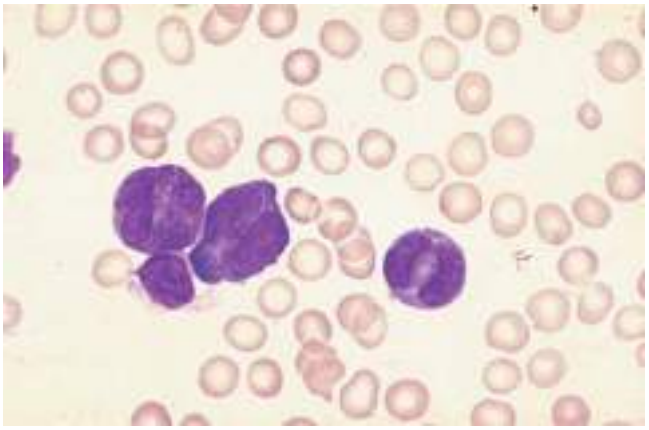


(a)



(b)

Figure 10.3 Blood films of two patients with acute promyelocytic leukaemia: (a) acute hypergranular promyelocytic leukaemia. (b) hypogranular/microgranular variant of promyelocytic leukaemia showing typical bilobed nuclei. These two subtypes of AML fall into a single category of 'AML with defining genetic abnormalities' in the 2022 WHO classification and are similarly a defined category in the International Consensus Classification (ICC). Peripheral blood films, MGG.

hypogranular and pseudo-Pelger–Huët neutrophils (Figure 10.12). Sometimes the blood film shows only non-specific, but nevertheless useful, features, for example eosinophilia, rouleaux formation, red cell agglutinates or cryoglobulin deposition.

Whatever the findings on the blood count and film, confirmatory tests are needed. The nature of these will vary according to circumstances, but several useful algorithms are guided by information that can be gained from the peripheral blood.

Bone marrow aspirate

A bone marrow aspirate is indicated in virtually all patients with suspected ALL, AML (Figure 10.13), CML, myelodysplastic neoplasm/syndrome (MDS) (Figure 10.14) or multiple myeloma (Figure 10.15). However, a bone marrow aspirate is not necessary for the diagnosis of CLL. The diagnosis of acute promyelocytic leukaemia may be more readily made on an aspirate than on the peripheral blood since, particularly in the hypergranular form, there may be few circulating leukaemic cells and in the microgranular/hypogranular form, there may be more hypergranular cells in the bone marrow, thus facilitating the diagnosis. The characteristic cytological features of AML with inv(16) or t(16;16) are apparent in the bone marrow (Figures 10.16 and 10.17), but less so in the peripheral blood, although the presence of eosinophils or eosinophil myelocytes

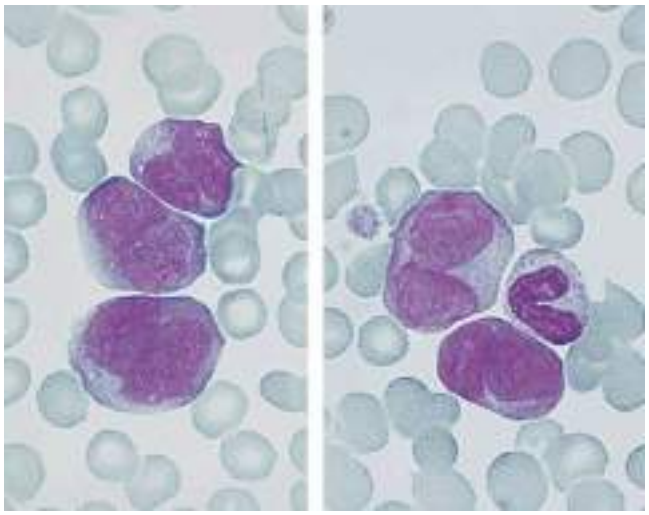


Figure 10.4 Acute hypogranular/microgranular variant of promyelocytic leukaemia showing a range of nuclear forms, but note the typical bilobed nucleus in which the two lobes are joined by an isthmus. Bone marrow film, MGG.

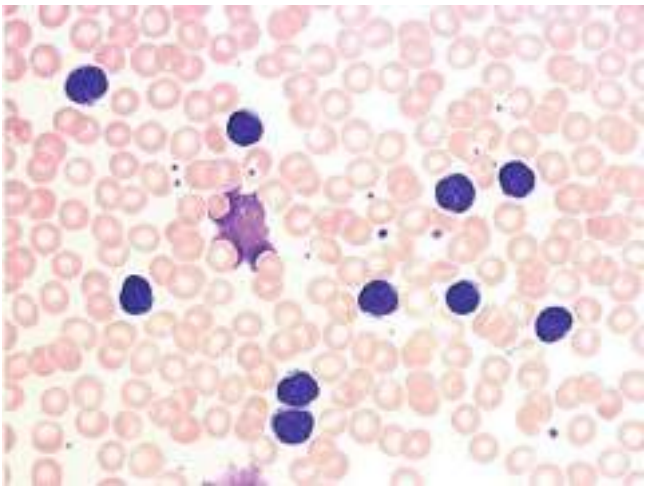

Figure 10.5 Chronic lymphocytic leukaemia showing mature small lymphocytes and a smear cell. Peripheral blood film, MGG.

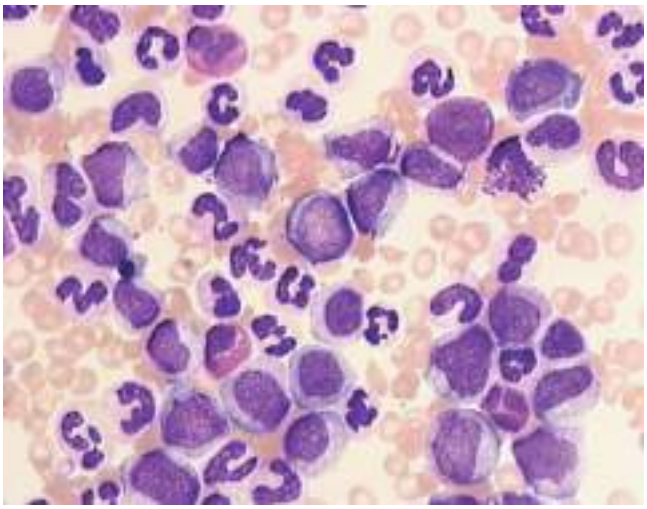

Figure 10.6 MGG-stained peripheral blood film of chronic myeloid leukaemia (*BCR::ABL1*-positive), showing the typical spectrum of granulocytic cells from immature to mature, including a basophil and some eosinophils.

with large basophilic granules is suggestive. In the acute leukaemias and in CML and other myeloproliferative neoplasms, a bone marrow aspirate provides material for cytogenetic analysis as well as for morphological assessment (Figure 10.18). Successful cytogenetic investigations from peripheral blood are only worth considering if immature leukaemic cells are present, but analysis of bone marrow cells is far more likely to be useful.

Bone marrow aspiration may also be indicated in patients with unexplained cytopenia or a leucoerythroblastic blood film. An aspirate can be useful in lymphoma diagnosis, particularly if accompanied by a trephine biopsy, and can provide suitable material for immunophenotyping and for fluorescence *in situ* hybridisation (FISH).

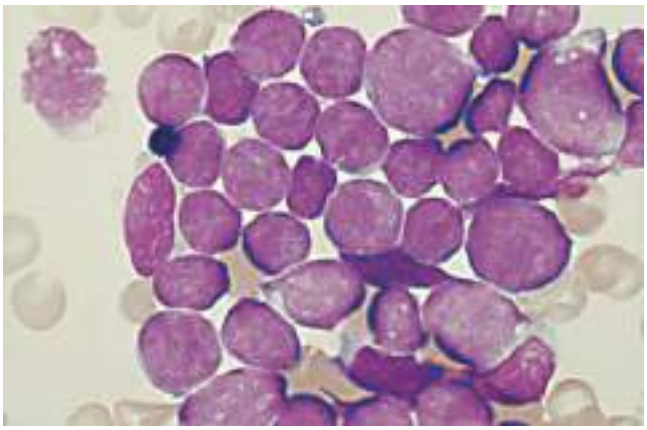

Figure 10.7 Acute lymphoblastic leukaemia showing blast cells that vary in size, but which otherwise have fairly uniform cellular characteristics; the nucleocytoplasmic ratio is high and there are small inconspicuous nucleoli. Bone marrow film, MGG.

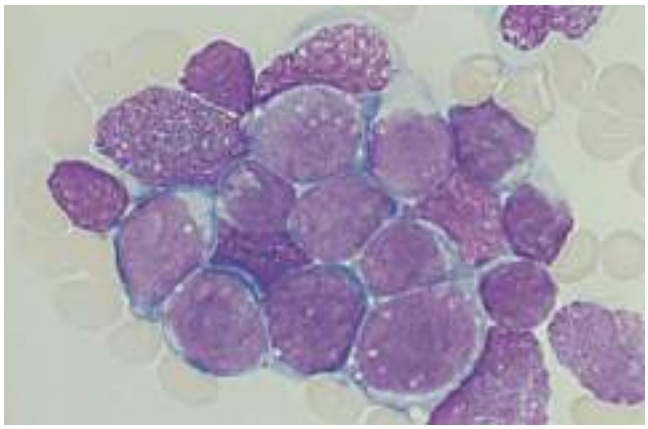

Figure 10.8 Acute lymphoblastic leukaemia showing medium-sized and large pleomorphic blast cells with one or two prominent nucleoli; there are no characteristics that identify the likely lineage. Bone marrow film, MGG.

Bone marrow trephine biopsy

A bone marrow trephine biopsy is indicated whenever there is a 'dry tap' or the aspirate obtained is aparticulate or dilute. A core biopsy is often necessary in hairy cell leukaemia, acute

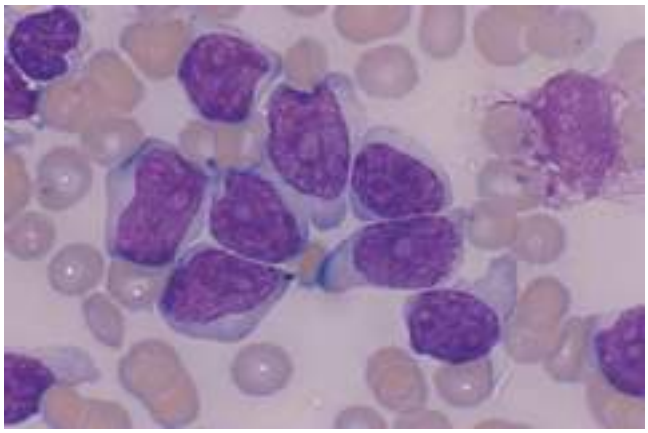

Figure 10.9 Acute myeloid leukaemia with minimal differentiation showing large blast cells with large prominent nucleoli; there are no cytological features that identify the lineage and Sudan black B and myeloperoxidase cytochemical stains were negative. On immunophenotyping, all B- and T-lineage markers were negative, but there was expression of CD13 and CD33. Without immunophenotyping such a case could not be distinguished from acute lymphoblastic leukaemia. Bone marrow film, MGG.

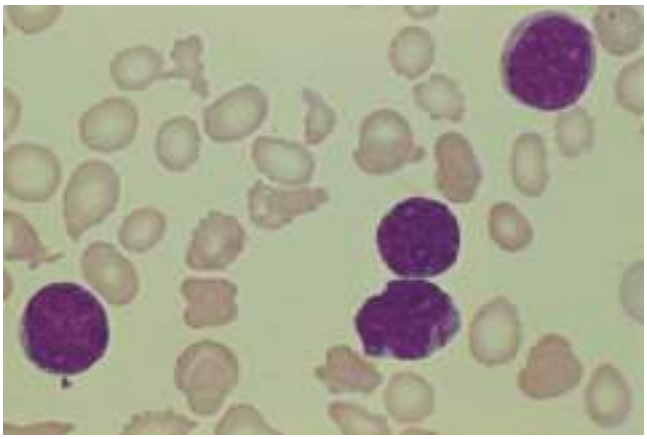

Figure 10.10 Acute myeloid leukaemia without maturation showing small- to medium-sized blast cells with a high nucleocytoplasmic ratio; one contains an Auer rod. Sudan black B and myeloperoxidase were positive. In the absence of Auer rods and granules, such cases of acute myeloid leukaemia may be indistinguishable from acute lymphoblastic leukaemia without the aid of cytochemistry or immunophenotyping. Peripheral blood film, MGG.

megakaryoblastic leukaemia (Figure 10.19) and in patients being investigated for pancytopenia, a leucoerythroblastic blood film or a suspected myeloproliferative neoplasm. If the bone marrow is being examined for suspected non-Hodgkin lymphoma (NHL), a trephine biopsy is always indicated since an aspirate may be normal cytologically and immunophenotypically despite there being focal infiltration readily detectable on a core biopsy. Hodgkin lymphoma is very rarely detected in an aspirate, whereas a trephine biopsy specimen may provide the primary diagnostic material, particularly in patients with HIV infection who can present with widespread disease. A trephine biopsy should be part of the initial investigation of suspected multiple myeloma; sometimes this confirms the diagnosis when the aspirate findings are equivocal and, even when this is not so, it is useful to have a baseline biopsy to compare with post-treatment investigations. A trephine biopsy is not generally necessary in CLL, whereas it is diagnostically important in suspected essential thrombocythaemia and polycythaemia vera and is essential in primary myelofibrosis and systemic mastocytosis. In CML, a trephine biopsy is not routinely required but may be useful in selected cases to assess bone marrow fibrosis.

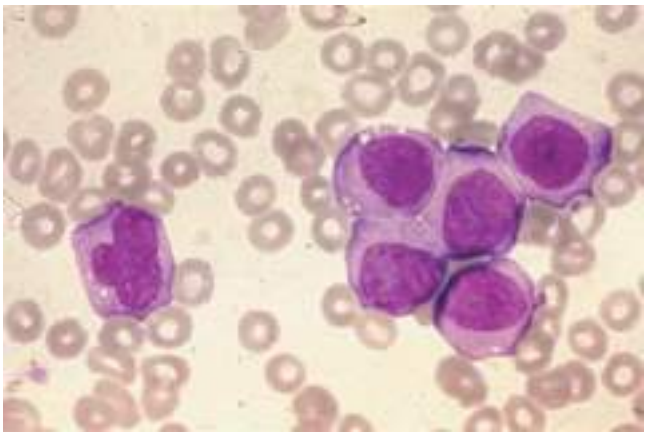

Figure 10.11 Acute monoblastic leukaemia associated with t(9;11)(p21.3;q23.3); *KMT2A::MLLT3* showing large cells with plentiful cytoplasm; one cell shows nuclear lobulation (defining it as a promonocyte in the WHO classification). In the 2022 WHO classification, this type of acute myeloid leukaemia is a specific entity within the group 'AML with defining genetic abnormalities' and similarly it is a genetic category in the ICC. Bone marrow film, MGG.

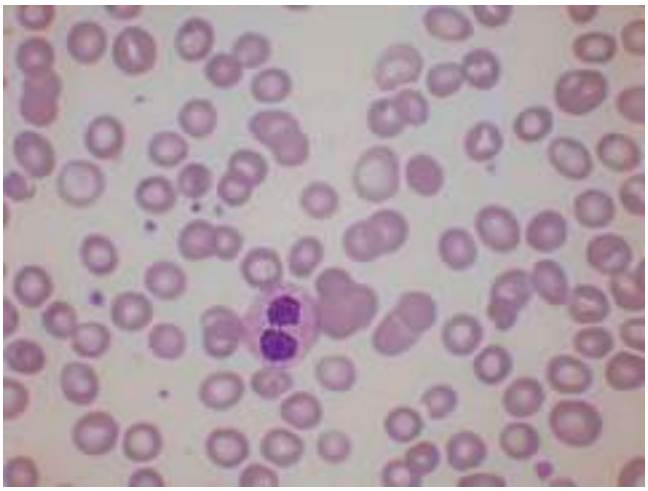

Figure 10.12 A pseudo-Pelger–Huët anomaly in a neutrophil of a patient with a myelodysplastic syndrome. Peripheral blood film, MGG.

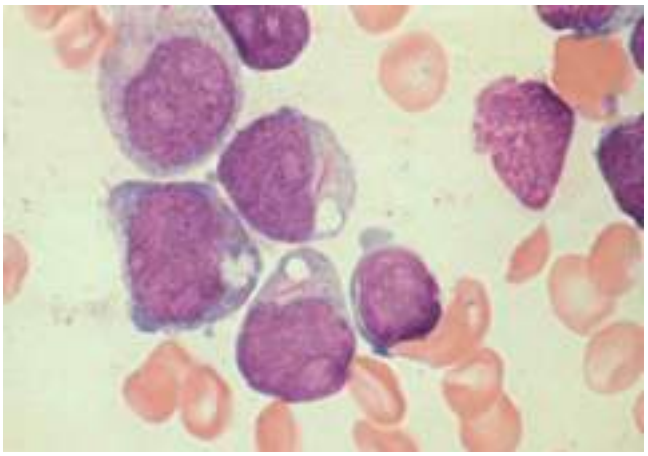

Figure 10.13 Acute myeloid leukaemia showing leukaemic blast cells, several with Auer rods. Bone marrow film, MGG.

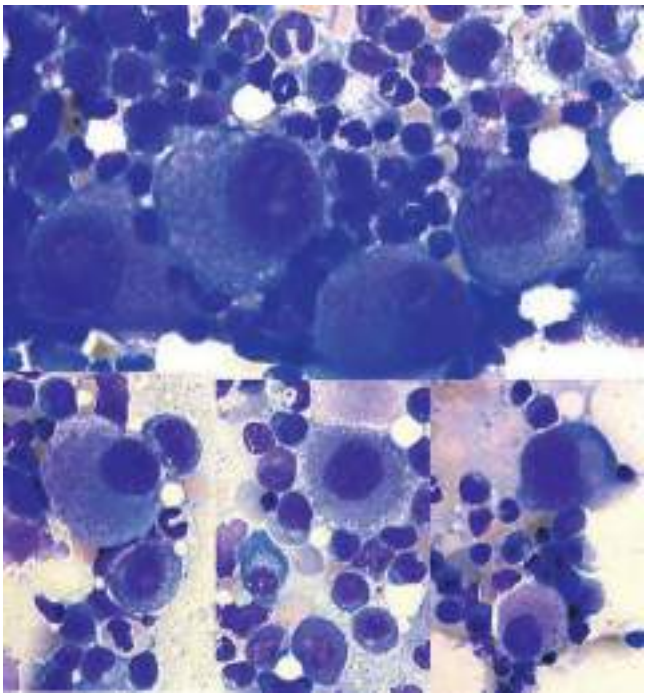

Figure 10.14 Composite image of myelodysplastic syndrome showing the hypolobulated megakaryocytes characteristic of the 5q– syndrome; myelodysplastic neoplasm with low blasts and isolated del(5q) is a specific category in the 2022 WHO classification, which in the ICC is designated MDS with del(5q). Bone marrow film, MGG.

There are other indications for trephine biopsy that are more controversial. This procedure may be necessary in ALL or AML if no aspirate or a poor aspirate is obtained. However, if there are numerous circulating neoplastic cells and if a cellular aspirate is obtained, it does not yield any important extra information. A trephine biopsy should be avoided in cases of suspected acute promyelocytic leukaemia due to the risk of bleeding. In suspected MDS, useful extra information that may contribute to the diagnosis is more likely since marrow architecture is often abnormal and immature ($CD34^+$) cells may be detected only on histology or immunohistochemistry.

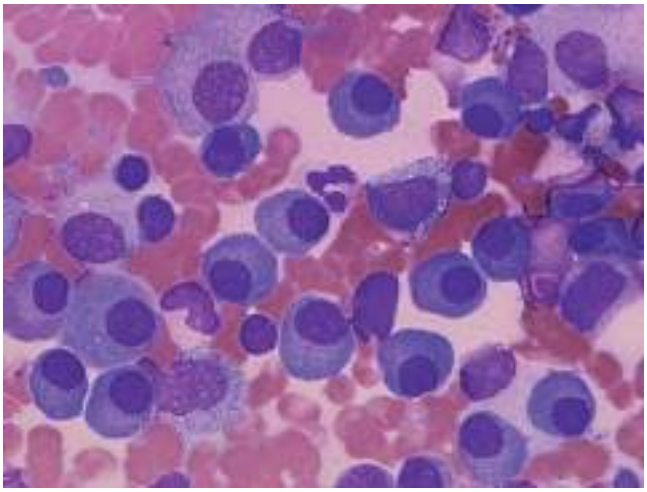

Figure 10.15 Multiple myeloma (plasma cell myeloma) showing virtual effacement of the marrow by myeloma cells. Bone marrow film, MGG.

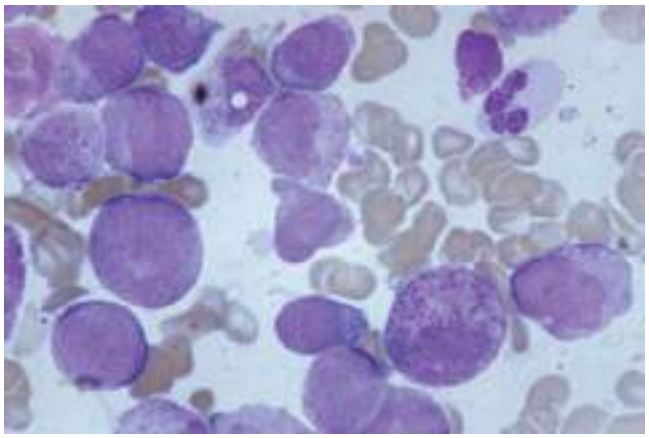

Figure 10.16 Acute myeloid leukaemia (AML) associated with inv(16)(p13.1q22); *CBFB::MYH11* showing myelomonocytic leukaemia with an abnormal eosinophil precursor that has proeosinophilic (purple-staining) granules. In the 2022 WHO classification this subtype of AML, together with similar cases with t(16;16), constitutes a specific entity within the category 'AML with defining genetic abnormalities' and is similarly an ICC category. Bone marrow film, MGG.

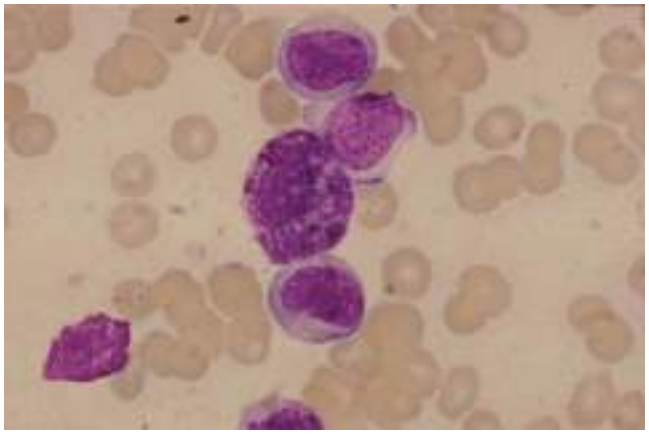

Figure 10.17 Acute myeloid leukaemia (AML) associated with t(16;16)(p13.1;q22); *CBFB::MYH11* showing blast cells and an abnormal eosinophil precursor with pro-eosinophilic granules. In the 2022 WHO classification this subtype of AML, together with similar cases with inv(16), constitutes a specific entity within the category 'AML with defining genetic abnormalities' and is similarly an ICC category. Bone marrow film, MGG.

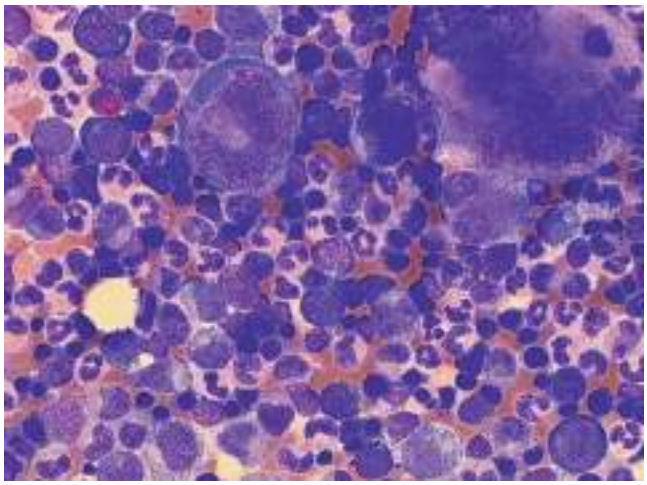

Figure 10.18 Polycythaemia vera with a *JAK2* V617F mutation showing panmyelosis; the large hyperlobulated megakaryocyte (top right) shows emperipolesis. Bone marrow film, MGG.

Cytochemistry

With advances in immunophenotyping and other techniques, the role of cytochemistry in haematological diagnosis has declined considerably. A limited role remains. In acute leukaemia, cytochemistry is indicated if there is limited access to immunophenotyping or if delay in obtaining results is expected.

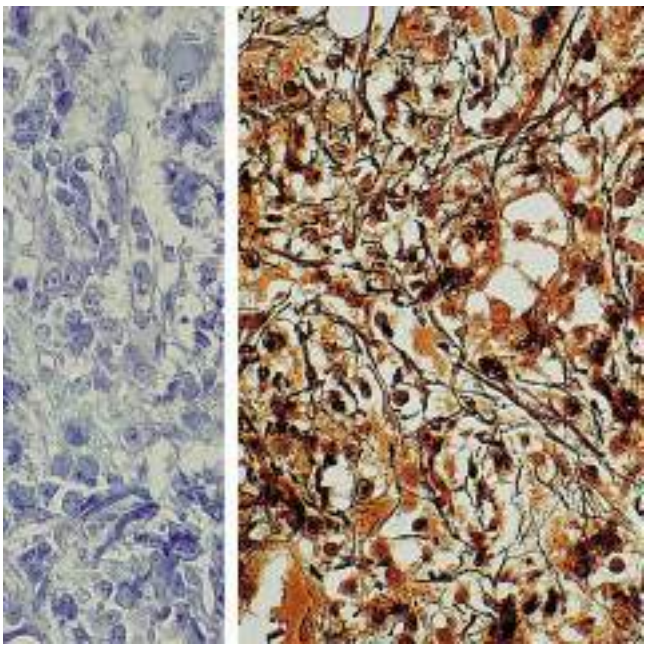

Figure 10.19 Acute megakaryoblastic leukaemia (FAB M7 subtype). Bone marrow trephine biopsy shows blast cells (left) and increased reticulin deposition (right).

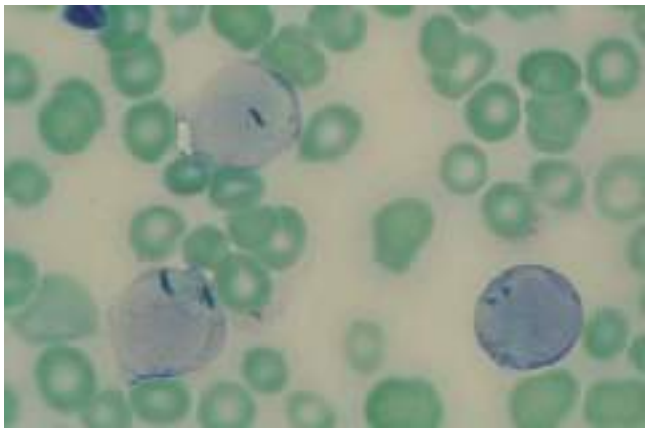

Figure 10.20 Acute myeloid leukaemia (AML) without maturation showing Auer rods. This patient had the translocation t(8;21) (q22;q22.1); *RUNX1::RUNX1T1*, identifying a specific entity within the 2022 WHO category 'AML with defining genetic abnormalities'; it is similarly a specific category in the ICC Peripheral blood film, myeloperoxidase reaction.

For example, the 2022 WHO category of AML without maturation can be distinguished from ALL by means of a Sudan black B or myeloperoxidase stain (Figure 10.20) and acute monoblastic/monocytic leukaemia can be distinguished from large-cell lymphoma by means of a non-specific esterase stain (Figure 10.21). Careful attention to cytological detail usually permits the distinction between the hypogranular/microgranular variant of acute promyelocytic leukaemia and acute monocytic leukaemia, but if there is any doubt the former diagnosis is supported by strong reactions for Sudan black B, myeloperoxidase and chloroacetate esterase and the latter by a positive non-specific esterase reaction. Rarely, a specific diagnosis of a subtype of AML is aided by demonstration of blast cells of basophil lineage

Figure 10.21 Acute monoblastic leukaemia showing strong reaction for non-specific esterase, which confirms the monocytic differentiation. Cytospin preparation, α-naphthyl-acetate esterase.

(b)

Figure 10.22 Acute myeloid leukaemia (AML) associated with t(6;9)(p23;q34.1); *DEK::NUP214,* identifying a specific entity within the 2022 WHO category 'AML with defining genetic abnormalities', which is also a defined ICC category: (a) MGG-stained bone marrow film shows blast cells and two degranulated basophil precursors. (b) Toluidine blue-stained bone marrow film demonstrates metachromasia.

showing metachromatic staining with a toluidine blue stain (Figure 10.22). Perls stain for iron remains a very important cytochemical stain in suspected MDS (Figure 10.23).

Periodic acid–Schiff and acid phosphatase reactions can help in the diagnosis of ALL (Figures 10.24 and 10.25), but reactions are not specific and we do not recommend their continued use in a routine diagnostic setting if immunophenotyping is available. A neutrophil alkaline phosphatase score is likewise redundant in the diagnosis of CML, which now depends on cytogenetic and molecular genetic analysis. A tartrate-resistant acid phosphatase reaction can confirm a diagnosis of hairy cell leukaemia, but is no longer necessary, as long as the immunophenotyping laboratory has an appropriate range of antibodies for this purpose; immunohistochemistry can be performed in the case of a 'dry tap' or *BRAF* mutation analysis can be performed.

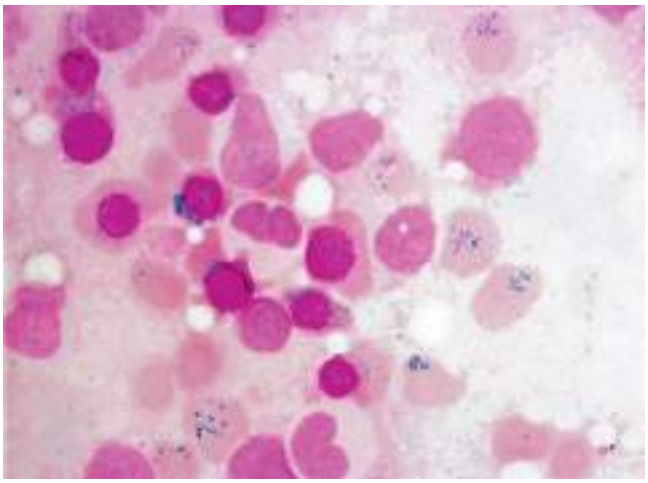

Figure 10.23 Ring sideroblasts and Pappenheimer bodies in erythrocytes in a myelodysplastic syndrome. Bone marrow aspirate, Perls stain.

Histology

Microscopic examination of sections of tissues other than bone marrow remains an essential technique for the diagnosis of many lymphomas. It may also be necessary for the diagnosis of myeloid sarcoma. Immunohistochemistry (see below) is an essential part of histological assessment for haematological neoplasms.

Flow cytometric immunophenotyping

Immunophenotyping can be based on flow cytometry, immunohistochemistry (on tissue sections) or immunocytochemistry (on cytospin preparations or films). The first two of these

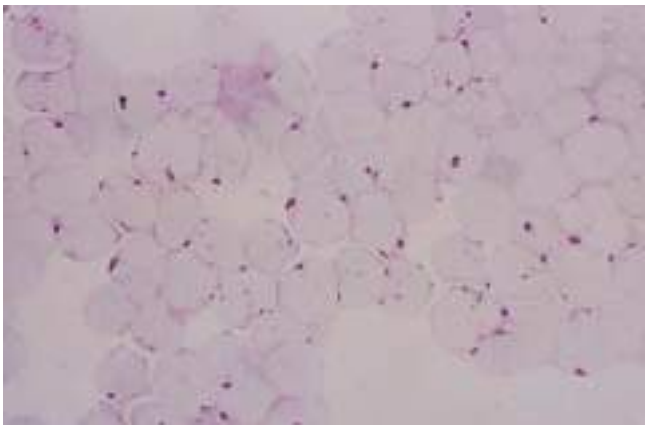

Figure 10.24 Acute lymphoblastic leukaemia showing block positivity to periodic acid–Schiff (PAS) stain. Cytospin preparation of cerebrospinal fluid, PAS stain.

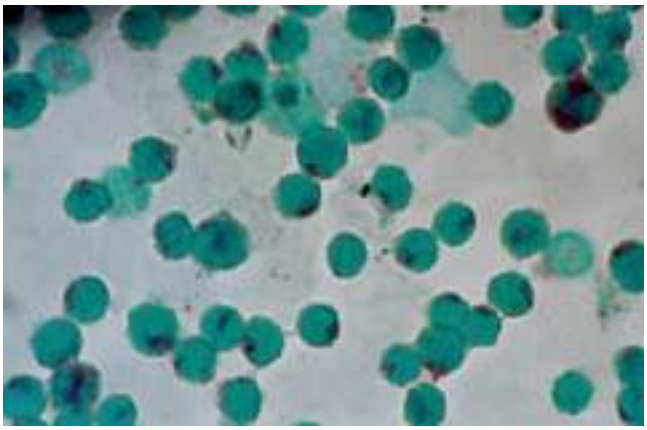

Figure 10.25 T-lineage acute lymphoblastic leukaemia showing focal (Golgi zone) positivity for acid phosphatase in lymphoblasts. Cytospin preparation, acid phosphatase reaction.

techniques are of major importance in haematological diagnosis. Flow cytometry is now carried out using multichannel instruments that permit the simultaneous assessment of forward light scatter (indicative of cell size), sideways light scatter (indicative of granularity and cell complexity) and the expression of 10 or more surface membrane antigens, all simultaneously in one vial (Figure 10.26). With the addition of techniques to 'permeabilise' the cells, cytoplasmic and nuclear antigens can also be studied. When there are numerous circulating neoplastic cells, immunophenotyping is conveniently done on a peripheral blood sample. Otherwise, it can be done on a bone marrow aspirate or on a cell suspension from any infiltrated tissue. The main indications for immunophenotyping are as follows:

1 Confirmation of a diagnosis of ALL and its subclassification (including recognition of early T-cell precursor acute lymphoblastic leukaemia) and identification of an aberrant immunophenotype (leukaemia-associated immunophenotype) that can be used to monitor measurable residual disease (MRD).

2 Confirmation of a diagnosis of AML with minimal differentiation and acute megakaryoblastic leukaemia and, if not already confirmed by cytochemistry, confirmation of a diagnosis of acute monoblastic leukaemia; support for a diagnosis of acute promyelocytic leukaemia by demonstration of lack of expression of CD34 and especially HLA-DR and by non-specific background autofluorescence observed in the isotype controls; identification of leukaemia-associated immunophenotype that can be used to monitor MRD.

3 Identification of mixed phenotype acute leukaemia.

4 Demonstration of light chain restriction, providing presumptive evidence of monoclonality, in B-lineage disorders.

5 Confirmation of a diagnosis of CLL and monitoring of MRD.

6 Confirmation of a diagnosis of NHL rather than CLL, and support for specific diagnoses such as follicular lymphoma (CD10 often positive) or mantle cell lymphoma (CD5 and nuclear cyclin D1 positive) (see also Chapter 23).

7 Confirmation of a diagnosis of hairy cell leukaemia by demonstration of expression of all or most of CD11c, CD25, CD103 and CD123; CD200 is also expressed (see also Chapter 23).

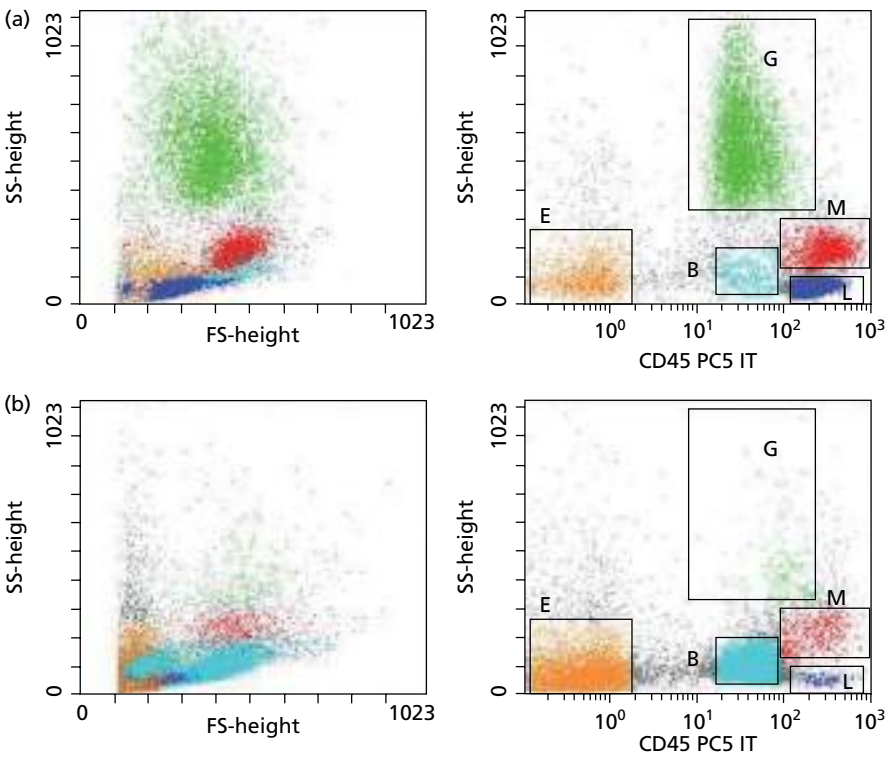

Figure 10.26 Flow cytometry immunophenotyping showing improvement of separation of populations by CD45 and sideways light scatter (SSC) gating. Forward light scatter (FSC) is also shown. (a) Normal bone marrow (left, SSC–FSC plot; right, SSC–CD45 plot). (b) acute myeloid leukaemia bone marrow (left, SSC–FSC plot; right, SSC–CD45 plot). G, granulocytes; M, monocytes; L, lymphocytes; E, erythrocytes; B, blasts. SSC–CD45 gating permits isolation of bone marrow blasts from all other populations, which is not possible by SSC–FSC gating.

8 Confirmation of a diagnosis of multiple myeloma or monoclonal gammopathy of undetermined significance (MGUS), by demonstration that plasma cells (identified by expression of CD138 and strong CD38) have light-chain-restricted cytoplasmic immunoglobulin and often aberrant expression of CD56, together with failure to express CD19 and CD45, and monitoring of MRD (see also Chapter 28).
9 Support for monoclonality of a T-lymphocyte population by demonstration of a uniform aberrant immunophenotype and restricted expression of CD158 (KIR) epitopes and support for specific diagnoses such as T-prolymphocytic leukaemia (CD7 often positive), adult T-cell leukaemia lymphoma (CD25 positive), large granular lymphocytic leukaemia (usually $CD8^+CD4^-$) and hepatosplenic T-cell lymphoma (usually T-cell receptor (TCR)-γδ positive and TCR-αβ negative).
10 Confirmation of a diagnosis of blastic plasmacytoid dendritic cell neoplasm by demonstration of expression of CD4, CD56, CD123 and possibly CD7 in the absence of expression of other lineage-specific markers.
11 Demonstration of an antigen that is a potential target of monoclonal antibody therapy, such as CD20, CD33 or CD52.
12 Demonstration of an antigen that is a potential target of chimaeric antigen receptor T cell (CAR T cell) therapy, such as CD19, CD30, CD33, CD123 and BCMA (B-cell maturation antigen).
13 Diagnosis of paroxysmal nocturnal haemoglobinuria by demonstrating that a subpopulation of neutrophils, monocytes or erythrocytes fails to express antigens, such as CD24, CD14, CD55 and CD59, that are bound to glycosylphosphatidylinositol, or fails to bind proaerolysin conjugated with fluorescein (FLAER).
14 Support for a diagnosis of MDS based on quantification of blasts and detection of aberrant antigen expression.
15 Support for a diagnosis of systemic mastocytosis, with bone marrow infiltration by neoplastic mast cells with aberrant expression of CD25, CD2 and/or CD30.
16 Assessment of infiltration of body fluids (cerebrospinal fluid, pleural effusion) by leukaemia or lymphoma.

Immunohistochemistry

Immunohistochemistry for haematological diagnosis is carried out on tissue sections, particularly from lymph nodes or bone marrow trephine biopsy specimens. It is an essential part of the diagnostic procedure in haematological neoplasms, particularly lymphoma, but also myeloid neoplasms. Examples that illustrate its value in lymphoma diagnosis include the following:
1 Confirmation of follicular lymphoma by demonstration that cells forming neoplastic follicles express CD10 and BCL2 (whereas follicles of reactive follicular hyperplasia are BCL2 negative).
2 Confirmation of mantle cell lymphoma by demonstration of CD5-positive B cells with nuclear expression of cyclin D1 or SOX11.
3 Confirmation of a diagnosis of classical Hodgkin lymphoma (CD15 usually positive, CD30 positive) and its distinction from nodular lymphocyte-predominant Hodgkin lymphoma (CD15 and CD30 usually negative and more likely to express B cell-associated antigens such as CD20 and CD79a).
4 Confirmation of Burkitt lymphoma by demonstration of BCL2-negative BCL6-positive B cells with a very high proliferative fraction (approaching 100%) shown using Ki-67 or an equivalent monoclonal antibody.
5 Division of diffuse large B-cell lymphoma (DLBCL) into prognostic groups (see below).
6 Confirmation of hairy cell leukaemia by showing that B cells are positive for CD25, DBA44 and annexin A1 and express mutant BRAF.
7 Confirmation of clonality in suspected MGUS or multiple myeloma by demonstration of light chain restriction of cytoplasmic immunoglobulin.
8 Confirmation of infiltration in a trephine biopsy specimen in non-Hodgkin and Hodgkin lymphoma (particularly important in patients in whom no neoplastic cells are detected in the bone marrow aspirate and for detection of subtle interstitial or intravascular infiltration in NHL).

DLBCL has been demonstrated by microarray analysis (see below) to be divisible into three major groups with different patterns of gene expression: (i) germinal centre cell; (ii) activated B-cell-like and (iii) other or indeterminate (see also Chapter 27). Lymphomas showing the gene expression pattern of germinal centre B cells were found to have a better prognosis than activated B-cell-like DLBCL (Chapter 27). It is now possible to assign DLBCL to these two major groups on the basis of immunohistochemistry. The germinal centre group express CD10 or, if they do not, they express BCL6 in the absence of MUM1 expression. DLBCL of the activated B-cell-like group are either negative for both CD10 and BCL6 or are CD10 negative, but express both BCL6 and MUM1. The prognostic significance is seen clearly in patients treated with CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone), but may no longer reach statistical significance in those treated with R-CHOP (CHOP plus rituximab). In R-CHOP-treated patients, prognostic significance is shown by the demonstration of BCL2 expression, the best prognosis being in those with a germinal centre phenotype, but without BCL2 expression, whose survival curves separate from the other three groups. However, it must be noted that scoring of these immunohistochemical markers is inconsistent between laboratories unless many technical factors are standardised; use of the assignment to germinal centre or non-germinal centre phenotypes to aid treatment decisions would be premature.

In ALL, it is usually possible to perform immunophenotyping on either peripheral blood or a bone marrow aspirate; immunohistochemistry is therefore usually redundant. In AML, immunohistochemistry should be viewed as supplementary to flow cytometric immunophenotyping. It is often

unnecessary. However, in the absence of peripheral blood blast cells and if a bone marrow aspirate cannot be obtained, it becomes essential for diagnosis. It can thus be important for the diagnosis of acute megakaryoblastic leukaemias, and some cases of acute erythroleukaemia, when bone marrow fibrosis may prevent an adequate aspirate from being obtained. It is needed for the diagnosis of myeloid sarcoma and blastic plasmacytoid dendritic cell neoplasm (which shows expression of CD4, CD56 and CD123). Immunohistochemistry can be a useful way to demonstrate the presence of an *NPM1* mutation in AML, cytoplasmic rather than nuclear expression being a surrogate marker for these mutations.

Immunohistochemistry for mast cell tryptase is important in confirming a diagnosis of systemic mastocytosis (Chapter 35). Aberrant expression of CD2 and CD25 by the mast cells is also useful (although this pattern of reactivity is not totally specific for systemic mastocytosis). Immunohistochemistry is much less often needed in other myeloproliferative neoplasms.

Cytogenetic analysis

Cytogenetic analysis refers to study of chromosomes by recognition of their morphology and their characteristic banding pattern, demonstrated by staining with a Giemsa stain (for viewing by light microscopy) (Figure 10.27) or a quinacrine stain (for viewing as fluorescent bands under UV illumination). Chromosomes or specific genes of interest in either interphase or metaphase can also be studied by FISH analysis; this technique is both a cytogenetic and molecular genetic technique since the morphology of the chromosomes can be recognised to some extent, at least in metaphase cells, but the probes used are dependent on hybridisation to specific DNA sequences. Cytogenetic, FISH and molecular techniques are complementary and which of these is most useful in an individual patient depends on the suspected diagnosis and the aberrations likely to be present. Classical cytogenetic analysis (chromosome banding analysis) requires cells in metaphase so that for conditions with a low mitotic rate, such as CLL and low-grade NHL, FISH or molecular analysis may be preferred. However, with the newer techniques, it is possible to achieve metaphases in more than 90% of cases of CLL using specific culture conditions, including DSP30. Cytogenetic analysis can: (i) provide evidence of clonality and thus confirm that a condition is neoplastic when other evidence is absent or equivocal (e.g. in MDS, chronic eosinophilic leukaemia, myeloproliferative neoplasms or NK cell leukaemia/lymphoma), (ii) confirm a specific diagnosis (e.g. CML, AML with recurrent translocations or Burkitt lymphoma) and (iii) give prognostic information (e.g. in CLL, AML, ALL, MDS, CML and other myeloproliferative neoplasms and multiple myeloma (the latter especially by FISH on CD138+ selected cells) or indicate that a neoplasm is therapy-related (t-AML and t-MDS).

It is particularly important that cytogenetic or molecular genetic analysis is performed whenever there is a specific treatment available for patients with a particular genetic abnormality. This includes the following:

1 Conditions sensitive to tyrosine kinase inhibitors (with either *BCR::ABL1,* rearrangement of *PDGFRA*, *PDGFRB, FGFR1* or *PCM1::JAK2*).

2 Acute promyelocytic leukaemia with *PML::RARA* (sensitive to all-*trans* retinoic acid and As_2O_3).

3 MDS with 5q– (sensitive to lenalidomide).

4 MDS with monosomy 7 (sensitive to azacitidine).

5 Burkitt lymphoma with juxtaposition of *MYC* to the immunoglobulin heavy chain, κ or λ locus (responsive to intensive

* Molecular genetic analysis or whole transcriptome sequencing is needed since the translocation is cryptic.

chemotherapy incorporating certain specific agents plus monoclonal antibody treatment).

Cytogenetic analysis can be considered appropriate whenever it contributes to diagnosis, indicates the prognosis or guides the selection of treatment. It can therefore be considered indicated in the following:

1 All cases of AML: essential for application of the WHO and ICC classifications, indicate prognosis and is thus relevant to treatment choice (Table 10.1).

2 All cases of ALL: essential for application of the WHO and ICC classifications, indicate prognosis and is thus relevant to treatment choice; necessary for detection of *BCR::ABL1*-positive cases, although for this purpose FISH and molecular analyses are alternatives (Table 10.2).

3 All cases of mixed-phenotype acute leukaemia: essential for detecting *BCR::ABL1*-positive cases.

4 All cases of suspected CML: essential to confirm *BCR::ABL1* and to identify additional chromosomal aberrations of prognostic relevance

5 All cases of suspected MDS: necessary for application of the WHO and ICC classifications, including identification of the 5q– syndrome (Figure 10.28) and essential for application of the revised International Prognostic Scoring System (IPSS-R) and WHO classification-based Prognostic Scoring System (WPSS).

6 Selected cases of myeloproliferative neoplasms to identify a clonal marker and to allow prognostic risk stratification (see Chapter 35).

7 All cases of suspected chronic eosinophilic leukaemia: necessary for detection of translocations that lead to *PDGFRB* rearrangement (imatinib sensitive) and *FGFR1* rearrangement.

8 All cases of suspected NK leukaemia/lymphoma: can demonstrate clonality and thus confirm the diagnosis.

If resources permit, cytogenetic analysis can also be useful in other myeloproliferative and myelodysplastic/myeloproliferative neoplasms. Cytogenetic analysis can be used for the confirmation of a diagnosis of Burkitt lymphoma, follicular lymphoma or mantle cell lymphoma, but FISH may be preferred. Use of the two techniques may give complementary information. Prognostically relevant information is also obtained in multiple myeloma. However, this is best done with

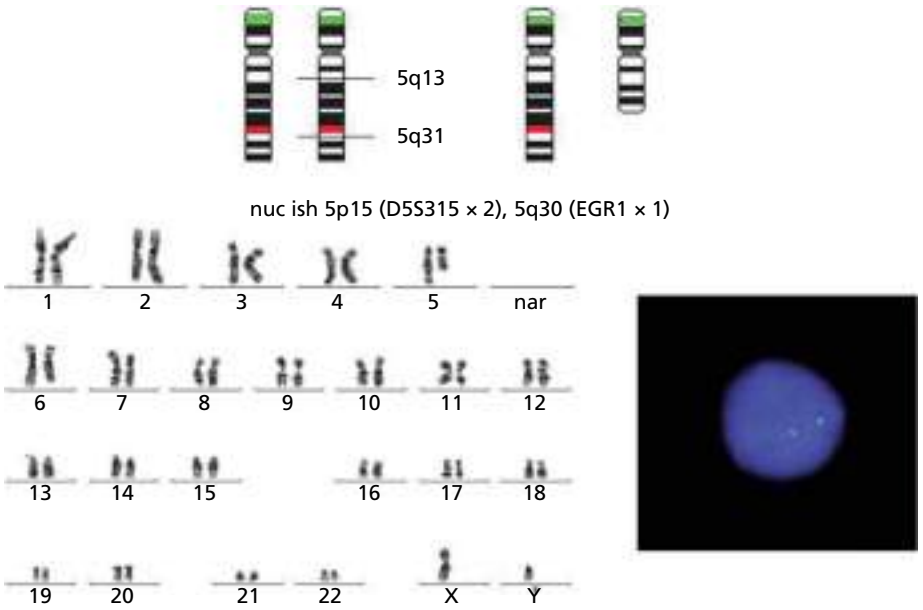

Figure 10.28 An explanatory diagram (top), karyogram of Giemsa-stained chromosomes showing del(5)(q13q31) (bottom left), and FISH showing retention of signal for 5p15 and loss of signal for 5q31 (bottom right) in a patient with 5q– syndrome.

preliminary magnetic activation cell sorting using CD138, CD269 or CD319 monoclonal antibodies, as plasma cells numbers may be low and FISH performed on direct bone marrow films may result in insufficient cells for analysis and give misleading results.

Fluorescence *in situ* hybridisation

FISH uses labelled oligonucleotide probes that bind to specific DNA sequences. These may be locus-specific probes (including those detecting oncogenes and tumour-suppressor genes), centromeric probes, telomeric probes and whole chromosome paints. Centromeric probes can be used for the detection of monosomies and trisomies. Otherwise, locus-specific probes are the most widely used. By labelling two probes with different fluorochromes, it is possible to study two genes that are involved in a specific translocation or other rearrangement. If the probes span the breakpoint, both will be disrupted by the translocation and signals will be adjacent or optically fused on the derivative chromosomes, a double-colour double-fusion technique. Often one probe gives a green signal and the other a red signal so that the fusion signal is yellow. Alternatively, two probes that span the 5′ locus and 3′ locus and overlap can be used in a double-colour break-apart technique; this can be useful when a single gene, such as *KMT2A*, is involved in rearrangements with a large number of other genes.

FISH is applicable to both metaphase cells and interphase cells (Figure 10.29). FISH is particularly useful in the following circumstances:

1 Screening for *BCR::ABL1* fusion (peripheral blood cells are suitable, whereas cytogenetic analysis is better done on bone marrow) (Figure 10.30).
2 Confirming a specific lymphoma diagnosis by demonstration of *BCL2::IGH* in follicular lymphoma, *CCND1::IGH* in mantle cell lymphoma or *MYC::IGH* in Burkitt lymphoma (Table 10.3).
3 Detection of translocations or inversions or aneuploidy that was not detected on metaphase cytogenetic analyses because the leukaemic cells did not enter mitosis or the metaphases were of too poor quality, e.g. detection of t(8;21)(q22;q22.1); *RUNX1::RUNX1T1*, t(15;17)(q24.1;q21.1); *PML::RARA*, inv(16)(p13.1q22); *CBFB::MHY11* or *KMT2A* rearrangement in AML (Figure 10.31) or detection, in ALL, of iAMP21 (using a *RUNX1* probe) or high hyperdiploidy (by using centromeric probes for the chromosomes that are most often triplicated).
4 Screening for a cryptic *FIP1L1::PDGFRA* fusion (by detection of loss of *CHIC2*) in myeloid/lymphoid neoplasm with *PDGFRA* rearrangement (including chronic eosinophilic leukaemia).
5 Producing prognostically relevant information in CLL by investigation for trisomy 12, del(6)(q21), del(11)(q22–23), del(13)(q14.3) (Figure 10.32) and del(17)(p13).

Spectral karyotyping, also known as 24-colour FISH, is a modification of FISH that permits visualisation of each pair of chromosomes in a unique colour. It can be used as a supplement to metaphase cytogenetics to clarify the nature of complex rearrangements (Figure 10.33). Inversions are not detected.

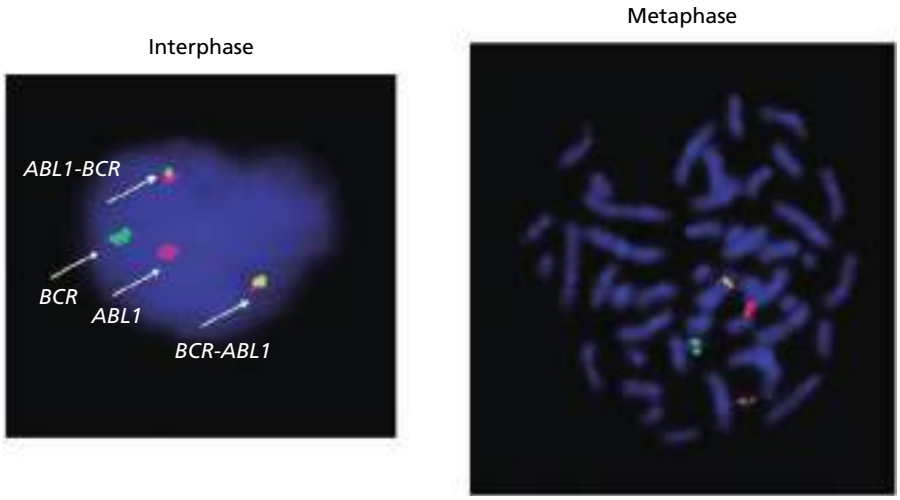

Figure 10.29 Locus-specific probes for *BCR* (green) and *ABL1* (red) applied to an interphase cell and to a metaphase of a patient with chronic myeloid leukaemia after hybridisation with probes for *ABL1* (red) and *BCR* (green) showing *BCR::ABL1* co-localisation signals (yellow) on the Philadelphia chromosome and *ABL1::BCR* co-localisation signals on derivative chromosome 9.

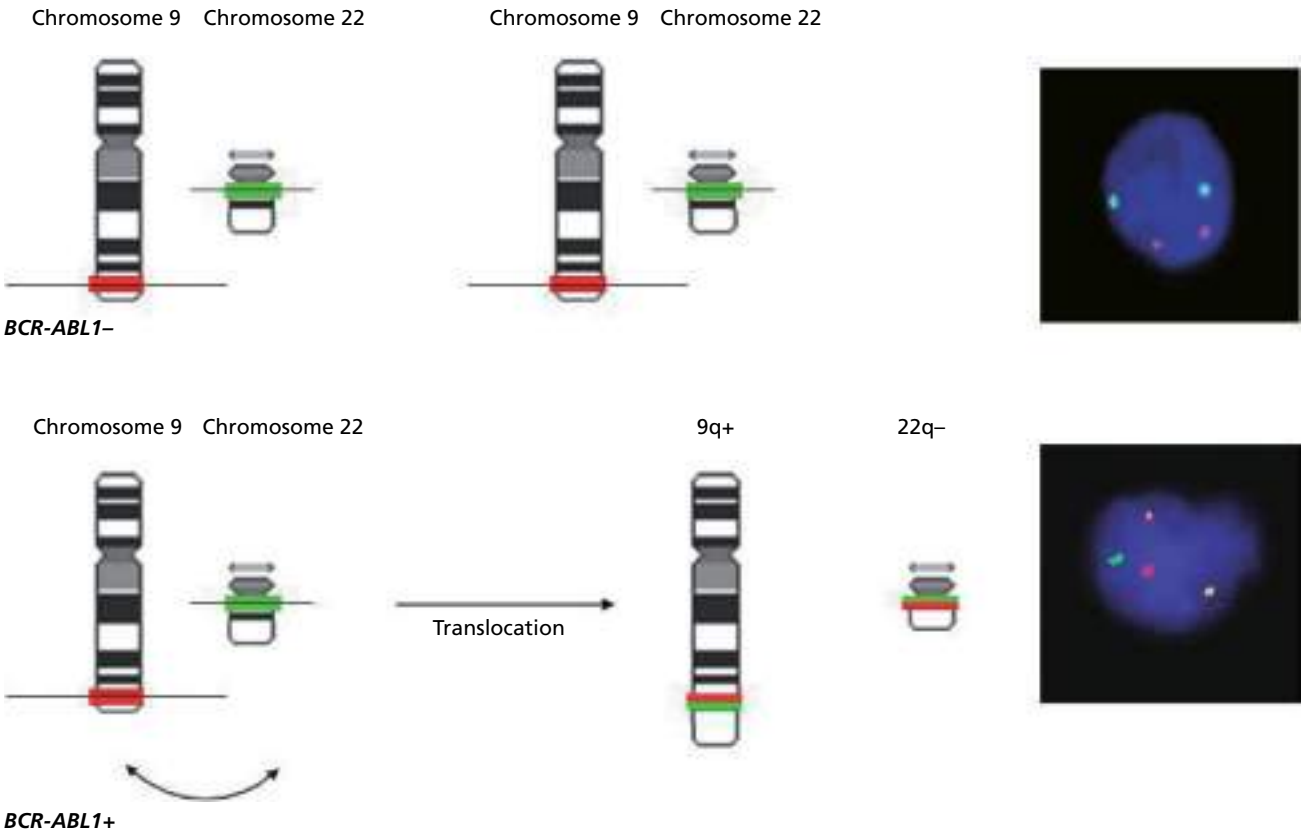

Figure 10.30 Diagram showing the principle of fluorescence *in situ* hybridisation for detection of *BCR::ABL1*. Locus-specific probes for *BCR* (green) and *ABL1* (red) have been applied to interphase cells. The normal cell (top) shows two red signals and two green signals, whereas the cell with *BCR::ABL1* shows two normal signals and two fusion signals (*BCR::ABL1* and *ABL1::BCR*).

Table 10.3 Cytogenetic/molecular genetic abnormalities that were incorporated into the 2016 WHO classification of neoplasms of mature T and B cells.

Genetic abnormality	Gene dysregulated	Diagnosis*
t(14;18)(q32;q21) or t(2;18)(p12;q21) or t(18;22)(q21;q11)	*BCL2*	Follicular lymphoma
t(11;14)(q13;q32) or, rarely, t(11;22)(q13;q11)	*CCND1*	Mantle cell lymphoma
t(8;14)(q24;q32) or t(2;8)(p12;q24) or t(8;22)(q24;q11.2)	*MYC*	Burkitt lymphoma
11q23 gain and 11q24.1-ter loss		Burkitt-like lymphoma with 11q aberration
inv(14)(q11.2q32.1) or t(14;14)(q11.2;q32.1) or, less often, t(X;14)(q28;q11.2)	*TCL1*	T-prolymphocytic leukaemia
t(2;5)(p23.2;q35.1) or one of at least eight variant translocations with a 2p23.2 breakpoint	*NPM1*::*ALK* fusion or other fusion gene incorporating part of *ALK*	Anaplastic large-cell lymphoma, ALK-positive

* The genetic abnormality confirms the diagnosis only in an appropriate cytological/histological and immunophenotypic setting.

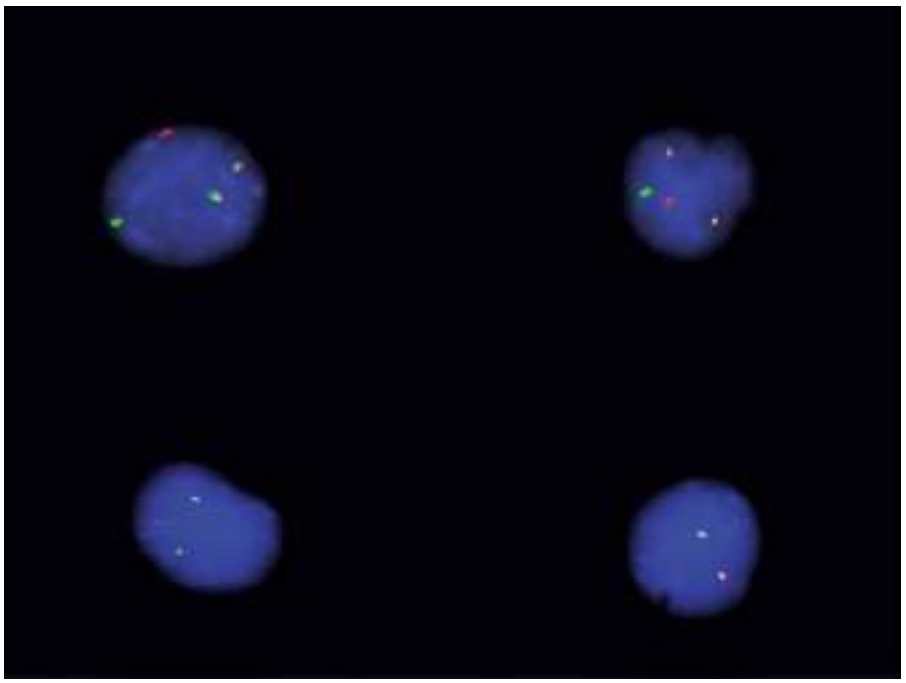

Figure 10.31 Fluorescence *in situ* hybridisation in four different patients with acute myeloid leukaemia showing four major cytogenetic/genetic categories of AML: *RUNX1*::*RUNX1T1* fusion indicative of t(8;21) (top left); *PML*::*RARA* fusion indicative of t(15;17) (top right); *CBFB* rearrangement, which is likely to indicate *CBFB*::*MYH11* (bottom left); *KMT2A* rearrangement (bottom right).

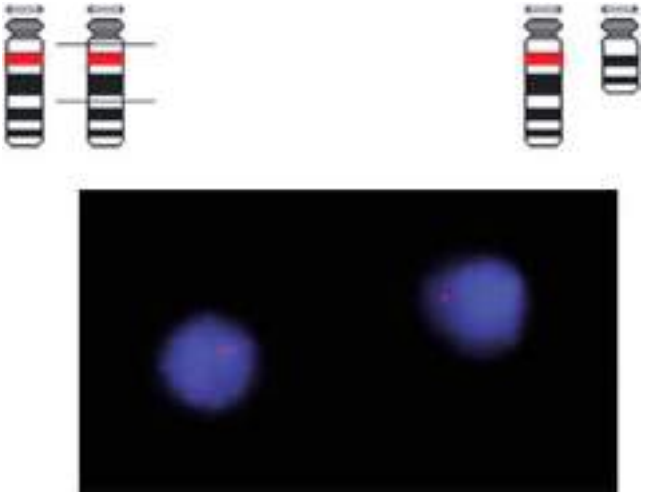

Figure 10.32 Explanatory diagram and fluorescence *in situ* hybridisation showing interstitial deletion of 13q14.3 in a patient with chronic lymphocytic leukaemia.

Molecular genetic analysis

Molecular genetic analysis includes the polymerase chain reaction (PCR) to study genomic DNA (Figures 10.34 and 10.35) and reverse transcriptase polymerase chain reaction (RT-PCR) to study RNA after its reverse transcription. A PCR reaction can also be made quantitative, as in real-time quantitative PCR, an important technique for monitoring MRD (Figure 10.36). PCR and RT-PCR can be alternatives to metaphase cytogenetic analysis in several subgroups of leukaemia and lymphoma. However, unlike metaphase cytogenetic analysis but similar to FISH, this is a targeted investigation so that only the abnormality that is specifically sought will be detected. Thus, in some diseases, additional diagnostic or prognostic information will be found only by using metaphase cytogenetics. On the other hand, PCR has the advantage that only a small amount of DNA is needed and there is no need for dividing cells. Molecular analysis permits the detection of prognostically and therapeutically relevant cryptic rearrangements, such as the *ETV6::RUNX1* rearrangement associated with a cryptic t(12;21)(p13.2;q22.1) in ALL. Genomic PCR can be applied to stored samples.

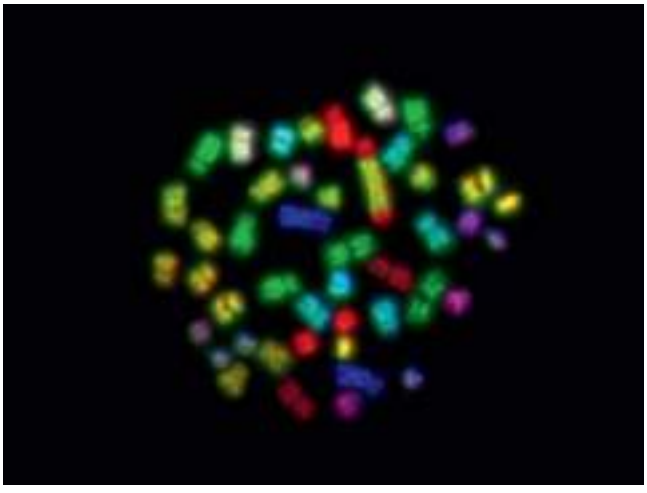

Figure 10.33 Metaphase of a patient with acute myeloid leukaemia and a complex aberrant karyotype after 24-colour fluorescence *in situ* hybridisation.

The roles of genomic PCR and RT-PCR include the following:

1 Detection of rearrangement of immunoglobulin heavy and light chain loci and *TCR* loci, providing evidence of a clonal disorder if a monoclonal rather than an oligoclonal or polyclonal pattern is detected.

2 Detection of leukaemia-related and lymphoma-related chromosomal rearrangements by demonstration of gene juxtaposition or fusion in order to confirm a diagnosis, for example detection of *CCND1::IGH* indicative of t(11;14)(q13;q32) to confirm suspected mantle cell lymphoma or detection of *BCL2::IGH* indicative of t(14;18)(q32;q21) to confirm suspected follicular lymphoma. Note that neither of these rearrangements is absolutely specific for the disease in question since *CCND1::IGH* also occurs in multiple myeloma and *BCL2::IGH* also occurs in DLBCL, but in the context of appropriate cytology or histology they do permit confirmation of a diagnosis.

3 Detection of gene mutations relevant to diagnosis, for example *KIT* D816V in systemic mastocytosis or either *JAK2* V617F or *JAK2* exon 12 mutation in polycythaemia vera. *JAK2* V617F also occurs in many patients with essential thrombocythaemia or primary myelofibrosis, but its detection in a patient with a high haemoglobin concentration confirms the diagnosis of polycythaemia vera and since it is present in the great majority of patients with this diagnosis, measurement of the total red cell mass and plasma volume is generally rendered unnecessary. Patients with suspected essential thrombocythaemia or primary myelofibrosis who are *JAK2* V617F-negative should be further investigated for *CALR* or *MPL* mutation.

4 Prognostic stratification, for example in ALL detection of *ETV6::RUNX1* associated with cryptic t(12;21)(p13.2;q22.1) (good prognosis), *TCF3::PBX1* associated with t(1;19)(q23;p13.3) (good prognosis), *KMT2A::MLLT2* associated with t(4;11)(q21;q23.3) (poor prognosis) and *BCR::ABL1* associated with t(9;22)(q34.1;q11.2) (intermediate prognosis); multiplex PCR, combining a number of primer pairs in a single reaction, is useful for screening simultaneously for more than one rearrangement.

5 Prognostic stratification in AML with normal karyotype, for example *FLT3* internal tandem duplication (ITD) (poor prognosis, depending on allele burden), *KMT2A* partial tandem duplication (PTD) (poor prognosis), *NPM1* mutation (good prognosis if not associated with *FLT3*-ITD), *CEBPA* mutation (good prognosis if biallelic or bZIP region mutated and not associated with *FLT3*-ITD) (see also Chapter 32).

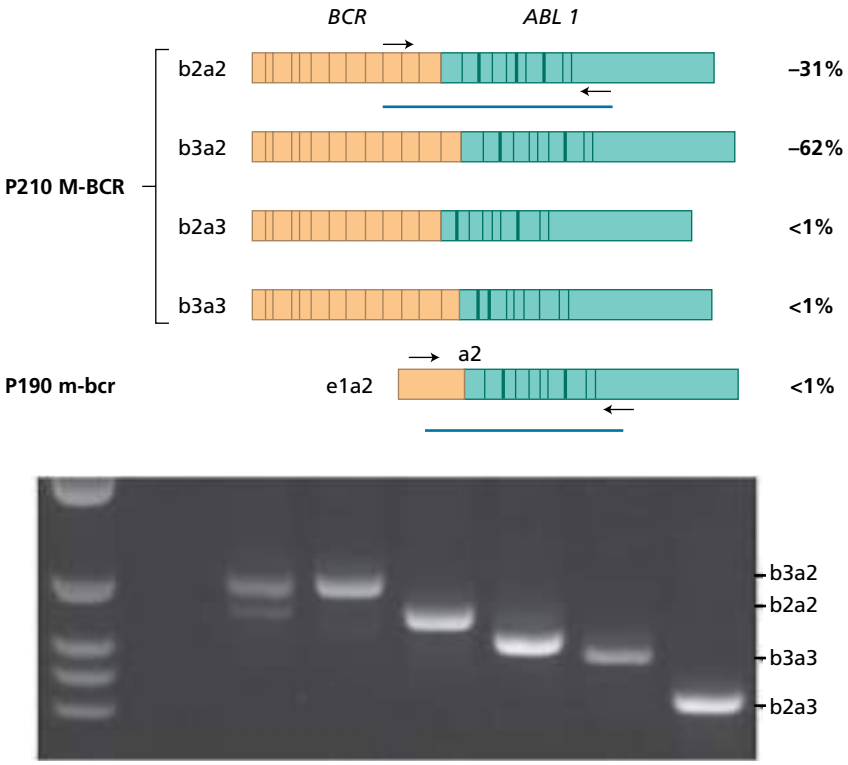

Figure 10.34 An explanatory diagram and a PCR gel showing the various *BCR::ABL1* transcripts that can be identified by PCR.

6 Prognostic stratification in CLL: somatic hypermutation, defined as *IGHV* showing less than 98% homology with germline, is found in 50–60% of all cases and correlates with a better prognosis than is found in patients with unmutated *IGHV* genes. *TP53* mutations are prognostically adverse and guide treatment.

7 MRD detection using *RUNX1::RUNX1T1*, *CBFB::MYH11*, *PML::RARA*, *KMT2A* rearrangement, *KMT2A*-PTD, *FLT3*-ITD, *NPM1* mutation or *CEBPA* mutation.

Whole-genome scanning

There are a number of molecular techniques available for whole-genome scanning. Thus far, these have mainly been used to address research topics, but they are now increasingly finding a place in routine diagnostic work. The NCCN guidelines 3/2023 in AML for the first time include whole genome sequencing (WGS) in the diagnostic approach to AML. These

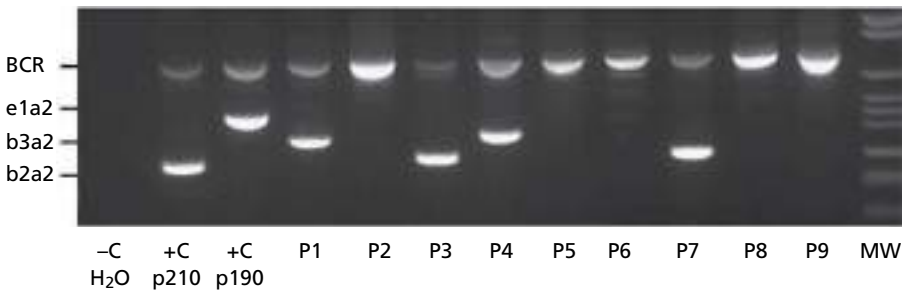

Figure 10.35 *BCR::ABL1* multiplex PCR containing different oligonucleotide ('oligo') combinations. –C: negative control sample containing water instead of a nucleic acid template; +C: positive controls for p210 and p190 fusion types; P: patient samples, P1 and P4 are positive for b3a2 fusion types, P3 and P7 are positive for b2a2 fusion types, P2, P5, P6, P8 and P9 are *BCR::ABL1*-negative patient samples; MW, molecular weight standard; BCR, amplification of the non-rearranged *BCR* gene as internal quality control reaction.

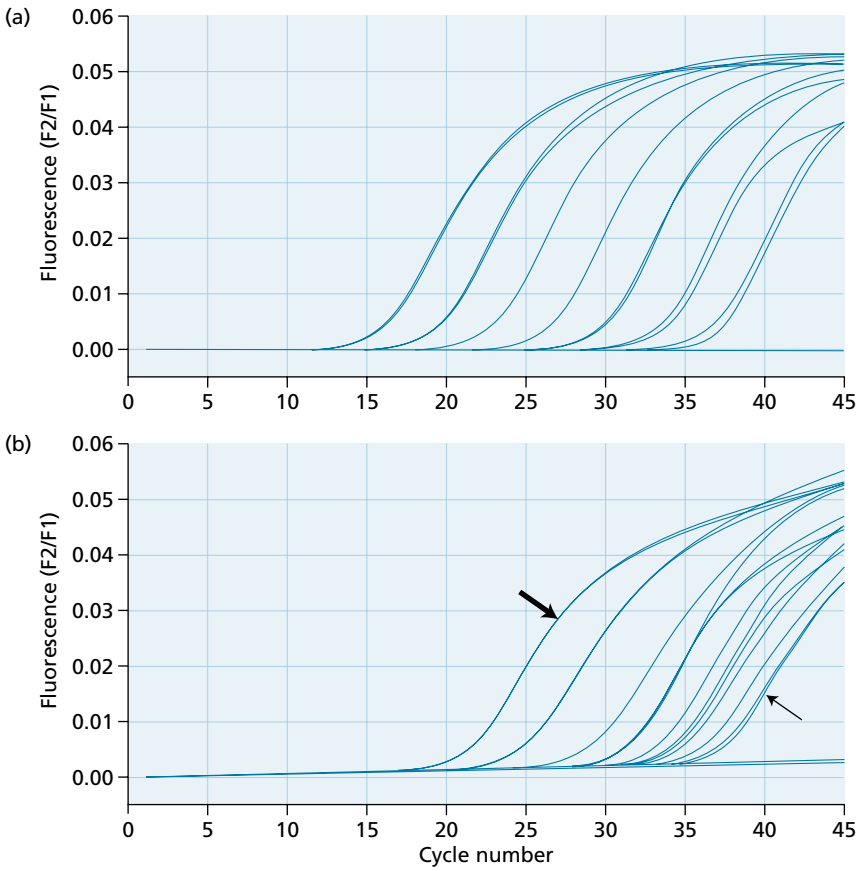

Figure 10.36 Real-time quantitative PCR. Fluorescence is plotted against PCR cycle number. (a) A 10-fold limited dilution series of a *BCR::ABL1*-containing plasmid showing high sensitivity of the PCR. It also serves as a calibration curve for subsequent *BCR::ABL1* calculations. (b) Run with chronic myeloid leukaemia follow-up samples: the large arrow shows a sample with high *BCR::ABL1* load and the small arrow low *BCR::ABL1* load.

techniques include comparative genomic hybridisation (CGH), in which labelled test DNA is hybridised to normal metaphase preparations, and microarray analysis, in which there is hybridisation of the labelled test DNA of interest to probes positioned in high density on a microarray surface. Microarray analysis includes CGH arrays and, more frequently used, genome-wide single-nucleotide polymorphism (SNP) arrays.

In CGH assays, test and reference DNAs are labelled with different fluorochromes before being hybridised to microarrays of either oligonucleotides or bacterial artificial chromosome (BAC) probes. CGH microarray analysis is used for the detection of under-representation or over-representation of specific genomic regions in the test DNA. Deletions and amplifications can thus be detected, for example deletion of 13q14 and 11q22 in CLL or iAMP21 in ALL.

In SNP array analysis, genomic DNA of a sample of interest is digested by restriction enzymes, amplified, labelled and hybridised to oligonucleotide probes. Probes are either bound to microbeads or are synthesised *in situ* in high density on a microarray surface (Figure 10.37). SNP analysis can be applied to genotyping and is able to distinguish heterozygosity from homozygosity. It can thus be used to detect both loss of heterozygosity and alterations of copy numbers of a genomic region (i.e. gains and losses). Acquired somatic uniparental disomy can be detected by comparison of tumour DNA with constitutional DNA. Sensitivity for the detection of a clonal population is similar to that of metaphase cytogenetics. With SNP array technology, it is possible to identify uniparental disomy for chromosomal regions that include mutated genes such as *JAK2*, *CEBPA*, *FLT3* and *RUNX1*. SNP array analysis does not typically detect chromosomal translocations.

Microarray analysis of gene expression

Microarray analysis was initially applied to the study of cellular gene expression by hybridisation of test and control RNA specimens, processed and labelled with different fluorochromes, to single-stranded DNA. The DNA probes were either complementary (c) DNA or synthetic oligonucleotides, arrayed in multiple rows of dots on a microarray surface with each dot interrogating a fragment of a single gene. High-density gene expression profiling (GEP) is a well-established molecular method and has been demonstrated to yield information of both diagnostic and prognostic value.

Primary mediastinal B-cell lymphoma can be distinguished from both DLBCL and Hodgkin lymphoma by its molecular signature. Burkitt lymphoma has a distinctive pattern of gene expression, which can help in making a distinction from DLBCL with *MYC* over-expression. Similarly, small lymphocytic lymphoma,

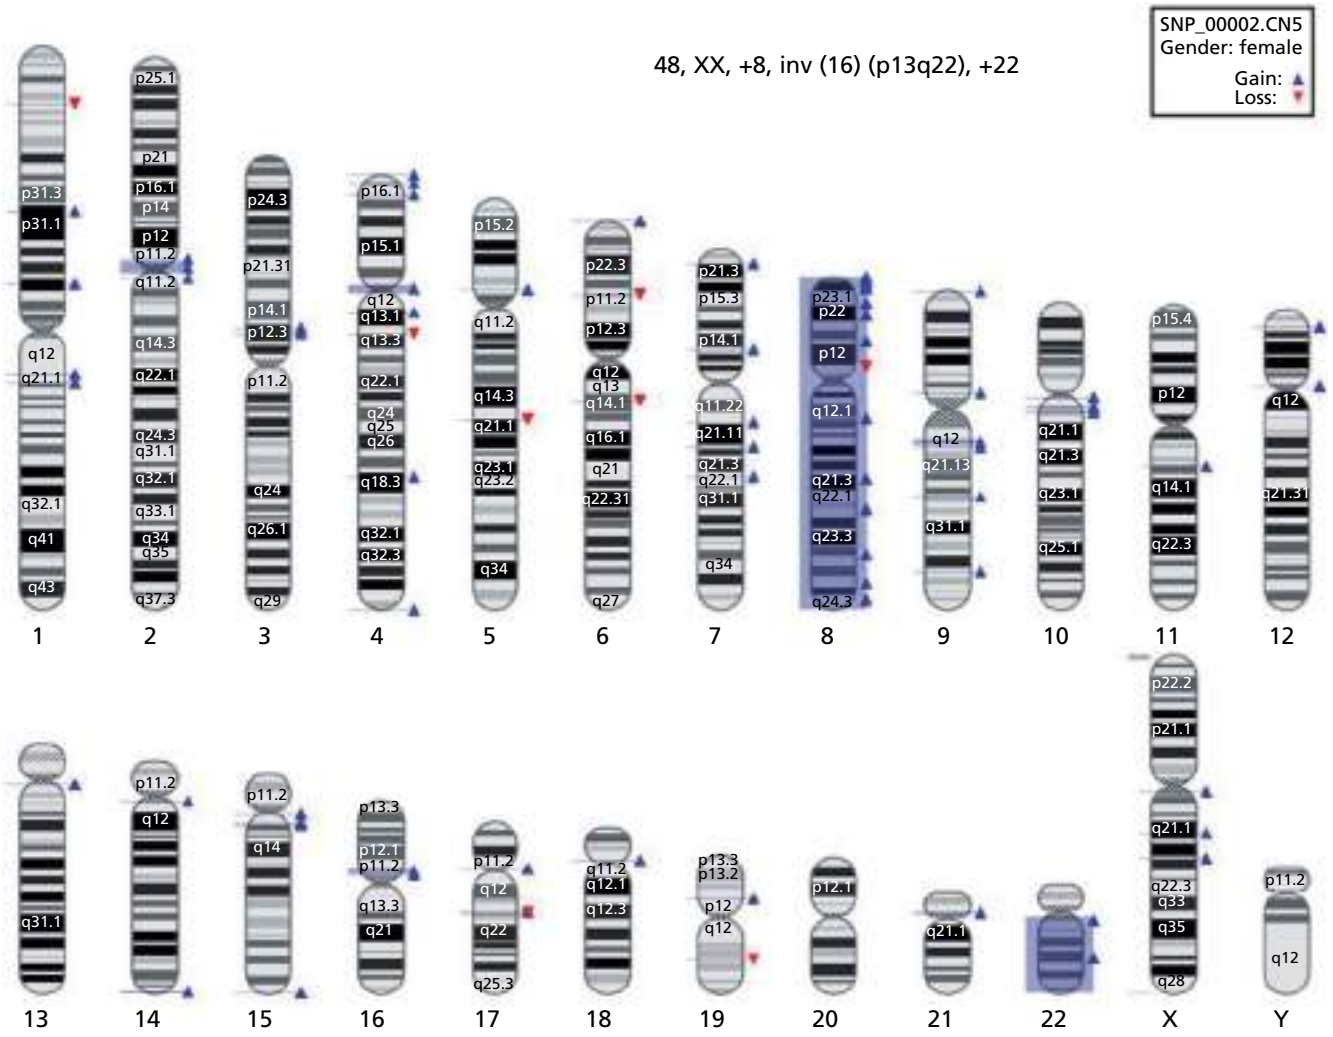

Figure 10.37 Molecular karyotype based on high-density SNP microarray analysis. Alterations are given by arrows indicating either gains or losses of chromosomal material. The karyotype using conventional chromosome banding techniques is given for comparison.

marginal zone B-cell lymphoma and mantle cell lymphoma can be characterised by their different gene expression signatures.

Prognostic information is provided in DLBCL. Microarray studies have shown that this diagnostic category encompasses at least two molecularly distinct diseases, differing in differentiation stage (i.e. cell of origin), oncogenic mechanisms and clinical outcome. Microarray analysis can also divide mantle cell lymphoma into groups with very different prognoses.

Next-generation sequencing

The constantly increasing spectrum of molecular mutations is a tremendous challenge for haematological laboratories. Thus, the introduction of high-throughput sequencing technologies, which allow the massive parallel analysis of hundreds of thousands of alleles in a short time, provides new options for molecular mutation analyses and for follow-up diagnostics in haematological neoplasms. Today, panel sequencing is already in routine use in many laboratories and whole exome sequencing (WES), whole genome sequencing (WGS) and whole transcriptome sequencing (WTS) are already in clinical use. These techniques and their application are discussed in detail in Chapter 8.

Laboratory techniques and the WHO classification of tumours of haemopoietic and lymphoid tissues

The 2022 WHO classification is based on the integration of clinical, pathological and molecular features. Amongst the pathological features, morphology (cytology and histology) is fundamental, but there is an increasing use of immunophenotyping for classification of lymphoid, mixed lineage and

some myeloid neoplasms and of cytogenetic and molecular genetic information for classification of both lymphoid and myeloid neoplasms. Tables 10.1 and 10.2 illustrate how cytogenetic and molecular genetic information is integrated into the classifications of AML and B-lineage ALL respectively. Two categories of acute leukaemia of ambiguous lineage are also defined by the presence, in addition to the required immunophenotypic characteristics, of t(9;22)(q34.1;q11.2); *BCR::ABL1* and 11q23/*KMT2A* rearrangement respectively. The 2022 WHO classification includes genetically defined categorisation for lymphoid and myeloid neoplasms, for example rearrangement of *PDGFRA*, *PDGFRB*, *FGFR1, JAK2, FLT3* and *ETV6::ABL1* as genetic abnormalities defining myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions. Otherwise, amongst the myeloproliferative neoplasms, only the demonstration of t(9;22)(q34.1;q11.2); *BCR::ABL1* to confirm or exclude a diagnosis of CML is essential for classification. However, the demonstration of the *JAK2* V617F mutation or a somatic *MPL* or *CALR* mutation is important for making a diagnosis of a myeloproliferative neoplasm rather than a secondary or familial disorder. A *JAK2* exon 12 mutation similarly confirms that polycythaemia is polycythaemia vera rather than a familial or secondary condition.

Cytogenetic and molecular genetic abnormalities are critical in the diagnosis of certain neoplasms of mature lymphocytes (Table 10.3). However, for the majority of cases of CLL and NHL, such analysis is not needed for diagnosis and classification, although it may provide information of prognostic value.

Conclusions

Modern diagnosis, classification and monitoring of haematological neoplasms require integration of multiple diagnostic tools in a systematic manner in order to provide all the information necessary for optimal management of the patient. In addition, application of new diagnostic tools is constantly increasing our understanding of these disorders. New research tools not only give new information but are often rapidly integrated into diagnostic practice. Classifications of lymphoid and myeloid neoplasms increasingly incorporate and depend on immunophenotypic and genetic analysis. High-throughput sequencing technologies investigating gene panels by next-generation sequencing have now been introduced into routine diagnostic algorithms. WES, WGS and WTS are also becoming routinely available in laboratory diagnostics and in certain settings look set to replace other more traditional diagnostic techniques over the coming years. Especially in ALL, some entities such as ALL with *DUX4* overexpression need WTS for diagnosis.

CHAPTER 11

Iron metabolism, iron deficiency and disorders of haem synthesis

11

Clara Camaschella[1] and Chaim Hershko[2]

[1] San Raffaele Hospital and Scientific Institute, Milan, Italy
[2] Shaare Zedek Medical Center, Jerusalem, Israel

Introduction

Iron is essential for many metabolic processes. It shares with other transition metals two properties of particular importance in biology: the ability to exist in more than one relatively stable oxidation state and the ability to form many complexes. Its ability to exist in both ferric and ferrous states underlies its role in critical enzyme reactions concerned with oxygen and electron transport and the cellular production of energy. As well as physiologically active iron compounds, many of which are haem proteins, there are also specialised proteins of iron absorption, transport and storage. The latter are necessary to enable iron to remain in solution at neutral pH, at which ferric iron is insoluble, and to limit the potential toxicity of this reactive metal. The insolubility of ferric iron also means that although the Earth's crust contains approximately 4% iron and iron may be plentiful in the diet, much of this is not bioavailable. As a result, the body is limited in the adjustments it can make to excessive loss of iron, which frequently occurs due to haemorrhage, and iron deficiency is the most common cause of anaemia throughout the world, affecting in the order of 1 billion people. The general need to conserve the metal is reflected in the absence of any physiological mechanism for excretion of iron, control of iron balance being at the level of iron absorption. This is important in the rarer, but potentially fatal disorders of iron overload (see Chapter 12).

Distribution of body iron

The amount of iron in the adult human body is normally about 50 mg/kg in males and 40 mg/kg in females. The largest component is circulating haemoglobin, with 450 mL (1 unit) of whole blood containing about 200 mg of iron. Much of the remainder is contained in the storage proteins ferritin and haemosiderin. These are found mainly in the macrophages of the liver, spleen and bone marrow (which gain iron from breaking down red cells), and in parenchymal liver cells (which normally obtain most of their iron from the plasma iron-transporting protein transferrin) (Figure 11.1).

Proteins important in iron metabolism

Haem proteins and iron-containing enzymes

Haemoglobin contains four haem groups linked to four globin chains and can bind four molecules of oxygen. Myoglobin accounts for 4–5% of body iron and has a single haem group attached to its one polypeptide chain. It has a higher affinity for oxygen than haemoglobin and behaves as an oxygen reserve in muscles. The mitochondria contain a series of haem and non-haem iron proteins (including the cytochromes *a*, *b* and *c*, succinate dehydrogenase and cytochrome oxidase) that form an electron transport pathway responsible for the oxidation of

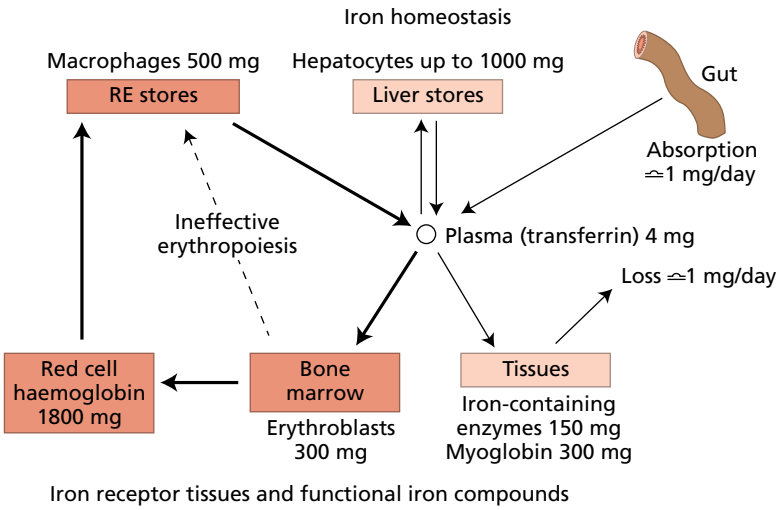

Figure 11.1 Iron homeostasis. The major compartments of iron in a 70-kg man. Iron supply for erythropoiesis and release of iron from senescent red cells dominate internal iron exchange. RE, reticuloendothelial. The dotted line indicates the low proportion of iron that derives from ineffective erythropoiesis in normal subjects.

intracellular substrates and the simultaneous production of adenosine triphosphate (ATP). Haem is an essential component of microsomal and mitochondrial cytochrome P450, which is concerned with hydroxylation reactions (including drug detoxification by the liver), and of cyclooxygenase, involved in prostaglandin synthesis. Other haem proteins include the enzymes catalase and lactoperoxidase, which are concerned with peroxide breakdown, and tryptophan pyrrolase, involved in the oxidation of tryptophan to formylkynurenine. There is a smaller but biologically important group of iron–sulfur proteins (e.g. xanthine oxidase, reduced nicotinamide adenine dinucleotide dehydrogenase and aconitase). Iron is also necessary for the function of ribonucleotide reductase, a key enzyme in DNA synthesis

Ferritin and haemosiderin

Ferritin is the primary iron storage protein and provides a reserve of iron. It consists of an approximately spherical apoprotein shell enclosing a core of ferric hydroxyphosphate (up to 4000 iron atoms). Human ferritin is made up of 24 subunits of two immunologically distinct types: H and L. There are multiple gene copies, which are mostly pseudogenes. An intronless gene codes for mitochondrial ferritin, an H-type ferritin. The internal cavity of the ferritin molecule communicates with the exterior via six channels, through which ferrous iron may enter (to interact with a ferroxidase centre on the ferritin H subunit) or leave (after reduction, e.g. by dihydroflavins or ascorbic acid).

Ferritin iron is mobilised by ferritinophagy, a process mediated by nuclear receptor co-activator 4 (NCOA4), which, degraded by proteasome in iron-replete cells, binds and addresses ferritin to lysosome degradation in iron deficiency thereby recovering intracellular iron. Variation in the proportion of H to L subunits explains the heterogeneity of ferritin from different tissues on isoelectric focusing: L-rich ferritins (from spleen and liver) are more basic than H-rich ferritins (from heart and red cells). The small amount of ferritin normally present in serum contains little iron and consists almost exclusively of L subunits. It is also heterogeneous, owing to glycosylation. This glycosylation and the direct relationship of serum concentration to storage of iron in macrophages suggest that serum ferritin is secreted by macrophages in response to changing iron levels.

Haemosiderin, unlike ferritin, is a water-insoluble, crystalline, protein–iron complex that is visible by light microscopy when stained by the Prussian blue (Perls') reaction. It has an amorphous structure, with a higher iron/protein ratio than ferritin, and is probably formed by the partial digestion of ferritin aggregates by lysosomal enzymes. In normal subjects, the majority of storage iron is present as ferritin, and haemosiderin is predominantly found in macrophages rather than hepatocytes. In iron overload, the proportion present as haemosiderin increases considerably in both cell types.

Transferrin and transferrin receptors

Transferrin is a single-chain polypeptide present in plasma (1.8–2.6 g/L) and extravascular fluid (Table 11.1). It has a plasma half-life of 8–11 days. The protein is synthesised predominantly by the liver, synthesis being inversely related to iron stores. Two atoms of ferric iron can bind to each molecule. Although transferrin contains only about 4 mg of body iron at any time, it is vital for iron transport, with over 30 mg of iron passing through this compartment each day (Figure 11.1). The uptake of iron from transferrin requires that the protein is attached to specific receptors on the cell surface. The transferrin receptor gene (*TFRC*) codes for TFR1 a transmembrane protein (identified as CD71). Each molecule of two subunits binds with high affinity one molecule of diferric (two iron molecules bound) transferrin.

A truncated form of TFR1 corresponding to the ectodomain is found in serum. This soluble TFR reflects the density of the

Hemojuvelin (*HJV*)	1q21.2	Liver, heart and muscle	Membrane-bound BMP coreceptor	Regulator of hepcidin synthesis	TMPRSS6 (posttranslational)	Juvenile HC
Hepcidin (*HAMP*)	19q13.1	Liver, heart, skin and retina	Mature peptide of 25 amino acids	Regulator of iron export to plasma	Diferric TF, BMPs, IL-6, ERFE, TMPRSS6	Juvenile HC
Hephaestin (*HEPH*)	Xq12	Enterocyte basolateral membrane	TMP, copper protein with homology to caeruloplasmin	Fe^{2+} oxidase	Not known	*Sla* mouse: iron deficiency anaemia
IRP1 (*ACO1*)	9p21.1	Widespread	Cytoplasmic	Regulation of FTH, FTL, TFRC, DMT1, ferroportin, ALAS2, HIF-2α	4Fe-4S clusters change it to aconitase	Normochromic anaemia with low ferritin
IRP2 (*IREB2*)	15q25.1	Widespread	Cytoplasmic	As IRP1	Iron-induced proteasomal degradation	Functional iron deficiency Neurodegeneration
Mitoferrin 1 (*SLC25A28*)	8p21	Erythroid, liver, skeletal muscle and heart	Mitochondrial inner Membrane	Mitochondrial iron importer	GATA1 in zebrafish	Not known
Matriptase-2 (*TMPRSS6*)	22q13.1	Mainly liver	Type II transmembrane serine protease	Cleaves haemojuvelin	Hypoxia	*Mask* mouse Autosomal recessive IRIDA
Nuclear receptor coactivator 4 (*NCOA4*)	10q11	Ubiquitous	Iron binding protein	Mediator of ferritinophagy. Regulator of DNA replication origins	Iron-induced proteasomal degradation	Not known

Six-transmembrane epithelial antigen of prostate 3 (*STEAP3*)	2q14.2	Erythroid, placenta (associated with TFR1)	Six-transmembrane epithelial antigen of prostate-3	Ferric reductase (endosomal) also reduces copper	Not known	Human microcytic anaemia
Solute carrier zinc transporter family member 14, ZIP14 (*SLC39A14)*	8p21.3	Widespread	Zinc and other metal transporter	Iron transport receptor for NTBI in liver and pancreas	Not known	Not known
Transferrin (*TF*)	3q21	Liver, all cells	Single-chain polypeptide, glycoprotein	Iron transport. Ligand (diferric) for TFR1 and TFR2	Hypoxia Iron stores (?)	Atransferrinaemia: autosomal recessive anaemia with iron overload
Transferrin receptor 1 (*TFRC*)	3q29	Widespread: highest number in erythroid precursors	TMP, dimeric	Binds transferrin	Fe (3′-IRE)	Embryonic lethality in knock out mouse. Immunodeficiency (*missense* recurrent mutation) in humans
Transferrin receptor 2 (*TFR2*)	7q22	Liver, erythroid precursors, osteoblasts and osteoclasts	TMP dimeric, 60% similarity to TFR1 in extracellular domain	Binds transferrin, regulator of hepcidin synthesis; EPOR partner	No IRE, Stabilised on membrane by diferric transferrin	Human HC, autosomal recessive

* In hyperferritinaemia/cataract syndrome, mutations affect the 5′-UTR IRE. In neuroferritinopathy, mutations affect *FTL* coding sequences.
BMP, bone morphogenetic protein; EPOR, erythropoietin receptor; Fe/S, iron sulfur cluster; HC, haemochromatosis; IL6, interleukin 6; IRE, iron responsive element; IRIDA, iron refractory iron deficiency anaemia; IRP, iron regulatory protein; MDS-RS, myelodysplasia with ring sideroblasts; NTBI, non-transferrin bound iron; TMD, transmembrane domain; TMP, transmembrane protein.

receptors on erythroblasts, which is especially enhanced in expanded erythropoiesis and in iron deficiency (see below).

A single homozygous *TFRC* mutation causes mild anaemia and severe immunodeficiency, strengthening that iron has an essential role in lymphocyte function.

A second receptor, TFR2, also binds diferric transferrin (Table 11.1) although with affinity lower than TFR1. Both receptors bind HFE and through this binding are involved in regulating hepcidin synthesis (see Figure 11.2). TFR2 binds erythropoietin receptor (EPOR) in erythroid precursors, negatively modulating EPO signalling through an unknown mechanism.

Lactoferrin is a glycoprotein that is structurally related to transferrin. It is found in milk and other secretions and in neutrophils. It has a bacteriostatic action at secreting surfaces by depriving microorganisms of the iron needed for their growth.

Divalent metal transporter 1

Divalent metal transporter (DMT)1 is an electrogenic pump that requires proton cotransport in order to transfer Fe^{2+} across cell membranes. This occurs at the apical membrane and subapical endosomes of the duodenal enterocyte and the transferrin-cycle endosome, both of which have a low pH. The intestinal DMT1 is produced by different mRNA splicing that produces endosomal DMT1. DMT1 expression is upregulated in iron deficiency/hypoxia (see later) and may be involved in absorption of other divalent metal cations, including Mn^{2+}, Co^{2+}, Zn^{2+}, Cu^{2+} and Pb^{2+}. The expression of DMT1 and DCYTb is increased in hypoxia by the hypoxia-inducible factor (HIF)-2α.

Ferroportin

This transmembrane domain protein is the basolateral transporter of iron, essential for iron release from macrophages, the intestinal absorptive enterocyte, hepatocytes and placental syncytiotrophoblasts. It is also present in intracellular compartments. Control of ferroportin occurs at multiple levels: inflammatory cytokines reduce ferroportin transcription, while IRPs, interacting with a 5′IRE, control its translation. Caeruloplasmin is required for the cell-surface localisation of ferroportin, whose concentration is post-translationally controlled by hepcidin, which triggers its internalisation and degradation in lysosomes. Hepcidin also blocks the iron channel in the

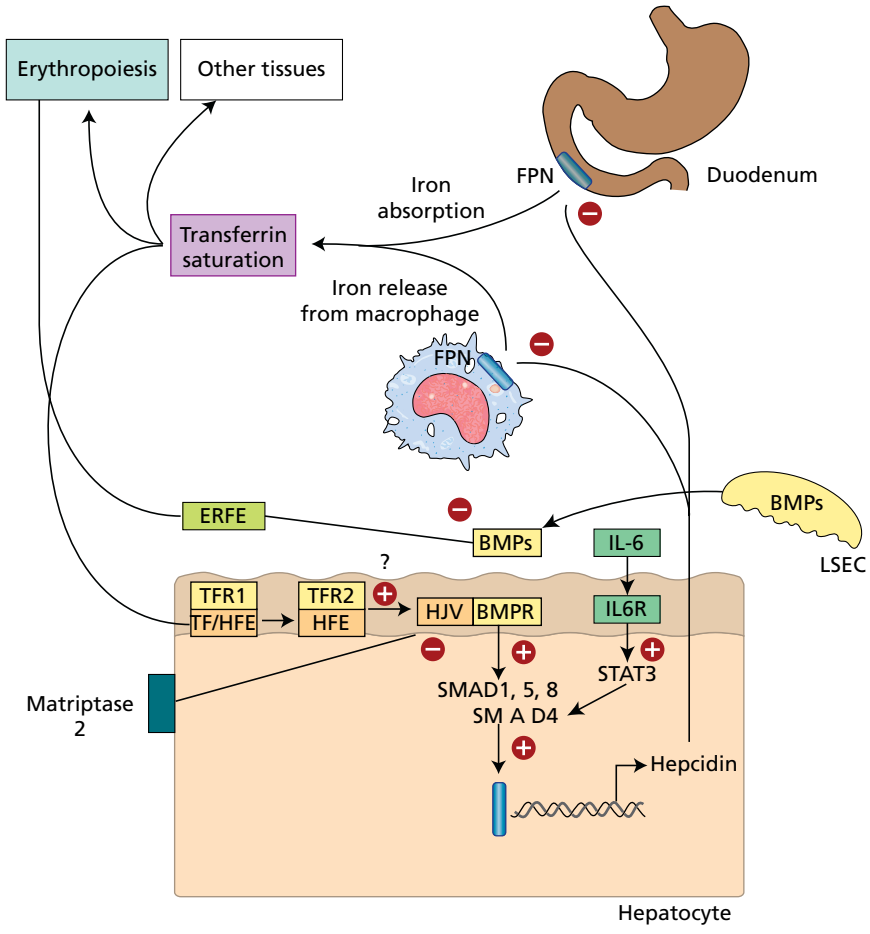

Figure 11.2 Stimulatory and inhibitory signals of hepcidin regulation. Hepcidin, as well as haemojuvelin (HJV), transferrin receptor 2 (TFR2) and HFE, are all produced in the hepatocyte. High plasma iron and inflammation cytokines (as IL-6) stimulate hepcidin synthesis, mediated by SMADs and STAT3, respectively. Conversely, low plasma iron, increased rates of erythropoiesis (including ineffective erythropoiesis) and hypoxia inhibit hepcidin production. This is mediated by matriptase 2 and ERFE. Hepcidin binds ferroportin (FPN), causing its destruction and so inhibits iron absorption and iron release from macrophages into plasma and from intracellular compartments. BMP, bone morphogenetic protein; ERFE, erythroferrone.

central cavity of the iron exported, as shown by the effect of hepcidin in cells unable to internalise ferroportin, as the erythrocytes. How iron homeostasis is finely tuned by the hepcidin-ferroportin axis has been recently explained by cryogenic electro-microscopy structure of the two proteins complex: hepcidin has a strikingly higher (80×) affinity for iron-bound than for iron-free ferroportin, inducing preferential degradation of the first.

Other proteins

The roles in iron metabolism of haemojuvelin (HJV), bone morphogenetic proteins (BMP-6 and BMP2), small mothers against decapentaplegic (SMADs), ferrioxidative and reduction enzymes, and caeruloplasmin are discussed under the headings of hepcidin regulation, iron absorption, iron uptake by erythroid cells and haem synthesis.

Hepcidin

Hepcidin has a central role in the regulation of iron metabolism, absorption and recycling (Figure 11.2). A product of the *HAMP* gene (Table 11.1), it is a small peptide (25 amino acids) released from a large prepropeptide of 84 amino acids. It is predominantly expressed in the liver. It regulates iron homeostasis by blocking the iron export and causing ferroportin internalisation and degradation in lysosomes. It therefore acts to inhibit iron absorption, iron release from macrophages and iron transport across the placenta. It is bound in plasma to α_2-macroglobulin and the major route of clearance is the kidney. Hepcidin can be measured in serum by ELISA or mass spectrometry-based techniques.

Regulation of hepcidin expression

The regulation of hepcidin expression is transcriptional. Hepcidin expression is increased in response to raised serum iron, iron overload and inflammation and is suppressed by iron deficiency, hypoxia and increased erythropoietic activity. Under basal conditions, expression depends on signalling through the BMP/SMAD pathway (Figure 11.2). The ligands BMP6 and BMP2 are cytokines produced by liver sinusoidal endothelial cells. BMP-6 is the master hepcidin activator in response to iron *in vivo* in murine models, while BMP2 likely determines basal hepcidin levels. More recent data suggest that full hepcidin stimulation requires as ligand the formation of BMP2/BMP6 heterodimers complex. HJV is a member of the repulsive guidance molecules (RGM) family that is highly expressed in liver, skeletal muscles and the heart. It is either associated with cell membranes through a glycosylphosphatidylinositol anchor or released as a soluble form. Membrane-bound HJV participates in the pathway regulating hepcidin expression as a BMP coreceptor, whereas soluble HJV is a BMP antagonist in murine models.

HFE and TFR2 are also involved in hepcidin expression (Figure 11.2). HFE is able to bind TFR1 and TFR2. During low or basal serum iron conditions, HFE and TFR1 exist as a complex at the plasma membrane, TFR1 serving to sequester HFE to silence its activity. Diferric serum transferrin (Fe^{2+}-TF) competes with HFE for binding to TFR1. Increased serum transferrin saturation therefore results in dissociation of HFE from TFR1. A model suggests that HFE then binds to TFR2 and conveys the Fe^{2+} TF status to the signal transduction effector complex. HJV binds to BMP interacting with BMP receptors, that phosphorylate SMADs to form a SMAD-1/-5/-8–SMAD-4 complex, which translocates to the nucleus and stimulates hepcidin production by activating its promoter. In keeping with this model, genetic mutations of HFE, TFR2, HJV and hepcidin all result in haemochromatosis with low serum hepcidin levels (see Chapter 12). Liver iron levels also control BMP-6 production by LSEC, but the mechanisms are still unclear.

A second type of transcriptional hepcidin regulation occurs in inflammation. Interleukin (IL)-6 and IL-1β induce transcription of the hepcidin gene by activating STAT3 (signal transducer and activator of transcription 3) that binds to a regulatory element in the hepcidin promoter. The full hepcidin expression in inflammation requires the integrity of the BMP pathway since the two signals (Figure 11.2) converge on a final shared SMAD-4-dependent pathway.

The hepcidin response is remarkably rapid. In humans, iron ingestion results in a sharp increase in serum hepcidin within a few hours of starting treatment lasting up to 48 hours. Likewise, infusion of recombinant IL-6 results in a significant increase in serum hepcidin and decreased serum iron and transferrin saturation within 2 hours of infusion. These observations imply that hepcidin expression is directly controlled by serum iron (through transferrin saturation) and IL-6. These physiological mechanisms explain the onset of anaemia in inflammatory disorders.

Response to anaemia and hypoxia

Hepcidin levels are reduced or undetectable in iron deficiency anaemia. Iron absorption is accelerated in iron deficiency, ineffective erythropoiesis and hypoxia (Figure 11.2), the latter two likely through common mechanisms mediated by the 'erythroid regulator'. In iron deficiency, *TMPRSS6* mediates hepcidin inhibition by attenuating the BMP signalling (see matriptase 2). A direct epigenetic inhibition on the hepcidin locus has also been reported.

Erythroferrone

Erythroferrone (ERFE or FAM123B) is the physiological erythroid regulator in mice. It is released by erythroid precursors and suppresses hepcidin after bleeding and erythropoietin treatment in order to increase intestinal iron absorption and macrophage iron release according to the erythropoietic needs. It is a member of the TNF-alpha-like protein family, that binds and sequesters

several BMPs, in particular BMP6 and likely BMP2/6 heterodimers, reducing their interactions with receptors and the BMP pathway activation. ERFE has a minor, if any, role in iron deficiency while it is essential when erythropoiesis is physiologically expanded by erythropoietin as in hypoxia. Hypoxia directly increases iron absorption through increased duodenal DMT1/DCYTB expression and indirectly through hepcidin suppression by increased erythropoiesis and ERFE. The latter mechanism may contribute to the harmful accumulation of iron in response to chronic anaemia associated with ineffective erythropoiesis in thalassaemia and other dyserythropoietic anaemias.

Matriptase-2

This is a type 2 member of the transmembrane serine protease family encoded by *TMPRSS6* and mainly expressed in the liver. Membrane-bound matriptase-2 regulates hepcidin expression by cleaving membrane-bound HJV or according to other models by cleaving/blocking multiple components of the BMP pathway. The factors that regulate matriptase-2 expression need to be elucidated. Matriptase-2 activity over-rides all known activating stimuli of hepcidin synthesis. Homozygous or compound heterozygous *TMPRSS6* mutations in humans and homozygous inactivation of the gene in mice result in marked upregulation of hepcidin and blockade of intestinal and macrophage iron transport into plasma, leading to a refractory hypochromic microcytic anaemia (see below).

Intracellular iron homeostasis

Synthesis of several of the proteins involved in iron metabolism is regulated at the level of RNA translation by two cytoplasmic iron-dependent proteins, IRP1 and IRP2 (Table 11.1). These are capable of binding to mRNAs that contain a sequence forming a stem-and-loop structure called an *iron-responsive element* or IRE (Figure 11.3). The 3′-untranslated region (3′-UTR) of TFR1 contains five IREs, whereas the 5′-UTR region of ferritin mRNA contains a single IRE. Binding of IRP when there are low levels of intracellular iron protects TFR1 mRNA from cytoplasmic degradation, but inhibits translation of ferritin mRNA, by interfering with the binding of initiation factors. In contrast, when intracellular iron is increased, the opposite effects occur. Thus, coordinated regulation of TFR1 and ferritin acts to maintain a constant intracellular iron content over the short term by balancing cellular iron uptake and storage.

Erythroid δ-aminolevulinic acid synthase (ALAS2) mRNA also has an IRE in its 5′-UTR region, whereas 'housekeeping' ALAS1 mRNA does not. The IRP–IRE system is therefore involved in matching iron supply to haem synthesis, with repression of protoporphyrin synthesis in iron-deficient erythroblasts. An intestinal isoform of DMT1 like TFR1 has a 3′-IRE and is upregulated in iron deficiency. Ferroportin has a 5′-IRE (Table 11.1) but, as occurs for DMT1, ferroportin may be translated in a non-IRE isoform that escapes the IRP control in some tissues, for example in erythroid and duodenal cells. The IRE-IRP system regulates a vast assortment of mRNA. Examples are hypoxia-inducible factor 2 (HIF-2α) and the cell cycle regulator CDC14A. HIF-2α has a 5′-IRE: its translation is repressed in iron deficiency in the kidney, reducing erythropoietin production and erythropoiesis expansion. CDC14A has a single 3′-IRE that acts to stabilize mRNA in condition of iron repletion.

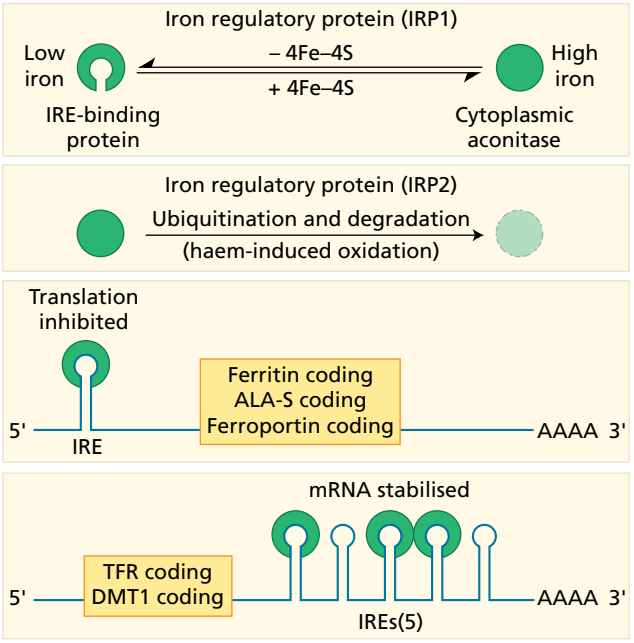

Figure 11.3 Coordinate regulation of expression of ferritin and transferrin receptor: the role of the iron response element (IRE)–iron regulatory protein (IRP) mechanism. When cellular iron levels are low, IRP binds to the IRE stem and loop structures of mRNA to inhibit translation of ferritin, ALA-S2 and ferroportin, but increases translation of transferrin receptors (TFR) and DMT1 by preventing degradation of the mRNA. When iron levels are high, the IRP functions as a cytoplasmic aconitase and no longer binds to the IREs. Ferritin, ALAS2 and ferroportin synthesis can thus proceed, while TFR and DMT1 synthesis is reduced. IRP2 binds to IREs when iron levels are low, but is degraded after ubiquitination (initiated by haem-induced oxidation) when iron levels are high. The IRPs therefore provide two ways of sensing iron requirements, either involving Fe–S proteins or haem proteins.

Normal iron balance

The amount of iron in the body at birth depends on the blood volume and haemoglobin concentration, birth weight (which determines blood volume) being particularly important. Delay in clamping the cord leads to an increased red cell mass by placental transfusion. The level of maternal iron stores has little effect on

Table 11.2 Daily iron losses and requirements.

Group (age, years)	Daily loss Urine, skin, faeces, etc.	Menses (mg)	Requirement for growth (mg)	Total (mg)

fetal iron. The newborn contains about 80 mg/kg at full term. Neonatal iron reserves are utilised for growth and from 6 months to 2 years virtually no iron stores are present. Thereafter, iron stores gradually accumulate during childhood to around 5 mg/kg. In men, there is a further increase between 15 and 30 years to about 10–12 mg/kg (total up to approximately 1 g), whereas iron stores remain lower in women (average 300 mg) until the menopause.

Requirements are higher in menstruating women and during periods of rapid growth in infancy and adolescence (Table 11.2). Menstrual blood loss has a median value of 30 mL, but the 95th centile value is 118 mL per month (equivalent to 1.9 mg iron per day), which has been found to be significantly associated with iron deficiency. Requirements are highest of all in pregnancy, about 3 mg in the second and about 4 mg in the third trimester.

Iron absorption

Iron absorption depends not only on the amount of iron in the diet but also, and more importantly, on the bioavailability of that iron, as well as the body's needs for iron. A normal Western diet provides approximately 15 mg of iron daily. Of that iron, digestion within the gut lumen releases about half in a soluble form, from which about 3 mg may be taken up by mucosal cells and only about 1 mg (or 5–10% of dietary iron) transferred to the portal blood in a healthy man. Iron absorption can thus be influenced at several different stages.

Dietary and luminal factors

Much of dietary iron is non-haem iron derived from cereals (commonly fortified with additional iron in the UK), with a lesser component of haem iron from meat and fish. Even in iron deficiency, the maximum iron absorption from a mixed Western diet is no more than 3–4 mg daily. This figure is much less with the predominantly vegetarian, cereal-based diets of most of the world's population since iron is better absorbed from animal than vegetable sources.

Iron is released from protein complexes by acid and proteolytic enzymes in the stomach and small intestine, and haem is liberated from haemoglobin and myoglobin. Iron is maximally absorbed from the duodenum and less well from

the jejunum, probably because the increasingly alkaline environment leads to the formation of insoluble ferric hydroxide complexes. Acid pH, vitamin C and some low-molecular-weight chelates (e.g. sugars and amino acids) enhance absorption. Therapeutic ferrous iron salts are well absorbed on an empty stomach, but when taken with a meal, absorption is reduced as a result of the same ligand binding processes that affect dietary non-haem iron; phytates, tannates in tea and bran inhibit absorption.

Mucosal factors: molecular aspects of iron absorption and its regulation

A variety of mechanisms for the binding of non-haem iron to the mucosal membrane have been described. Specific, saturable and receptor-mediated mechanisms, and passive diffusion at higher doses, may occur. Iron absorption is regulated both at the stage of mucosal uptake and at the stage of transfer to the blood. The process is illustrated in Figure 11.4. Non-haem iron is released from food as Fe^{3+} and reduced by duodenal cytochrome b_1 (DCytb) to Fe^{2+}. This is transported across the brush border membrane by DMT1, which is upregulated in iron deficiency and by HIF-2α activation in the local hypoxic environment of duodenum. It is assumed that iron enters the labile pool and some may be incorporated into ferritin and lost when the cells are exfoliated. Iron destined for retention by the body is transported across the basolateral membrane by ferroportin before uptake by transferrin as Fe^{3+}. The regulation of duodenal cell iron release by hepcidin through its action on ferroportin is rapid. Hephaestin is a copper-containing ferroxidase expressed predominantly in villous cells of the small intestine that converts Fe^{2+} to Fe^{3+} in the basolateral transfer step of iron absorption.

Haem iron initially bound to an unknown receptor at the brush border membrane is released intracellularly by haem oxygenase before entering the labile iron pool and following a common pathway with iron of non-haem origin.

Microbiota in the gut compete for iron, producing metabolites (as 1,3-diaminopropane and reuterin) that inhibit HIF-2α function in iron deficiency, decreasing iron absorption in mice. However, data in humans are still lacking.

Iron uptake by erythroid cells

About 85% of transferrin iron normally enters developing red cells for incorporation into haemoglobin. This tissue distribution of transferrin-bound iron reflects the expression of transferrin receptors, which are present in high concentration of cells with a high iron requirement. The latter includes any rapidly dividing cells but is normally dominated by the cells of the erythron. A soluble truncated form of the transferrin receptor derived from these cell surfaces is detectable in serum.

Transferrin receptors have the highest affinity for diferric transferrin. The transferrin–receptor complex is taken up by a process of receptor-mediated endocytosis (Figure 11.5). The iron is released at the low pH of the endosome, reduced from Fe^{3+} to Fe^{2+} by STEAP3, a ferrireductase, before the apotransferrin and receptor are recycled to the plasma and the cell membrane, respectively. Iron release from the endosome is via DMT1 (Figure 11.5) and the iron is transported into mitochondria by mitoferrin or enters ferritin. A mitochondrial version of ferritin, which likely protects mitochondria from iron-induced oxidative damage, is elevated in congenital or acquired sideroblastic anaemias. Direct transfer of ferritin from macrophages to erythroblasts (rhopheocytosis) in the erythroblastic islands of the bone marrow may also occur.

Some 80–90% of iron taken into developing erythroblasts is converted to haem within 1 hour. Any iron taken up in excess of the requirement for haem synthesis is incorporated in ferritin (Figure 11.5). Mitochondrial iron is also utilised for the production of iron/sulfur clusters, prosthetic groups essential for enzymes of the haem synthesis in erythroid cells, as ferrochelatase and aminolevulinic acid dehydratase. This important role is clearly

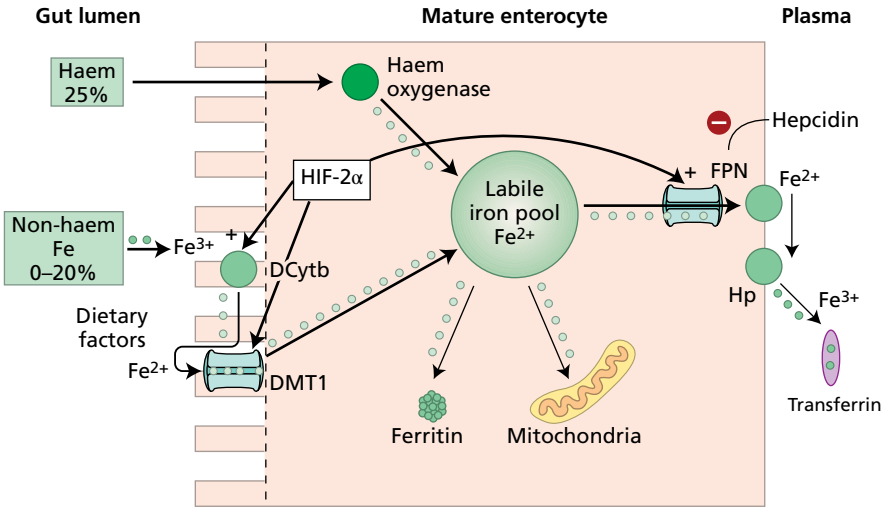

Figure 11.4 Molecular pathways of iron absorption HIF-2α and hepcidin dependent. The area enclosed in the dotted box refers to the uptake of iron from the plasma in the developing enterocyte in the intestinal crypt. Otherwise, the diagram refers to iron absorption by the villous epithelial cell. DCYTB, duodenal cytochrome B; DMT1, divalent metal transporter 1; FPN, ferroportin; Hp, hephaestin. For further details see text and Table 11.1.

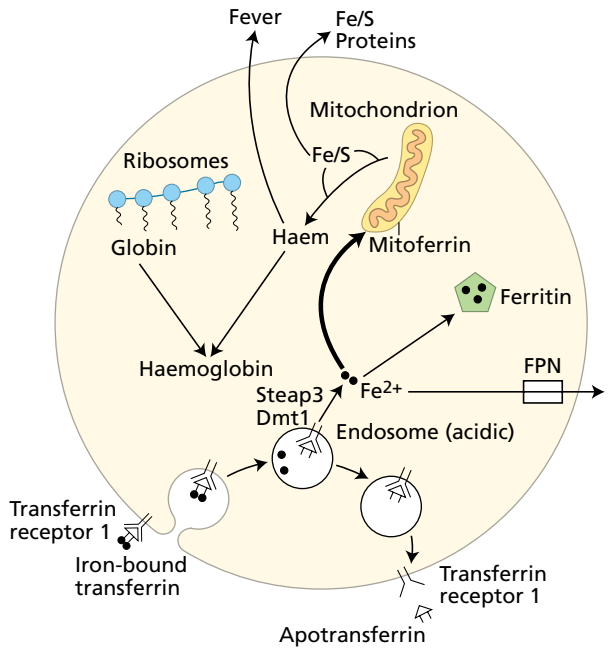

Figure 11.5 Incorporation of iron from plasma transferrin into haemoglobin in developing red cells. Uptake of transferrin iron is by receptor-mediated endocytosis. strengthened by rare forms of sideroblastic anaemia due to mutations of proteins involved in biogenesis of iron–sulfur cluster (see below). The red cell ferritin content is therefore increased when haemoglobin synthesis is impaired, as in thalassaemia where excess iron may be seen in the cytoplasm of mature red cells as one or more siderotic granules. These are composed of haemosiderin, and stain blue with Perls' reaction and purplish blue with Romanowsky stains, when they are called Pappenheimer bodies. The spleen removes these granules by its pitting action. In sideroblastic anaemia, iron is trapped in mitochondria giving origin to ringed sideroblasts (see below) while the cytosol is relatively iron-poor.

Haem synthesis and mitochondrial iron metabolism

Haem consists of a protoporphyrin ring with an iron atom at its centre. Haem is synthesised from the precursors succinyl-CoA and glycine, which condense to form δ-aminolevulinic acid (ALA) under the action of ALAS, with pyridoxal phosphate as a coenzyme. Housekeeping ALAS is ALAS1; in erythroid cells, erythroid-specific ALAS2 predominates. ALA can be utilised for the formation of both purines and haem. Four molecules of porphobilinogen condense under the influence of porphobilinogen deaminase and uroporphyrinogen cosynthase to form the tetrapyrrole ring compound uroporphyrinogen III. The latter is converted to protoporphyrin IX. Finally, iron in the ferrous form is incorporated by the enzyme ferrochelatase. Iron in haem has six coordinating valencies: four links the iron to nitrogen atoms in each pyrrole ring, whereas the remaining two link haem to histidine residues in the globin chain, the distal bond being unstable and easily replaced by oxygen to form oxyhaemoglobin. A haem exporter, group C feline leukaemia virus receptor (FLVCR) (Table 11.1) (Figure 11.5), is present in erythroid cells and rids them of any toxic haem made in excess.

The mitochondria play a major role in haem synthesis as they contain ALAS, coproporphyrinogen oxidase and ferrochelatase, the enzyme sequence from ALA to coproporphyrinogen being situated in the cytoplasm. Besides haem, mitochondria utilise iron in the synthesis of iron–sulfur clusters, prosthetic groups essential for the function of several mitochondrial (respiratory chain complexes, ferrochelatase, aconitase), cytosolic (δ-aminolevulinic acid dehydratase, aconitase) and nuclear proteins (DNA helicase, DNA repair enzymes). A number of porphyrins are formed by side reactions during the synthesis of protoporphyrin. In the porphyrias (see below), many of these compounds accumulate in the major sites of haem synthesis, the liver and the red cells.

The assembly of iron–sulfur clusters is a complex process that requires multiple proteins. The best known is frataxin, a likely iron donor in this pathway. The gene encoding frataxin is mutated in Friedreich ataxia. *ABCB7*, a member of a family of transmembrane proteins characterised by the ABC domain that binds and hydrolyses ATP, transfers iron–sulfur clusters from mitochondria to the cytosol and interacts with other ABC members and ferrochelatase in the haem synthetic pathway. Mutations of *ABCB7* cause an X-linked form of sideroblastic anaemia with ataxia (see below). Other proteins active in the pathway, as glutaredoxin-5 (GLRX5), heat shock protein (HSP)A9 and heat shock cognate protein 20 (HSC20 or HSCB), that facilitate the transfer of nascent 2-iron, 2-sulfur clusters to recipient proteins have been found mutated in rare recessive forms of sideroblastic anaemia. Iron–sulfur cluster convert IRP1 to aconitase to stimulate the citric acid cycle; at the same time, this precludes the IRE binding activity and signals iron sufficiency.

The mitochondria are also the site of the citric acid cycle, which supplies succinate to initiate haem synthesis. The mature red cell, which lacks mitochondria, is therefore unable to synthesise haem. Overall these data confirm the essential role of iron–sulfur clusters for erythropoiesis, highlight the coordination of iron–sulfur clusters and haem synthesis and cell metabolism and the requirement for haem synthesis of an intact Fe/S cluster biogenesis.

Intracellular transit iron and plasma non-transferrin-bound iron

It has been suggested, but not experimentally proved, that there is a transit pool of 'metabolically active' or 'labile' iron within cells, which receives iron from degraded haem or ferritin, exchanges with transferrin and is incorporated into newly synthesised

iron-containing proteins. This iron is considered to be sensed by iron regulatory proteins and available for chelation. Within cells, low-molecular-weight chelates (e.g. citrate) may be present. In iron overload, non-transferrin-bound iron (NTBI) may also exist as oligomeric iron oxide, when transferrin saturation exceeds 50–60%, either free or bound to albumin, and is particularly toxic to organs such as liver and pancreas that uptake NTBI through the cation (Zinc) transporter ZIP14 (*SLC39A14*) (Chapter 12).

Breakdown of haemoglobin and iron recycling

After phagocytosis by macrophages, haem from senescent red cells is broken down by haem oxygenase (HMOX1) to release iron. As ferrous iron, it can then either enter ferritin (where it is oxidised to ferric iron by the ferritin protein) or be released into plasma (via ferroportin), where its binding to transferrin (also as the ferric form) may be facilitated by a plasma ferrous oxidase (e.g. caeruloplasmin). The release of macrophage iron provides most (25 mg/day) of iron for erythropoiesis and is controlled by hepcidin, with high levels, as in inflammation or iron overload, reducing iron release and even causing anaemia. Changes in hepcidin concentration may account for the diurnal rhythm of serum iron concentration, which is highest in the morning and lowest in the evening. A diurnal increase in serum hepcidin at noon and 8 p.m. is observed in healthy volunteers.

Diagnostic methods for investigating iron metabolism

The large amount of iron present as haemoglobin means that the degree of any anaemia must always be considered in assessing iron status. Reduced amounts of haemoglobin accompany an overall reduction in body iron in iron deficiency anaemia or after acute blood loss. In other anaemias, including the anaemia of inflammation and most haemolytic and megaloblastic anaemias, iron is redistributed from the red cells to macrophage iron stores, with a corresponding increase in marrow-stainable iron and serum ferritin. No single measurement is ideal for all clinical circumstances, as all are affected by confounding factors and changes may develop sequentially (as in progressive negative iron balance) or may affect particular body iron compartments. Table 11.3 summarises the changes in measures of iron status accompanying various types of hypochromic anaemia. The assessment of *iron overload* is discussed in Chapter 12.

Serum ferritin

In healthy subjects, the serum ferritin concentration correlates with iron stores. Normal concentrations of serum ferritin range from about 30–300 μg/L and are higher in men (median about 90 μg/L) than in premenopausal women (median 30 μg/L). In neonates, the concentration in cord blood (median approximately 100 μg/L) rises further over the first 2 months of life as fetal haemoglobin is broken down, and thereafter falls to low levels (median 20–30 μg/L) throughout childhood and adolescence.

Serum ferritin concentrations below 15 μg/L are virtually specific for storage iron depletion, but normal values do not exclude this. Values <30 μg/L are accepted as more specific and sensitive cut-off for iron deficiency. On the contrary values above 300 μg/L do not necessarily, or even usually, indicate iron overload. This is because ferritin synthesis is influenced by factors other than iron (in particular, it behaves as an acute-phase reactant in many inflammatory diseases). For this reason, serum ferritin concentrations <100 μg/L may be associated with a lack of storage iron in patients with the anaemia of

Table 11.3 Differential diagnosis of hypochromic anaemia.

IRIDA, iron refractory iron deficiency anaemia; MCH, mean corpuscular haemoglobin; MCV, mean corpuscular volume; N, normal; TFR, transferrin receptor; TIBC, total iron-binding capacity.

inflammation, or anaemia of chronic disease. When serum ferritin is an unreliable indicator of iron deficiency because of concomitant inflammation low transferrin saturation is used as marker of deficiency (see below).

Bone marrow aspiration

Staining the bone marrow for iron gives an indication of stores as well as erythroblast iron (Figure 11.6a). In iron deficiency anaemia, macrophage and erythroblast iron are absent (Figure 11.6b). In the anaemia of chronic diseases/inflammation macrophage iron is present, but erythroblast iron is absent.

Serum iron and iron-binding capacity

The serum iron and, more particularly, the saturation of the total iron-binding capacity of transferrin (TIBC) gives a measure of the iron supply to the tissues. A serum transferrin saturation of less than 15% is insufficient to support normal erythropoiesis. A rise in TIBC is characteristic of iron deficiency. A reduced serum iron concentration with a normal or reduced TIBC is a characteristic response to inflammation (see below). A value <20% is considered an indicator of iron deficiency in inflammation.

Serum transferrin receptors

Plasma concentrations of soluble transferrin receptors (TFRs) reflect both the number of erythroid precursors and iron supply to the bone marrow, TFRs being raised in erythroid hyperplasia and in iron deficiency. In anaemia of inflammation, the assay has been proposed as a valuable indicator of deficiency of body iron stores. Serum TFRs only increase in this situation in the absence of storage iron. The test, however, is not standardised amongst different laboratories and that limits its clinical use.

Red cell protoporphyrin

When iron supply to the erythron is limited, iron incorporation into haem is restricted, leading to accumulation of the immediate precursor, protoporphyrin IX bound to zinc. This is lost only slowly from circulating red cells; concentrations greater than the normal upper limit of 80 µmol/mol haemoglobin, therefore, indicate that a reduction in iron supply has been present over the previous few weeks. Protoporphyrin levels may also increase in patients with sideroblastic anaemias, except those due to *ALAS2* mutations, and in lead poisoning. The test is not uniformly available, but analysers that are portable and easy to operate are useful in large-scale field studies of iron deficiency anaemia as an initial screening test.

(c)

Figure 11.6 (a) A bone marrow showing plentiful iron in macrophages (Perls' stain) with iron granules in erythroblasts (insets). (b) Iron deficiency: bone marrow showing absence of stainable iron (Perls' stain). (c) Iron deficiency: peripheral blood film showing hypochromic microcytic red cells.

Percentage of hypochromic red cells

As iron supply to the erythron diminishes, the new red cells produced are increasingly hypochromic. Assessment of the

haemoglobin content of individual red cells, which is possible using some automated cell counters, allows measurement of the percentage of hypochromic cells. Values rising to above 6% may help in the early identification of impaired iron supply in patients with chronic kidney injury who are receiving treatment with recombinant erythropoietin, when associated inflammatory disease means that other measures of iron status can be misleading. The utility of this assay in other anaemias of inflammation to diagnose a concomitant iron deficiency is under evaluation.

Reticulocyte haemoglobin content

Measurement of the reticulocyte content of haemoglobin is now used as a test of functional iron status. This parameter (CHr or Re–He according to the type of automated counter used) is useful in screening iron status, particularly for the assessment of iron-deficient erythropoiesis, as in dialysis patients treated with erythropoietin. Moreover, CHr may serve as a predictor of the response of anaemia to iron treatment. When response to treatment is positive, an increase in CHr may be discerned within a few days of starting treatment before overall mean corpuscular haemoglobin (MCH) has changed.

Iron deficiency

Iron deficiency may be absolute or functional. Absolute iron deficiency entails a decrease in total body iron including circulating, tissue and stored iron. Functional iron deficiency refers to conditions where circulating iron is low, tissue iron may be decreased, while iron stores are normal or even increased; it is a form of iron sequestration and tissue maldistribution, prevalently related to inflammatory conditions. Functional iron deficiency may occur also in patients treated with erythropoiesis-stimulating agents, where the demand for iron by the expanded erythron may outstrip the ability to mobilise iron from stores. When used without specification iron deficiency refers to absolute iron deficiency.

Absolute iron deficiency

Usually, iron deficiency develops slowly and anaemia is the final outcome of a sequence of events that start with depletion of iron stores, followed by iron-deficient erythropoiesis and culminate with decreased red blood cell production.

When the body is in a state of negative iron balance, the first event is depletion of body stores, which are mobilised for haemoglobin production. Iron absorption is increased when stores are reduced, before anaemia develops and even when the serum iron level is still normal, although the serum ferritin will have already fallen.

With further iron depletion, manifested by a serum ferritin below 15 μg/L and a fall in serum transferrin saturation to less than 15%, iron-deficient erythropoiesis develops with increasing concentrations of serum transferrin receptor and red cell protoporphyrin. At this stage, the haemoglobin, mean corpuscular volume (MCV) and mean corpuscular haemoglobin (MCH) may still be within the reference range, although they may rise significantly when iron therapy is given.

If there is no progression iron deficiency is present without anaemia. Even in these cases, symptoms may occur due to lack of iron for proteins and enzymes in different tissues.

Iron deficiency anaemia

If the negative balance continues, frank iron deficiency anaemia develops. The red cells become obviously microcytic and hypochromic (Figure 11.6c) and poikilocytosis becomes more marked. The MCV and MCH are reduced, and target cells may be present. The reticulocyte count is low for the degree of anaemia. The serum TIBC rises and the serum iron falls, so that the percentage saturation of TIBC is usually less than 10%.

The erythroblasts, devoid of siderotic granules, have a ragged vacuolated cytoplasm and relatively pyknotic nuclei. The bone marrow macrophages show a total absence of iron, except where very rapid blood loss outstrips the ability to mobilise the storage iron. Platelets are frequently increased.

The evaluation of the global anaemia burden in the last 20 years showed that, notwithstanding some recent improvement, iron deficiency remains the top-ranking cause of anaemia worldwide, especially in developing countries, due to a combination of inadequate iron intake and blood loss from hookworm, *Schistosomiasis* infestation and other causes of haemorrhage.

Functional iron deficiency

This condition develops when there is a disproportion between high iron demand and limited supply. Examples are anaemia of inflammation in which iron supply becomes limited and erythropoietin administration when stimulates excessive erythropoiesis.

Anaemia of inflammation

Anaemia of inflammation is the second most frequent anaemia worldwide and the first amongst hospitalised patients. It affects patients with underlying chronic disorders characterised by immune activation including chronic infections, autoimmune disorders, cancer.

The sequence of events in anaemia of inflammation starts with the recruitment of inflammatory cells and the production of cytokines as IL-1beta, IL-6, TNF-alpha and INF-gamma. These molecules reduce erythropoietin production by the kidney and bone marrow response to erythropoietin, increasing myeloid at the expenses of erythroid commitment. IL-6 also stimulates hepcidin transcription, causing a rapid reduction of iron absorption and recycling and iron-restricted erythropoiesis. High hepcidin impairs serum iron and transferrin saturation and causes anaemia in the presence of high ferritin. Decreased

red cell survival is a component of anaemia in acute inflammation associated with macrophage activation.

Although iron deficiency anaemia and anaemia of inflammation are distinct entities, they may frequently coexist in a sort of mixed anaemia, often difficult to diagnose.

Tissue effects of iron deficiency

When iron deficiency is severe and chronic, widespread tissue changes may be present, including koilonychia (ridged or spooned nails, breaking easily), hair thinning, angular stomatitis, glossitis and pharyngeal webs (Paterson–Kelly syndrome). Partial villous atrophy, with minor degrees of malabsorption of xylose and fat, reversible by iron therapy, has been described in infants suffering from iron deficiency, but not in adults. Pica is sometimes present; in some who eat clay or chalk, this may be the cause rather than the result of iron deficiency.

Iron-dependent enzymes in the tissues are usually better preserved than other iron-containing compounds. In severe iron deficiency, however, these enzymes are not inviolate and their levels may fall. This may be partly responsible for the general tissue changes, poor lymphocyte transformation and diminished cell-mediated immunity, and impaired intracellular killing of bacteria by neutrophils.

A particular concern has been the finding that infants with iron deficiency anaemia may have impaired mental development and function and that this deficit may not be completely restored by iron therapy. It remains controversial whether impaired work performance seen in adults results from the anaemia or from depletion of mitochondrial iron-containing enzymes.

Tissue iron deficiency may be present in anaemia of inflammation, due to the reduction of circulating iron. Tissue effects of iron deficiency can occur even in the absence of anaemia as exemplified by chronic heart failure where correction of the deficiency by intravenous iron improves symptoms even in the absence of anaemia (see below). Treatment with intravenous iron in non-anaemic premenopausal women with fatigue and serum ferritin <15 µg/L, significantly improved fatigue compared to a placebo-treated group; however, the same treatment seems not to benefit asymptomatic patients. Thus, in the absence of anaemia, it is suggested to treat symptomatic iron deficiency while carefully monitoring asymptomatic patients. In all cases, a cause should be sought.

Causes of absolute iron deficiency

The main causes of absolute iron deficiency are summarised in Table 11.4.

Table 11.4 Causes of absolute iron deficiency.

Dietary
Especially vegetarian diet
Malabsorption
Gluten-induced enteropathy (child or adult), gastrectomy, duodenal bypass, atrophic gastritis, IBD, clay eating, etc.
Blood loss
Uterine: menorrhagia, postmenopausal bleeding, parturition
Gastrointestinal: oesophageal varices, hiatus hernia, *Helicobacter pylori*, peptic ulcer, aspirin ingestion, hookworm, schistosomiasis, hereditary telangiectasia, carcinoma of the stomach, caecum or colon, ulcerative colitis, angiodysplasia, Meckel diverticulum, diverticulosis, haemorrhoids, etc.
Renal tract: haematuria (e.g. renal or bladder lesion), haemoglobinuria (e.g. paroxysmal nocturnal haemoglobinuria, mechanical haemolyis)
Pulmonary tract: overt haemoptysis, idiopathic pulmonary haemosiderosis
Widespread bleeding disorders
Frequent blood donors
Self-inflicted (Munchausen syndrome)
Genetic
Iron refractory iron deficiency anaemia (IRIDA)

Diet

Defective intake of iron is rarely the sole or major cause of iron deficiency in adults in Western communities. It takes more than 4 years for an adult male to develop iron deficiency anaemia on a diet completely devoid of iron. The diet may contain insufficient or poorly available iron as a result of poverty, religious tenets or food faddism. Iron deficiency is more likely to develop in subjects taking a largely vegetarian diet – the majority of the world's population – and who also have increased physiological demands for iron.

Increased physiological iron requirements

Iron deficiency is common in infancy, when demands for growth may be greater than dietary supplies. It is aggravated by prematurity, infections and delay in mixed feeding. Young children (<5 years) in low and middle-income areas are the age group most affected, with little variation in prevalence of anaemia over the last 20 years, according to a recent large study. Iron deficiency is also frequent in adolescence and in females (Table 11.2). The gender gap in iron deficiency anaemia has widened in recent years on a worldwide basis. Pregnancy also favours iron deficiency. The fetus acquires about 280 mg of iron and a further 400–500 mg is required for the temporary expansion of maternal red cell mass. Another 200 mg of iron is lost with the placenta and with bleeding at delivery. Although iron absorption increases throughout pregnancy and increased requirements are partly offset by amenorrhoea, this may not be sufficient to meet the resultant net maternal outlay of over 600 mg iron. Routine iron prophylaxis is not recommended in pregnancy in the UK, but is given for

anaemia (haemoglobin <110 g/L in first trimester, <105 g/L in second or third trimesters and <100 g/L postpartum).

Blood loss

Blood loss is the most common cause of iron deficiency in adults. A loss of more than about 6–8 mL of blood (3–4 mg iron) daily becomes of importance, as this equals the maximum amount of iron that can be absorbed from a normal diet. The loss is usually from the genital tract in women or from the gastrointestinal tract in either sex. The most common cause on a worldwide basis is infestation with hookworm, in which anaemia is related to the degree of infestation. Another important cause in developing countries that can affect any age is schistosomiasis, infection by *Schistosoma (S.) mansoni* causing bleeding from the gut and *S. haematobium* from the bladder, although in both cases anaemia of inflammation may coexist with iron deficiency. In the UK, menorrhagia, haemorrhoids and peptic ulceration are common, as well as gastric bleeding because of salicylates or other non-steroidal anti-inflammatory drugs, hiatus hernia, colonic diverticulosis and cancer (Table 11.4). Haemodialysis results in loss of 4–8 mg iron daily. Investigation often involves, particularly in older subjects, occult blood tests, upper and lower gastrointestinal endoscopy or computed tomography pneumocolon and if these are negative capsule endoscopy. Serum tumour markers CEA and Ca19-9, helpful in monitoring colon cancer when increased, are less useful for screening since normal values do not exclude the possibility of colon cancer being present.

Some unusual causes of blood loss also deserve mention. Cow's milk intolerance in infants may lead to gastrointestinal haemorrhage. Self-induced haemorrhage may occur as an unusual form of Munchausen syndrome. Chronic intravascular haemolysis, such as that in paroxysmal nocturnal haemoglobinuria or mechanical haemolytic anaemia, may be a serious source of urinary iron loss.

Malabsorption

Malabsorption may be the primary cause of iron deficiency, or it may prevent the body from adjusting to iron deficiency from other causes. Dietary iron is poorly absorbed in gluten-induced enteropathy, in both children and adults. Gluten-induced enteropathy is encountered in about 5% of patients presenting with unexplained iron deficiency anaemia and, conversely, about 50% of patients with newly diagnosed coeliac disease have coexistent iron deficiency anaemia. Patients with this disease often show decreased or no response to oral therapy with inorganic iron.

Helicobacter pylori gastritis appears to be a common cause of iron deficiency, responding favourably to eradication with triple therapy. *H. pylori* gastritis inhibits gastric hydrochloric acid secretion, interfering with the solubilisation and absorption of inorganic food iron, but it is also possible that gastrointestinal blood loss plays a significant role in the causation of the iron deficiency. Achlorhydria associated with autoimmune gastritis, an entity that may progress to pernicious anaemia, is an important cause of iron malabsorption due to impaired food iron solubilisation. It is encountered in about 20% of patients with unexplained or refractory iron deficiency anaemia, mostly women of fertile age in whom achlorhydria aggravates the consequences of menstrual blood loss. In inflammatory bowel diseases iron deficiency may coexist with anaemia of inflammation.

Genetic iron deficiency

Homozygous or doubly heterozygous mutations of matriptase-2 are a cause of iron refractory iron deficiency anaemia (IRIDA). The mutations may affect different conserved domains of the protein, including the trypsin-like serine protease domain. The patients show a microcytic hypochromic anaemia due to inappropriately high hepcidin levels and low serum iron and percentage saturation of iron-binding capacity. The patients absorb iron poorly and are refractory to oral iron therapy but are partially responsive to parenteral iron. In IRIDA serum hepcidin (high) is discrepant with transferrin saturation (low); the TSAT/hepcidin ratio is a proposed tool to help with diagnosis.

Iron deficiency in clinics is often multifactorial. Examples are reduced intake of bioavailable iron and blood loss as in low-income countries or vegetarians and vegan or malabsorption and blood loss.

Causes of anaemia of inflammation

Anaemia of inflammation is mainly associated with chronic infectious or autoimmune diseases, advanced cancer, chronic kidney disease (CKD), congestive heart failure and a proportion of cases of anaemia in the elderly. The cytokine effect is common to all types, while some features may characterise specific forms, as erythropoietin deficiency in CKD or cardiomyocyte iron deficiency in congestive heart failure.

Anaemia of inflammation is more and more recognised in disorders with subtle, even subclinical inflammation as obesity, diabetes and other metabolic conditions, as outlined in Table 11.5.

Features of the anaemia of inflammation

The anaemia of inflammation is heterogeneous and multifactorial according to the underlying disorder. Common aspects are a moderate degree of anaemia, (Hb around 80–100 g/L), hypoferraemia, and hyperferritinaemia. Red cells are normocytic and normochromic, unless the degree of anaemia is severe; in these cases, anaemia is microcytic often associated with true iron deficiency. In patients with acute, severe inflammation evidence of haemolysis may be present.

Table 11.5 Causes of functional iron deficiency, anaemia of inflammation or mixed anaemia.

Condition	Details
Infections	Bacterial, viral (including COVID-19), parasitic, fungal
Autoimmune disorders	Rheumatoid arthritis, SLE, autoimmune vasculitis, etc.
Inflammatory bowel diseases	During flare-ups
Chronic kidney disease (CKD)	End-stage dialysis patients
Advanced cancer	GI tract cancer, lymphoma, myeloma
Critically ill patients	Intensive Care Unit patients
Chronic heart failure	Subclinical inflammation
Chronic obstructive pulmonary disease	Especially during exacerbations
Obesity	Subclinical inflammation
Anaemia of the elderly	Part (1/3) of cases
ESA treatment	CKD, MDS, cancer

CKD, chronic kidney disease; ESA, erythropoiesis-stimulating agents; GI, gastrointestinal; MDS, myelodysplastic syndrome; SLE, systemic lupus erythematosus.

The iron restriction induced by cytokines may worsen in chronic disorders for several reasons such as anorexia, malnutrition, decreased absorptive mucosa, blood loss, side effects of drugs such as antithrombotic or proton pump inhibitors, age and comorbidities. Examples of mixed anaemia are the already mentioned *Schistosoma* infections in low-income countries and inflammatory bowel disease, whose components are inflammation and blood loss, especially during acute flares. Iron deficiency in congestive heart failure is due to malabsorption and blood loss often due to drug side effects. CKD patients under dialysis have significant blood loss and insufficient erythropoietin production associated with increased hepcidin.

Mild forms of iron deficiency and mixed anaemia are present in severly obese patients, before and after bariatric surgery. Athletes, especially endurance athletes, and mainly females, may present with iron deficiency caused by concomitant conditions, insufficient iron absorption, training, inflammation, gastrointestinal bleeding and iron loss in sweat during competitions.

Management of iron deficiency

Management of absolute iron deficiency entails: (i) identification and treatment of the underlying cause and (ii) correction of the deficiency by therapy. Iron deficiency is commonly due to blood loss and, wherever possible, the site of this must be identified and the lesion treated. Functional iron deficiency usually reverts with successful treatment of the underlying disorder. When not, and especially in cancer, erythropoietin or iron may be options.

Oral iron therapy

In most patients with absolute iron deficiency, body stores of iron can be restored by oral iron therapy based on ferrous iron salts; ferrous sulfate, being the cheapest, is usually the drug of first choice: 200 mg of ferrous sulfate contains 67 mg of iron, 300 mg of ferrous gluconate provides 36 mg of iron. Liquid iron preparations are available for infants and children.

Traditional therapy suggested high dose (100–200 mg/day) elementary iron to overcome the limited absorption and administration in refracted (2–3) doses. Reevaluation of this therapeutic approach has shown that hepcidin increases after each iron dose, suggesting that changing from daily to alternate-day schedules and from divided to single morning doses increases the efficacy and reduces side effects of oral treatment. In iron deficiency without or with mild anaemia low dose (60–120 mg) iron salts in the morning of alternate day may be considered an effective treatment. In severe anaemia, higher and daily doses restore haemoglobin faster.

Oral therapy may cause gastrointestinal side effects due to local iron toxicity of non-absorbed iron. Nausea, epigastric pain, diarrhoea and constipation are dose-related and can usually be ameliorated by reducing the dose or taking the iron with food, but this also reduces the amount absorbed. Enteric-coated and sustained-release preparations should not be used, as much of the iron is carried past the duodenum to sites of poor absorption. Iron reduces absorption of tetracyclines (and vice versa) and of ciprofloxacin.

The minimum rate of response should be a 20 g/L rise in haemoglobin every 3 weeks, and the usual rate is 1.5–2.0 g/L daily. This will be slower when the dose tolerated is less than 100 mg/day, but this is seldom of clinical importance. It is usually necessary to give iron for 3–6 months to correct the deficit of iron in circulating haemoglobin and in stores (shown by a rise in serum ferritin to normal).

Failure to respond to oral iron is most commonly due to the patient not taking the medication, although there may be continued haemorrhage or malabsorption. Refractoriness to oral iron is defined as <10 g/L haemoglobin increase after 4 weeks of treatment. In non-responding patients, it is important to reassess the diagnosis to exclude other causes of microcytic anaemia and iron-loading anaemias (see Chapter 14).

A poor response is usually observed in case of anaemia other than iron deficiency anaemia. In anaemia of inflammation, oral iron has limited role since when levels of serum hepcidin are high intestinal iron absorption is strongly reduced.

Oral iron may be used for prevention in areas where iron deficiency anaemia is endemic. Protocols suggested by WHO

are available: for example, low dose oral (30–60 mg elemental iron) twice a week for 3 months/year. Iron supplementation in children in areas endemic for malaria may worsen the infection, especially cerebral malaria, and should be associated with malarial treatment.

Parenteral iron therapy

This is indicated in subjects who genuinely cannot tolerate oral iron, particularly if gastrointestinal disease, such as inflammatory bowel disease, is present. It is also necessary for gluten-induced enteropathy and when it is essential to replenish body stores rapidly (e.g. where severe iron deficiency anaemia is first diagnosed in the second-third trimester of pregnancy) or when oral iron cannot keep pace with continuing haemorrhage (e.g. in patients with hereditary haemorrhagic telangiectasia).

When iron is used in functional iron deficiency or in mixed anaemia, parenteral preparations may be indicated because high levels of hepcidin cause refractoriness to oral therapy. Patients with chronic kidney disease who are being treated with recombinant erythropoietin also require parenteral iron therapy. Increased red cell loss at dialysis contributes to iron needs and oral iron therapy is usually inadequate to prevent an impaired response to erythropoietin. High hepcidin levels because of reduced clearance and inflammation contribute to erythropoietin resistance in renal failure. This occurs in other chronic inflammatory conditions: for example, the anaemia of cancer when treated with erythropoietin requires parenteral iron as well. Intravenous iron is indicated in flare-ups of inflammatory bowel diseases to avoid further intestinal mucosal damage by non-absorbed oral iron. Intravenous iron has been shown to improve functional capacity and quality of life in patients with congestive heart failure and iron deficiency, even in the absence of anaemia.

From all parenteral preparations, the iron complex is taken up by macrophages, from which iron is released to circulating transferrin, which then transports it to the marrow. High-molecular weight iron dextran has been abandoned because of potentially severe side-effects, including anaphylaxis. An iron–sucrose complex, Venofer, is given by intravenous infusion to a maximum of 200 mg in 1–2 hours and not repeated in less than 48 hours. The deficit in body iron should be calculated from the degree of anaemia; it is usually 1–2 g. In patients receiving erythropoietin treatment in chronic kidney disease, smaller intravenous doses of Venofer (25–150 mg/week) may be used, with regular monitoring of serum ferritin to avoid iron overload. Other compounds can provide all necessary iron (up to 1000 mg) in one infusion. Amongst these low-molecular-weight iron dextran, available in the UK as Cosmofer ferric derisomaltose (once isomaltoside) 1000 and ferricarboximaltose (Ferrinject), a macromolecular iron(III)-hydroxide carbohydrate complex (molecular weight approximately 150 kDa). The latter can be administered as slow infusion (maximum single dose 1000 mg over 15 min). These compounds have an improved safety profile and may be indicated in selected patients who have limited hospital access, when is urgent to restore haemoglobin, as in pregnancy, or to replete the exhausted stores. Headache, flushing, nausea, skin rashes, urticaria, shivering, general aches and pains, dyspnoea and syncope remain possible immediate adverse effects of intravenous iron. Delayed reactions including arthralgia, fever and lymphadenopathy can persist for several days and are treated with paracetamol. Administration by trained personnel and adherence to protocols to recognise and promptly manage reactions are advised.

Other rare anaemias due to alterations in iron metabolism are discussed in Chapter 12 since these are usually associated with iron overload.

Pathological alterations in haem synthesis

Porphyrias

These are a group of inherited or acquired diseases, each characterised by a partial defect in one of the enzymes of haem synthesis (Chapter 3) that may present as acute or chronic diseases. Increased amounts of the intermediates of haem synthesis accumulate, the disorders being classified by whether the effects are predominantly in the liver or the erythron (Table 11.6). A full discussion of these disorders is beyond the scope of this chapter, but those with a particular haematological overlap are mentioned briefly.

Congenital erythropoietic porphyria

This is a very rare autosomal recessive disorder that is due to reduced uroporphyrinogen III synthase activity. Most patients are compound heterozygotes for mutations in the uroporphyrinogen III synthase gene. In rare cases, a germline mutation of the X-linked erythroid-specific transcription factor GATA1 has been described. In uroporphyrinogen III synthase deficiency, large amounts of porphyrinogens accumulate, and their conversion by spontaneous oxidation to photoactive porphyrins leads to severe, and disfiguring, cutaneous photosensitivity and dermatitis, as well as a haemolytic anaemia with splenomegaly. Increased amounts of uroporphyrin and coproporphyrin, mainly type I, are found in bone marrow, red cells, plasma, urine and faeces. The age of onset and clinical severity of the disease are highly variable, ranging from non-immune hydrops fetalis to a later onset in which there are only cutaneous lesions. Treatment, including avoidance of sunlight and splenectomy to improve red cell survival, is only partially effective. High-level blood transfusions to suppress erythropoiesis (combined with iron chelation therapy) have been used to reduce porphyrin production sufficiently to abolish the clinical symptoms. Allogeneic bone marrow transplantation is indicated in severe cases.

Table 11.6 Human porphyrias.

Form	Inheritance	Enzyme defect	Clinical features*
Hepatic			
Acute intermittent porphyria	Autosomal dominant	Porphobilinogen deaminase	A
Hereditary coproporphyria	Autosomal dominant	Coproporphyrinogen oxidase	A + P
Porphyria variegate	Autosomal dominant	Protoporphyrinogen oxidase	A + P
Porphyria cutanea tarda	Acquired or (rare) autosomal dominant	Uroporphyrinogen decarboxylase	P
Erythropoietic			
Congenital erythropoietic porphyria	Autosomal recessive	Uroporphyrinogen cosynthase	P
Erythropoietic protoporphyria	Autosomal dominant	Ferrochelatase	P
X-linked protoporphyria		Rarely ALAS2	

* Acute attacks (A) of the gastrointestinal and/or nervous system are related to the accumulation of porphyrin precursors (δ-aminolevulinic acid and porphobilinogen). Photosensitive skin lesions (P) are seen when the level of the enzyme defect in the haem synthetic pathway leads to the accumulation of formed porphyrins.

Erythropoietic protoporphyria

This is the most common erythropoietic porphyria and is usually caused by an autosomal dominant inherited deficiency of ferrochelatase, which results in increased free (not Zn-linked) protoporphyrin concentrations in bone marrow, red cells, plasma and bile. Bone marrow reticulocytes are the primary source of the excess protoporphyrin. This leaks from cells and is excreted in the bile and faeces. In >90% of patients, EPP results from coinheritance of a rare pathogenic variant in trans of a common hypomorphic variant c.315-48T>C (minor allele frequency 0.05). The onset of the disease is usually in childhood.

Expression of ferrochelatase is variable, and photosensitivity and dermatitis range from mild or absent to moderate in degree. The disease often remains undiagnosed. There is little haemolysis, but mild hypochromic anaemia may occur, and accumulation of protoporphyrins can occasionally lead to severe liver disease. Treatment is by the avoidance of sunlight; β-carotene may also diminish photosensitivity. Iron deficiency should be avoided as this may increase the amount of free protoporphyrin.

Rare patients with a variant, X-linked erythropoietic protoporphyria, have a gain-of-function mutation of *ALAS2*, usually responsible for X-linked sideroblastic anaemia (see below). Truncations of *ALAS2* C-terminal inhibitory domain lead to erythropoietic protoporphyria because upregulated *ALAS2* activity causes excessive protoporphyrin IX production.

Porphyria cutanea tarda

This is the most common of the hepatic porphyrias and occurs worldwide. The incidence in the UK has been estimated at 2–5 per million. 'Sporadic' porphyria cutanea tarda (PCT) accounts for about 75% of cases. The underlying metabolic abnormality is decreased activity of uroporphyrinogen decarboxylase (UROD) in the liver. Familial PCT accounts for about 25% of cases and is either an autosomal dominant disorder caused by mutations in the *UROD* gene or in few cases result from unknown inherited defects that affect hepatic UROD activity. There is a marked increase in porphyrins in liver, plasma, urine and faeces. The disease is characterised by photosensitivity and dermatitis. It is precipitated in middle or later life, more often in men than women, by factors such as liver disease, alcohol excess, hepatitis C or HIV infection, smoking or oestrogen therapy. A modest increase in liver iron is a common feature. Susceptibility to develop hepatocellular carcinoma is reported.

Either the homozygous or heterozygous presence of the C282Y and H63D mutations in the *HFE* gene (Chapter 12) may predispose to the development of PCT. Prevalence of the C282Y mutation is increased in both sporadic and familial PCT. In the UK, only homozygosity for C282Y (found in about 25% of patients) is significantly more common than in the general population (0.7%). In southern Europe, where C282Y is much less common, the H63D mutation is associated with PCT. Iron is known to inhibit UROD. Removal of the iron by repeated phlebotomy is standard treatment, usually leading to remission. Iron chelation is used when phlebotomy is contraindicated. Sun exposure should be avoided. Antimalarial agents, as chloroquine or hydroxychloroquine, have some effects on skin lesions, although the mechanism is unclear.

Homozygosity or compound heterozygosity for *UROD* mutations causes hepatoerythropoietic porphyria with early onset of both erythroid and cutaneous manifestations, similar to congenital erythropoietic porphyria.

Lead poisoning

Chronic ingestion of lead in humans causes an anaemia that is usually normochromic or slightly hypochromic. Red cell lifespan is shortened and there is a mild increase in reticulocytes, but jaundice is rare. Basophilic stippling is a characteristic, though not universal, finding and it is thought to be due to precipitation of RNA, resulting from inhibition of the enzyme pyrimidine 5′-nucleotidase. Siderotic granules, and occasionally Cabot rings, are found in circulating red cells. The bone marrow shows increased sideroblasts, in some patients with ring sideroblasts. Red cell protoporphyrin and coproporphyrin are raised, as is urinary excretion of ALA, coproporphyrin III and uroporphyrin I.

The cause of the anaemia appears to be multifactorial. Haemolysis, probably due to the blocking of sulfydryl groups with consequent denaturation of structural proteins, and damage to mitochondria, with defective haemoglobin production due to inhibition of the enzymes of haem synthesis are the major factors.

Sideroblastic anaemia

The sideroblastic anaemias comprise a group of refractory anaemias (Table 11.7) in which there are variable numbers of hypochromic cells in the peripheral blood, with an excess of iron in the bone marrow; at least 15% of the developing erythroblasts in the primary forms of anaemia contain iron granules arranged in a ring around the nucleus (Figure 11.7). These ring sideroblasts (more than four perinuclear granules per cell and covering one-third or more of the nuclear circumference) are the diagnostic feature of the anaemia. Ring sideroblasts may comprise a small (<15%) population of the erythroblasts in a wide variety of clinical disorders. SA can be inherited or acquired (Table 11.7).

Table 11.7 Classification of sideroblastic anaemias.

Hereditary non syndromic	Inheritance	Anaemia type
ALAS2 mutations	X-linked	Microcytic
Mitochondrial glycine importer *(SLC25A38)* mutations	Recessive	Microcytic
ABCB7 (mitochondrial ATP-binding cassette) mutations; spinocerebellar ataxia	X-linked	Microcytic
Glutaredoxin-5 (*GLRX5)* mutations	Recessive	Microcytic
Heat shock protein (HSPA9) deficiency	Recessive	Normo/microcytic
Heat shock cognate protein (HSC20) deficiency	Recessive	Normocytic
Hereditary syndromic		
NDUFB11 (subunit of respiratory complex I) mutations	X-linked	Normocytic
MLASA I pseudouridine synthase-1 *(PUS1)* mutations; mitochondrial myopathy	Recessive	Normo/macrocytic
MLASA II *YARS2* mutations, mitochondrial myopathy	Recessive	
THTR-1 (*SLC19A2*) mutations, DIDMOAD syndrome, Thiamine responsive	Recessive	Macrocytic
tRNA-nucleotidyltransferase1(*TRNT1)* mutations; with SIFD: immunodeficiency, periodic fever and developmental delay	Recessive	Microcytic

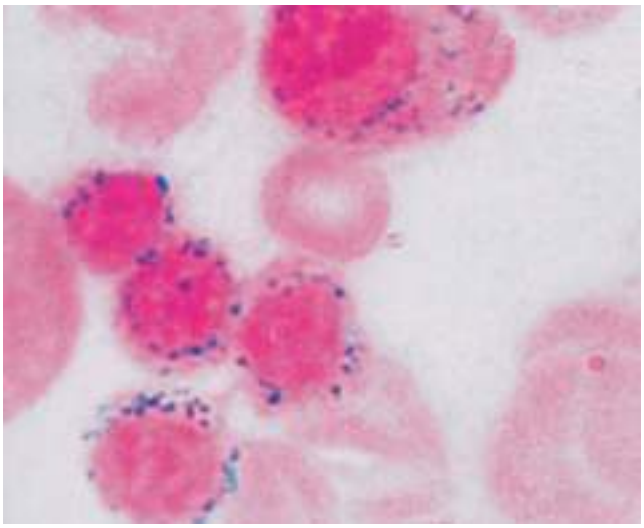

Figure 11.7 Sideroblastic anaemia. Erythroblasts showing perinuclear (mitochondrial) rings of iron (Perls' stain).

Inherited sideroblastic anaemias

These are rare disorders manifesting usually in childhood or adolescence, but occasionally presenting late in life, when they need to be distinguished from the more common acquired form termed 'refractory anaemia with ring sideroblasts'. Inherited sideroblastic anaemias may show exclusively anaemia as the main symptom or present within a syndrome that includes anaemia in the context of other non-haematologic manifestations (syndromic sideroblastic anaemia) (Table 11.7). This is because they may affect proteins relevant only in erythropoiesis or in several other tissues because are proteins of mitochondrial translation, or a component of the mitochondrial respiratory chain. A detailed discussion of syndromic forms is beyond the scope of this chapter; their haematologic features are mentioned.

Defective haem synthesis

X-linked sideroblastic anaemia (*ALAS2* mutations)

In most reported families, inheritance follows an X-linked pattern. More than 100 different mutations of the gene for erythroid-specific *ALAS2* have been identified. All have been single-base substitutions, mostly missense mutations, that lead to changes in protein structure, causing instability or loss of function. They are found scattered over the exons encoding the catalytically active domain of the protein. Mutations affecting the promoter have also been shown to cause disease. Function may be rescued to a variable degree by administration of pyridoxal phosphate (the essential cofactor for *ALAS2*), the best responses occurring when the mutation affects the pyridoxal phosphate-binding domain of the enzyme. The response is better if iron overload is reduced by phlebotomy or chelation.

Female carriers of X-linked sideroblastic anaemia may show partial haematological expression, usually with only mild or no anaemia, although rarely a severe dimorphic anaemia occurs. This may depend on variation in the severity of the defect, as well as the degree of lyonisation of the affected X chromosome. Late-onset in some patients is observed since the degree of lyonisation increases with age. Iron loading may also aggravate the defect in haem synthesis in both males and females with sideroblastic anaemia.

Patients with X-linked sideroblastic anaemia show a hypochromic, often microcytic, anaemia. There may be a few circulating siderocytes, normoblasts and cells with punctate basophilia, but these features become pronounced only if the spleen has been removed. The bone marrow shows erythroid hyperplasia and the erythroblasts tend to be microcytic with a vacuolated cytoplasm. Ring sideroblasts account for more than 15% of erythroblasts. The ineffective erythropoiesis is not usually accompanied by bone deformities, but some bossing of the skull and enlargement of the facial bones may result from the erythroid expansion. The spleen may be enlarged. Patients may present with severe iron overload even when the anaemia is relatively mild, but the rate of iron loading is accelerated if red cell transfusions are needed. Iron loading, however, aggravates anaemia, while iron reduction improves this.

A form of X-linked sideroblastic anaemia is seen due to mutations in the ATP-binding cassette transporter gene (*ABCB7*). It also causes early-onset, non-progressive cerebellar ataxia. The anaemia is mild to moderately severe. The enzyme deficiency induces disruption in the maturation/export of iron–sulfur clusters to cytosol. The ataxia may be due to iron damage to mitochondria in neural cells.

Mutations of mitochondrial glycine importer (*SLC25A38*)

This is the second most frequent form of sideroblastic anaemia. The mitochondrial Solute Carrier Family 25 Member 38 carrier (*SLC25A38)* encodes an erythroid-specific transporter involved in glycine import from cytosol to the mitochondria, an essential step in synthesis of ALA. Mutations in congenital sideroblastic anaemia are described in >50 families from different ethnic groups with recessive inheritance. The degree of anaemia, which is microcytic and hypochromic, is usually severe since infancy and transfusion-dependent. Some patients have been cured by allogeneic bone marrow transplantation.

Mutations of proteins of the iron–sulfur cluster biogenesis

Glutaredoxin 5 *(GLRX5)* participates in iron–sulfur cluster mitochondrial trafficking. A few families worldwide have been described with autosomal recessive hypochromic microcytic anaemia with ring sideroblasts with inherited mutations of the enzyme. Other rare forms of sideroblastic anaemia are due to mutations of proteins of iron–sulfur cluster pathway, as heat

shock protein (HSP)A9 or heat shock cognate protein 20 (HSC20) that with *GLRX5* facilitate the transport of nascent 2-iron/2sulfur clusters to recipient mitochondria proteins. The common molecular pathogenic mechanism is the reduction of iron–sulfur cluster for ferrochelatase and other enzymes of haem biosynthesis, which underline how the two pathways of iron utilisation by mitochondria are interconnected.

Syndromic forms of sideroblastic anaemia

These forms are due to defective proteins relevant in mitochondrial translation or respiratory chain function. Patients present multiple and variable phenotypes since infancy, usually severe and in some cases even lethal. The main forms are described here.

Associated with mitochondrial myopathy

Mitochondrial myopathy, lactic acidosis and sideroblastic anaemia (MLASA) result from a homozygous mutation in the nuclear-encoded gene for pseudouridine synthase. As in Pearson syndrome (see mitochondrial DNA mutations), there are defects of the mitochondrial electron transport chain affecting reduced access to ferrochelatase. Mutations affecting the pseudouridylate synthase 1 (*PUS1*) gene cause deficient pseudouridylation of mitochondrial tRNAs. Mutations of the *YARS2* gene product, mitochondrial tyrosyl-tRNA synthetase may cause the same MLASA phenotype through respiratory chain dysfunction.

Associated with immunodeficiency

A syndromic form of recessive sideroblastic anaemia leads to immunodeficiency, periodic fevers, and developmental delay (SIFD); it is caused by mutations in transfer RNAs (tRNA)-nucleotidyltransferase 1 (*TRNT1*), the gene encoding the enzyme adding the nucleotide sequence CCA to the 3′ end of tRNA, essential for maturation of both nuclear and mitochondrial tRNAs.

Associated with megaloblastic anaemia

Abnormalities of *SLC19A2* gene encoding a putative thiamine transporter (THTR-1) are responsible for thiamine-responsive megaloblastic anaemia (Roger syndrome). This syndrome, inherited in an autosomal recessive manner, may also combine diabetes insipidus, diabetes mellitus, optic atrophy and deafness (DIDMOAD), which respond in varying degrees to pharmacological doses of thiamine (vitamin B_1). Ring sideroblasts in varying numbers are typically present and onset is usually in childhood, although some symptoms may be present in infancy. A direct link between the presence of the mutation and mitochondrial iron loading has yet to be demonstrated. High doses of thiamine (vitamin B1; 25–75 mg per day) are administered to alleviate anaemia and possibly improve diabetes control.

Defective mitochondria respiratory chain

A rare form is due to NADH ubiquinone oxidoreductase subunit B11 (*NDUFB11)* mutations. The gene encodes a component of the mitochondrial complex 1 of the respiratory chain. A recurrent mutation is responsible for variably syndromic, normocytic normochromic sideroblastic anaemia. Hemizygosity for a null mutation is likely lethal. The partial inactivation of a recurring mutation causes a mitochondrial respiratory phenotype such as lactic acidosis and myopathy, which will distinguish this disorder from other CSAs.

Deletions of mitochondrial DNA, sometimes associated with duplications, are known to be the cause of the Pearson marrow–pancreas syndrome, typically consisting of sideroblastic anaemia, pancreatic exocrine dysfunction and lactic acidosis. This is a severe disorder of early onset, presenting usually with failure to thrive, persistent diarrhoea and lactic acidosis. All haemopoietic cell lineages can be affected, and the anaemia is typically macrocytic with prominent vacuoles in cells of both myeloid and erythroid lineages.

Mitochondrial DNA encodes mitochondrial tRNA and ribosomal RNA as well as several mitochondrial proteins. In Pearson syndrome, deletions may encompass tRNA as well as mitochondrial genes and therefore have an effect on the function of all mitochondrion-encoded proteins, causing considerable loss of mitochondrial function. The presence of many different mitochondria within nucleated cells enables the coexistence of normal and abnormal species, the proportion of which is likely to vary within different tissues, a phenomenon known as *heteroplasmy*. The extent to which different tissues are affected depends to some extent on this proportion and detection often requires the study of different tissues. Inheritance is difficult to determine for the same reason and most cases are described as of 'sporadic' occurrence. There is no specific treatment.

There are still a limited number of cases of inherited sideroblastic anaemia in which the exact underlying genetic defect remains obscure, with variable inheritance and often a macrocytic or dimorphic picture.

Acquired sideroblastic anaemia

Refractory anaemia with ring sideroblasts

This is a form of myelodysplasia and arises as a clonal disorder of haematopoiesis (see also Chapter 35). According to the last nomenclature, it is classified as a low-risk myelodysplsia with ring sideroblasts (MDS-RS) with uni-lineage or multi-lineage involvement. The anaemia is often macrocytic with raised red cell protoporphyrin concentrations, in contrast to X-linked sideroblastic anaemia. Marked erythroid hyperplasia may be present, together with increased iron stores. In these low-risk patients, transformation to acute myeloid leukaemia appears less than in other myelodysplastic disorders. Somatic mutations

may be present as in other clonal forms; mutations of the spliceosome *SF3B1* gene have been found in more than 90% of patients with refractory anaemia with ring sideroblasts (once called RARS) and allow diagnosis by molecular testing (Chapter 34). Smaller numbers (<15%) of ring sideroblasts may be present in patients with any of the other myelodysplastic and myeloproliferative diseases. Acquired defects of mitochondrial DNA may underlie iron transport abnormalities in refractory anaemia with ring sideroblasts.

Secondary sideroblastic anaemias

Sideroblastic anaemia may be found as a complication of antituberculous chemotherapy, particularly with isoniazid and cicloserine (pyridoxine antagonists). Sideroblastic anaemia occurs in alcohol use disorder if there is associated malnutrition and folate deficiency. Suggested mechanisms include interference with haem formation and pyridoxine metabolism. The anaemia rapidly reverses with abstinence from alcohol, a normal diet and pyridoxine therapy. Chloramphenicol inhibits mitochondrial protein synthesis and, in some patients, causes ring sideroblast formation, presumably as a result of impaired haem formation in the mitochondria. Lead inhibits several enzymes involved in haem synthesis and may damage structural mitochondrial proteins. In some cases, ring sideroblasts are visible in the marrow. Ring sideroblasts may also occur in erythropoietic porphyrias and have been rarely documented in severe iron-loaded beta-thalassaemia.

Treatment

A proportion of patients with X-linked sideroblastic anaemia respond to pyridoxine, given initially in doses of 100–200 mg daily. The response is usually partial. Patients may require only small doses (less than 10 mg daily) to maintain a higher haemoglobin concentration. Pyridoxine therapy is ineffective in RARS. However, some secondary sideroblastic anaemias may be completely reversed by pyridoxine therapy. This has been described in alcohol excess, haemolytic anaemia and gluten-induced enteropathy, as well as in patients receiving antituberculous chemotherapy, in whom the drugs have been stopped and pyridoxine administered.

Folic acid may benefit patients with secondary sideroblastic anaemia. For refractory patients, the anaemia may remain stable and, if the patient is transfusion independent, no treatment is needed. Patients under regular red cell transfusions require iron chelation therapy (see Chapter 12). Iron loading may aggravate the anaemia and, in some patients, improvement in the anaemia has followed iron removal by phlebotomy or iron chelation therapy. Splenectomy should usually be avoided as it does not benefit the anaemia and leads to persistently high platelet counts postoperatively, with a high incidence of thromboembolism. Bone marrow transplantation may be proposed for severe non-syndromic forms of sideroblastic anaemia as *SLC25A38* deficiency. The activin ligand trap, luspatercept reduces transfusion requirement in a proportion of acquired forms and is now approved for the treatment of transfusion-dependent patients with MDS and ring sideroblasts refractory to erythropoiesis-stimulating agents.

Introduction

Excessive iron accumulation may lead to tissue damage. Iron overload of the parenchymal cells of the liver, endocrine organs and the heart may arise when there is excessive iron absorption, whereas iron administered parenterally (e.g. as multiple transfusions) is first taken up by macrophages, which destroy senescent red cells. However, there is no absolute distinction between the two sources of iron loading, as iron in macrophages is slowly released to transferrin from which it is taken up by parenchymal cells. The causes of iron overload are shown in Table 12.1. Severe iron overload, arbitrarily defined as an excess of storage iron of more than 5 g, is confined to the hereditary forms of haemochromatosis and the iron-loading anaemias.

Hereditary haemochromatosis

Hereditary haemochromatosis (HH) is now classified according to the genetic defect causing iron overload (Table 12.2). The vast majority of cases are of Type 1, involving the *HFE* gene (Chapter 11). In populations of northern European origin, most patients with HH are homozygous for the *HFE* pCys282TyrC mutation (pC282Y). All the other types, often indicated as non-HFE HH, are very rare. Types 1, 2 and 3 HH are autosomal recessive diseases and share common features due to hepcidin deficiency, including high transferrin saturation and hepatocyte iron accumulation. Type 4 HH, inherited as a dominant condition, is a heterogeneous disease with variable clinical phenotype.

HFE haemochromatosis

HFE HH is one of the most common genetic conditions in populations of northern European origin, associated with mutations in the *HFE* gene.

The *HFE* gene is an atypical MHC class I-like gene located at 6p21. The association of HH with HLA-A3 suggested a founder mutation in a chromosome carrying the A3 haplotype. Homozygosity for a G→A substitution at nucleotide 845 of the *HFE* gene results in a cysteine to tyrosine substitution at amino acid 282 (pC282Y). A second variant (187C→G) results in a histidine to aspartic acid substitution at amino acid 63 (pHis63Asp or pH63D).

HFE genotypes have been reported from large population studies throughout the world. In a study of 100,000 multiethnic participants from primary care practices, the estimated prevalence of the pC282Y homozygous genotype was higher in white (1 in 227, 0.44%) than in black individuals and was extremely rare in Asian people. The frequency is higher in northern Europe than in Italy and Greece. In the UK, about 1 in 8 people are carriers of the pC282Y mutation, and about 1 in 200 are homozygous for this mutation. Homozygosity is strongly associated with HH, with about 90% of patients with genetic iron overload having this genotype in northern Europe and about 60% in southern Europe. The HH gene may have increased in frequency because of a selective advantage for heterozygotes and protection against iron deficiency anaemia. Homozygotes would be unlikely to suffer the effects of iron overload before reproducing.

Neonatal haemochromatosis
Chronic liver diseases
African iron overload

The pH63D mutation is found throughout the world with a mean allele frequency of 15%. A small proportion of HH patients are compound heterozygotes for the pC282Y and pH63D mutations. Other *HFE* gene mutations/deletions associated with iron accumulation have been described, mostly in individual families.

That *HFE* was the HH gene was confirmed by the demonstration that *HFE* knockout mice and mice homozygous for the pC282Y mutation develop iron overload. In addition, tissue-specific inactivation of HFE protein in hepatocytes, but not in duodenal cells or macrophages, leads to iron overload, indicating a specific function of HFE in the liver. A model of the pathophysiology of the disease suggests that HFE competes with diferric transferrin for TFR1 binding and that when diferric transferrin binds TFR1, liver HFE binds TFR2, thus forming a complex that activates hepcidin synthesis (Chapter 11). Low serum hepcidin explains the findings in the early stages of HH: increased iron absorption, a raised serum iron and transferrin saturation, iron accumulation in hepatocytes with a periportal distribution and a paucity of iron in macrophages.

Iron parameters and clinical status of patients with *HFE* mutations

Transferrin saturation and serum ferritin are significantly higher in pC282Y/pC282Y subjects than in other genotypes. Increased levels of iron parameters are present in 75–100% of males and 40–60% of females in different studies. In population surveys slightly, but significantly, higher values for serum iron and transferrin saturation have been found in heterozygotes for either pC282Y or pH63D compared with subjects lacking these mutations. The differences in serum ferritin levels are small and not significant, except in rare cases where mutations in other genes involved in iron metabolism may be present. In compound heterozygotes, and those homozygous for pH63D, significant iron accumulation is rare and liver fibrosis exceptional. The frequency of homozygosity or heterozygosity for pC282Y or pH63D mutations is not increased in patients with arthritis, diabetes and heart disease.

In pC282Y, homozygotes increased non-transferrin-bound iron (NTBI) is taken up by several organs. A gradual accumulation of iron may lead to tissue damage, which may present as cirrhosis of the liver, diabetes, hypogonadism, cardiomyopathy, arthritis and a slate-grey skin (melanin) pigmentation. Only the most severe forms develop cardiac involvement that in the early

Table 12.2 Classification of hereditary haemochromatosis.

Type	Gene	Inheritance and phenotype	Severity	Incidence
1	*HFE*	AR, parenchymal iron overload	Highly variable	Common

stages is characterised by diastolic dysfunction and arrhythmias, in the later stages by dilated cardiomyopathy. Hepatocellular carcinoma may develop up to 25% of established cases with cirrhosis. Most patients present between the ages of 40 and 60 years; menstrual losses and pregnancies account for a generally delayed onset in women. Thus the clinical penetrance is low, estimated around 25% in males and 1% in females. The *HFE* pC282Y homozygous genotype only confers susceptibility to develop iron overload. Full phenotypic expression of the disorder is dependent on environmental factors, including dietary iron intake, blood donations or blood loss and other genetic factors modifying the genotype, although the latter effect is mild. Alcohol is a definite risk factor for the development of cirrhosis in patients homozygous for pC282Y.

Subjects homozygous for *HFE* pC282Y compared with control subjects with normal *HFE* genotype have shown the same frequencies of haemochromatosis symptoms and complications such as lethargy, arthralgia and diabetes. There is, however, a small but significant increase in subjects with either raised serum transaminases or fibrosis/cirrhosis in the pC282Y homozygous group. Homozygosity for pC282Y is more frequent in patients with cirrhosis and hepatoma than in the general population. The relative risk for hepatocellular carcinoma in cirrhotic patients with HH is approximately 20, with an annual incidence of 3–4%. Monitoring the serum α-fetoprotein is needed in both untreated and treated cases, because risk of liver cancer remains also in iron-depleted cirrhotic patients.

There is evidence that ferritin concentration above 1000 μg/L is a risk factor for liver fibrosis with a prevalence of 20–45%. A serum ferritin level >1000 μg/L has 100% sensitivity and 70% specificity for identification of cirrhosis. The ferritin cut-off might be lower in the presence of cofactors for liver disease such as alcohol. Patients with serum ferritin level >1000 μg/L should undergo liver biopsy or magnetic resonance imaging (MRI) for iron quantitation and Fibroscan for fibrosis evaluation (see below) and complete cardiac and endocrinological evaluation. Only about 50% of homozygous women have raised transferrin saturation and progression through iron accumulation and tissue damage is usually, but not always, slower.

Population surveys have shown that less than 5% of subjects homozygous for pC282Y ever receive a diagnosis of HH. Most men who are homozygous for pC282Y will have a raised transferrin saturation before the age of 30 years; a proportion will have an elevated serum ferritin concentration, but only a minority will eventually develop fibrosis and cirrhosis of the liver. Studies in Australia and Norway found that 5% of homozygote males, but no females, showed cirrhosis. Time-dependent ferritin increase is slow.

Clinical and laboratory diagnosis

Although the biochemical penetrance of pC282Y homozygosity is substantial (about 70%), the disease penetrance is significantly lower (about 25%) amongst men and (1%) amongst women.

Figure 12.1 Radiograph of hand: patient with haemochromatosis showing loss of joint space and erosion of cartilage at the metacarpophalangeal joints (arrow).

The variety of clinical presentations and their lack of specificity for HH mean that a high degree of clinical suspicion is needed. Fatigue, abdominal pain, diabetes mellitus, signs and symptoms of gonadal failure and arthritis may be present for several years before the diagnosis is made. Arthritis particularly affects the second and third metacarpophalangeal joints (Figure 12.1), and destructive arthropathy of hip and knee joints occurs in 10% of patients. There is chondrocalcinosis with pyrophosphate deposition in the joints. Abdominal pain may result from hepatic enlargement or hepatocellular carcinoma. Grey skin pigmentation results from excess melanin deposition.

In asymptomatic subjects, iron accumulation is indicated by a raised transferrin saturation (>45%). Most men and about 50% of women who are homozygous for *HFE* pC282Y will have a raised transferrin saturation. As iron accumulates, the serum ferritin concentration rises, and values in excess of 200 μg/L (women) and 300 μg/L (men) suggest iron overload. Serum ferritin concentrations largely reflect iron turnover in phagocytic cells and do not provide an early indication of iron accumulation

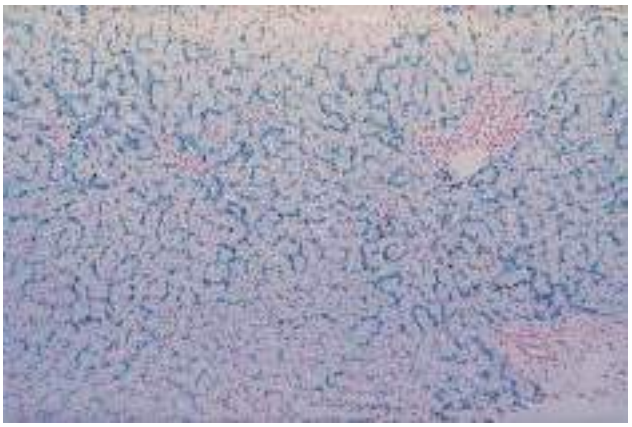
in liver parenchymal cells. Thus, measurement of transferrin saturation is essential for early detection of iron loading. However, in patients with infection, inflammation or malignancy or in those undergoing surgery, transferrin saturation may be depressed and the serum ferritin concentration elevated. In most cases, *HFE* genotyping will confirm the diagnosis of HH.

Testing adult first-degree relatives of a pC282Y homozygous patient may identify subjects homozygous for *HFE* pC282Y with normal serum ferritin concentration and without evidence of liver disease: they should have transferrin saturation and serum ferritin measured at yearly intervals. Compound heterozygotes are at lesser risk of iron overload but should also be tested by measuring iron parameters. Widespread population screening by iron status or genetic testing is considered unwarranted as the level of risk for a pC282Y homozygote developing iron overload appears to be low. Screening based on iron parameters is advisable in high-risk populations.

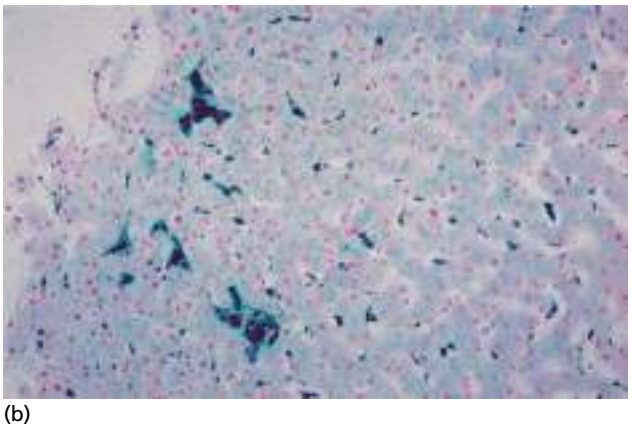
Associations with other conditions

The pC282Y mutation is relatively common (see above); heterozygosity, and even homozygosity, may occur with other haematological conditions, including inherited sideroblastic anaemia, β-thalassaemia trait or other haemolytic anaemias and aggravate a tendency to iron load. The mutation may worsen liver disease in conjunction with hepatitis C infection, alcohol and non-alcoholic fatty liver disease. Porphyria cutanea tarda, which may be associated with iron overload, an important trigger of disease manifestations, is discussed in Chapter 11.

The *HFE* pC282Y mutation was identified in multiple genome-wide association studies for quantitative loci as erythrocyte and iron traits, blood pressure and HbA1C levels in diabetics and others, likely through indirect effects or due to the association of the *HFE* gene with the HLA complex.



(a)



(b)

Figure 12.2 Liver histology (Perls' stain). (a) Liver biopsy from a patient with Type 1 haemochromatosis, showing staining predominantly in parenchymal cells. (b) Liver biopsy from a patient with ferroportin disease showing iron staining predominantly in Kupffer cells.

Body iron quantitation

Liver iron concentration is a good estimate of total body iron. Liver iron can be measured on a dried fragment of liver biopsy. The normal ranges are 0.17–1.8 mg/g dry weight. Values in excess of 3.0 mg/g dry weight indicate iron overload. Since the advent of genetic testing, liver biopsy is not usually performed. Iron quantitation in liver, heart and other organs is performed by non-invasive methods, mainly MRI techniques.

In patients homozygous for pC282Y with evidence of liver disease, hepatomegaly, increased transaminases and serum ferritin concentration >1000 μg/L, liver biopsy may be advisable to assess tissue damage. The biopsy reveals the hepatocyte iron accumulation with typical periportal predominance (Figure 12.2a). The amount of iron removed to reach iron depletion can be calculated (see Treatment) and provides a good estimate of total body iron. The amount of iron removed at each venesection is calculated by weighing the blood bag before and after venesection (density of blood is 1.05 g/mL) and assuming that 450 mL of blood (haemoglobin concentration 135 g/L) contains approximately 200 mg of iron. Iron absorption should be allowed at the rate of 3 mg daily (20 mg/week). With these assumptions, 25 weekly venesections will remove 4.5 g of iron. The amount of storage iron measured by the technique in normal adults has been shown to be about 750 mg in men and 250 mg in women.

Treatment

Although no randomised controlled trial is available to compare phlebotomy versus no phlebotomy in the treatment of HH, retrospective studies show that removal of excess iron by regular phlebotomy greatly reduces the morbidity and mortality from cardiac failure and diabetes complications. However, hepatocellular carcinoma accounts for a substantial proportion of deaths in those with established cirrhosis. Early diagnosis is therefore a priority, as patients identified and treated before the onset of cirrhosis and/or diabetes have a normal life expectancy.

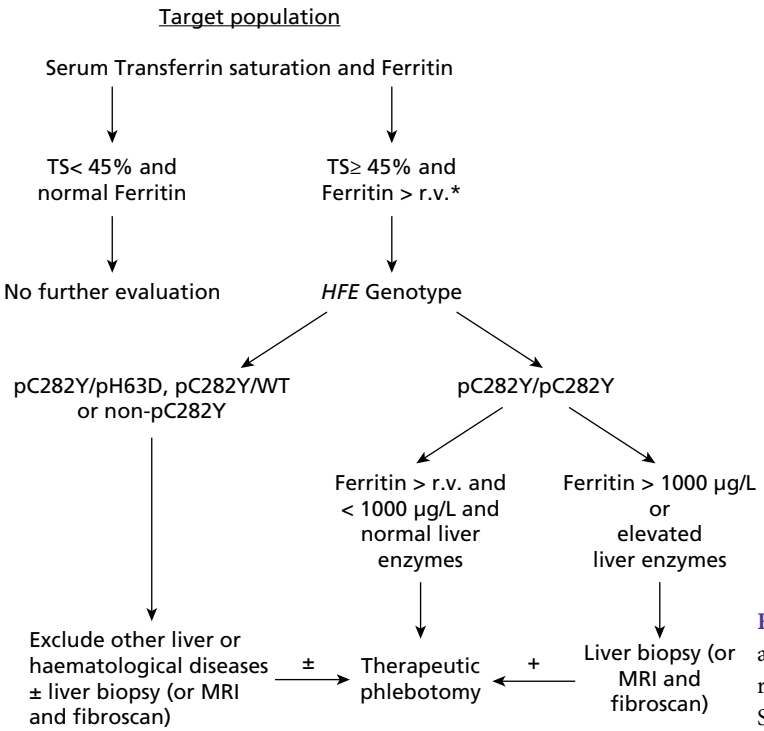


Figure 12.3 Algorithm for haemochromatosis diagnosis and treatment. The scheme is modified from the recommendations of the American Association for the Study of Liver Diseases (AASLD), and other scientific societies. TS, transferrin saturation; MRI, magnetic resonance imaging.

Since no test is available to identify those patients who will progress to fibrosis and those who will not, the present recommendation is to phlebotomise all patients with evidence of iron overload. No evidence-based guidelines for HH treatment by phlebotomy are available. Treatment is conventionally initiated when serum ferritin levels exceed the normal range. An algorithm for diagnosis and treatment of the disease based on current recommendations is shown in Figure 12.3.

Phlebotomy should be at a rate of 400–450 mL of blood each week and is performed until a target serum ferritin <100 µg/L is reached. Haemoglobin levels should be measured weekly and the rate of venesection reduced if anaemia develops. Serum ferritin should be monitored monthly. Weekly phlebotomy will need to be continued to remove total iron excess, which is usually greater than 5 g in established symptomatic disease, but may be >20 g. When iron stores are normalised, the frequency of phlebotomy should be reduced to two to four units each year, to continue indefinitely. The aim is to prevent re-accumulation of iron by maintaining a serum ferritin in the normal range (50–100 µg/L). The use of proton pump inhibitors has been shown to reduce the annual number of phlebotomy sessions. Fatigue, abdominal pain, transaminase elevation, mild fibrosis and skin pigmentation usually reverse on venesection. In some patients, diabetes mellitus, hypogonadism and arthralgia improve, but cirrhosis and destructive arthritis are irreversible. Early cardiac disease may respond to phlebotomy, while severe cardiomyopathy requires iron chelation (see below). Patients with end-stage liver disease and HCC may undergo orthotopic liver transplantation, after iron depletion. Post-transplantation survival rates in untreated patients are reduced compared with those of non-iron-loaded patients due to iron toxicity and infectious complications.

No diet recommendation is needed except limiting alcohol intake and avoiding raw shellfish for possible infection with *Vibrio vulnificus*, which is a particular risk in iron-loaded patients. This occurs because *Vibrio vulnificus* avidly takes up NTBI, the levels of which increase in patients with high transferrin saturation.

Iron chelation with subcutaneous desferrioxamine (DFO) may be used in patients who do not tolerate phlebotomy or have concomitant anaemia. DFO given as a continuous intravenous infusion with or without an oral iron chelator (see iron chelation therapy), an off-label treatment, may have a role in the short-term management of patients with life-threatening cardiac failure. Oral iron chelators such as deferasirox at low doses are likely to be used for selected patients in the future. Targeting the hepcidin pathway to increase hepcidin production ameliorates iron overload in preclinical models of the disease.

Non-HFE haemochromatosis

Non-*HFE* HH is a clinical definition applied to all the other types of HH (Table 12.2). These forms are all rare, accounting for <5% of all cases. In juvenile HH, clinical symptoms usually appear in the

second and third decades of life. The disease can be due either to haemojuvelin mutations, that strongly decrease hepcidin production (see Chapter 11), or, more rarely, to mutations in the hepcidin (*HAMP*) gene. In both cases iron absorption is greater than in *HFE* HH and iron deposition occurs not only in the hepatocytes, but also in cardiac myocytes, pancreas and pituitary; symptoms of cardiomyopathy, diabetes and hypogonadism are prominent (Table 12.2). HH Type 3 is phenotypically similar to *HFE* HH, although it may present at an earlier age. It is due to mutations in the gene that encodes the iron sensor transferrin receptor 2 (*TFR2*) (Table 12.2). All types of HH except Type 4 (Table 12.2) are recessive and characterised by low hepcidin secretion, the defect being the most severe in juvenile HH. Mutations in all of the genes of non-*HFE* HH (haemojuvelin, hepcidin, transferrin receptor 2 and ferroportin) have been found in rare patients from the Asia-Pacific region, where the *HFE* mutations are exceptional.

HH Type 4 is inherited as an autosomal dominant trait due to heterozygous missense mutations in the gene for the iron exporter ferroportin. All patients have increased serum ferritin levels, but some have normal transferrin saturation and a mixed pattern of iron accumulation, both in hepatocytes and macrophages. In the typical form (Type 4a, Table 12.2), so-called ferroportin disease, due to loss-of-function ferroportins that are unable to target correctly the cell surface and so export iron from macrophages. The phenotype differs from HH: iron accumulates predominantly in the macrophages (Figure 12.2b) and transferrin saturation is normal or low. In the rare Type 4b with mutations occurring in the binding site of ferroportin for hepcidin, gain-of-function ferroportins reach the cell surface, but are resistant to the effect of hepcidin, causing increased iron export to plasma, saturation of transferrin and iron deposition in hepatocytes similar to *HFE* HH (Figure 12.2a).

Second-level genetic testing is required for the precise diagnosis of non-*HFE* HH. Next-generation sequencing (NGS)-based panels of mutations available in some referral centres may facilitate diagnosis. This approach may also reveal digenic inheritance or mutations in multiple genes. Phlebotomy is indicated as in pC282Y homozygotes; juvenile HH may require even more intensive regimens. Tolerance to phlebotomy should be carefully monitored and intensive regimens are not indicated in ferroportin disease, because of anaemia development. Patients with juvenile forms of HH presenting with life-threatening cardiac failure should be treated with combination of iron chelators (see iron chelation therapy).

Rare genetic causes of iron overload associated with anaemia

Atransferrinaemia

This is a rare recessive disorder associated with a severe hypochromic anaemia with low hepcidin levels and excessive deposition of NTBI in the parenchymal cells. This phenotype underlies the dual role of transferrin to release iron to erythroblasts and to signal for hepcidin synthesis. In all cases tested, some iron-transferrin has been detected by iron-binding ability or immunologically, defining a type of hypotransferrinaemia. Complete absence of transferrin would presumably lead to fetal death. Treatment is based on plasma or transferrin infusions.

DMT1 deficiency

A microcytic hypochromic anaemia with liver iron overload has been described in a few patients with homozygous or doubly heterozygous mutations of *SLC11A2* encoding DMT1. Liver iron stores are increased, but erythroid iron utilisation is impaired and serum hepcidin levels are low for the degree of iron overload. These patients may respond to erythropoietin injections with partial correction of anaemia and iron overload.

Acaeruloplasminaemia

This is a rare recessive disorder in which there is a deficiency of ferroxidase activity as a consequence of mutations in the caeruloplasmin gene (Chapter 11). Clinically, the condition presents in middle age, with progressive degeneration of the retina and basal ganglia and with diabetes mellitus. Iron accumulates in the liver, pancreas and brain, with smaller amounts in the heart, kidneys, thyroid, spleen and retina. Deficiency of ferroxidase activity impairs iron mobilisation from stores and leads to low serum iron and mild hypochromic microcytic anaemia in the presence of normal or high ferritin levels. Early diagnosis requires a high degree of suspicion. Unfortunately, no effective treatment is available to reduce neurodegeneration.

Acaeruloplasminaemia belongs to the group of rare genetic disorders that are classified as neurodegeneration with brain iron accumulation (NIBIA). In these conditions, as well as in Friedereich ataxia and Parkinson disease, iron accumulation may be found in specific areas of the brain, irrespective of systemic iron. Low-dose iron chelation with deferiprone provided limited improvement of iron deposition in prospective double-blind pilot clinical trials of these patients.

Other causes of iron overload

Neonatal haemochromatosis

This is a severe liver disease recognised at birth but usually occurring *in utero*. It is characterised by heavy parenchymal iron deposition in several organs and irreversible liver failure. A genetic cause has been excluded in favour of an *in utero* acquired disorder triggered by an immunological pathogenesis. It is a gestational alloimmune disease due to an alloantibody against fetal hepatocytes, but the target antigen is unknown. The result may be stillbirth or acute liver failure of the newborn or congenital cirrhosis. There is a high risk of recurrence in subsequent pregnancies; thus the disease is familial, but not heritable. Infusions

of γ-globulin in pregnancy appear to reduce the severity of the condition. The other therapeutic option is liver transplantation.

Chronic liver diseases

Moderate iron overload limited to the liver can be found in various chronic viral or metabolic liver diseases in the context of alcohol excess, necro-inflammatory processes and in liver steatosis associated with the so-called metabolic syndrome. Often these conditions are characterised by increased serum ferritin, but normal transferrin saturation and slightly increased hepcidin in the context of an inflammatory process.

'African' iron overload

Historically African iron overload was described in sub-Saharan Africa (Bantu siderosis), as the combination of a dietary component (a traditional beer that contains iron) and a genetic susceptibility unrelated to haemochromatosis genes, but never clearly defined. The proposed variant in ferroportin (pGln248His) that is common in Africa is unlikely to be the cause. Iron deposition is of mixed type and occurs in both hepatocytes and macrophages and may lead to hepatic fibrosis and cirrhosis. Serum ferritin is usually elevated, but transferrin saturation may be normal. In African-Americans iron overload is rare; a common genetic variant (pGlu75del) in the gene that encodes the mechanosensor *PIEZO1*, mutated in inherited stomatocytosis, associates with increased transferrin saturation.

Excess parenteral iron

Erroneous administration of excessive doses of oral iron does not cause iron overload because iron absorption is limited by hepcidin increase. Iron accumulation might occur after high-dose parenteral iron preparations inappropriately administered, due to lack of an iron excretion mechanism. However, the accumulation is usually limited to the reticuloendothelial system.

Hereditary hyperferritinaemia-cataract syndrome

This condition is characterised by isolated hyperferritinaemia not associated with iron overload, early-onset bilateral cataracts and normal serum iron and transferrin saturation. It is due to heterozygous point mutations in the L-ferritin iron-responsive element so that a monoclonal ferritin is synthesised due to impaired negative feedback of ferritin synthesis. The mutation is in the gene promoter and constitutively increases gene transcription. High ferritin accumulates exclusively in the lens, causing congenital or early-onset cataracts.

Iron-loading anaemias

In different forms of anaemia, iron overload occurs when iron intake is increased over a sustained period of time. This may be due either to red blood cell transfusions, as in transfusion-dependent thalassaemia (TDT), or to increased iron absorption through the gastrointestinal tract, because of inhibition of hepcidin synthesis by erythroferrone released from erythroblasts (Chapter 11), as in non-transfusion-dependent thalassaemia (NTDT) and in other anaemias characterised by ineffective erythropoiesis. Secondary iron overload may occur in patients transfused for different forms of inherited and acquired anaemias and in patients after successful allogeneic bone marrow or HSC transplantation for various haematological disorders, who have been heavily transfused.

Iron chelation therapy is essential in patients with transfusion-dependent anaemia, to prevent death from iron overload, usually caused by cardiac failure or arrhythmia. Red blood cell requirements are about 160 mL/kg annually in non-splenectomised and 120 mL/kg annually in splenectomised TDT patients. The iron content of each transfusion is determined by volume (mL) × haematocrit × 1.16 mg. Intake of iron ranges from 0.32 to 0.64 mg/kg body weight daily. Patients with anaemias associated with increased iron absorption who are too anaemic to be venesected to remove iron may also require iron chelation therapy.

The available iron-chelating drugs are: DFO, which is given by slow subcutaneous or intravenous infusion, deferiprone (DFP) and deferasirox (DFX), which are orally active. Their iron-binding properties, pharmacokinetics and routes of elimination differ (Table 12.3).

Iron chelation therapy is monitored by:

1 tests of body iron burden;

2 tests of damage to the organs sensitive to iron overload (Table 12.4);

3 tests to detect potential side-effects of the particular chelating drug being used.

Tests of body iron burden

Serum ferritin

Serum ferritin generally relates to body iron stores and it is relatively inexpensive and easily measured repeatedly. Serum ferritin is useful in monitoring changes in body iron, although measures do not always predict body iron or trends in body iron accurately. This is partly because inflammation increases serum ferritin, while other factors affect it, such as vitamin C status, and partly because the distribution of liver iron between macrophages (Kupffer cells) and hepatocytes has a major impact on plasma ferritin. A sudden increase in serum ferritin should prompt a search for hepatitis, other infections, or inflammatory conditions. The Thalassaemia International Federation (TIF) guidelines recommend maintaining the level below 1000 μg/L in TDT and <800 μg/L in NTDT.

Liver iron

Liver iron may be measured chemically after liver biopsy or by MRI. Chemical estimation was the gold standard, but can be inaccurate if fibrosis is present. Levels >7 mg/g tissue dry weight,

Table 12.3 Characteristics of desferrioxamine, deferiprone and deferasirox.

	Desferrioxamine (DFO)	Deferiprone (DFP)	Deferasirox (DFX)
Structure	Hexadentate	Bidentate	Tridentate
Molecular weight (Da)	560	139	373
Iron–chelator complex	1:1	1:3	1:2
Plasma clearance ($t_{1/2}$)	20 min	1–3 hours	1–16 hours
Absorption	Negligible	Peak 45 min	Peak 1–2.9 hours
Iron excretion	Urine + faecal	Urine	Faecal
Therapeutic daily dose	40 mg/kg	75–100 mg/kg	20–40 mg/kg (dispersible tablet) 7–21 mg/kg (coated tablet)
Route	Parenteral	Oral	Oral
Clinical experience	>40 yrs	>30 yrs	>15 yrs
Side-effects	Ototoxicity, retinal toxicity, growth defects, cartilage and bone abnormalities	Agranulocytosis, arthropathy, gastrointestinal disturbance, transient transaminitis, zinc deficiency	Skin rashes, gastrointestinal disturbance, rising serum creatinine

and in non-transfusion-dependent anaemia >5 mg/g dry weight are almost always associated with organ damage, while levels <3 mg/g are not associated with clinical complications. Although no clear guidelines are available with liver iron between 3–7 mg/g dry weight, the target of chelation therapy should be to achieve a LIC <3 mg/g dry weight.

MRI techniques are being increasingly used as indirect measures of liver and cardiac iron (Figure 12.4). They have the advantage of being non-invasive and are now widely available. MRI is also the only practical method of performing sequential studies of iron in the liver and heart. Pituitary or other endocrine organs may also be evaluated by MRI, but validation of the software is still required. Different MRI techniques have been used. They all rely on a shortening of relaxation time and thus reduction in signal intensity with iron overload. The R2 or Ferriscan technique is convenient and reproducible for liver iron over the range of clinical interest. The normal ranges of liver iron content by Ferriscan are 0.17–1.8 mg/g dry weight. Gradient echo imaging with the calculation of the $T2^*$ is also applicable, it has a short total imaging time, reducing movement artefacts.

The following formula $[1/(T2^*/1000)] \times 0.0254 + 0.202$ allows us to transform T2* ms in mg/g dw.

Cardiac iron

As cardiac failure or arrhythmia is the usual cause of death in transfusional iron overload, it is essential to monitor cardiac iron. Iron is deposited in myocytes and interstitial fibrosis develops. Direct measurement of cardiac iron by endomyocardial biopsy is inappropriate and inaccurate.

$T2^*$ cardiovascular magnetic resonance offers a reproducible (around 5% coefficient of variation between different observers or between two studies of the same patient), sensitive, albeit indirect measure: the lower the $T2^*$ value, the greater the cardiac iron (Figure 12.5). The majority of patients with $T2^*$ >20 ms have normal left ventricular (LV) function.

A $T2^*$<20 ms correlates with the presence of cardiac dysfunction detected by echocardiography (left and right ventricles) or

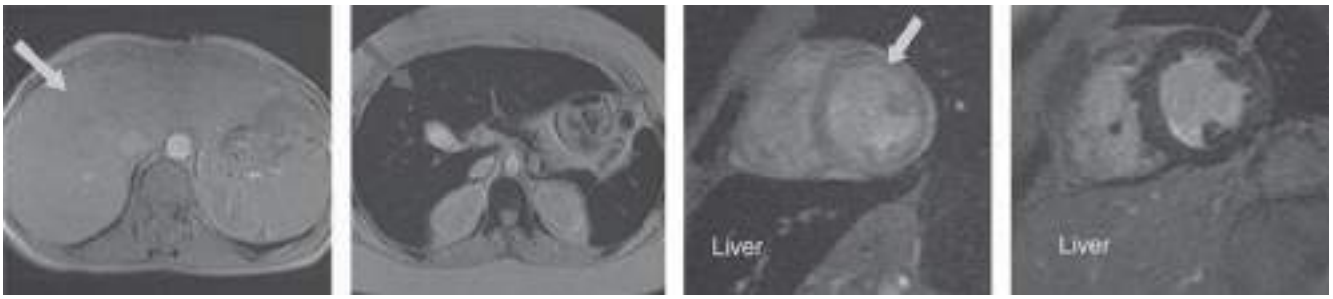

Figure 12.4 Magnetic resonance imaging T2* technique. Tissue appearances of liver and spleen: (a) normal. (b) tissue iron overload. (c) severe liver iron overload with normal cardiac iron. (d) severe cardiac iron deposition with minimal liver iron deposition. White arrows point to normal tissue, grey arrows to iron-loaded tissue (Source (parts (c) and (d)): Anderson *et al.* (2001). Reproduced with permission from Oxford University Press.)

by 24-hour rhythm monitoring or the need for cardiac therapy (Figure 12.5). Most patients who develop cardiac failure have T2* <10 ms. The risk of developing heart failure increases with T2* values <10 ms, which is associated with 160-fold increased risk of heart failure in the next 12 months without adequate chelation. This risk may be substantially less in patients taking regular chelation (see below).

Poor correlation has been found between myocardial iron and liver iron (MRI derived) or serum ferritin in patients receiving iron chelation; thus liver iron and serum ferritin cannot be used as surrogate measures of cardiac iron in these patients.

Urine iron excretion

Iron excretion after a single infusion of a standard dose of DFO or an oral dose of DFP is related to body iron. Urine iron is derived from the labile iron pool chelated mainly extracellularly with DFO and probably intracellularly with DFP. The test may be useful when commencing therapy with DFO or DFP, with which iron excretion is highly dose-related. However, several estimations must be performed at any given dose in view of the variability found.

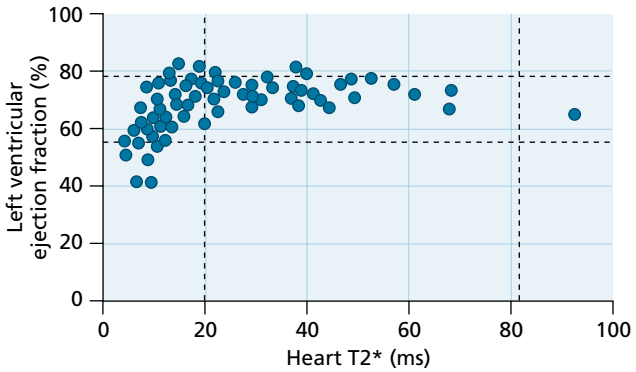

Figure 12.5 Relationships of myocardial T2* and left ventricular ejection fraction in patients with thalassaemia major and iron overload (Source: Anderson *et al.* (2001) *Eur. Heart J.* **22**: 2171–9. Reproduced with permission of Oxford University Press.)

Non-transferrin-bound iron

This is present in the plasma in patients with gross iron overload and high transferrin saturation. It is highly toxic, promoting the formation of free radicals that cause peroxidation of membrane lipids. Part of the early improvement in liver and cardiac function with chelation therapy may be due to removal of this fraction, even before iron burden is substantially lowered. Its clearance by DFO is short-lived as it reappears in plasma within hours of stopping an infusion. DFX, with its long clearance time, provides 24-hour removal of NTBI after a single oral dose. DFP removes NTBI for about 3 hours after a single dose. NTBI is absent from the plasma of well-chelated patients.

Tests for organ damage

The tests that are usually needed are listed in Table 12.4. Heart function is best tested by measurement of left ventricular ejection fraction (LVEF) by echocardiography or by MRI and by tests for rhythm disturbance. Liver function assessment requires routine liver function tests, as well as liver biopsy to assess liver structure, particularly in the presence of chronic viral hepatitis C. When MRI is available to measure the liver iron concentration, abdominal ultrasound and Fibroscan may be used to avoid liver biopsy. α-Fetoprotein should be tested regularly in patients with cirrhosis. The endocrine system is also damaged by iron and appropriate tests are listed in Table 12.4. The anterior pituitary is particularly sensitive, with damage resulting in reduced growth and impaired sexual maturation. Direct damage to the ovaries or testes is usually less important. Hypogonadic hypogonadism, defects of growth hormone secretion and its receptor, and deficiency of insulin-like growth factor mainly account for growth failure. Diabetes mellitus and prediabetes, due to iron deposition in the pancreatic islets, are frequent, especially in patients with genetic susceptibility. Hypothyroidism and hypoparathyroidism are also common in poorly chelated patients. Osteoporosis is well recognised in iron-overloaded thalassaemia patients; it is due to multiple factors and is detected by bone density studies.

Iron chelation therapy

The largest experience in the use of iron chelators comes from patients with thalassaemia and this chapter is prevalently based on such experience. However, since the introduction of oral chelators, especially DFX, iron chelation is increasingly used in several other genetic and acquired anaemias, as outlined below. The main features of the available iron chelating drugs DFO, DFP and DFX are summarised in Table 12.3.

Desferrioxamine

Pharmacokinetics

DFO is not absorbed orally, and after parenteral injection is rapidly cleared from the plasma, being excreted in the urine, taken up by hepatocytes or metabolised in the tissues (Table 12.3). This accounts for the great mobilisation of iron by continuous intravenous or slow subcutaneous infusions, which allow prolonged exposure of the drug to the chelatable iron. It is a trihydroxamic acid (hexadendate), one molecule binding covalently to all six oxygen sites on one ferric ion to form the red chelate, ferrioxamine which is excreted in urine and bile. Faecal iron is derived from hepatocytes. Urinary iron excretion tends to level off at higher doses, but this does not occur with bile excretion so bile iron may predominate at high doses, and this is also the major route of excretion when total body iron has been reduced to relatively low levels.

Clinical studies

DFO was the first chelator used and shown to reduce complications and improve survival in TDT. Its main disadvantage is that it must be administered parenterally, which may often result in poor compliance. The increased toxicity of DFO at low levels of body iron means that guidelines have been conservative, generally recommending not starting therapy until serum ferritin levels reach 1000 ng/mL after approximately 10 units of blood and with care to avoid over-chelation.

In children, tissue damage from iron may be present from very early life; regular iron chelation should begin in TDT after transfusion of about 10 units of blood or when serum ferritin exceeds 1000 µg/L, but it should be started at 20 mg/kg to prevent tissue damage due to iron without causing toxicity due to excess DFO. The standard adult dose of DFO is 40 mg/kg administered subcutaneously given as an 8–12 hour infusion on at least 5 days each week. It is given intravenously at the time of blood transfusion only in patients not complying with any type of chelation and grossly iron overloaded. Vitamin C increases iron excretion by increasing the availability of chelatable iron, but if given in excess may increase the toxicity of iron. It is recommended not to give more than 2–3 mg/kg/day taken at the time of DFO infusion. The response to DFO chelation depends on the amount of blood and consequently of iron being transfused. For those with iron-induced cardiomyopathy, continuous intravenous DFO may be given via an indwelling catheter (e.g. Hickman) or Port-a-Cath chamber. Removal of liver iron is more rapid than removal of cardiac iron with this intensive chelation regimen. Combined therapy with DFP or DFX is indicated if there is iron-induced cardiac disease (see below).

Growth and pubertal development are improved in many, but not all, patients; with adequate chelation diabetes and other endocrine abnormalities are less frequent and MRI studies have shown that about a third of TDT patients chelated with DFO have cardiac $T2^*$ values <10 ms. Through lack of compliance with DFO, premature deaths, usually from iron-induced cardiac damage may occur. Combination therapy or orally active drugs are improving the survival in these DFO failures.

Side-effects

These include rare generalised sensitivity reactions, local soreness related to the site of injection (usually due to the needle being inserted too superficially) and exacerbation of some infections, notably of the urinary tract and precipitation of *Yersinia* enterocolitis. Auditory (high-tone sensorineural hearing loss) and visual neurotoxicity (night blindness, visual field loss, retinal pigmentation) are relatively frequent. Growth and bone defects may also occur. The spine may be affected, with sitting height reduced; rickets-like bone lesions, *genu valgum* and metaphyseal changes are described, especially in children.

Auditory, visual and growth side-effects of DFO occur mainly if the body iron burden is low and doses of DFO high, particularly in children. A therapeutic index can be calculated as follows: mean daily dose (mg/kg)/current serum ferritin (µg/L). If this is below 0.025 at all times, these side-effects of DFO do not occur.

Deferiprone

Pharmacokinetics

Deferiprone (1,2-dimethyl-3-hydroxypyrid-4-one) is an orally rapidly absorbed bidentate, appearing in plasma within 15 min of ingestion (Table 12.3). The chelator–iron complex is excreted with the free drug and glucuronide derivative in urine. Its iron chelation site is inactivated by glucuronidation, the speed of which varies from patient to patient. This explains much of the individual variation in response. It is available both as tablets (500 mg) and as a liquid formulation containing 100 mg/mL, which is particularly useful in children. DFP mobilises iron from parenchymal and reticuloendothelial pools and from transferrin, ferritin and haemosiderin. Its enhanced ability to cross cell membranes may underlie its superior ability compared with DFO to protect the heart from iron. It crosses the blood–brain barrier and has been used in trials to treat neurological conditions with iron loading in the brain.

Clinical studies

The usual dose used has been 75–100 mg/kg daily given as three divided doses. MRI studies suggest that liver iron may generally be higher in patients treated with DFP (75 mg/kg 7 days per week) compared with those treated with DFO (40 mg/kg 5 days per week) or DFX (30 mg/kg daily). In the liver, DFO has the advantage of facilitated transport into cells by an active mechanism. DFP, on the other hand, has greater penetration of myocardial cells. Retrospective and prospective studies have shown, on the basis of $T2^*$ MRI measurement of cardiac iron, echocardiography, clinical incidence of cardiac disease, need for cardiac therapy and survival, that DFP 75 mg/kg is more effective than DFO at protecting the heart from iron-induced cardiomyopathy in routine clinical practice.

Side-effects

The most severe side-effect is agranulocytosis (neutrophils $<0.5 \times 10^9$/L on two consecutive counts), with an estimated incidence of around 0.5–1.0% (0.2–0.3 episodes per 100 patient-years). It is most frequent in the first year of therapy. Lesser degrees of neutropenia ($0.5–1.5 \times 10^9$/L) are more frequent, around 3.5%, occurring more frequently in non-splenectomised patients. Agranulocytosis and neutropenia spontaneously recover when the drug is immediately discontinued, usually within 4–28 days (median duration 9 days), but occasionally are more prolonged. Granulocyte colony-stimulating factor may produce a faster recovery. The mechanism appears to be idiosyncratic, more common in females, with no definite evidence of an immune mechanism established. Patients should be monitored by blood counts every week for at least the first 12 weeks of therapy and every 2 weeks thereafter for 2 years.

Painful joints, especially the knees, occur in around 5–10% in most large series. The incidence has been highest in Indian patients. Some but not all studies show that this complication is most frequent in the most iron-loaded patients and with higher doses of DFP. It usually, but not invariably, resolves with withdrawal of the drug and it is often possible to reintroduce the drug, commencing with lower doses. About 2.0% of patients permanently discontinue therapy because of joint symptoms.

Gastrointestinal side-effects (e.g. nausea and abdominal pain) occur in about 30% of patients in the first year but decrease to 3% in subsequent years. In most, the drug can be reintroduced long-term, initially at a lower dose. The liquid preparation appears to produce fewer GI symptoms. Zinc deficiency has been described in diabetic and prediabetic patients. Rarely, it can lead to clinical features, such as skin rashes and hair loss. It is easily treated by oral zinc therapy. Transient increases in liver enzymes have been associated with DFP therapy in about 7% of patients and about 1% of patients have been withdrawn from therapy because of a persistent rise in liver enzyme levels. Embryo toxicity and teratogenicity have been reported in non-iron-loaded animals treated with deferiprone. Women of childbearing age should be counselled to avoid the drug or use contraception, but a few uneventful pregnancies with healthy newborns have been reported.

Deferasirox

Pharmacokinetics

Deferasirox (DFX), 4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol1-yl]benzoic acid, is an oral tridentate chelator forming a 2:1 chelator–iron complex and increases predominantly faecal iron excretion (Table 12.3). It is highly selective for iron. Peak plasma concentration after a single oral dose occurs at about 2 hours, and the drug is still detectable in plasma in almost all patients at 24 hours, with a mean elimination half-life of between 11 and 19 hours after multiple-dose administration. The single daily dose ranges from 20 to 40 mg/kg for dispersible tablets and from 7 to 28 mg/kg for coated tablets. The latter are now the preferred preparation, because, being better tolerated, improves patient compliance.

Clinical studies

DFX has been shown to be effective at eliminating NTBI in plasma and reducing serum ferritin and liver iron in heavily iron-loaded patients. The effect is dependent on dose and on transfusion requirements of the patient. The drug has been shown to be safe and effective in children as young as 2 years. The starting dose in children is 7 mg/kg daily (coated tablet) with subsequent dose adjustments. In adults, 14–28 mg/kg daily of the same preparation may be required, according to iron stores. Fifteen years of experience with DFX in children and adults have shown a tolerable safety profile and there are no reports of DFX having negative impact on growth or sexual development. Available data indicate that DFX is also effective at removing cardiac iron and preventing cardiac siderosis in TDT.

Side-effects

The most common adverse effects have been abdominal pain, nausea, diarrhoea, vomiting and skin rashes. These effects were mainly observed with the dispersible formulation. They decrease in frequency annually and usually respond to dose adjustments, taking the drug in the evening or adding products such as Lactaid to the diet. Non-progressive increases in serum creatinine (defined as a rise above the mean pretreatment measurement by more than 33% on two consecutive tests) occur in about one-third of patients. These increases are dose-dependent and resolve spontaneously. Serum creatinine should be measured in duplicate before therapy and then monthly, with significantly increased levels managed by dose reduction or interruptions.

Combination therapy

Combination therapy of DFO and DFP or DFO and DFX is superior to single-agent therapy. There is evidence for a 'shuttle' effect in which DFP or DFX enters cells, chelates iron and then returns to plasma, where the iron is transferred to DFO for excretion in urine or bile and the oral chelator may re-enter cells. Indications to combination therapy are severely overloaded patients, severe myocardial siderosis and complications of cardiomyopathy especially heart failure.

For DFO and DFP given simultaneously, iron excretion is equivalent to or greater than the use of single agents. Studies of combination therapies, for example, DFP on 7 days a week and DFO on 2 days, have shown a significant fall in serum ferritin and improvement in cardiac and liver iron, improved survival and reversal of endocrinological complications including diabetes, hypothyroidism and hypogonadism. The combination has also proved successful in reversing severe myocardial siderosis. Alternating therapy, for example, 4 or 5 days of DFP and 2 or 3 days of DFO each week, improves compliance and iron status in previously poorly compliant (with DFO) children or adults.

Experience with DFO and DFX combination has been evaluated in a clinical trial (Hyperion) in patients with severe transfusional myocardial siderosis (T2* 5<10 ms, left ventricular ejection fraction (LVEF >56%). The mean dose of DFX was 30.5 mg/kg per day and DFO 36.3 mg/kg per day on a 5-day regimen. A significant improvement of T2* was observed in 24 months and T2* >10 ms was achieved in one-third of the patients, while LVEF was unchanged. Liver iron concentration decreased substantially from a baseline of 33.4–12.8 mg Fe/g dry weight at month 24. The results showed clinically meaningful improvement both in cardiac and liver iron accumulation. Safety was consistent with monotherapies.

Non-transfusion-dependent thalassaemia

Non-transfusion-dependent thalassaemia (NTDT) includes anaemic thalassaemic patients (Hb levels between 70 and 100 g/L) who do not require regular transfusion for survival, as the various genetic forms of β-thalassaemia intermedia, haemoglobin H disease and mild/moderate forms of HbE/ β-thalassaemia (Chapter 15). For these patients, who are not transfusion-dependent or only need a few transfusions each year, iron loading occurs mainly through increased iron absorption due to hepcidin suppression. Venesection is not applicable in most cases because of the severity of the anaemia and danger of increasing bone marrow expansion and bone deformities, thus DFO has been occasionally used in the past. In a randomised clinical trial, DFX has been shown to be effective in 'de-ironing' such patients, reducing serum ferritin and liver iron (Thalassa study). Liver iron concentration should be targeted to below 5 mg/g dry weight to avoid iron toxicity-related complications. It has been shown that in NTDT a serum ferritin level of 300 μg/L corresponds to approximately 3.0 mg LIC, while a serum ferritin level of 800 μg/L corresponds with a level of 5 mg/dry weight.

A rise in haemoglobin level may occur in iron-chelated patients with NTDT. This may be due to removal of iron from the renal oxygen sensor, augmenting the effect of hypoxia and increasing erythropoietin secretion from the kidney. Increased haemoglobin may also be the result of iron restriction that may reduce ineffective erythropoiesis and haemolysis.

Iron chelation in other anaemias

Transfusion-dependent patients with several other inherited (e.g. Diamond–Blackfan syndrome, Fanconi anaemia, sickle cell anaemia and sideroblastic anaemia) or acquired disorders (especially myelodysplasia, myelofibrosis, red cell aplasia or aplastic anaemia) require iron chelation therapy. In these conditions, as well as in elderly patients with acquired, transfusion-dependent, refractory anaemias and otherwise good prognosis, DFO was sporadically used if iron overload was likely to cause significant morbidity or mortality. With the available oral compounds iron chelation in these patients has been implemented with reduction of iron overload and its complications.

Adverse effects in these groups appear similar to those with TDT. The use of DFP in patients with bone marrow failure as in aplastic anaemia and Diamond–Blackfan syndrome should be avoided since agranulocytosis may be more frequent in these patients. As in NTDT, improved haemopoiesis and haemoglobin levels have been described in congenital sideroblastic anaemia and low-risk myelodysplastic syndrome after intensive iron chelation (Chapter 34).

Patients affected by any type of congenital or acquired anaemia cured by bone marrow transplantation may still require iron chelation (in some cases phlebotomy) until safe levels of ferritin are reached.

The increased understanding of the hepcidin function and the results of preclinical studies in animal models indicate that enhancing hepcidin levels might benefit iron-loading anaemias. Based on these results clinical trials are ongoing with new molecules aimed at increasing hepcidin (i.e. inhibitors of *TMPRSS6*) or decreasing iron export to plasma (i.e. inhibitors of ferroportin). The aim is to redistribute iron to the reticuloendothelial system to both decrease toxicity and reduce ineffective erythropoiesis.

CHAPTER 13

Megaloblastic anaemia

13

A Victor Hoffbrand

Emeritus Professor of Haematology, University College London, London, UK
Honorary Consultant Haematologist, Royal Free Hospital, London, UK

Introduction

The megaloblastic anaemias are a group of disorders characterised by the distinctive morphological appearances of developing erythroid cells in the bone marrow. The cause is usually deficiency of either cobalamin (vitamin B_{12}, B12) or folate, but megaloblastic anaemia may arise because of inherited or acquired abnormalities affecting the metabolism of these vitamins or because of defects in DNA synthesis not related to cobalamin or folate (Table 13.1).

Underlying basic science

Biochemical basis of megaloblastic anaemia

The common feature of all megaloblastic anaemias is a defect in DNA synthesis that affects rapidly dividing cells of the bone marrow and of other tissues. All conditions that give rise to megaloblastic changes share in common a reduced rate of synthesis or of polymerisation of the four immediate precursors of DNA: the deoxyribonucleoside triphosphates (Figure 13.1). In deficiencies of either folate or cobalamin, there is a failure to convert deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP). The coenzyme 5,10-methylene tetrahydrofolate polyglutamate is needed for this reaction and the availability of this co-enzyme is reduced in either deficiency (see further on).

The reduced supply of deoxythymidine triphosphate (dTTP) in megaloblastic anaemia due to folate or cobalamin deficiency slows elongation and ligation of newly originated replicating segments of DNA at multiple sites of origin during cell mitosis. Thus, small DNA fragments accumulate, single-stranded areas become points of weakness where mechanical or enzymatic breakage may occur, and the failure to form bulk DNA impairs contraction of newly replicated lengths of DNA, leaving the chromosomes elongated, despirillated and with random breaks. Late-replicating DNA is particularly affected and some cells become arrested at this stage and die by apoptosis. An alternative hypothesis for megaloblastic anaemia in cobalamin or folate deficiency is the misincorporation of uracil into DNA because of a build-up of deoxyuridine triphosphate (dUTP) at the replication fork as a consequence of the block in conversion of dUMP to dTMP (Figure 13.1). Data on this hypothesis are conflicting. It does not explain megaloblastic anaemia due to defects of DNA synthesis at sites other than at thymidylate synthesis, for example with drugs such as hydroxycarbamide (hydroxyurea), cytarabine or 6-mercaptopurine, or with enzyme deficiencies such as orotic aciduria or thiamine-responsive megaloblastic anaemia (see further on).

Cobalamin–folate relationship

Folate is required for many other reactions in mammalian tissues, including two in purine synthesis (Table 13.2), but impairment of these is far less important clinically. Only two reactions in the body are known to require cobalamin (Figure 13.2). Methylmalonyl-CoA isomerisation, which requires deoxyadenosyl(ado)-cobalamin, is discussed later.

The methylation of homocysteine to methionine requires both 5-methyltetrahydrofolate (methyl-THF) as methyl donor and

Table 13.1 Causes of megaloblastic anaemia.

Cobalamin deficiency or abnormalities of cobalamin metabolism (Table 13.4)
Folate deficiency or abnormalities of folate metabolism (Table 13.6)
Therapy with antifolate drugs (e.g. methotrexate)
Independent of either cobalamin or folate deficiency and refractory to cobalamin and folate therapy:
Some cases of acute myeloid leukaemia, myelodysplasia*
Therapy with drugs interfering with DNA synthesis (e.g. cytarabine, hydroxycarbamide, 6-mercaptopurine, azidothymidine)
Orotic aciduria (responds to uridine)
Lesch–Nyhan syndrome (may respond to adenine)

* Folate deficiency also occurs frequently in these diseases.

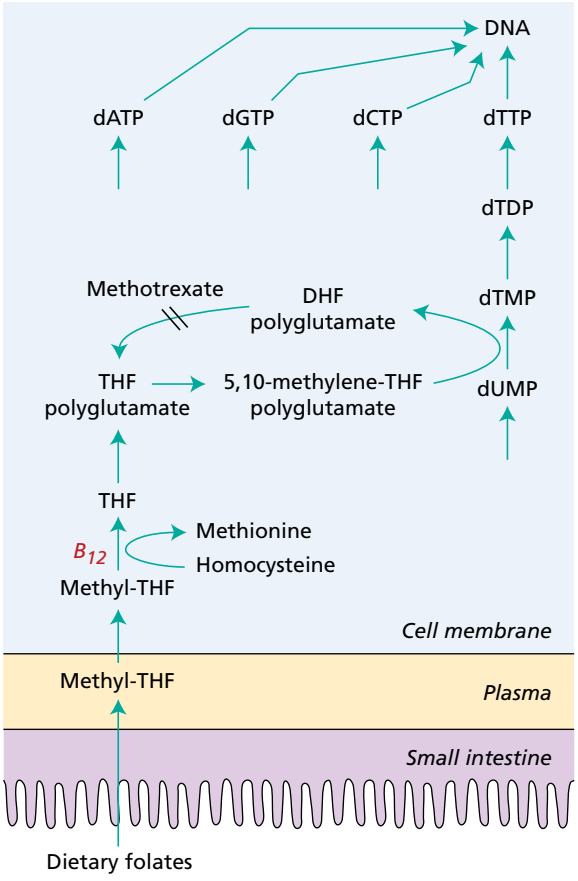

Figure 13.1 Role of folate (as 5,10-methylene-THF polyglutamate) and methylcobalamin in DNA synthesis. A, adenine; B12, vitamin B12, cobalamin; C, cytosine; d, deoxyribose; G, guanine; MP, monophosphate; T, thymine; THF, tetrahydrofolate; TP, triphosphate.

methylcobalamin as co-enzyme (Figures 13.1 and 13.3). This reaction, which is almost completely irreversible, is the first step in the pathway by which methyl-THF, which enters bone marrow and other cells from plasma, is converted into all the intracellular folate co-enzymes (Figure 13.1). The co-enzymes are all polyglutamated (the larger size aiding retention in the cell), but the enzyme folate polyglutamate synthase requires THF and not methyl-THF as substrate. In cobalamin deficiency, methyl-THF accumulates in the plasma, while intracellular folate concentrations fall due to failure of formation of intracellular folate polyglutamates including 5,10-methylene-THF because of 'THF starvation'. The 'methylfolate trap' will also cause THF starvation at the polyglutamate level.

This theory explains the abnormalities of folate metabolism that occur in cobalamin deficiency (high serum folate, low cell folate, reduced thymidylate synthesis, raised purine precursor AICAR excretion; Table 13.2) and also why the anaemia that occurs in cobalamin deficiency will respond to folic acid in large doses. The explanation of why serum cobalamin falls in folate deficiency may also be related to impairment of the homocysteine–methionine reaction, with reduced formation of methylcobalamin, the main form of cobalamin in plasma, but other mechanisms may be responsible.

Clinical features

Many symptomless patients are detected through the finding of a raised mean corpuscular volume (MCV) on a routine blood count. The main clinical features in more severe cases are those of anaemia. Anorexia is usually marked and there may be weight loss, diarrhoea or constipation. Other particular features include glossitis, angular cheilosis, a mild fever in the more severely anaemic patients, jaundice (unconjugated) and reversible melanin skin hyperpigmentation. Thrombocytopenia sometimes leads to bruising (and this may be aggravated by vitamin C deficiency in malnourished patients). The low leucocyte count may predispose to infections, particularly of the respiratory or urinary tracts. Cobalamin deficiency has also been associated with impaired bactericidal function of phagocytes.

General tissue effects of cobalamin and folate deficiencies

Epithelial surfaces

These deficiencies, when severe, affect all rapidly growing (DNA-synthesising) tissues. After the marrow, the next most affected tissues are the epithelial cell surfaces of the mouth, stomach, small intestine and respiratory, urinary and female genital tracts. The cells show macrocytosis, with increased numbers of multinucleate and dying cells. The deficiencies may cause cervical smear abnormalities.

Complications of pregnancy

The gonads are also affected and infertility is common in both men and women with either deficiency if severe. Maternal folate deficiency has been implicated as a cause of prematurity and both folate and cobalamin deficiency have been implicated in recurrent fetal loss.

Table 13.2 Biochemical reactions of folate co-enzymes.

Reaction	Co-enzyme form of folate involved	Single-carbon unit transferred	Importance
Formate activation	THF	—CHO	Generation of 10-formyl-THF
Purine synthesis Formation of glycinamide ribonucleotide	5,10-Methenyl-THF	—CHO	Formation of purines needed for DNA, RNA synthesis, but reactions probably not rate limiting
Formylation of aminoimidazole-carboxamideribotide (AICAR)	10-Formyl-THF	—CHO	
Pyrimidine synthesis Methylation of deoxyuridine monophosphate (dUMP) to thymidine monophosphate (dTMP)	5,10-Methenyl-THF	$—CH_3$	Rate limiting in DNA synthesis Oxidises THF to DHF Some breakdown of folate at the C-9–N-10 bond
Amino acid interconversion Serine–glycine interconversion	THF	$=CH_2$	Entry of single-carbon units into active pool
Homocysteine to methionine	5-Methyl-THF	$—CH_3$	Demethylation of 5-methyl-THF to THF; also requires cobalamin, flavine adenine dinucleotide, ATP and adenosylmethionine
Forminoglutamic acid to glutamic acid in histidine catabolism	THF	—HN—CH=	Basis of the Figlu test (now obsolete)

DHF, dihydrofolate; THF, tetrahydrofolate.

Neural tube defects

Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy when the neural tube is forming reduce, if 5 mg daily, by 80% the incidence of neural tube defects (NTDs) – anencephaly, meningomyelocele, encephalocele and spina bifida – in the fetus. Most of this protective effect can be achieved by taking folic acid 0.4 mg daily. The incidence of cleft palate and harelip can also be reduced by prophylactic folic acid. There is no clear simple relationship between maternal folate status and these fetal abnormalities, although the lower the maternal folate (and cobalamin) plasma levels, the greater the risk of NTD or, in diabetic mothers of other birth defects, in

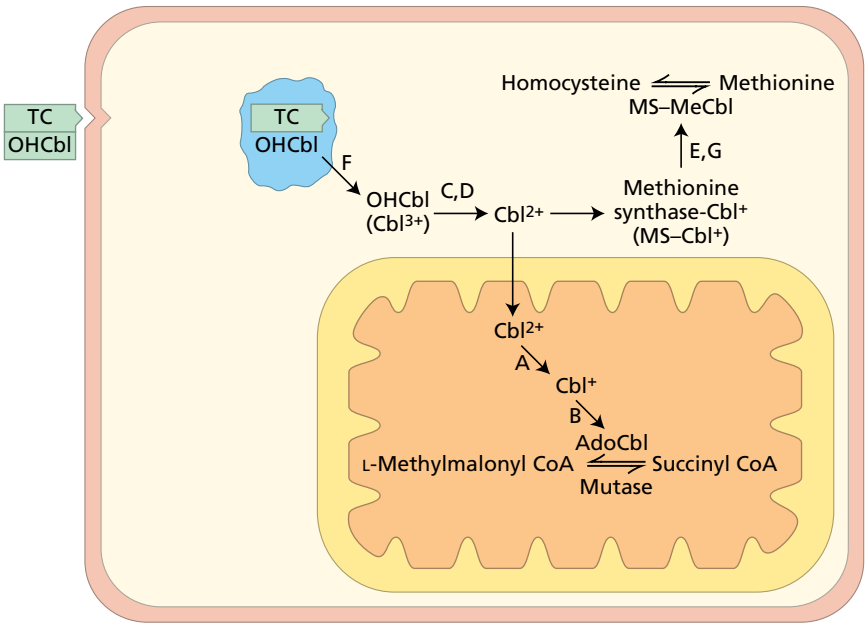

Figure 13.2 Intracellular cobalamin metabolism. Cbl^{1+}, Cbl^{2+} and Cbl^{3+} refer to the oxidation state of the central cobalt atom of cobalamin Cbl^{3+} being the most oxidised. A–G refers to the sites of blocks that have been identified by complementation analysis in infants with metabolic defects. AdoCbl, adenosylcobalamin; MeCbl, methylcobalamin; TC, transcobalamin. The mitochondrial, lysosomal and cytoplasmic compartments are indicated (Source: Lilleyman JS, Hann IM, and Blanchette VS (eds) (1999) *Paediatric Haematology*, 2nd edn. Churchill Livingstone, Edinburgh. Reproduced with permission from Elsevier.)

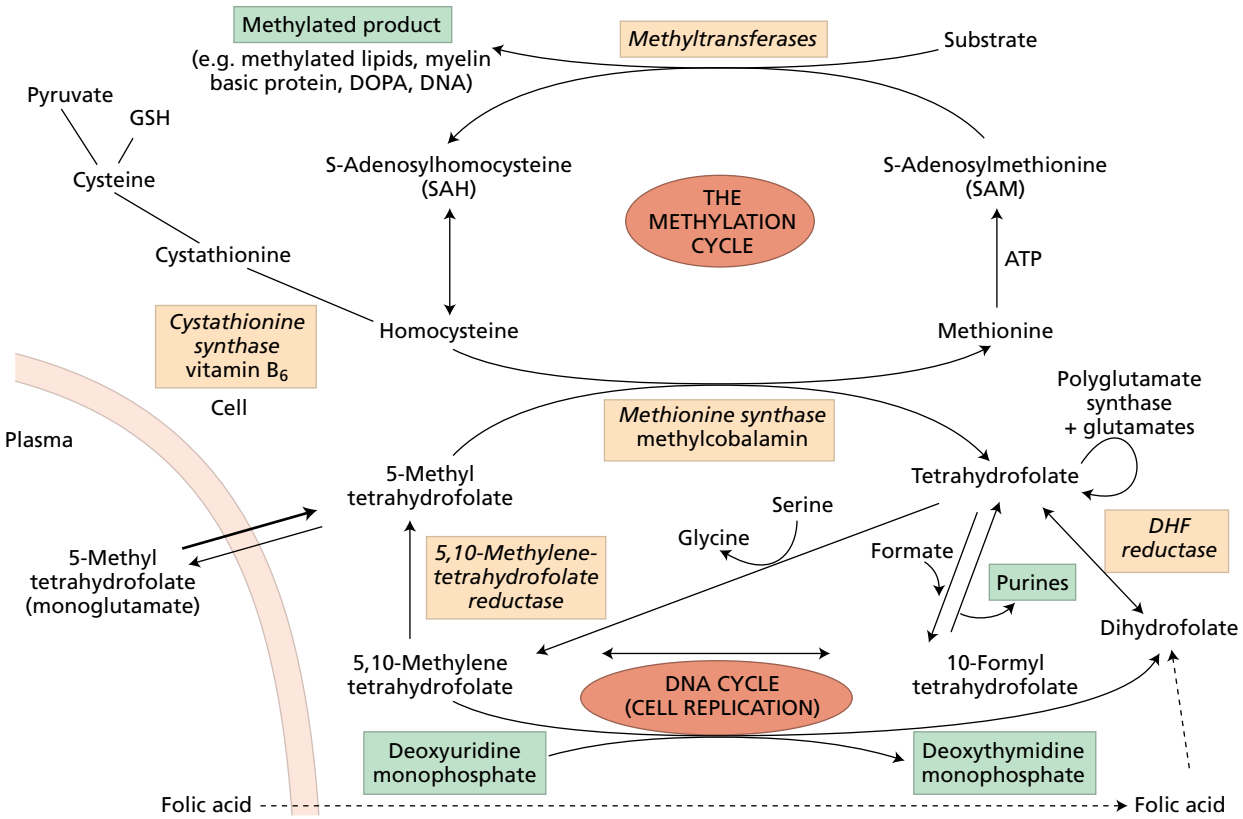

Figure 13.3 The role of folates in DNA synthesis and in formation of *S*-adenosylmethionine (SAM), which is involved in numerous methylation reactions. Enzymes are shown in pink boxes. (Figure prepared in conjunction with Professor John Scott.)

infants. Doubling the maternal serum folate level approximately halves the risk of an NTD pregnancy. This applies even when the maternal serum folate level is in the conventional normal range. NTDs can also be caused by antifolate and antiepileptic drugs, especially valproic acid. There is also an association between lower maternal cobalamin levels and an increased incidence of an NTD pregnancy.

An underlying maternal folate metabolic abnormality has also been postulated. One abnormality has been identified: reduced activity of the enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR) (Figure 13.3) caused by a common 677C→T polymorphism in the *MTHFR* gene. In one study, the prevalence of this polymorphism was found to be higher in the parents of NTD fetuses and in the fetuses themselves: homozygosity for the TT mutation was found in 13% compared with 5% in control subjects. The polymorphism codes for a thermolabile form of MTHFR. The homozygous state results in lower mean serum and red cell folate compared with control subjects, as well as significantly higher serum homocysteine levels. Tests for mutations in other enzymes possibly associated with NTDs, have been negative.

About 20% of NTDs cannot be prevented even by high doses of folic acid. It seems that metabolic abnormalities unrelated to folate underlie these.

Cardiovascular disease

Children with severe homocystinuria (blood levels of 100 µmol/L or more) due to deficiency of one of three enzymes, methionine synthase, MTHFR or cystathionine synthase (Figure 13.3) suffer from vascular disease (e.g. ischaemic heart disease, cerebrovascular disease or pulmonary embolus) as teenagers or in young adulthood. Meta-analysis shows a significant association between lesser degrees of raised serum homocysteine (normal range 5–15 µmol/L) and of homozygosity for mutated *MTHFR* with ischaemic heart disease, stroke, deep vein thrombosis and pulmonary embolism.

It remains possible that homocysteine levels may be high as a consequence of vascular damage or may merely be a marker for some other underlying factor that is responsible for both the vascular damage and the raised homocysteine. Folate deficiency, for example, may be such a factor. Folate levels have been found in various studies to be lower in patients with myocardial infarct and carotid artery disease than control subjects. Meta-analysis of data from large multicentre prospective trials of folic acid in prevention of coronary arterial disease, however, does not show a positive effect, whereas a reduction of the risk of stroke by 18% has been reported from China, but even for this, there are conflicting data. For coronary disease aspirin may over-ride any effect of folic acid.

Extremely high levels of homocysteine (>50 μmol/L) are toxic to endothelia. When homocysteine levels are only mildly or moderately elevated, other mechanisms have been proposed, including oxidant damage interaction of homocysteine with cysteine residues on coagulation factors, platelets, adhesion molecules or endothelial cells or promotion of vascular wall inflammation.

Malignancy

Prophylactic folic acid in pregnancy has been found in some, but not all, studies to reduce the subsequent incidence of acute lymphoblastic leukaemia (ALL) in childhood. A significant negative association has been found with the *MTHFR* 677C→T and 1298A→C polymorphisms and the incidence of both paediatric and adult ALL. There are various positive and negative associations between polymorphisms in other folate-dependent enzymes and the incidence of paediatric and adult ALL. Other tumours that have been associated with folate polymorphisms or status include follicular lymphoma, breast cancer and gastric cancer.

Meta-analysis of 10 randomised trials of folic acid at daily doses of 0.5 mg or more for an average of 5.2 years to prevent coronary heart disease, as well as of three trials for prevention of colonic adenomas (total 49,621 individuals) has not shown a significant difference for cancer generally or for any specific cancer between folic acid and placebo. This is reassuring, both for those taking folic acid as a vitamin supplement and for countries where food fortification with folic acid is carried out.

Other tissues

Folate deficiency causes reduced regeneration of cirrhotic liver. Patients with gluten-induced enteropathy and those with sickle cell anaemia have also been reported to show stunted growth, which has been improved coincidentally with commencement of folic acid therapy, but it is not certain how much the growth improvement in these children was due to folic acid and how much to other, simultaneously administered vitamins. There are experimental data in animals and some clinical observations that long-term cobalamin deficiency can affect bone formation. In the fragile X syndrome, sister chromatid exchange and DNA breaks are increased *in vitro* in a folate-deficient medium, apparently at the Xq28 site. No *in vivo* abnormality of folate metabolism can be detected.

Neurological manifestations

Cobalamin deficiency may cause bilateral peripheral neuropathy or degeneration (demyelination) of the posterior and pyramidal tracts of the spinal cord and, less frequently, optic atrophy or cerebral symptoms. The patient classically presents with paraesthesiae in the legs, muscle weakness or difficulty in walking and sometimes dementia, psychotic disturbances or visual impairment. Orthostatic hypotension has also been described as a complication of even mild cobalamin deficiency and in a few small studies the underlying autonomic neuropathy shown to improve with cobalamin therapy. Long-term nutritional cobalamin deficiency in infancy leads to poor brain development and impaired intellectual development. Folate deficiency may cause mental changes such as depression and slowness, and has been suggested to cause organic nervous disease, but this is uncertain. Methotrexate injected into the cerebrospinal fluid may cause brain or spinal cord damage. Neural tube defects in the fetus are discussed above.

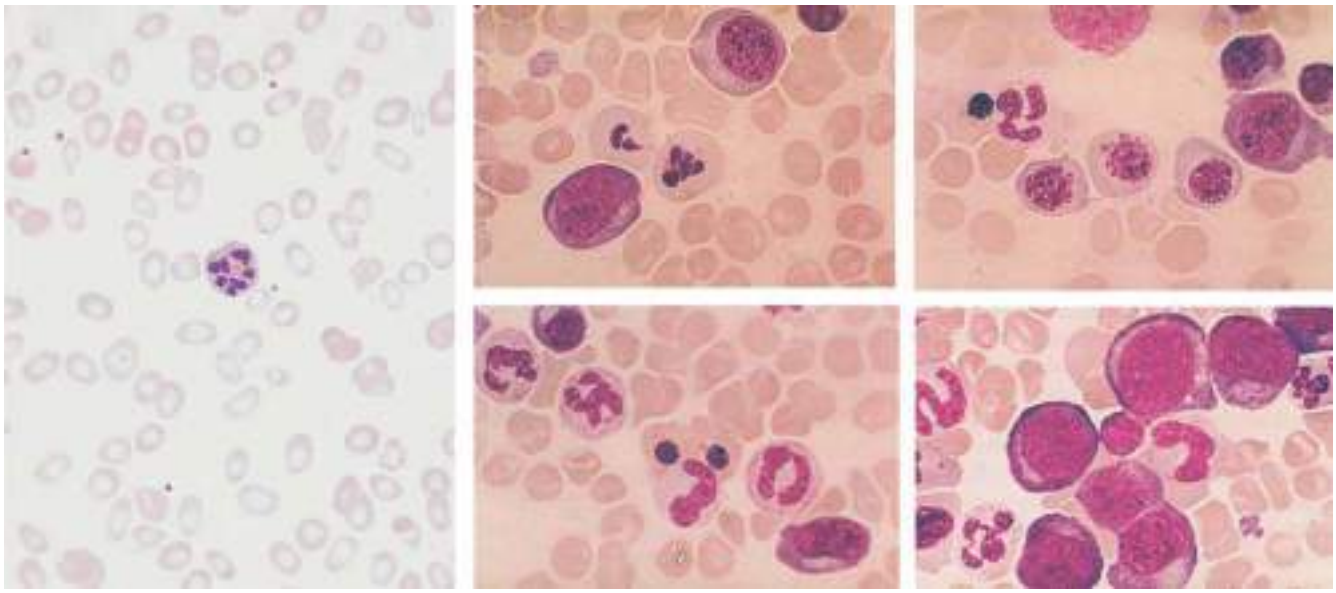
Studies showing an association between lower serum levels of folate or cobalamin and higher homocysteine levels and Alzheimer disease, loss of cognitive function or brain volume loss have been reported. Serum cobalamin levels even in the low normal range if associated with raised homocysteine levels have also been associated with cognitive impairment. One trial has shown that supplementation with folic acid, cobalamin and vitamin B_6 delayed brain atrophy in such subjects with also raised serum homocysteine levels compared to a control group. More recent trials mainly in China have shown a benefit of cobalamin and folic acid in improving or slowing progression of mild cognitive impairment but such benefit remains controversial.

The biochemical basis for cobalamin neuropathy remains obscure. Its occurrence in the absence of methylmalonic aciduria in transcobalamin deficiency, and monkeys given nitrous oxide (N_2O), suggests that the neuropathy is related to the defect in conversion of homocysteine to methionine. Accumulation of *S*-adenosylhomocysteine (SAH) in the brain, resulting in inhibition of transmethylation reactions due to an altered *S*-adenosylmethionine (SAM) to SAH ratio, has been suggested. SAM is needed in methylation of biogenic amines (e.g. dopamine), as well as of proteins, phospholipids and neurotransmitters in the brain (Figure 13.3).

Haematological findings

Peripheral blood

Oval macrocytes, usually with considerable anisocytosis and poikilocytosis, are the main features (Figure 13.4a). The MCV is usually more than 100 fL unless a cause of microcytosis (e.g. iron deficiency or thalassaemia trait) is present when there is a raised red cell distribution width (RDW) and the film is dimorphic. The MCV may also be normal owing to excess fragmentation of red cells. Some of the neutrophils are hypersegmented (more than five nuclear lobes). Both macrocytosis and hypersegmented neutrophils may also occur in other situations (Table 13.3). Together, however, they strongly suggest megaloblastic haemopoiesis. There may be leucopenia due to a reduction in granulocytes and lymphocytes; the platelet count may be moderately reduced, rarely to less than 40×10^9/L.



(a) (b)

Figure 13.4 Severe megaloblastic anaemia: (a) peripheral blood (Source: Historical Library.) (b) bone marrow.

Occasionally, a leucoerythroblastic blood picture is seen. In the non-anaemic patient, the presence of a few macrocytes and hypersegmented neutrophils in the peripheral blood may be the only abnormalities.

Table 13.3 Conditions in which macrocytosis or hypersegmented neutrophils may occur in the absence of megaloblastic anaemia.

Macrocytosis
Alcohol
Liver disease (especially alcoholic)
Reticulocytosis (haemolysis or haemorrhage)
Aplastic anaemia or red cell aplasia
Hypothyroidism
Myelodysplasia
Myeloma and macroglobulinaemia
Leucoerythroblastic anaemia
Myeloproliferative disease
Pregnancy
Newborn
Congenital dyserythropoietic anaemia (type II)
? Chronic respiratory failure
Hypersegmented neutrophils
Renal failure
Congenital (familial)
? Iron deficiency

Falsely high MCV recorded when cold agglutinins, paraproteins or marked leucocytosis are present.

Bone marrow

In severely anaemic patients, the marrow is hypercellular with accumulation of primitive cells due to selective death of more mature forms. There is dissociation between nuclear and cytoplasmic development in the erythroblasts, with the nucleus maintaining a primitive appearance despite maturation and haemoglobinisation of the cytoplasm; fully haemoglobinised (orthochromatic) erythroblasts may be seen. The nucleus of the megaloblast has an open, fine and lacy appearance; the cells are larger than normoblasts and an increased number of cells with eccentric lobulated nuclei or nuclear fragments may be present (Figure 13.4b). Mitotic and dying cells are seen more frequently than normal. Giant and abnormally shaped metamyelocytes and enlarged hyperpolyploid megakaryocytes are characteristic. Severe florid megaloblastic changes may be confused with acute erythroid leukaemia. Rarely, the marrow may be hypocellular or red cell precursors are lost almost completely from the marrow and a mistaken diagnosis of myeloid leukaemia may be made. Iron staining shows increase in both reticuloendothelial stores and in the developing megaloblasts.

In less anaemic patients, the changes in the marrow may be difficult to recognise. The terms 'intermediate', 'mild' and 'early' have been used. The changes may be mild and difficult to recognise, even in a severely anaemic patient, if the anaemia is largely due to other factors (e.g. iron deficiency, infection, malignant disease and haemolysis) and the megaloblastosis is an incidental phenomenon. The term 'megaloblastoid' has several different connotations, including the dysplastic changes seen in the myelodysplastic syndromes, and is best avoided.

Chromosomes

Bone marrow cells, transformed lymphocytes and other proliferating cells in the body show a variety of changes including random chromosomal breaks, reduced contraction of chromatin, spreading of the centromere, and exaggeration of secondary chromosomal constrictions and prominent satellites. Similar abnormalities may be produced by antimetabolite drugs (e.g. cytarabine, hydroxycarbamide and methotrexate) that interfere with either DNA replication or folate metabolism and which also cause megaloblastic appearances.

Ineffective haemopoiesis

There is accumulation of unconjugated bilirubin in plasma due to the death of nucleated red cells in the marrow (ineffective erythropoiesis). Other evidence for this includes raised urine urobilinogen, reduced haptoglobins and positive urine haemosiderin, raised serum lactate dehydrogenase and raised serum iron, non-transferrin-bound iron and ferritin levels. Carbon monoxide production has also increased. Serum lysozyme may also be raised, suggesting ineffective granulopoiesis.

In rare patients, ineffective haematopoiesis is associated with features of disseminated intravascular coagulation, with raised serum fibrin degradation products. Thrombocytopenia, when it occurs, is usually caused by ineffective megakaryopoiesis. A weakly positive direct antiglobulin test due to complement can lead to a false diagnosis of autoimmune haemolytic anaemia.

Cobalamin

Cobalamin (vitamin B_{12}) exists in a number of different chemical forms. The molecule consists of two halves: a planar group and a nucleotide set at right angles to it (Figure 13.5). The planar group is a corrin ring and the nucleotide consists of a base, 5,6-dimethylbenzimidazole, and a phosphorylated sugar, ribose-5-phosphate. In nature, the vitamin is mainly in the 5′-deoxyadenosyl (ado) form. This is the main form in human tissues and is located in the mitochondria. It serves as the co-factor for methylmalonyl-CoA mutase. The other major natural cobalamin is methylcobalamin, the main form in human plasma and cell cytoplasm, which serves as the co-factor for methionine synthase. There are also minor amounts of hydroxocobalamin, the form to which methyl- and adocobalamin are rapidly converted by exposure to light, hydroxocobalamin having its cobalt atom in the fully oxidised Cbl^{3+} state, whereas the cobalt exists as reduced Cbl^{1+} in the methyl- and ado-cobalamin forms (see Figure 13.2).

Dietary sources and requirements

Cobalamin is synthesised solely by microorganisms. Ruminants obtain cobalamin from the foregut, but the only source for humans is food of animal origin. The highest amounts are found

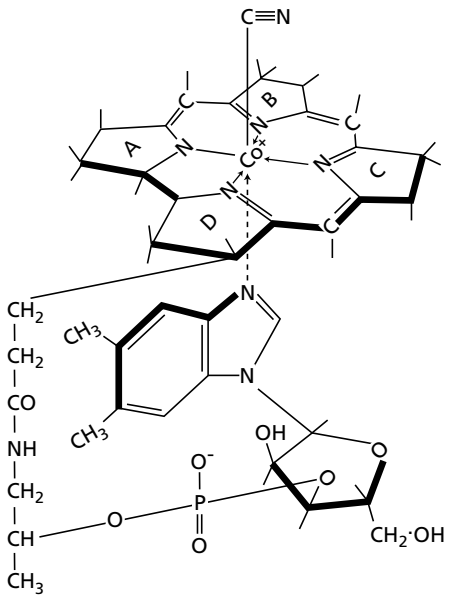


Figure 13.5 The structure of vitamin B_{12} (cyanocobalamin). There is a corrin ring with a cobalt atom at its centre. Above is attached the cyano, hydroxo, methyl or deoxyadenosyl ligand. Below is the nucleotide 5,6-dimethylbenzimidazole.

in liver and kidney (up to 100 µg per 100 g), but it is also present in shellfish, organ and muscle meats, fish, chicken and dairy products (eggs, cheese and milk) in small amounts (6 µg/L). Vegetables, fruits and all other foods of non-animal origin are free from cobalamin unless they are contaminated by bacteria. Cooking does not usually destroy cobalamin.

A normal Western diet contains 5–30 µg of cobalamin daily. Adult daily losses (mainly in the urine and faeces) are about 1–2 µg and because the body does not have the ability to degrade cobalamin, daily requirements are also about 1 µg. Body stores are of the order of 2–3 mg and are sufficient for 3–4 years if supplies are completely cut off.

Absorption

Two mechanisms exist for cobalamin absorption. One is passive, occurring equally through the duodenum and the ileum; it is rapid but inefficient as less than 1% of an oral dose can be absorbed by this process. Passive absorption of cobalamin can also occur through other mucous membranes such as the sublingual and nasal mucosae. The other mechanism is active; it occurs through the ileum in humans and is efficient for small (a few micrograms) oral doses of cobalamin. This is the normal mechanism by which the body acquires cobalamin and is mediated by gastric intrinsic factor (IF).

Dietary cobalamin is released from protein complexes by enzymes in the stomach, duodenum and jejunum; it combines rapidly with a salivary gastric glycoprotein (R binder) related to

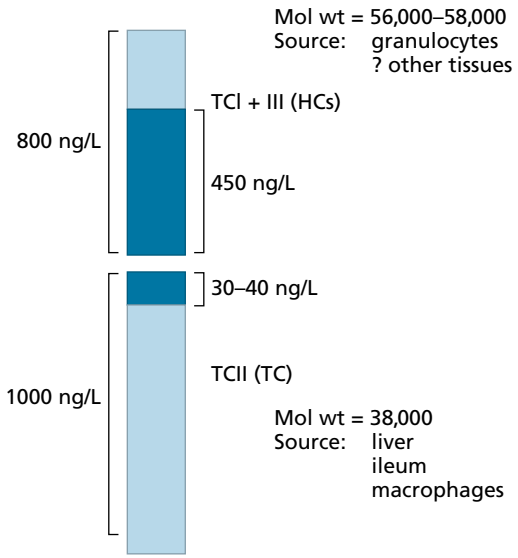

Figure 13.6 The serum cobalamin-binding proteins (TCs, transcobalamins). Dark blue rectangles indicate endogenous serum cobalamin; light blue rectangles indicate unsaturated cobalamin-binding protein; HCs, haptocorrins.

plasma transcobalamin I (TCI). These proteins are isoforms of cobalamin-binding proteins known as haptocorrins (HCs), which differ from each other only in their patterns of glycosylation. They are products of a single gene (*TCN1*), and they occur in saliva, gastric juice, bile, milk and other body fluids. Subsequently, HC is digested by pancreatic trypsin and the cobalamin transferred to IF. Binding of cobalamin to IF is favoured by an alkaline pH; it binds one molecule for one molecule. All forms of cobalamin are absorbed by the same IF mechanism (Figure 13.6). Intrinsic factor is a glycoprotein (molecular weight 45,000) encoded by a gene on chromosome 11q13. It is produced in gastric parietal cells in the fundus and body of the stomach. The IF–cobalamin complex, in contrast with free IF, is resistant to enzyme digestion, having a more closed structure. It passes to the ileum, where IF attaches to a specific receptor (cubilin) on the brush border surface of the ileal absorptive cells. Cubilin is also present in the yolk sac and renal proximal tubular epithelium. The attachment of the IF–cobalamin complex requires calcium ions and a pH around neutral. It is probably a physical process, not requiring energy. Cubilin traffics by means of the protein called amnionless (AMN). AMN binds tightly to cubilin and directs sublocalisation and endocytosis of cubilin with its ligand (IF–cobalamin complex). Defects in cubilin and AMN are implicated in autosomal recessive megaloblastic anaemia, characterised by intestinal malabsorption of cobalamin. A third protein, megalin (LRP2), has been suggested to play a role in stabilising the cubilin–AMN complex.

Cobalamin then enters the ileal cell. IF is digested and after a delay of about 6 hours absorbed cobalamin appears in portal blood attached to transcobalamin (TCII), which is synthesised in the ileum, either by mucosal cells or by venous endothelial cells in the submucosa.

The ileum has a restricted capacity to absorb cobalamin because of limited receptor sites. Although 50% or more of a single dose of 1 µg of cobalamin may be absorbed, with doses above 2 µg the proportion absorbed falls rapidly. Moreover, after one dose of IF–cobalamin complex has been presented, the ileal cells become refractory to further doses for about 6 hours.

Enterohepatic circulation

Between 0.5 and 5.0 µg of cobalamin enter the bile each day. This binds to IF and a portion of biliary cobalamin is reabsorbed together with cobalamin derived from sloughed intestinal cells. Bile may enhance cobalamin absorption. Cobalamin deficiency develops more rapidly in individuals who malabsorb cobalamin than it does in vegans, who ingest no cobalamin but in whom reabsorption of biliary cobalamin is intact.

Transport

Two main cobalamin-binding proteins exist in human plasma; they both bind cobalamin one molecule for one molecule (Figure 13.6). One HC (also known as TCI) is a glycoprotein. TCIII is a minor isoprotein of TCI in plasma. These HCs are derived primarily from the specific granules in neutrophils and are normally about two-thirds saturated with cobalamin, which they bind tightly. They do not enhance cobalamin entry into tissues. Glycoprotein receptors on liver cells are concerned with the removal of HCs from plasma, and HC may have a role in the transport of cobalamin analogues to the liver for excretion in bile. The gene, *TCN1* on chromosome 11q11–q12.3, has nine exons and codes a protein of 433 amino acids. Heterozygous, homozygous or compound heterozygous mutations in the gene may cause mild or severe reductions in serum vitamin B_{12}, respectively, with no known clinical consequences.

The other major cobalamin transport protein in plasma is transcobalamin (TC, also known as TCII). This is synthesised by liver, and by other tissues, including macrophages, endothelial and possibly ileal cells. It normally carries only 20–60 ng of cobalamin per litre of plasma and readily gives up cobalamin to marrow, placenta and other tissues, which it enters by receptor-mediated endocytosis via clathrin-coated pits. TC is not reutilised. The gene is on chromosome 22q11–q13.1 and, as for IF and HC, there are nine exons. The three proteins are likely to have a common ancestral origin. TC has 20% amino acid homology and more than 50% nucleotide homology with human HC and with rat IF. The regions of homology of HC, TC and IF are involved in cobalamin

binding. Five different inherited isoproteins of TC have been described; all are functionally active. TC is also present in cerebrospinal fluid and binds cobalamin (approximately 10 ng/L) there. Alterations may occur in TC and HC levels in a variety of disease states. In general, an increase in HC is found particularly in myeloproliferative diseases and hepatoma and causes an increase in serum cobalamin, whereas an increase in TC does not.

The TC receptor belongs to the low-density lipoprotein receptor family. It is more heavily expressed in dividing than quiescent cells and is recycled to the cell surface. Megalin (LRP-2) is also involved in the endocytosis of TC–cobalamin.

Cobalamin analogues

Cobalamin analogues are corrinoids, which exist as cobamides (containing substitutions in the place of ribose, e.g. adenosyl) or as cobinamides (which have no nucleotide whatever). They do not bind to IF and are not absorbed. HC may carry analogues to the liver for excretion in the bile. It is unclear whether they are inert or inhibit cobalamin-dependent reactions. The proportion of analogues derived from diet, gut bacteria or endogenous breakdown of cobalamins is unknown. They are present in fetal blood and tissues.

Causes of cobalamin deficiency

Cobalamin deficiency is usually due to malabsorption. The only other cause is inadequate dietary intake. Cobalamin deficiency due to excess degradation does not occur. Inactivation may occur as a result of exposure to the anaesthetic gas N_2O. N_2O causes irreversible oxidation of the active Cbl^{1+} during catalytic shunting of labile methyl groups in the methionine synthase reaction (see Figure 13.2).

Inadequate dietary intake adults

Dietary cobalamin deficiency arises in vegans who omit meat, fish, eggs, cheese and other animal products from their diet. The largest group in the world consists of Hindus, and many millions of Indians are at risk of deficiency on a nutritional basis. However, not all vegans develop cobalamin deficiency of sufficient severity to cause anaemia or neuropathy, even though subnormal cobalamin levels have been found in up to 50% of randomly selected, young, adult Indian vegans. Dietary cobalamin deficiency may also arise rarely in non-vegetarian subjects who exist on grossly inadequate diets because of poverty or psychiatric disturbance. Nutritional cobalamin deficiency may not progress to megaloblastic anaemia because the diet is not totally lacking cobalamin, the enterohepatic circulation is intact and body losses will reduce as stores diminish.

Infants

Cobalamin deficiency occurs in infants born to severely cobalamin-deficient mothers. These infants develop megaloblastic anaemia at about 3–6 months of age since they are born with low stores of cobalamin and are then fed breast milk of low cobalamin content. This occurs most commonly not only in Indian vegans, but also in unrecognised maternal pernicious anaemia and in strict practitioners of veganism living in Western countries whose offspring have shown growth retardation, impaired psychomotor development and other neurological sequelae.

Gastric causes of cobalamin malabsorption

Pernicious anaemia

Pernicious anaemia (PA) may be defined as a severe lack of IF due to gastric atrophy (Tables 13.4 and 13.5). It is a common disease in northern Europeans but occurs in all countries and ethnic groups. The overall incidence is about 120 per 100,000 population in the UK, but there is wide variation between one area and the next. The prevalence rate in Western countries may be as high as 2–3%. The ratio of incidence in men and women is approximately 1:1.6 and the peak age of onset is 60 years, with only 10% of patients being less than 40 years of age. In some ethnic groups, notably black people and Latin Americans, the age of onset of PA is generally lower. The disease occurs more commonly than by chance in close relatives, in subjects or families with other organ-specific autoimmune diseases of the thyroid, adrenal or parathyroid, in those with premature greying, blue eyes and vitiligo, and in persons of blood group A. An association with human leucocyte antigen (HLA)-3 has been reported in some but not all series and in

Table 13.4 Causes of cobalamin deficiency causing megaloblastic anaemia.

Nutritional
Vegans
Malabsorption
Pernicious anaemia
Gastric causes
Congenital intrinsic factor deficiency or functional abnormality. Total or partial gastrectomy
Intestinal causes
Intestinal stagnant loop syndrome: jejunal diverticulosis, ileocolic fistula, anatomical blind loop, intestinal stricture, etc.
Ileal resection and Crohn's disease
Selective malabsorption with proteinuria
Tropical sprue
Transcobalamin deficiency
Fish tapeworm

Table 13.5 Malabsorption of cobalamin may occur in the following conditions but is not usually sufficiently severe and prolonged to cause megaloblastic anaemia.

Gastric causes
Simple atrophic gastritis (food cobalamin malabsorption)
Zollinger–Ellison syndrome
Gastric by-pass (bariatric) surgery
Use of proton pump inhibitors
Intestinal causes
Gluten-induced enteropathy
Severe pancreatitis
HIV infection
Radiotherapy
Graft-versus-host disease
Deficiency states
Cobalamin, folate, protein, riboflavin?, nicotinic acid?
Drug therapy
Colchicine, *p*-aminosalicylate, neomycin, slow-release potassium chloride, anticonvulsant drugs, ?metformin, ?phenformin, cytotoxic drugs
Alcohol

those with endocrine disease, with HLA-B8, -B12 and -BW15. The life expectancy has been estimated as normal in women once regular treatment has begun. Men have been reported to have a slightly lower life expectancy as a result of a higher incidence of carcinoma of the stomach than in control subjects.

Diagnosis

This is usually suspected from the clinical picture and the findings of megaloblastic anaemia due to cobalamin deficiency. Tests for circulating gastric autoantibodies and serum gastrin levels are important. The *serum gastrin* level is usually raised in PA (>200 µg/L), the hormone coming from endocrine cells in the gastric fundus. Raised serum gastrin also occurs in simple atrophic gastritis. Serum pepsinogen I levels are low (<30 µg/L) in over 90% of those affected and a low ratio of serum pepsinogen I to pepsinogen II correlates with the presence of chronic atrophic gastritis.

Gastric biopsy

This shows atrophy of all layers of the body and also fundal atrophy, with loss of glandular elements, an absence of parietal and chief cells and replacement by mucous cells, a mixed inflammatory cell infiltrate and sometimes intestinal metaplasia. The infiltrate of plasma cells and lymphocytes contains an excess of CD4 cells. The antral mucosa is usually well preserved. *Helicobacter (H.) pylori* infection is infrequent in PA, but it has been suggested that *H. pylori* gastritis may represent an early phase of atrophic gastritis, often associated with iron deficiency, which is gradually replaced, in some individuals, by an immune process with disappearance of *H. pylori* infection. Corticosteroid therapy may restore acid and IF secretion temporarily.

Antibodies to gastric antigens

IF antibodies: Two types of IF antibodies may be found in the sera of patients with PA, both being IgG. One, the 'blocking' or 'type I' antibody, prevents the combination of IF and cobalamin, whereas the other, the 'binding', 'type 2' antibody, which attaches to IF whether joined to cobalamin or not, prevents attachment of IF to ileal mucosa. Type 1 antibody occurs in the serum of about 55% of patients, type 2 antibody in 35%. IF antibodies cross the placenta and cause temporary IF deficiency in the newborn infant. Patients with PA also show cell-mediated immunity to IF. IF antibodies are rarely found in conditions other than PA. Type I antibody has been detected rarely in the sera of patients without PA but with thyrotoxicosis, myxoedema, Hashimoto disease or diabetes mellitus, and in relatives of PA patients. IF antibodies have also been detected in gastric juice in about 80% of patients with PA. These antibodies may reduce absorption of dietary cobalamin by combining with small amounts of remaining IF in the gastric juice. Achlorhydria favours the formation of this antigen–antibody complex.

Parietal cell and gastrin receptor antibodies: Parietal cell antibody is present in the sera of almost 90% of adult patients with PA, but it is frequently present in other subjects. Thus, it occurs in as many as 16% of randomly selected female subjects aged over 60 years and in a smaller proportion of younger control subjects; it is found more frequently than in control subjects in relatives of PA patients. These antibodies are also found more frequently in patients with simple atrophic gastritis, chronic active hepatitis and thyroid disorders and their relatives, as well as in Addison disease, rheumatoid arthritis and other conditions. The parietal cell antibody is directed against the α and β-subunits of the gastric proton pump (H^+/K^+ -ATPase). The sera of PA patients may also contain an autoantibody to the gastrin receptor, although this test is not used clinically.

Hypogammaglobulinaemia

PA is found more often than by chance in patients with a deficiency of IgA or with complete hypogammaglobulinaemia. These subjects resemble others with PA, except that they often present relatively early (before the age of 40 years), they have a lower incidence of serum IF and parietal cell antibodies, and they may show intestinal malabsorption. They may also have a history of recurrent infections. The gastric lesion is similar to that in other cases, except that plasma cells are absent from

the inflammatory cell infiltrate and the antrum is involved. Serum gastrin levels are normal.

Juvenile pernicious anaemia

This usually occurs in older children and resembles PA in adults. Gastric atrophy, achlorhydria and serum IF antibodies are all present, although parietal cell antibodies are usually absent. About half of these patients show an associated endocrinopathy such as autoimmune thyroiditis, Addison disease or hypoparathyroidism; in some, mucocutaneous candidiasis occurs.

Congenital intrinsic factor deficiency or functional abnormality

The affected child usually shows no demonstrable IF but has a normal gastric mucosa and normal secretion of acid. The inheritance is autosomal recessive. These patients usually present with megaloblastic anaemia in the first, second or third year of life when stores of cobalamin accumulated from the mother *in utero* are used up; a few have presented as late as the second decade. Parietal cell and IF antibodies are absent. Variants have been described in which the child is born with IF that can be detected immunologically, but which is unstable or functionally inactive, being unable either to bind cobalamin or to facilitate its uptake by the ileum.

Gastrectomy

Following total gastrectomy, cobalamin deficiency is inevitable and prophylactic cobalamin therapy should be commenced immediately following the operation. After partial gastrectomy, 10–15% of patients also develop this deficiency. The exact incidence and time of onset are most influenced by the size of the resection and the pre-existing size of the cobalamin body store. Gastric plication for obesity (bariatric surgery) may also cause malabsorption of cobalamin.

Simple atrophic gastritis (food cobalamin malabsorption)

The normal IF-mediated mechanism of cobalamin absorption requires adequate gastric output of acid and pepsin to ensure the release of food cobalamin. Failure of this mechanism is believed to be responsible for a condition more common in the elderly known as *food cobalamin malabsorption*. The syndrome has also been described in association with *H. pylori* infection, long-term use of histamine H_2 -receptor antagonists and proton pump inhibitors, chronic alcohol excess, pancreatic exocrine failure, Sjögren syndrome and systemic sclerosis. The syndrome is associated with low serum cobalamin levels, with or without evidence of cobalamin deficiency, such as raised serum levels of methylmalonic acid and homocysteine. A minority of patients with food cobalamin malabsorption may go on to develop clinically significant cobalamin deficiency, but the frequency of occurrence and reasons for this progression are not clear.

Intestinal causes of cobalamin malabsorption

Malabsorption of cobalamin occurs in a variety of intestinal lesions in which there is colonisation of the upper small intestine by faecal organisms. This may occur in patients with jejunal diverticulosis, entero-anastomosis, intestinal stricture or fistula, or with an anatomical blind loop due to Crohn's disease, tuberculosis or an operative procedure. Bacterial overgrowth in the small intestine may also cause spurious elevation of serum methylmalonate (see further on). Removal of 1.2 m or more of terminal ileum causes malabsorption of cobalamin. In some patients, following ileal resection, particularly if the ileocaecal valve is incompetent, colonic bacteria may contribute further to cobalamin deficiency.

Nearly all patients with acute and subacute tropical sprue show malabsorption of cobalamin; this may persist as the principal abnormality in the chronic form of the disease, when the patient may present with megaloblastic anaemia or neuropathy due to cobalamin deficiency. Absorption of cobalamin usually improves after antibiotic therapy and, in the early stages, after folic acid therapy. Malabsorption of cobalamin occurs in about 30% of untreated patients with gluten-induced enteropathy and correlates with the degree of steatorrhoea. Cobalamin deficiency is not usually severe in these patients and is probably never the cause of megaloblastic anaemia unless another lesion causing malabsorption of cobalamin (e.g. stagnant loop syndrome) is present. The absorption improves when these patients are treated with a gluten-free diet.

Selective malabsorption of cobalamin with proteinuria (also known as Imerslünd syndrome, Imerslünd–Grasbeck syndrome, megaloblastic anaemia Type 1 (MGA1) is an autosomal recessive disease and is the most common cause of megaloblastic anaemia due to cobalamin deficiency in infancy in Western countries. There are familial clusters in Finland, Norway, the Middle East and North Africa. The patients usually present with anaemia between the ages of 1 and 5 years, and secrete normal amounts of IF and gastric acid. In some cases, such as in Finland, impaired synthesis, processing or ligand binding of cubilin due to inherited mutations, for example c.391C→T (named FM1) and a mutation at an intron causing a truncated protein (FM2), have been implicated. In others, for example in Norway, mutation of the gene for AMN has been reported. Other tests of intestinal absorption are normal. Over 90% of these patients show non-specific proteinuria but renal function is otherwise normal and renal biopsy has not shown any consistent renal defect. A few of these patients have shown aminoaciduria and congenital renal abnormalities, such as duplication of the renal pelvis.

The fish tapeworm (*Diphyllobothrium latum*) lives in the small intestine of humans and accumulates cobalamin from food, rendering this unavailable for absorption. People acquire the worm by eating raw or partly cooked fish. Infestation is common around the lakes of Scandinavia, Germany, Japan, North America and Russia. Megaloblastic anaemia or cobalamin neuropathy occurs only in those with a heavy infestation, with the worm high in the small intestine. Many carriers have no cobalamin deficiency.

In severe chronic pancreatitis, lack of trypsin is thought to be why dietary cobalamin attached to gastric non-IF (R) binder is unavailable for absorption. It has also been proposed that in pancreatitis, the concentration of calcium ions in the ileum falls below the level needed to maintain normal cobalamin absorption. Serum cobalamin levels tend to fall in patients with HIV infection and are subnormal in 10–35% of those with AIDS. Malabsorption of cobalamin not corrected by IF has been shown in some, but not all, patients with subnormal serum cobalamin levels. Malabsorption of cobalamin has been reported in Zollinger–Ellison syndrome. It is thought that there is a failure to release cobalamin from R binding protein due to inactivation of pancreatic trypsin by high acidity, as well as interference with IF binding of cobalamin.

Both total body irradiation and local radiotherapy to the ileum (e.g. as a complication of radiotherapy for carcinoma of the cervix) may cause malabsorption of cobalamin. Graft-versus-host disease commonly affects the small intestine: malabsorption of cobalamin due to abnormal gut flora, as well as damage to ileal mucosa, is frequent. Some drugs cause malabsorption of cobalamin, but rarely megaloblastic anaemia (Table 13.5). Metformin may lower serum cobalamin by lowering TCI. The use of histamine H_2-blockers for treatment of peptic ulcer disease causes decreases in cobalamin absorption, and continued use may lower serum cobalamin level. Other causes of cobalamin malabsorption are listed in Table 13.5.

Abnormalities of cobalamin metabolism: congenital transcobalamin deficiency or abnormality

Infants with TC deficiency usually present with megaloblastic anaemia within a few weeks of birth. Serum cobalamin and folate levels are normal, but the anaemia responds to massive (e.g. 1 mg 3 times weekly) injections of cobalamin, which cause free cobalamin to enter marrow cells by passive diffusion in the absence of functional TC. Some cases show neurological complications. In some cases, the protein is present in normal amounts but is unable to bind cobalamin or to attach to the cell surface and so is functionally inert. Genetic abnormalities found include mutations of an intra-exonic cryptic splice site, extensive or single nucleotide deletion, nonsense mutation and an RNA editing defect. These infants do not show methylmalonic aciduria, but malabsorption of cobalamin occurs in all cases and reduced immunoglobulins in some. Less severe cases present later in childhood. Failure to institute adequate cobalamin therapy or treatment with folic acid may lead to neurological damage.

Congenital methylmalonic acidaemia and aciduria

Infants with this abnormality are ill from birth, with vomiting, failure to thrive, severe metabolic acidosis, ketosis and intellectual disability. Anaemia, if present, is normocytic and normoblastic. The condition may arise as a result of a functional defect in either the mitochondrial methylmalonyl-CoA mutase or its co-factor adocobalamin (Figure 13.2). Mutations in methylmalonyl-CoA mutase are not responsive, or only poorly responsive, to treatment with cobalamin. Two disorders result in cobalamin-responsive methylmalonic acidaemia. In cobalamin (Cbl)A disease, there is failure of reduction of cobalamin III (Cbl^{3+}) or cobalamin II (Cbl^{2+}) to cobalamin I (Cbl^{1+}) in mitochondria; in CblB disease, there is a defect of an adenosyltransferase required for synthesis of ado-cobalamin (Figure 13.2). A proportion of infants with CblA and CblB disease respond to cobalamin in large doses, whereas others are unresponsive. In those who do not respond to cobalamin, the enzyme methylmalonyl-CoA mutase is lacking (mut^0) or defective (mut^-). Some children have combined methylmalonic aciduria and homocystinuria due to defective formation of both cobalamin co-enzymes. The defects are in the transfer of cobalamin from the endocytic compartment of lysosomes to the cytoplasm (CblF disease) or in the reduction of cobalamin 3^+ to cobalamin 2^+ after transfer to the cytoplasm (CblC and CblD diseases). Over 100 cases of CblC disease have been described. It usually presents in the first year of life with feeding difficulties, developmental delay, microcephaly, seizures, hypotonia and megaloblastic anaemia.

Some patients present with homocystinuria and megaloblastic anaemia, often with neurological defects, but without methylmalonic aciduria. There is a selective deficiency of methylcobalamin. These conditions have been termed CblE and CblG disease and are due to lack of association of methylcobalamin with methionine synthase.

Acquired abnormality of cobalamin metabolism: nitrous oxide inhalation

N_2O irreversibly oxidises methylcobalamin from its active, fully reduced Cbl^{1+} state to an inactive Cbl^{2+} precursor. This has been shown to inactivate methylcobalamin and methionine synthase. This occurs in both humans and experimental animals and was of importance in the megaloblastic anaemia that occurred in patients undergoing prolonged N_2O anaesthesia (e.g. in intensive care units). A neuropathy resembling cobalamin neuropathy has

been described in dentists and anaesthetists who are repeatedly exposed to N_2O and in monkeys exposed to the gas for many months. Recovery from N_2O exposure requires regeneration of methionine synthase, as this protein is damaged by active oxygen derived from the N_2O–cobalamin reaction.

Diagnosis of cobalamin deficiency

The diagnosis of cobalamin or folate deficiency has traditionally depended on the recognition of the relevant abnormalities in the peripheral blood and/or bone marrow and subsequent analysis of the blood levels of the vitamins. Other causes of macrocytosis and hypersegmented neutrophils are listed in Table 13.3. However, assays of serum methylmalonic acid and homocysteine (see further on) have shown these to be raised in some subjects without haematological abnormalities, including a proportion with normal levels of serum cobalamin and folate in whom, nevertheless, the levels of the metabolites fall to normal with cobalamin and/or folate therapy. The significance of these biochemical changes remains controversial. They may imply functional cobalamin or folate deficiency, also termed insufficiency, not reflected by subnormal levels of the vitamins or by disturbed haemopoiesis. If so, it would imply that the accepted normal serum and red cell levels of the vitamins reflect body stores that are sufficiently high to prevent haematological changes, but which in some subjects may not be optimal for prevention of other complications of the deficiencies, including neurological decline and NTDs in the fetus. The extensive review of Smith, Warren and Refsum (2018) addresses these issues in relation to cobalamin.

Measurement of serum cobalamin

Serum cobalamin is usually measured by one of a number of enzyme-linked immunosorbent assays or by a two-step chemiluminescent microparticle immunoassay (CMIA). In this assay serum B12 competes with a B12-acridium-labelled conjugate for binding to intrinsic factor-coated paramagnetic microparticles, the higher the serum B12 the lower the final luminescence of the intrinsic factor-conjugate complex. These assays are frequently automated. Normal serum cobalamin levels range in different assays from 160–200 ng/L to about 1000 ng/L (ng × 0.738 = pmol; 200 ng/L = 148 pmol/L). In patients with megaloblastic anaemia due to cobalamin deficiency, the level was usually less than 100 ng/L (74 pmol/L) with the earlier microbiological assays but is subnormal but more variable with the more modern immunosorbent assays. In general, the more severe the deficiency, the lower the serum cobalamin level. In patients with spinal cord damage due to the deficiency, levels are usually very low even in the absence of anaemia.

Subnormal or low normal serum cobalamin levels without haematological or vitamin B12 neuropathy are found most frequently in vegans, the elderly and in patients with other causes of mild cobalamin deficiency (Table 13.5). The significance of these findings and whether treatment should be given are discussed above and in the treatment section of this chapter.

Subnormal levels may also occur in pregnancy, returning to normal after delivery, and in patients with megaloblastic anaemia due to folate deficiency, which correct along with the anaemia with folic acid therapy. They are also found without haematological or other clinical manifestations in patients with mutations of the *TCN1* gene that codes for HC (TCI). False normal levels have been described with some of the assays in patients with IF antibodies in serum. The relative concentrations of HC and TC also influence the total serum cobalamin level. False normal levels have been described in patients with megaloblastic anaemia due to cobalamin deficiency if serum HC is raised, as in the myeloproliferative neoplasms. Raised serum cobalamin levels (if not due to recent therapy) are usually due to a rise in HC in these haematological neoplastic diseases or to liver or renal disease with increased saturation of HC and TC.

Serum holotranscobalamin (holoTCII, holoTC)

Since TC is the plasma cobalamin transport protein that is responsible for cellular uptake and delivery of cobalamin, the idea was put forward that measurement of only circulating cobalamin that was bound to TC (holoTC) would provide a more meaningful measure of cobalamin status than total serum cobalamin. Commercial kits for measurement by immunoassay of holoTC (also called 'active B12' or 'active cobalamin') are now available and used diagnostically. The expected values in healthy individuals are from 35–171 pmol/L. The lower limit of the normal range given by the manufacturers of commercial kits 19–42 pmol/L and the upper limit form 134–157 pmol/L. The assays are considered to have a narrower 'grey zone' (uncertainty range) than serum cobalamin assays, to be more sensitive and specific.

Serum methylmalonate and homocysteine levels

In patients with cobalamin deficiency, the serum methylmalonate (MMA) and homocysteine levels are raised. Sensitive methods for measuring MMA and homocysteine in serum have been introduced and recommended for the early diagnosis of cobalamin deficiency, even in the absence of haematological abnormalities or subnormal levels of serum cobalamin or folate. However, serum MMA fluctuates in patients with renal failure. Mildly elevated serum MMA and/or homocysteine levels occur in up to 30% of apparently healthy volunteers, with serum cobalamin levels up to 350 ng/L and normal serum folate levels and in 15% of elderly subjects, even with cobalamin levels above 350 ng/L. These findings bring into question the exact cut-off points for normal MMA and homocysteine levels. It is also unclear at present whether these mildly raised metabolite levels have clinical consequences and how many of the subjects will

progress to clinically overt cobalamin deficiency. When cobalamin supplies to the cell are suboptimal, there may be preferential use of methylcobalamin for methionine synthesis compared with adocobalamin for MMA metabolism. Urinary MMA excretion may also be used to screen for cobalamin deficiency, but this is also increased in aminoaciduria (e.g. Fanconi syndrome).

Homocysteine exists in plasma as single molecules, as two molecules linked together (homocystine) and as mixed homocysteine–cysteine disulfides. Serum homocysteine levels are raised in both early cobalamin and folate deficiency, but they may be raised in other conditions, for example chronic renal disease, alcohol excess, smoking, pyridoxine deficiency, hypothyroidism, therapy with steroids, ciclosporin and other drugs. Levels are also higher in serum than in plasma, in men than in premenopausal women, in women taking hormone replacement therapy or oral contraceptive users and in elderly subjects and patients with several inborn errors of metabolism affecting enzymes in trans-sulfuration pathways of homocysteine metabolism. Thus, homocysteine levels are not widely used for diagnosis of cobalamin or folate deficiency.

Tests for the cause of cobalamin deficiency

The diet history reveals whether the subject is vegan or a strict vegetarian. Studies of cobalamin absorption were used, but because of the unavailability of radioactive cobalamin have become obsolete. Serum tests for gastrin and antibodies to parietal cells and intrinsic factor aid in the diagnosis of PA. Upper GI endoscopy, including gastric biopsy, helps to confirm the diagnosis and exclude gastric neoplasms. A history of gastric or ileal surgery and small intestinal imaging studies may point to a small intestinal cause of cobalamin malabsorption.

Folate

Dietary folate

Folic acid (pteroylglutamic acid) is a yellow, crystalline and water-soluble substance (molecular weight 441 kDa). It is the parent compound of a large family of folate compounds. Pteroylglutamic acid consists of three parts: pteridine, *p*-aminobenzoate and l-glutamic acid (Figure 13.7). It is only a minor component of normal food folates (probably less than 1%), which differ from it in three respects (Figure 13.7): (i) they are partly or completely reduced at positions 4, 5, 7 and 8 in the pteridine portion to dihydrofolate or THF derivatives; (ii) they usually contain a single carbon unit of varying degrees of reduction, such as a methyl group at N-5 or N-10; and (iii) 70–90% of natural folates contain a chain of three or more glutamate residues linked to each other by the unusual γ-peptide bond and are called pteroyl- or folate-polyglutamates (Figure 13.7). In human cells, four, five and six glutamate residues are usual.

Most foods contain some folate. The highest concentrations are found in liver and yeast (>200 μg per 100 g), spinach, other greens and nuts (>100 μg per 100 g). The total folate content of an average Western diet is about 250 μg daily, but the amount varies widely according to the type of food eaten and the method of cooking. Folate is easily destroyed by heating, particularly in large volumes of water; over 90% may be lost.

Body stores and requirements

Total body folate in the adult is about 10 mg, the liver containing the largest store. Daily adult requirements are about 100–200 μg. Up to 13 μg of folate is lost as such in the urine each day, but breakdown products of folate are also lost in urine. Losses of

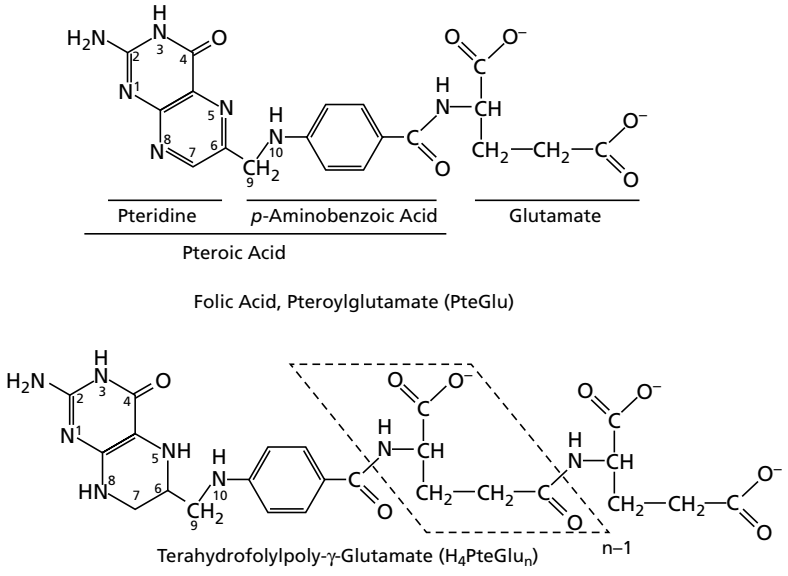

Figure 13.7 The structure of folic acid (pteroylglutamic acid) and of a tetrahydrofolate polyglutamate.

folate also occur in sweat and skin; faecal folate is largely derived from colonic bacteria. Stores are only sufficient for about 4 months in normal adults, so severe folate deficiency may develop rapidly.

Absorption

The principal site of folate absorption is the upper small intestine, and there is a steep fall-off in absorptive capacity in the lower jejunum and ileum. The absorption of all forms tested is rapid, with a rise in blood level occurring within 15–20 min of ingestion.

The small intestine has a tremendous capacity to absorb folate monoglutamates: about 90% of a single dose is absorbed, regardless of whether this is a small (100 μg) or large (15 mg) amount. A proton-coupled high-affinity folate transporter with a low pH optimum, termed PCFT/HCP1, is located at the apical brush border of the duodenal, and to a lesser extent jejunal mucosa and in other cells, including the blood–brain barrier. It accounts for the bulk of folate absorption, including folic acid itself, and loss of function in hereditary folate malabsorption is not compensated by other folate transporters expressed on intestinal cells.

The absorption of folate polyglutamates with higher numbers of glutamate residues is less. This may be due to the limited capacity of the small intestine to hydrolyse these compounds or to their limited transfer in the mucosal cell. On average, about 50% of food folates is absorbed.

Polyglutamate forms are hydrolysed to monoglutamate derivatives, either in the lumen of the intestine or within the mucosa; they do not enter portal blood intact. Monoglutamate or polyglutamate forms of dietary folate, which are already partly or completely reduced, are converted to 5-methyl-THF within the small intestinal mucosa before entering the portal plasma. The monoglutamates are actively transported across the enterocyte by a carrier-mediated mechanism. Pteroylglutamic acid at doses greater than 400 μg is absorbed largely unchanged and converted to natural folates in the liver. Doses <400 μg are largely converted to 5-methyl-THF during absorption through the intestine.

Enterohepatic circulation

About 60–90 μg of folate enters the bile each day and is excreted into the small intestine. Loss of this folate, together with the folate of sloughed intestinal cells, accelerates the speed with which folate deficiency develops in malabsorption conditions.

Transport

Folate is transported in plasma, about one-third loosely bound to albumin and two-thirds unbound. In all body fluids (plasma, cerebrospinal fluid, milk, bile) folate is largely, if not entirely, 5-methyl-THF in the monoglutamate form. A carrier-mediated active process is involved in the entry of folate into cells, the rate of uptake being linked to the rate of folate polyglutamate synthesis in the cell, which in replicating cells is related to the rate of DNA synthesis. In most cells, folates are retained with tight binding to folate-binding proteins, three of which are enzymes involved in methyl group metabolism (sarcosine dehydrogenase, dimethylglycine dehydrogenase and glycine *N*-methyltransferase), until the cell dies. Intact liver cells can release folate. Two types of folate-binding protein are involved in entry of methyl-THF into cells. The reduced folate carrier SLC19A1 is a facilitative transporter with a pH optimum of 7.4 and the characteristics of an anion exchanger. Two glycosylphosphatidylinositol (GPI)-linked folate receptors mediate cellular folate uptake by an endocytic mechanism, with internalisation in a vesicle (caveola), which is then acidified, releasing folate into the vesicle lumen. Folate is then carried by the membrane folate transporter PCFT/HCPI into the cytoplasm; the caveola recycles to the cell surface, where its high-affinity receptors are reutilised. The GPI-linked transporters may be involved in transport of oxidised folates and folate breakdown products to the liver for excretion in bile.

Biochemical functions

Folates (as the intracellular polyglutamate derivatives) act as co-enzymes in the transfer of single-carbon units from one compound to another (see Figure 13.3 and Table 13.2). Two of these reactions are involved in purine and one in pyrimidine synthesis necessary for DNA and RNA replication. Folate is co-enzyme for methionine synthesis, in which cobalamin is also involved and THF is generated. THF, the substrate for polyglutamate synthesis, is also the acceptor of single-carbon units newly entering the active pool via conversion of serine to glycine. Methionine, the other product of the methionine synthase reaction, is the precursor for SAM, the universal methyl donor involved in over 100 methyltransferase reactions.

During thymidylate synthesis, 5,10-methylene-THF is converted to dihydrofolate (Figure 13.3). The enzyme dihydrofolate reductase converts this to THF. The drugs methotrexate, pyrimethamine and, mainly in bacteria, trimethoprim inhibit dihydrofolate reductase, and this prevents formation of the active folate co-enzymes from dihydrofolate. A small fraction of the folate co-enzyme is not recycled during thymidylate synthesis but is degraded at the C-9–N-10 bond.

Causes of folate deficiency

Nutritional

Dietary folate deficiency is common (Table 13.6). Indeed, in most patients with folate deficiency, a nutritional element is present. Certain individuals are particularly at risk of having diets

Table 13.6 Causes of folate deficiency.

Dietary
Particularly in old age, infancy, poverty, alcohol use disorder, and some forms of psychiatric illness; may be associated with scurvy or kwashiorkor
Malabsorption
Major causes of deficiency
Tropical sprue, gluten-induced enteropathy in children and adults, and in association with dermatitis herpetiformis, specific malabsorption of folate, intestinal megaloblastosis caused by severe cobalamin or folate deficiency
Minor causes of deficiency
Extensive jejunal resection, Crohn's disease, partial gastrectomy, congestive heart failure, Whipple disease, scleroderma, amyloid, diabetic enteropathy, systemic bacterial infection, lymphoma, sulfasalazine
Excess utilisation or loss
Physiological
Pregnancy and lactation, prematurity
Pathological
Haematological diseases: chronic haemolytic anaemias, sickle cell anaemia, thalassaemia major, myelofibrosis
Malignant diseases: carcinoma, lymphoma, leukaemia, myeloma
Inflammatory diseases: tuberculosis, Crohn's disease, psoriasis, exfoliative dermatitis, malaria
Metabolic disease: homocystinuria
Excess urinary loss: congestive heart failure, active liver disease
Haemodialysis, peritoneal dialysis
Antifolate drugs
Anticonvulsant drugs (phenytoin, primidone, barbiturates), sulfasalazine
Nitrofurantoin, tetracycline, anti-tuberculosis (less well documented)
Mixed causes
Liver diseases, alcohol use disorder, intensive care units

In severely folate-deficient patients with causes other than those listed under Dietary, poor dietary intake is often present.

containing inadequate amounts of folate, including the elderly, edentulous, poor, those with alcohol use disorder and some psychiatric illnesses, and those who have undergone gastric surgery. With total cessation of intake or absorption, depletion of stores will occur in 3–6 months. In the USA and other countries, where fortification of the diet with folic acid has been adopted to reduce the incidence of NTDs, the prevalence of folate deficiency has dropped dramatically and is now almost restricted to high-risk groups with increased folate needs. Nutritional folate deficiency occurs in kwashiorkor and scurvy, and in infants with repeated infections or who are fed solely on goats' milk, which has a low folate content (6 μg/L) compared with human or cows' milk (50 μg/L).

Malabsorption

Malabsorption of dietary folate occurs in tropical sprue and in gluten-induced enteropathy in children and in adults. In the rare recessive congenital syndrome of selective malabsorption of folate, there is an associated defect of folate transport into the cerebrospinal fluid, and these patients show megaloblastic anaemia from the age of a few months, responding to physiological doses of folic acid given parenterally but not orally, or large oral doses of 5-formyl-THF. They show intellectual disability, convulsions and other central nervous system abnormalities. Loss-of-function mutations, usually homozygous in the gene coding for the low pH transporter PCFT/HCPI, underlie the disease. Minor degrees of malabsorption may also occur following jejunal resection or partial gastrectomy, in Crohn's disease and in systemic infections but, in these conditions, if severe deficiency occurs, it is usually largely due to poor nutrition.

Malabsorption of folate has been described in patients receiving sulfasalazine, cholestyramine and triamterene. It has also been associated with anticonvulsant drug therapy and alcohol excess. In the intestinal stagnant loop syndrome, the predominant effect of the small intestinal bacteria is to cause a rise in serum, red cell and urinary folate by synthesising folate, which is then absorbed.

Excess utilisation or loss

Pregnancy

Folate requirements are increased by 200–300 μg to about 400 μg daily in a normal pregnancy, partly because of transfer of the vitamin to the fetus, but mainly because of increased folate catabolism due to cleavage of folate co-enzymes in rapidly proliferating tissues. Megaloblastic anaemia due to this deficiency is now largely prevented by prophylactic folic acid therapy. It occurred in 0.5% of pregnancies in the UK and other Western countries, but the incidence is much higher in countries where the general nutritional status is poor. The deficiency is more common in pregnant women who, because of an inadequate diet, are also iron deficient than in those with normal iron stores. Occasionally, when there is an associated infection, acute arrest of haemopoiesis with pancytopenia may occur; this resembles aplastic anaemia, except that the marrow shows obvious megaloblastic changes.

A number of consequences of folate deficiency in pregnancy have been described, including antenatal and postpartum

haemorrhages, prematurity and congenital malabsorption in the fetus. These have not been fully established, but many studies have shown that prophylactic folic acid therapy reduces the incidence of NTDs.

Prematurity

The newborn infant has higher serum and red cell folate concentrations than the adult, but the newborn infant's demand for folate has been estimated to be up to 10 times that of adults on a weight basis and the neonatal folate level falls rapidly to the lowest values at about 6 weeks of age. The falls are steepest and liable to reach subnormal levels in premature babies, a number of whom develop megaloblastic anaemia responsive to folic acid at about 4–6 weeks of age. This occurs particularly in the smallest babies (<1500 g birth weight) and in those who have feeding difficulties or infections, or who have undergone multiple exchange transfusions. In these babies, prophylactic folic acid should be given.

Haematological disorders

Folate deficiency frequently occurs in chronic haemolytic anaemia and other conditions of increased cell turnover because it is not completely reutilised after performing co-enzyme functions, and it is partly lost as pteridines. Patients with primary myelofibrosis may develop folate deficiency at some stage of the illness. There is also a high incidence of mild folate deficiency in patients with forms of leukaemia, lymphoma, myeloma or carcinoma, although it is unusual for this to progress to megaloblastic anaemia. Treatment with folic acid should be avoided (as it may 'feed' the tumour) unless severe megaloblastic anaemia due to folate deficiency is clinically important.

Inflammatory conditions

Chronic inflammatory diseases, such as tuberculosis, rheumatoid arthritis, Crohn's disease, psoriasis, exfoliative dermatitis, bacterial endocarditis and chronic bacterial infections, cause deficiency by reducing the appetite and by increasing the demand for folate. Systemic infections may also cause malabsorption of folate. Severe deficiency is virtually confined to those patients with the most active disease and the poorest diet. Fever *per se* has also been suggested to interfere with folate metabolism by inhibiting temperature-dependent folate enzymes. In patients with subclinical folate deficiency from causes other than infections, intercurrent infections may precipitate severe megaloblastic anaemia.

Homocystinuria

This is a rare metabolic defect in the conversion of homocysteine to cystathionine. Folate deficiency occurring in most of these patients may be due to excessive utilisation because of compensatory increased conversion of homocysteine to methionine.

Long-term dialysis

As folate is only loosely bound to plasma proteins, it is easily removed from plasma by haemodialysis or peritoneal dialysis (in contrast, cobalamin is not removed from plasma by dialysis as it is firmly protein bound). The amount of body folate that can be removed in this way is relatively small. Nevertheless, in patients with anorexia, vomiting, infections and haemolysis, folate stores may become depleted and megaloblastic anaemia can supervene. Routine folate prophylaxis is now given.

Congestive heart failure, liver disease

Excess urinary folate losses of more than 100 µg per day may occur in some of these patients. The explanation appears to be release of folate from damaged liver cells.

Antifolate drugs

A large number of people with epilepsy who are receiving long-term therapy with phenytoin (Dilantin) or primidone (Mysoline), develop low serum and red cell folate levels. In some of these patients, megaloblastic anaemia supervenes. A number of mechanisms have been suggested: inhibition of folate absorption, inhibition of the action or synthesis of folate-dependent enzymes, displacement of folate from its plasma transport protein and induction of folate-utilising enzymes. A dietary element is present in the patients with the severest deficiencies.

Alcohol may also be a folate antagonist, as patients who are drinking spirits may develop megaloblastic anaemia that will respond to normal quantities of dietary folate or physiological doses of folic acid only if the alcohol is withdrawn. Chronic alcohol intake is associated with macrocytosis even when folate levels are normal. Inadequate folate intake is the major factor in the development of deficiency in individuals with alcohol use disorder who drink spirits. Beer is relatively folate-rich in some countries, depending on the technique used for brewing.

The drugs that inhibit dihydrofolate reductase include methotrexate, pyrimethamine and trimethoprim. Methotrexate has the most powerful action against the human enzyme, whereas trimethoprim is most active against the bacterial enzyme and is only likely to cause megaloblastic anaemia when used in conjunction with sulfamethoxazole in patients with pre-existing folate or cobalamin deficiency. The activity of pyrimethamine is intermediate. The antidote to these drugs is folinic acid (5-formyl-THF).

Congenital abnormalities of folate metabolism

A number of infants have been described with congenital defects of folate enzymes (e.g. cyclohydrolase or methionine synthase). Some had megaloblastic anaemia.

Diagnosis of folate deficiency

Serum folate

This is measured by an enzyme-linked immunosorbent assay (ELISA) or as for vitamin B12 a two-step chemiluminescent immunoassay (CMIA). In this serum folate is bound to folate binding protein coated paramagnetic microparticles. Pteroic acid acridium-labelled conjugate is then added. The final strength of chemiluminescence from the conjugate is in inverse relationship with the serum folate. Serum folate is low in all folate-deficient patients. In most laboratories, the normal range is from 3.0 μg/L (16.5 nmol/L) to about 15 μg/L (82.5 nmol/L). The serum folate is markedly affected by recent diet; inadequate intake for as little as 1 week may cause the level to become subnormal.

The serum folate level rises in severe cobalamin deficiency because of blockage in conversion of methyl-THF, the major circulating form, to THF; raised levels have also been reported in the intestinal stagnant loop syndrome, acute kidney injury and active liver damage. (High levels are also obtained when the patient is taking folic acid dietary supplementation or therapy, or, if the blood sample is haemolysed, because of the high concentration of folate in red cells.)

Red cell folate

The red cell folate assay is a valuable test of body folate stores. It is less affected by recent diet and traces of haemolysis than is the serum assay. In normal adults, concentrations range from 160 to 640 μg/L of packed red cells. Subnormal levels not only occur in patients with megaloblastic anaemia due to folate deficiency, but also occur in nearly two-thirds of patients with megaloblastic anaemia due to cobalamin deficiency. If cobalamin deficiency is excluded, however, a low red cell folate can be used as an indication that severe folate deficiency is present and warrants full investigation and treatment. False normal results may occur if the folate-deficient patient has received a recent blood transfusion or if the patient has a raised reticulocyte count (e.g. due to haemorrhage or haemolytic anaemia).

Serum homocysteine

See previously

General management of megaloblastic anaemia

It is usually possible to establish which of the two deficiencies, folate or cobalamin, is the cause of the anaemia and to treat only with the appropriate vitamin. In patients who enter hospital severely ill, however, it may be necessary to treat with both vitamins in large doses once blood samples have been taken for cobalamin and folate assay and a bone marrow has been performed (if deemed necessary). Transfusion is usually unnecessary and inadvisable. If it is essential, packed red cells should be given slowly and one or two units will be ample. Exchange transfusion, as well as the usual treatment for heart failure, should be considered in patients with extreme anaemia and congestive heart failure. Platelet concentrates are of value in reducing spontaneous bleeding in rare patients with severe thrombocytopenia.

Treatment of cobalamin deficiency

It is usually necessary to treat patients who have developed cobalamin deficiency with haematological and neurological manifestations with lifelong regular cobalamin therapy. In the UK, the form used is hydroxocobalamin; in the USA, cyanocobalamin is used. In a few instances, the underlying cause of cobalamin deficiency can be permanently corrected, for instance, the fish tapeworm, tropical sprue or an intestinal stagnant loop that is amenable to surgery.

The indications for starting cobalamin therapy are well-documented megaloblastic anaemia or neuropathy due to the deficiency. It is also necessary to treat any patients with haematological abnormalities due to cobalamin deficiency, even in the absence of anaemia (e.g. hypersegmented neutrophils, macrocytosis or megaloblastic erythropoiesis). Patients with borderline serum cobalamin levels, but no haematological or clinical abnormality, negative tests for parietal and intrinsic factor antibodies and with normal serum gastrin levels should, if practicable, be followed, for example at yearly intervals, to ensure that the cobalamin deficiency does not progress. If serum homocysteine levels are also raised hydroxocobalamin, for example 1 mg every 6 months or oral cyanocobalamin can be started. Cobalamin should be given routinely to all patients who have had a total gastrectomy or ileal resection. Patients who have undergone gastric reduction for control of obesity or who are receiving long-term treatment with proton pump inhibitors should be screened and given cobalamin replacement as necessary.

Cobalamin therapy has been used in a wide range of conditions such as the chronic fatigue syndrome, multiple sclerosis and other neurological diseases with normal serum cobalamin levels and no haematological evidence of deficiency. There are no controlled trials showing that any benefit is more than a placebo effect. It seems appropriate, however, to treat with cobalamin, either oral or intramuscular, elderly people with cognitive decline, subnormal cobalamin or low normal cobalamin levels and raised serum homocysteine levels. Controlled clinical trials are, however, needed to confirm this approach in order to establish more clearly which patients will benefit, whether folic acid as well as cobalamin is needed.

Replenishment of body stores should be complete with six 1 mg intramuscular injections of hydroxocobalamin given at 3–7-day intervals. More frequent doses for a more prolonged period are usually used in patients with cobalamin neuropathy, but there is no evidence that these produce a better

response. For maintenance therapy, hydroxocobalamin 1 mg intramuscularly once every 3 months is satisfactory. In the USA, hydroxocobalamin has not yet been approved for routine cobalamin replacement and cyanocobalamin is used. Because of the poorer retention of cyanocobalamin, maintenance treatment protocols generally use higher and more frequent doses (1 mg I.M. monthly). Toxic reactions to cobalamin therapy are extremely rare and are usually due to contamination in its preparation rather than to cobalamin itself.

Even when there is complete failure of the physiological IF-dependent mechanism, large daily oral doses (1 mg) of cyanocobalamin can be used for replacement and maintenance of normal cobalamin status, for example in those who cannot have injections. If this approach is used, it is important to monitor compliance and serum B12 levels, for example annually, particularly with elderly forgetful patients. Sublingual and nasal routes have also been proposed, but no long-term follow-up data are available.

Treatment of folate deficiency

There is probably never any need to give folic acid parenterally, except in patients receiving parenteral nutrition who cannot swallow tablets. Oral doses of 5–15 mg folic acid daily are satisfactory, as sufficient folate is absorbed from these extremely large doses even in patients with severe malabsorption. The length of time therapy must be continued depends on the underlying disease. It is customary to continue therapy for about 4 months when all folate-deficient red cells will have been eliminated and replaced by new folate-replete populations.

Before large doses of folic acid are given, cobalamin deficiency must be excluded and, if present, corrected, otherwise cobalamin neuropathy may develop as the cobalamin deficiency progresses, despite response of the anaemia of cobalamin deficiency to folate therapy. Long-term folic acid therapy as 5 mg weekly is required when the underlying cause of the deficiency cannot be corrected and the deficiency is likely to recur, for instance in chronic haemolytic anaemias such as thalassaemia major and sickle cell anaemia, and in primary myelofibrosis. It may also be necessary for gluten-induced enteropathy if this does not respond to a gluten-free diet. Where mild but chronic folate deficiency occurs, it is preferable to encourage improvement in the diet after correcting the deficiency with a short course of folic acid. In any patient receiving long-term folic acid therapy, it is important to measure the serum cobalamin level at regular (e.g. once yearly) intervals to exclude the coincidental development of cobalamin deficiency.

Folinic acid (5-formyl-THF)

This is a stable form of fully reduced folate. It is given orally or parenterally to overcome the toxic effects of methotrexate or other dihydrofolate reductase inhibitors (as present in co-trimoxazole).

Prevention of neural tube defects

Fortification of the diet with folic acid

In over 80 countries, food is fortified with folic acid (in grain or flour) to reduce the incidence of NTDs. In Europe this has not occurred, partly due to unfounded concern that fortification would delay the diagnosis of pernicious anaemia and allow a neuropathy to develop. The levels of fortification recommended are below those which would elicit a haematological response in cobalamin deficiency; particularly since small amounts of folic acid (<400 ug) in any meal is largely converted by the gut to methyl-THF, which cannot be used by cobalamin deficient cells. Studies have shown no exacerbation by high blood folate levels of metabolic abnormalities or of cognitive impairment in subjects with low vitamin B12 status. Moreover there has been no increase in the proportion of subjects with low serum cobalamin levels and no anaemia, since fortification of the diet in the USA since 1998 and no reports in any country of an increased incidence of cobalamin neuropathy or other harmful effects. Concerns about the risk of causing or accelerating the course of cancer of any type have been allayed by the meta-analysis involving nearly 50,000 subjects discussed above. The level of fortification and the exact foods to be fortified whether whole grain, refined flour, maize or rice vary from country to country. In 2000 a UK Government Committee on Medical Aspects of Food and Nutrition Policy recommended addition of 240 µg/100 grams of flour. In 2024 the UK Government announced its intention to make addition of folic acid 250 µg/100 g to non-wholemeal flour mandatory

Folic acid before and during pregnancy

Women of child bearing age are recommended to take folic acid before and for the first three months of any pregnancy. In the UK women are divided (British National Formulary) into those considered at low risk of an NTD pregnancy and those at high risk. High risk is defined as either partner having an NTD or a family history of this or a previous NTD pregnancy or if the mother has diabetes mellitus, coeliac disease or other cause for malabsorption, is taking anti-epileptic drugs or has sickle cell anaemia. In these situations the mother is recommended to take 5 mg folic acid daily if she intends to become pregnant or is at risk of this and to continue this dose for the first 3 months of pregnancy. In sickle cell anaemia then to continue this or their normal dose of folic acid throughout the pregnancy. For the vast majority of women considered at low risk, the recommendation is to take 400 µg daily. There is no logic in this since 5 mg daily would a give them substantially greater protection against having a NTD pregnancy. There are no harmful effects of women taking folic acid 5 mg daily for weeks or a few months before becoming pregnant and for the first three months of the pregnancy. As discussed earlier there is no clear evidence that large doses of folic acid precipitate neuropathy due to cobalamin deficiency. Moreover cobalamin deficiency of sufficient severity to cause a neuropathy is also a cause of infertility. The change in

recommendation would need to be accompanied by making 5 mg tablets of folic acid available for purchase by women of child bearing age from pharmacies and not, as at present in UK, only available to them on a doctor's prescription.

Surveys have shown poor uptake of folic acid supplements by women of child-bearing age likely to become pregnant, especially in certain ethnic groups and that reinforces the need for fortification of the diet.

Prematurity

The incidence of folate deficiency is so high in the smallest premature babies during the first 6 weeks of life that folic acid (e.g. 1 mg daily) should be given routinely to babies weighing less than 1500 g at birth and to larger premature babies who require exchange transfusions or develop feeding difficulties, infections or vomiting and diarrhoea.

Haemolytic anaemia and dialysis

As discussed above folic acid is usually given to patients with a severe chronic haemolytic anaemia, for example sickle cell anaemia, or to those who are undergoing long-term haemodialysis.

Megaloblastic anaemia not due to cobalamin or folate deficiency or altered metabolism

This may occur with many antimetabolic drugs (e.g. hydroxycarbamide, cytarabine, 6-mercaptopurine) that inhibit DNA replication at a particular point in the supply of precursors or inhibit DNA polymerase. In the rare disease orotic aciduria, two consecutive enzymes in purine synthesis are defective. The condition responds to therapy with uridine, which bypasses the block. In thiamine-responsive megaloblastic anaemia, there is a genetic defect in the high-affinity thiamine transport (*SLC19A2*) gene. This causes defective RNA ribose synthesis through impaired activity of transketolase, a thiamine-dependent enzyme in the pentose cycle. This leads to reduced nucleic acid production and consequent induction of cell cycle arrest or apoptosis. It may be associated with diabetes mellitus and deafness and the presence of many ringed sideroblasts in the marrow. The biochemical explanation is unclear for megaloblastic changes in the marrow in patients with acute myeloid leukaemia, and other leukaemias and myelodysplasia in the absence of cobalamin or folate deficiency.

Other nutritional anaemias

Protein deficiency

Anaemia is usual in children and adults with severe protein deficiency (kwashiorkor). The anaemia, which may be partly masked by haemoconcentration, is usually normoblastic, but megaloblastic changes have been described in 10–60% of patients in different series. Hypoplasia, or even aplasia, of the marrow has also been reported. The mechanism by which protein deficiency causes anaemia is not completely understood. Lack of protein does not seem to reduce haemoglobin synthesis directly. Studies in experimental animals suggest that the major factor is diminution of erythropoietin secretion. This is probably due to a reduction in general tissue metabolism and therefore oxygen consumption, with a consequent reduced stimulus for erythropoietin secretion. In most patients, other factors contribute to the anaemia. These include infections, deficiencies of folate and iron, and also, possibly, deficiencies of vitamins C, E and B_{12}, and other trace substances. Riboflavin deficiency may cause anaemia in humans, resembling the anaemia of protein deficiency that it usually accompanies. The deficiency only occurs in the severely malnourished usually with other major clinical problems. Riboflavin deficiency may only become apparent during the response to protein.

Scurvy

There is usually a moderate or severe normocytic, normochromic anaemia in scurvy because of external haemorrhage and haemorrhage into tissues, and from impaired erythropoiesis. In some patients, the anaemia is megaloblastic, which appears to be partly due to associated nutritional folate deficiency and partly due to impairment of folate metabolism caused by vitamin C deficiency. However, vitamin C is not established as playing a role in normal folate metabolism.

Other deficiencies

Deficiencies of nicotinic acid and pantothenic acid cause anaemia in experimental animals but have not been shown to do so in humans. Copper is essential for haemopoiesis and normal iron metabolism; and deficiency of copper may rarely cause anaemia or more generalised marrow dysfunction. Copper excess (as in Wilson disease) causes a haemolytic anaemia.

Introduction

Inherited disorders of haemoglobin are the commonest single-gene disorders, with an estimated carrier rate of 7% amongst the world population. They occur at particularly high frequencies in populations of the tropical and subtropical belt, and consist mainly of the α- and β- thalassaemias, and the haemoglobin variants S, C and E. In many low-income countries, as economic conditions improve and infant death rates from infection and malnutrition fall, the genetic disorders of haemoglobin start to become a major burden on the health services, a phenomenon that has already been observed in many parts of the world. As a result of migrations of populations, these conditions are being seen with increasing frequency in many countries in which they had not been recognised previously.

The structure, genetic control and synthesis of haemoglobin

Different haemoglobins are synthesised in the embryo, fetus and adult, each adapted to their particular oxygen requirements (Figure 14.1). They all have a tetrameric structure made up of two different pairs (one α-like and one β-like) of globin chains, each attached to one haem molecule, the moiety responsible for the reversible binding and transfer of oxygen.

The embryonic haemoglobins include Hb Portland ($\zeta_2\gamma_2$), Hb Gower 1 ($\zeta_2\varepsilon_2$) and Hb Gower 2 ($\alpha_2\varepsilon_2$). In the fetus, HbF ($\alpha_2\gamma_2$) predominates; in adults, HbA ($\alpha_2\beta_2$) comprises over 95% of the total haemoglobin, with a minor component of HbA_2 ($\alpha_2\delta_2$) in the red blood cells. There are two kinds of HbF composed of γ-chains that differ in their amino acid composition at position 136, where they have either glycine or alanine; those with glycine are called $^{G}\gamma$-chains and those with alanine $^{A}\gamma$-chains. The $^{G}\gamma$ and $^{A}\gamma$ chains are the products of separate globin gene loci ($^{G}\gamma$ and $^{A}\gamma$). These different types of haemoglobin are adapted to the changes in physiological requirements that occur during development. Fetal haemoglobin (HbF) exhibits a higher oxygen affinity than adult haemoglobins *in vivo*; the higher oxygen affinity of HbF relative to adult haemoglobin facilitates the transfer of oxygen across the placenta from the maternal to the fetal circulation.

The sigmoid shape of the oxygen dissociation curve, which reflects the allosteric properties of haemoglobin, ensures that oxygen is rapidly taken up at the high oxygen tensions found in the lungs and is released readily at the low tensions encountered in the tissues. It is quite different from myoglobin, a molecule that consists of a single globin chain with haem attached to it and which has a hyperbolic dissociation curve. The transition from a hyperbolic to a sigmoid curve reflects cooperativity between the four haem molecules. When one haem takes on oxygen, the affinity for oxygen of the remaining haem molecules of the tetramer increases markedly. This is because haemoglobin can exist in two configurations, deoxy(T) and oxy(R) (T and R

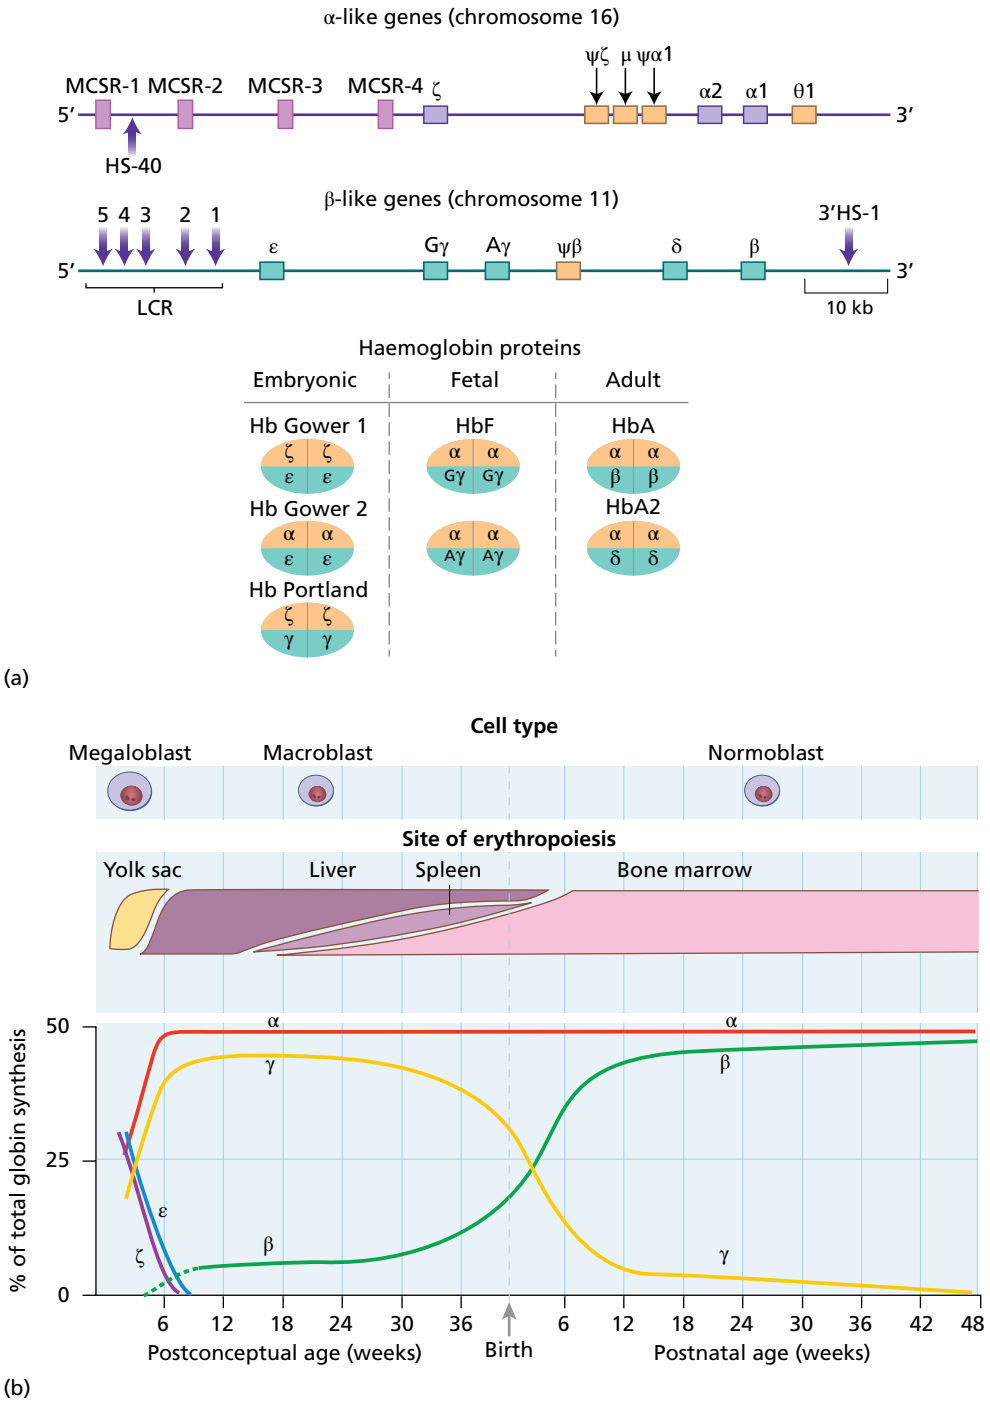

Figure 14.1 (a) The genomic structure of the clusters of α-like and β-like globin genes, on chromosomes 16 and 11, in human beings. HSs1–5 represent the set of five DNase I hypersensitivity sites distributed 5–25 kb 5′ of the ε globin gene, and which constitute the β-locus control region (β-LCR). MCSR1, R2, R3 and R4 are the four upstream erythroid-specific enhancers in the α-globin cluster. (b) The timeline of the expression of the human globin genes from early stages of fetal development to the changes that occur at birth and in the first year of life (Source: Schechter, 2008 [*Blood* 2008; **112**: 3927–38]. Reproduced with permission of the American Society of Hematology.)

stand for tight and relaxed states, respectively). The T form has a lower affinity than the R form for ligands such as oxygen. At some point during the sequential addition of oxygen to the four haems, transition from the T to R configuration occurs and the oxygen affinity of the partially liganded molecule increases dramatically. The oxygen dissociation curve, which reflects these changes, can be modified in several ways. First, oxygen affinity is decreased with increasing CO_2 concentrations – the Bohr effect. This facilitates oxygen loading to the tissues, where a drop in pH due to CO_2 influx lowers oxygen affinity. In contrast, in the lungs, efflux of CO_2 and an increase in intracellular pH increases oxygen affinity and hence uptake. Oxygen affinity is also modified by the level of 2,3-diphosphoglycerate (2,3-DPG) in the red cell. Increasing concentrations shift the oxygen dissociation curve to the right (i.e. reduce oxygen affinity), whereas diminishing concentrations have the opposite effect.

Genetic control, regulation and synthesis

Human haemoglobin production is characterised by two 'switches'. The switch from embryonic to fetal haemoglobin production begins as early as week 5 of gestation and is completed by week 10 (Figure 14.1). Expression of β-globin starts as early as week 8, but synthesis remains low, increasing to approximately 10% at weeks 30–35 of gestation, with a dramatic upregulation of β-globin synthesis just before birth, coinciding with a decrease in γ-globin expression that constitutes the fetal to adult haemoglobin switch. At birth, HbF ($\alpha_2\gamma_2$) comprises 60–80% of the total haemoglobin, falling to about 5% at 6 months of age and eventually reaching the adult level of 0.5–1.0% at 2 years. The relative synthesis of $^{G}\gamma$ and $^{A}\gamma$ chains also changes with the switch, from a $^{G}\gamma/^{A}\gamma$ ratio of 3:1 in fetal life to a ratio of 2:3 in adults. The switch from fetal to adult haemoglobin production is not total, production of variable levels of HbF persisting throughout adult life. These residual amounts are unevenly distributed; erythrocytes that contain measurable amounts of HbF are termed F cells.

Each of the α-like and β-like globin chains is encoded by genetically distinct loci, the α-like cluster on the tip of chromosome 16p and the β-like cluster on chromosome 11p15.5 (Figure 14.1). In both clusters, the genes are arranged along the chromosome in the order in which they are expressed during development: 5′ -ε-$^{G}\gamma$-$^{A}\gamma$-ψβ-δ-β-3′ and 5′ -ζ-μ-ψζ-ψα1-α2-α1-θ1-3′. The ψβ, ψζ and ψα-genes are pseudogenes, that is they have sequences that resemble the β, ζ or α-genes but contain inactivating mutations that prevent them from being expressed. They may be 'burnt out' remnants of genes that were functional at an earlier stage of evolution. Like most mammalian genes, the globin genes have one or more non-coding inserts, called intervening sequences or introns, interrupting the coding sequences or exons.

The β-like globin genes have three exons (coding regions) interrupted by two intervening sequences or introns of 122–130 and 850–900 bp, respectively. The β-genomic sequence codes for 146 amino acids; intron 1 interrupts the sequence between codons 30 and 31, and intron 2 between codons 104 and 105. The α-globin genes code for 141 amino acids and contain similar, but smaller, introns between codons 30 and 31 and between codons 99 and 100. Within each α- and β-globin complex, in addition to the primary *cis* determinants of individual globin gene expression, which are found in the immediate vicinity and within each gene, there are other local regulatory elements known as enhancers, which are located at variable distances from the individual genes.

The local *cis*-acting sequences controlling globin gene expression include the promoter region, splicing donor and acceptors and poly-A addition sites. The promoter, in the 5′ flanking region, includes blocks of nucleotide homology that are found in analogous positions in many species (Figure 14.2). The three positive *cis*-acting elements include the TATA box (position −28−−31, i.e. between 28 and 31 bases upstream from the mRNA 'cap' site), a CCAAT box (position −72−−76), and a CACCC motif which may be inverted or duplicated (position −80−−140). These promoter elements are recognised by transcription factors and are involved in the initiation of transcription. It is interesting that while the CCAAT and TATA elements are found in many eukaryotic promoters, the CACCC sequence is found predominantly in erythroid cell-specific promoters.

The 5′ untranslated region (UTR) occupies a region of about 50 nucleotides between the 5′ terminus or 'cap' site of globin mRNA and the initiation (ATG) codon. The cap appears to be important for maintaining the stability of the nuclear precursor mRNA. Within the 5′-UTR of the various globin genes there are conserved sequences that are important in the regulation of gene expression. The 3′-UTR constitutes the region between the termination codon and the poly-A tail. It consists of about 130 nucleotides with one conserved sequence, AATAAA, located 20 nucleotides upstream of the poly-A tail. The conserved hexanucleotide AATAAA acts as a signal for cleavage of the 3′ end of the primary transcript and addition of the poly-A tail, which confers stability on the processed mRNA and enhances translation. The importance of all these *cis* elements for normal globin gene expression has been validated by the discovery of thalassaemias caused by several mutations affecting these regions, as well as by deletion experiments.

Throughout development, the appropriate genes of the α- and β-globin gene clusters are coordinately expressed, maintaining a balance in the production of α- and β-like globins needed for the synthesis of normal haemoglobin. The regulation of globin gene expression is mediated at several levels; although most occur at the transcriptional level, there is some fine-tuning during and after translation. Most DNA that is not involved in gene transcription is tightly packaged into a compact, chemically modified form that is inaccessible to transcription factors and polymerases and which is heavily methylated. Activity is associated with a change in the structure of the chromatin surrounding a gene, which can be identified

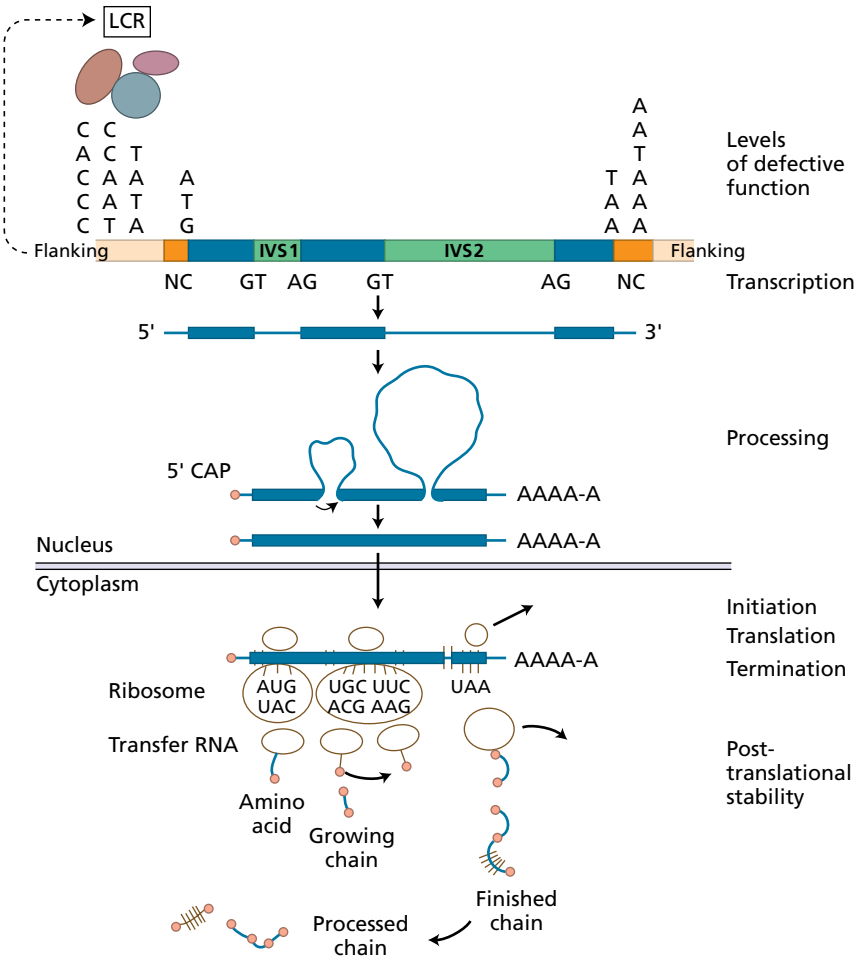

Figure 14.2 A prototype globin gene and the genetic control of globin chain synthesis. Levels of action of mutations are indicated on the right.

by enhanced sensitivity to nucleases. Erythroid lineage-specific nuclease hypersensitivity sites are found at several locations in both the β-globin and α-globin gene clusters. A set of five DNase I hypersensitivity sites (designated HSs1–5), distributed 5–25 kb 5′ of the ε globin gene, constitute the β-locus control region (β-LCR) (see Figure 14.1). This region was originally implicated in the control of the β-globin complex by the discovery of natural mutants that removed sequences upstream but left the downstream globin genes intact and yet resulted in no output from the cluster. The human β-LCR was the first LCR to be identified and was functionally defined as a DNA element that provides high levels of tissue-specific expression to a *cis*-linked gene in a copy number-dependent manner, and which is independent of host genome integration site. The corresponding region in the α-globin cluster consists of four multispecies conserved sequence (MCS) regions lying 10–48 kb upstream of the α-globin genes called MCS-R1 to MCS-R4: 10 kb (MCS-R4), 33 kb (MCS-R3), 40 kb (MCS-R2) and 48 kb (MCS-R1) upstream (see Figure 14.1). The four upstream erythroid-specific enhancers vary in their capacity to enhance α globin expression but MCS-R2, which consists of a single DNase hypersensitive site, appears to be the most critical. MCS-R2, which lies 40 kb upstream of the cluster, is previously known as HS-40. The β-LCR establishes a transcriptionally active chromatin domain that encompasses the whole β-globin cluster and acts as a unique enhancer, whereas the α-globin MCS-R2 which is most similar to HS2 of the β-LCR is capable of enhancing α globin expression on its own. Importance of the MCS-R2 is further confirmed by the naturally occurring upstream human deletions that downregulate α globin expression, all involve the MCS-R2 site. In both clusters, expression of the respective genes is critically dependent on the presence of the upstream regulatory elements that physically interact with upstream promoters of the respective globin gene mediated by a complex of transcription factors.

Several other enhancer sequences have also been identified in both globin gene clusters. All these regulatory regions bind a number of key erythroid-specific transcription factors, notably GATA-1, GATA-2, NF-E2, KLF1 (also known as EKLF) and SCL, as well as various cofactors (e.g. FOG, pCAF and p300) and factors that are more ubiquitous in their tissue distribution, such as Sp1. Tissue-specific expression may be explained by the presence of

binding sites for the erythroid-specific transcription factors. The binding of haemopoietic-specific factors activates the LCR, which renders the entire β-globin gene cluster transcriptionally active. Transcription factors also bind to enhancer and local promoter sequences within each gene, which work in tandem to regulate the expression of the individual genes in the clusters. Some of the transcription factors are developmental-stage specific and may be involved in the (still poorly understood) differential expression of embryonic, fetal and adult globin genes.

The mechanisms by which developmental regulation is controlled have become clearer in the last decade, building on the proposed dual mechanism of autonomous gene silencing and gene competition for direct interaction with the upstream LCR. It appears that the ε and ζ genes are switched on in embryonic cells and autonomously switched off (transcriptionally silenced) in definitive cells (liver and bone marrow) in which they cannot be substantially reactivated. The second switch, from γ- to β-gene expression, is more complex and involves both autonomous silencing of the γ-genes and competition between the γ- and β-genes for the β-LCR. In the γ- to β-gene switch, the γ globin genes are autonomously silenced at the appropriate developmental stage, and expression of the adult β globin gene depends on lack of competition from the upstream γ gene for the LCR sequences. In accordance, when 'silencing' of the γ gene fails due to point mutations in their promoter causing a persistence of fetal haemoglobin production, expression of the *cis* β gene is downregulated. The transcriptional factor environment is thus critical in determining the balance between γ- and β-gene expression and is thought to be mediated by changes in the repertoire and/or abundance of various nuclear factors favouring particular promoter–LCR interactions. The erythroid Krüppel-like factor (*EKLF*, also known as *KLF1*) was the first example of a developmental stage-specific regulatory factor without which the β-genes cannot be fully activated in the definitive cells. Not only is KLF1 expression restricted mainly to erythroid cells, but it is also a highly promoter-specific activator, binding with high affinity to the β-globin CACCC box. Its greater affinity for the β-globin than the γ-globin promoter accelerates the shutdown of γ in transgenic mice over-expressing klf1. Genome wide association (GWA) studies identified BCL11A as the first key repressor protein for silencing of the γ globin genes (joined later by ZBTB7A/LRF). KLF1 is a direct activator of *BCL11A*. KLF1 is key in the switch from γ-globin to β-globin expression; it not only activates the β-globin gene directly, providing a competitive edge, but also silences the γ-globin genes indirectly via activation of *BCL11A*. A genetic network regulating the switch from γ- to β-globin expression has emerged, involving the interaction of KLF1, BCL11A, LRF and MYB with each other, and other transcription factors (e.g. GATA-1) and corepressor complexes that involve chromatin modelling and epigenetic modifiers. KLF1 may also play a role in the silencing of the embryonic globin genes. KLF1 has emerged as a major erythroid transcription factor with pleiotropic roles underlying many of the previously uncharacterised anaemias (e.g. congenital dyserythropoietic anaemia type IV). KLF1 variants have also been associated with variable increases in HbF and HbA_2 levels.

It is still not clear how KLF1 interacts with LRF/ZBTB7A, the other major γ globin repressor. High-resolution studies of BCL11A and LRF in the *HBB* cluster by two groups showed that BCL11A and LRF each bind to a cognate recognition site within the γ-globin promoter. The repressive activity of both BCL11A and LRF is mediated through physical interaction with the multicomponent nucleosome remodelling and deacetylase (NuRD) complex. The important role of the NuRD complex in silencing of the γ-globin genes is provided by recent findings that repression of the NuRD subunit CHD4 expression by ZNF410 increases HbF expression.

The binding sites of LRF and BCL11A coincides with positions of the base substitutions observed in subjects with hereditary persistence of fetal haemoglobin (HPFH). Thus, one approach to increasing γ-globin expression could involve reducing expression of the repressors BCL11A or LRF, or to disable binding of BCL11A or LRF by genome-editing, i.e. mimicking the naturally occurring HPFH variants in the γ-globin promoters. Besides its role as γ-globin repressor, BCL11A has pleiotropic roles in B-lymphoid and neurological development. Identification of the key erythroid-specific enhancer elements was critical and important in the development of the clinical trials aimed at downregulating BCL11A for therapeutic activation of fetal haemoglobin.

Transcription and processing of mRNA

Genetic information in the DNA of the globin genes is transcribed into an RNA copy which is then translated into a specific globin chain (Figure 14.2). The TATA box acts as the initial DNA target for the progressive assembly of an initial transcription complex, which involves the interaction of transcription factors, TATA-binding protein and other proteins with the β-LCR or α-MCS, mediated by RNA polymerase II.

The primary transcript is a large mRNA precursor (pre-mRNA) that contains both introns and exons. While in the nucleus, it undergoes a number of modifications before it can be translated into protein (Figure 14.2). This includes the removal of introns by a complex series of reactions involving several different proteins that constitute the spliceosome, and splicing of the exons. Consensus sequences are universally found encompassing the 5′ (donor) and 3′ (acceptor) ends. Each intron invariantly starts with the dinucleotide GT (5′) and finishes with AG (3′). Mutations that alter the normal consensus sequences or mutations that create similar consensus sequences at new sites in globin genes cause aberrant splicing and constitute the molecular basis of many types of thalassaemia. Other modifications of the nascent mRNAs include the addition of a 'cap' structure at the 5′ end and the addition of a string of

adenylic acid residues (poly-A) at the 3′ end. Proper cleavage of the primary RNA transcript and polyadenylation of the 3′ ends of mRNA is guided by a consensus hexanucleotide (AATAAA) sequence about 20 nucleotides upstream of the poly-A tail. The processed mRNA now moves into the cytoplasm to act as a template for globin chain production on defined organelles known as ribosomes.

Translation

Amino acids are transported to the mRNA template on carriers called transfer RNAs; there are specific transfer RNAs for each amino acid. The order of amino acids in a globin chain is determined by the order of nucleotides (reading frame); three bases (codon) code for a particular amino acid. The transfer RNAs also contain three bases, the anticodon, which are complementary to mRNA codons for particular amino acids. The transfer RNAs carry amino acids to the template, where they find the right position by codon–anticodon base-pairing. The mRNA is translated from the 5′ to the 3′ end (left to right) starting with a specific initiation codon (AUG) and ending with a termination codon (UAA, UAG, UGA). When the ribosome reaches the termination codon, translation ceases, the completed globin chain is released, and the ribosomal subunits fall apart and are recycled. Individual globin chains combine with haem, which is synthesised through a separate pathway, and with themselves to form definitive haemoglobin molecules.

Termination codons are also called nonsense codons because they do not usually encode any amino acid. Approximately 50% of the mutations causing β-thalassaemia are caused by termination codons that are premature. Premature termination codons (PTCs) can result from different types of mutations. Single nucleotide substitutions can convert a sense codon to a nonsense codon and are often referred to as nonsense mutations. Frameshift mutations are insertions or deletions of a few bases that are not multiples of three that shift the reading frame, resulting in a nonsense codon that is premature (i.e. PTC). mRNAs with PTCs lead to production of encoded truncated proteins that are potentially harmful. They are kept in check by a cellular surveillance mechanism referred to as nonsense-mediated mRNA decay (NMD). NMD is usually triggered when translation stops prematurely at PTCs, resulting in termination of the mutant mRNA transcript and thus absence of abnormal protein. However, PTCs situated less than 50–55 nucleotides upstream of the 3′ -most exon–exon junction or downstream of this junction generally fail to trigger NMD, and result in production of abnormal mRNA species. In the case of the β-globin gene, PTCs within the last exon (exon 3) and 3′ half of exon 2 result in the production of highly unstable β-globin variant chains and a dominantly inherited form of β-thalassaemia. However, there are exceptions to the 50–55 rule; PTCs within β-globin exon 1 and a PTC within exon 2 have been reported to fail to elicit NMD efficiently despite residing more than 55 nucleotides upstream of the exon 2–exon 3 junction.

The multistep process in the conversion of DNA into protein offers numerous opportunities for mishaps to occur that result in downregulation of gene expression, clearly illustrated by the different mutations causing thalassaemias and haemoglobinopathies.

Classification of the disorders of haemoglobin

Mutations in the globin genes can cause a quantitative reduction in output from that gene, alter the amino acid sequence of the protein produced or a combination of the two (Table 14.1). Quantitative defects cause thalassaemia syndromes, whereas qualitative changes referred to as haemoglobin variants, cause a wide range of problems, including sickle cell disease (Chapter 15), unstable haemoglobins, decreased oxygen affinity, increased oxygen affinity and methaemoglobinaemia. However, the majority of qualitative mutations cause no significant change in haemoglobin properties or clinical problems. Some mutations combine both features, resulting in a haemoglobin variant that is made in reduced amounts; HbE (β26 Glu→Lys) is the most common example of this. The substitution at codon 26 (GAG→AAG), which causes HbE, also causes alternative splicing of the β-globin mRNA, leading to a reduction in the normally spliced β-message encoding the variant, and a

thalassaemia phenotype. Other haemoglobin variants result in a thalassaemia phenotype caused by extreme instability and functional deficiency of the globin chain variant; for example, Hb Geneva, a dominantly inherited β-thalassaemia. Mutations in the globin gene complex might also alter the switch from fetal to adult haemoglobin synthesis, resulting in persistence of γ-globin expression, and hereditary persistence of fetal haemoglobin (HPFH).

The thalassaemias and related disorders

The thalassaemias are the most common single-gene disorders. Thalassaemia was first recognised by Cooley and Lee in 1925 as a form of severe anaemia associated with splenomegaly and bone changes in children. The term 'thalassaemia' is derived from the Greek θαλασσα-(meaning 'the sea') since many of the early cases came from the Mediterranean region. However, it is now clear that the disorder is not just limited to the Mediterranean region, but occurs throughout the world, prevalent in the tropical and subtropical regions, including the Middle East, parts of Africa, Indian subcontinent and Southeast Asia. Heterozygotes for thalassaemia are protected from the severe effects of malaria and natural selection has increased and maintained their gene frequencies in these malarious regions.

Definition and classification

The thalassaemias are classified into α-, β-, δβ-, γδβ-, δ-, γ- and εγδβ-thalassaemias, according to the type of globin chain(s) that is produced in reduced amounts (Table 14.1). The two major categories are the α- and β-thalassaemias, while the rare forms include the γ-, δ- and εγδβ- thalassaemias.

Functionally, some thalassaemia mutations cause a complete absence of globin chain synthesis, and these are called α^0 or β^0-thalassaemias; in others, the globin chain is produced at a reduced rate and these are designated α^+ or β^+-thalassaemias. The δβ-thalassaemias are subdivided in the same way. HPFH syndromes refer to the group of disorders in which the switch from fetal to adult haemoglobin production is incomplete and variable levels of fetal haemoglobin levels persist in otherwise normal individuals. Because of their concomitant increased HbF levels, the δβ- and γδβ-thalassaemias are often considered with the HPFH syndromes.

Because thalassaemia occurs in populations in which structural haemoglobin variants are common, it is not unusual to inherit a thalassaemia gene from one parent and a gene for a structural haemoglobin variant from the other. Furthermore, both α- and β-thalassaemia occur commonly in some countries, and individuals may coinherit genes for both types. These different interactions produce a clinically diverse family of genetic disorders that range in severity from death *in utero* to extremely mild, symptomless and hypochromic anaemias.

Most thalassaemias are inherited in a Mendelian recessive fashion. Heterozygotes are mostly symptomless, although usually they can be recognised by simple haematological analysis. More severely affected patients are either homozygotes for α- or β-thalassaemia or compound heterozygotes for different molecular forms of α- or β-thalassaemia or for one or other form of thalassaemia and a gene for a haemoglobin variant. Clinically, the thalassaemias are classified according to their severity into major, intermediate and minor forms. Thalassaemia major is a severe and transfusion-dependent disorder. Thalassaemia minor is the symptomless trait or carrier state. Thalassaemia intermedia is characterised by anaemia (with or without splenomegaly), though not of such severity as to require regular transfusion. In practice, thalassaemia intermedia encompasses a wide spectrum of clinical severities intermediate between the two extremes of thalassaemia major and trait. Thalassaemia intermedia, also referred to as non-transfusion-dependent thalassaemia (NTDT) remains a clinical definition and includes β-thalassaemia intermedia, HbH disease and the HbE/β-thalassaemias.

The β-thalassaemias

The β-thalassaemias pose by far the most important public health problems because they are common and usually produce severe anaemia in their homozygous and compound heterozygous states.

Distribution

The β-thalassaemias occur widely in a broad belt, ranging from the Mediterranean and parts of North and West Africa through the Middle East and Indian subcontinent to Southeast Asia. The disease is particularly common in Southeast Asia, where it occurs in a line starting in southern China and stretching down through Thailand and the Malay Peninsula and Indonesia to some of the Pacific Island populations. In this region, and in some of the Mediterranean island and mainland countries, gene frequencies range between 2 and 30%. It should be remembered that β-thalassaemia is not confined entirely to these high-incidence regions and it occurs sporadically in every racial group.

Genetic basis of disease: molecular pathology

The β-thalassaemias are considered to be autosomal recessive disorders since individuals who have inherited one abnormal β-gene (carrier) are asymptomatic and the inheritance of two abnormal β-globin genes is required to produce a clinically detectable phenotype. Molecular analysis of the β-thalassaemia genes has demonstrated a striking heterogeneity. Although almost 300 β-thalassaemia alleles (including deletions) have been characterised, population studies indicate that probably only 20 β-thalassaemia alleles account for more than 80% of the

β-thalassaemia mutations in the whole world (https://www.ithanet.eu; http://globin.bx.psu.edu/hbvar). This is because in each of the high-frequency areas, only a few (four to six) mutations are common, reflecting local selection due to malaria, with a varying number of rare ones. Each of these populations thus has its own unique group of mutations.

The vast majority (approximately 250) of β-thalassaemia mutations are point mutations (i.e. single-base substitutions) and small insertions or deletions of one to two bases. These may involve any step in globin chain production: transcription, translation or post-translational stability of the globin gene product (Figure 14.2). Approximately half of these mutations completely inactivate the β-gene with no β-globin production resulting in β^0 -thalassaemia. Mutations that allow the production of some β-globin cause β^+ – or β^{++} -thalassaemia, depending on whether there is a marked or mild reduction in the output of β-chains, respectively.

Transcription

The mutations that interfere with transcription include deletions and point mutations involving the globin gene promoter regions. With the exception of a deletion of about 600 bases at the 3′ end of the β-globin gene, which is restricted to certain Indian populations, major deletions are uncommon. A large number of point mutations involve the promoters or adjacent regions, most of which downregulate the β-globin gene to a variable degree and cause relatively mild forms of β-thalassaemia.

A couple of β-thalassaemia mutations in this class are 'silent' i.e. carriers who do not have any evident haematological phenotypes, with red cell indices and HbA_2 levels within the normal range, the only abnormality being imbalanced globin chain synthesis. These β-thalassaemia mutations have usually been 'discovered' in individuals with thalassaemia intermedia resulting from compound heterozygosity for one of those 'silent' mutations in combination with a typical β-thalassaemia mutation. In this case, one parent has typical β-thalassaemia trait and the other is apparently normal. Overall, the 'silent' β-thalassaemia alleles are uncommon, except for the −101 C→T mutation that has been observed fairly frequently in the Mediterranean region, where it interacts with a variety of more severe β-thalassaemia mutations to produce milder forms of β-thalassaemia intermedia.

Processing

A wide variety of mutations interfere with processing of the primary mRNA transcript. Those involving the invariant GT or AG sequences at intron–exon junctions prevent splicing altogether and cause β^0-thalassaemia. Mutations involving the consensus sequences adjacent to the GT or AG dinucleotides in the introns allow some normal splicing and causes β^+-thalassaemia. Several β-thalassaemia mutations involve other parts of the introns; alternative splicing sites are produced leading to variable degrees of both normal and abnormal mRNA synthesis. An incorrectly spliced mRNA is not functional because it contains intron sequences, generating a frameshift and a PTC. Sequences that resemble the consensus sequences at intron–exon junctions are also present in exons. Mutations may activate these 'cryptic' sites, again leading to abnormal splicing.

Translation

About half of the β-thalassaemia alleles completely inactivate the gene, mostly by generating PTCs, either by single-base substitution to a nonsense codon or through a frameshift mutation. As part of the surveillance mechanism that is active in quality control of the processed mRNA, mRNA harbouring a PTC is destroyed and not transported to the cytoplasm (a phenomenon called nonsense-mediated mRNA decay, NMD) to prevent the accumulation of mutant mRNAs coding for truncated peptides. However, some in-phase PTCs that occur later in the β-sequence, in the 3′ half of exon 2 and in exon 3, escape NMD and are associated with substantial amounts of mutant β-mRNA, leading to synthesis of β-chain variants that are highly unstable and non-functional with a dominant negative effect (see next section). Other mutations of RNA translation involve the initiation (ATG) codon. Nine of these have been described; apart from an insertion of 45 bp, all are single base substitutions and again result in β^0 -thalassaemia.

Mutations affecting post-translational stability

Instability of the β-globin gene product is the basis for the dominantly inherited β-thalassaemias (Figure 14.3). As discussed earlier, in-phase PTCs within the 3′ half of exon 2 and in exon 3 cannot efficiently elicit NMD and hence abnormal mRNA containing the PTCs are transported to the cytoplasm and translated. However, these truncated variant β-chains are highly unstable, non-functional and not able to form viable tetramers. They precipitate in the erythroid precursors together with the redundant α-chains, causing premature death of these cells, and accentuating the ineffective erythropoiesis. Severe anaemia and clinical disease result even in the heterozygous state. Highly unstable β-globin chains can also result from single-base substitutions or minor insertions/deletions that affect a critical amino acid of the β-globin peptide that is involved in α/β dimer formation or haem binding. In other cases, the minor insertions/deletions lead to shifts in the reading frame resulting in long unstable β-globin gene products that form prominent inclusion bodies in red cell precursors.

Deletions restricted to the β-globin gene

β-Thalassaemia is rarely caused by deletions (Figure 14.4). Of these, only the 619-bp deletion at the 3′ end of the β-gene is common, but even that is restricted to the Sind populations of

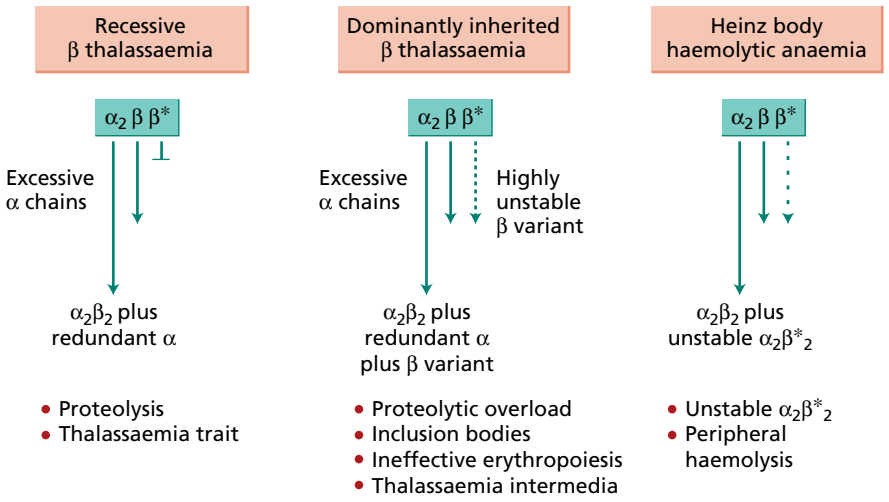

Figure 14.3 Heterozygous mutations in the β-globin gene and the different phenotypes.

India and Pakistan where it constitutes about 30% of the β-thalassaemia alleles. The other deletions, although extremely rare, are of particular clinical interest because they are associated with unusually high levels of HbA_2 and HbF in heterozygotes. The increase in HbF is adequate to compensate for the complete absence of HbA in homozygotes for these deletions. The mechanism underlying the elevated levels of HbA_2 and HbF appears to be related to removal of the 5′ promoter region of the β-globin gene, which removes competition for the upstream β-LCR and limiting transcription factors, resulting in increased interaction of the LCR with the γ- and δ-genes in *cis*, thus enhancing their expression. This mechanism may also explain the unusually high HbA_2 levels that accompany the point mutations in the β-promoter region.

Unusual causes of β-thalassaemia

These are extremely rare and are mentioned here not just for the sake of completeness but also to illustrate the numerous molecular mechanisms that downregulate the β-globin gene.

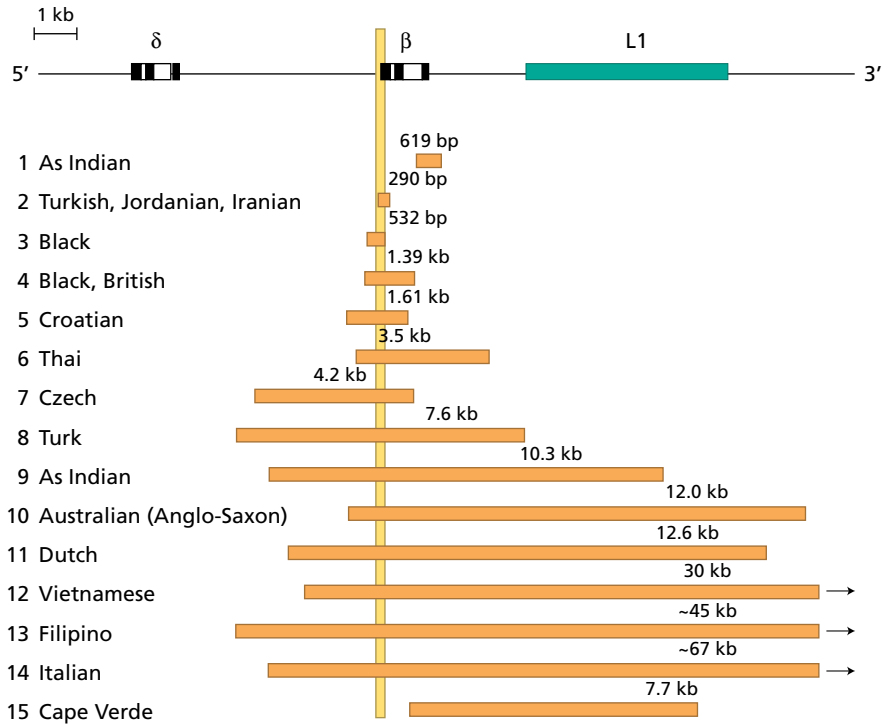

Figure 14.4 Deletions causing β-thalassaemia. The vertical bar indicates the β-globin promoter region that is removed in common by these deletions, except for the 619 bp deletion. The horizontal arrows indicate that the 3′ end of the deletions have not been defined.

Transposable elements may occasionally disrupt human genes and result in their inactivation. The insertion of such an element, a retrotransposon of the LI family, into intron 2 of the β-globin gene has been reported to cause β^+-thalassaemia. Rarely, mutations in other genes distinct from the β-globin complex can downregulate β-globin expression. Such *trans*-acting mutations have been described, affecting the XPD protein, which is part of the general transcription factor TF11H, and the key erythroid-specific transcription factor GATA-1. Somatic deletion of the β-globin gene contributed to thalassaemia intermedia in three unrelated families of French and Italian origins. The affected individuals with thalassaemia intermedia were constitutionally heterozygous for β^0-thalassaemia, but subsequent investigations revealed a somatic deletion of chromosome 11p15, including the β-globin gene complex, in *trans* to the mutation in a subpopulation of erythroid cells. This results in a somatic mosaic: 10–20% of the cells were heterozygous with one normal copy of the β-globin gene, and the rest hemizygous (i.e. without any normal β-globin gene). Unusually severe anaemia can also result from uniparental isodisomy of chromosome 11p, which encompasses the β-globin gene complex. In one case, thalassaemia major in a Chinese patient was caused by homozygosity for a paternal β-thalassaemia allele due to unipaternal isodisomy of chromosome 11p15.5, and in another, a previously healthy Portuguese adolescent carrier for β-thalassaemia became transfusion-dependent due to mosaicism of chromosome 11p14.3-11p15 that contained a β^0 CD15 mutation.

Pathophysiology

The molecular defects in β-thalassaemia result in absent or reduced β-chain production while α-globin synthesis is unaffected, resulting in an imbalance in globin chain production and an excess of α-chains. The free α-globin chains are the central causative factor in the cellular pathology and pathophysiology of β-thalassaemia. The unchaperoned α-globin chains are highly unstable and precipitate in red cell precursors, forming intracellular inclusions that interfere with red cell maturation (Figure 14.5). There is a variable degree of intramedullary destruction of erythroid precursors (i.e. ineffective erythropoiesis) that characterises all β-thalassaemias. Those red cells that mature and enter the circulation contain α-chain inclusions that interfere with their passage through the microcirculation, particularly in the spleen. However, the damage to red cell precursors and their progeny in β-thalassaemia is not entirely mechanical. The degradation products of excess α-chains, particularly haem and iron, produce a wide range of deleterious effects on red cell membrane proteins and lipids, manifested by marked abnormalities of electrolyte homeostasis and membrane deformability. The end result is an extremely rigid red cell with a shortened survival.

Thus, the anaemia of β-thalassaemia results from a combination of ineffective erythropoiesis and haemolysis. The anaemia stimulates erythropoietin production, which causes expansion of the bone marrow and may lead to serious deformities of the skull and long bones. Because the spleen is being constantly

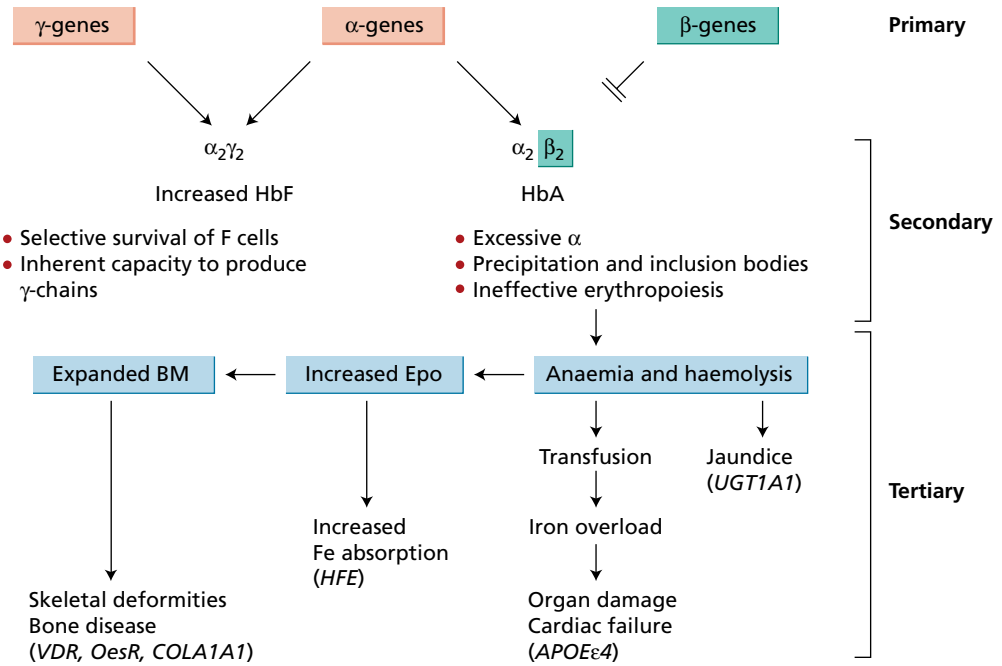

Figure 14.5 The pathophysiology of β-thalassaemia. BM, bone marrow; Epo, erythropoietin (Source: Thein, 2004 [*Br J Haematol* **124**: 264–74]. Reproduced with permission of Wiley.)

bombarded with abnormal red cells, it hypertrophies. The resulting splenomegaly, together with bone marrow expansion, causes a major increase in plasma volume, which also contributes to the anaemia.

As mentioned previously, HbF production almost ceases after birth. However, some adult red cell precursors retain the ability to produce a variable amount of γ-chains. Because the latter can combine with excess α-chains to form HbF, cells that make relatively more γ-chains in the bone marrow are partly protected against the deleterious effect of α-chain precipitation. These F cells come under selection in the marrow and peripheral blood and thus individuals with β-thalassaemia have variable increases in HbF due to selective survival of these F cells. In some cases, there is also a genuine increase in HbF production, as well as selection of F cells due to coinheritance of genetic determinant(s), or quantitative trait loci (QTL), which increase HbF production.

It follows therefore that if the anaemia is corrected with blood transfusion, the erythropoietin drive is shut off, growth and development are normal, bone deformities do not occur and splenomegaly is less marked. On the other hand, each unit of blood contains 200–250 mg of iron, and with regular transfusion there is steady accumulation of iron in the liver, endocrine glands and myocardium. Thus, although well-transfused thalassaemic children grow and develop normally, they die of iron overload unless steps are taken to remove iron.

Genotype–phenotype relationships

The β-thalassaemias show remarkable phenotypic variability, ranging from severe life-threatening anaemia to an extremely mild condition that may be identified only by chance. The molecular basis for this diversity is at least partly understood.

The genetic modifiers of the β-thalassaemia phenotype can be divided into primary, secondary and tertiary (Figure 14.5). Primary modifiers are the different mutations that affect the β-globin gene. These have variable effects on β-globin gene expression that may affect the output of β-globin chains, ranging from zero to a very mild reduction. Secondary modifiers are those that reduce the degree of imbalance of the globin chains. They include the coinheritance of α-thalassaemia and a variety of genetic modifiers of γ-chain production in adult life. So far, three major QTLs – *Xmn*1-^{G}γ site, *HBS1L-MYB* intergenic polymorphisms (*HMIP*) on chromosome 6q, and *BCL11A* gene on chromosome 2 – have been mapped. It seems likely that the genetic variance that remains unaccounted for may be due to many common and/or rare alleles with small effects on the trait, i.e. a polygenic component.

Coinheritance of α-thalassaemia reduces chain imbalance and disease severity in individuals who have inherited two copies of β-thalassaemia alleles, while the increased output of α-globin through coinheritance of extra α-globin genes in β-thalassaemia heterozygotes increases chain imbalance, converting a typically asymptomatic state to that of thalassaemia intermedia. The outcome depends on the number of α-globin genes inherited as one or two copies of triplicated (/ααα) or quadruplicated (/αααα) α-globin complexes, and the type of β-thalassaemia mutation (β^0 or β^+). A rarer mechanism of inheriting extra α-globin genes involves segmental duplication of the whole α-globin gene cluster.

Tertiary modifiers are those that affect the complications of disease; the severity of bone disease, iron loading and jaundice may be affected by polymorphisms of genes involved in the metabolic pathways concerned with these complications. Bone mass, like HbF, is a quantitative trait under strong genetic control involving multiple QTLs, those implicated including oestrogen receptor gene, vitamin D receptor (*VDR*) gene, collagen type α1 genes and transforming growth factor β1 (*TGFB1*) gene. Studies have shown that the levels of bilirubin and incidence of gallstones are related to a polymorphic variant (seven TA repeats) in the promoter of the uridine diphosphate glucuronosyltransferase 1A (*UGT1A1*) gene, also referred to as Gilbert syndrome. Iron loading in β-thalassaemia results not just from blood transfusion but also from increased iron absorption. Variants in the *HFE* gene have a modulating effect on iron absorption, and as other genes in iron homeostasis become uncovered, it is likely that there will be genetic variants in these loci that influence the different degrees of iron loading in β-thalassaemia. Similarly, it seems very likely that the propensity to infection is modified by polymorphisms involving the immune system and its regulation. Finally, it should be remembered that environmental factors, long neglected, may also play an important role in modifying the β-thalassaemic phenotype.

Clinical findings in severe β-thalassaemia

In many high-income countries, neonatal screening programmes will identify babies with more severe forms of β-thalassaemia, before the development of any symptoms; in some cases, antenatal screening of the parents and possibly prenatal diagnosis will have identified the fetus to be at high risk of β-thalassaemia before birth. Mutations in the β-globin gene almost never cause clinical symptoms *in utero* or neonatally due to the predominance of γ-globin at this stage. However, in many countries, neonatal screening programmes do not exist and diagnosis in the child will depend on their symptomatic presentation. Severe β-thalassaemia usually presents in the first year of life. Typically, there is failure to thrive, with poor weight gain and growth with developmental delay. The parents may have noticed that the infant is pale and jaundiced, with a protruding abdomen. There may be a family history of severe anaemia, and typically the family will not be of northern European origin. Examination confirms the pallor and jaundice, with palpable hepatosplenomegaly. There may be evidence of marked erythroid hyperplasia, with typical 'thalassaemic facies' including expansion of the skull vault and maxillary bones. The symptoms and signs are not specific

and differential diagnoses include gastrointestinal or hepatic disease, chronic infection and malignancy.

Laboratory diagnosis of severe β-thalassaemia

In untransfused patients with severe β-thalassaemia, the full blood count shows marked anaemia with the haemoglobin usually less than 50 g/L. Mean corpuscular haemoglobin (MCH) and mean corpuscular volume (MCV) are low, with a very wide red cell distribution width. The nucleated cell count may be very high due to the presence of large numbers of nucleated red cells. A blood film shows marked anisopoikilocytosis, with basophilic stippling and small red cell fragments (Figure 14.6). The reticulocyte count is elevated, but less than expected for the degree of anaemia, due to the ineffective erythropoiesis. Renal function is normal, but liver function tests show elevation of bilirubin, aspartate aminotransferase and lactate dehydrogenase, with a normal alanine aminotransferase. Erythropoietin levels will be high, with soluble transferrin receptor levels up to 30 times greater than normal, reflecting marked expansion of the erythron. White cell and platelet counts should be normal unless there is hypersplenism. A bone marrow aspirate is not essential to make the diagnosis, but if performed shows very marked erythroid hyperplasia, with dyserythropoiesis. Many of the erythroid precursors show inclusions after incubation with methyl violet; similar inclusions are found in the peripheral red cells after splenectomy. Immunoelectron microscopy confirms that the inclusions in β-thalassaemia consist of precipitated α-globin chains.

Haemoglobin analysis is needed to confirm the diagnosis, typically using either electrophoretic or chromatographic techniques. This will usually show an increased amount of HbA_2, with the vast majority of the remainder consisting of HbF; small amounts of HbA may be present depending on the β-globin mutation, the age of the child and whether the child has been transfused. The absence of HbA confirms a diagnosis of β^0 thalassaemia, while presence of HbA (pretransfusion sample) confirms β^+-thalassaemia. Testing of the parents should confirm the diagnosis, both typically being carriers of β-thalassaemia, with HbA_2 levels greater than 3.5% and MCH below 27 pg. These findings are sufficient to make a diagnosis of severe β thalassaemia, although where DNA analysis is available it is often used to identify the β-globin mutations and confirm the diagnosis.

Management of severe β-thalassaemia

Any child presenting in the first year of life with the features described above is likely to require regular red cell transfusions to grow and develop normally; this is referred to as thalassaemia major or transfusion-dependent thalassaemia. If such children are not transfused regularly, as happened historically, and as happens currently in many low-income countries, progressive deterioration occurs. Growth and development continue to be severely impaired. The child often has muscle wasting due to increased metabolic demands, and in particular, may become folate deficient. The spleen and liver become progressively enlarged; the spleen can become massive with hypersplenism and resulting cytopenias. There is marked erythroid hyperplasia with bony distortion and extramedullary haemopoiesis. Bones become enlarged, and this is most apparent in the face, with maxillary hyperplasia, dental malocclusion and development of a 'tower' skull. Extramedullary haemopoiesis can occur anywhere but is typically paraspinal and may cause compression of spinal nerves with resulting pain and weakness; intracranial haemopoiesis may cause cranial neuropathies and symptoms of raised intracranial pressure. There is an increased tendency to infection, and without transfusion the child typically dies from either infection or high-output cardiac failure. Radiography may show lacy trabecular patterns in long bones and a 'hair-on-end' appearance of the skull (Figure 14.7).

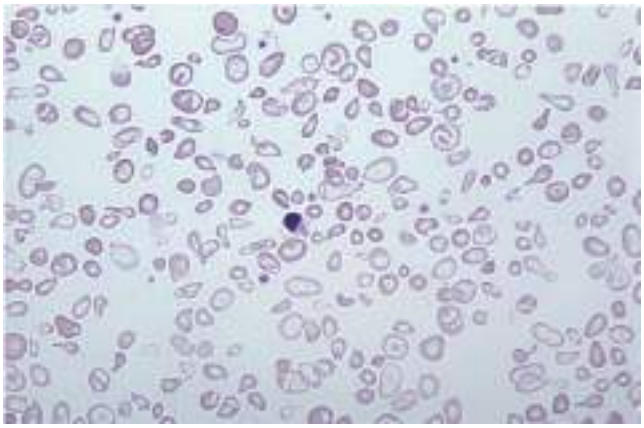

Figure 14.6 The peripheral blood appearances in β-thalassaemia.

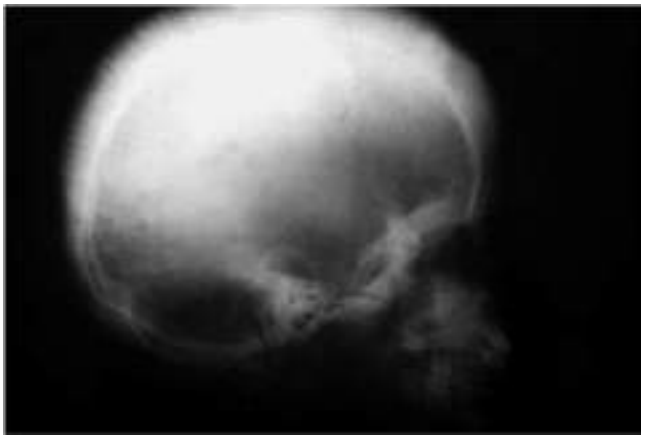

Figure 14.7 Radiograph of a skull of a thalassaemia major patient showing 'hair-on-end' appearance.

This picture is completely transformed by an appropriate transfusion regimen. The decision to start regular blood transfusions is based on clinical factors and not dependent on a particular haemoglobin level or molecular diagnosis. Occasional blood transfusions may be necessary because of an acute exacerbation of anaemia, often related to infection, and do not necessarily mean that the child is transfusion dependent. It is a bigger decision to institute a regular transfusion regimen, in that typically transfusions are then continued lifelong. Stopping transfusions in a child or adult who is adapted to a high haemoglobin level inevitably results in a prolonged period of symptomatic anaemia and ill health, which may not be tolerated. Regular transfusions should be started if the child is failing to thrive, or if erythroid expansion is causing extramedullary haemopoiesis, bony distortion or hypersplenism; abnormal facial appearances, if allowed to progress, may be irreversible without maxillofacial surgery.

Blood transfusions

The aim of regular transfusion is to correct anaemia and suppress erythroid hyperplasia. Correcting anaemia improves oxygen delivery to the tissues and facilitates normal growth and development. Suppression of erythropoiesis limits damage to bones, reduces hypermetabolism and excessive iron absorption and reduces extramedullary haemopoiesis. Measurement of soluble transferrin receptor levels, which are proportionate to the size of the erythron, suggest that suppression of erythropoiesis requires the haemoglobin to be kept above 95 g/L; in practice, this means aiming for a pretransfusion haemoglobin of 90–100 g/L. This can usually be achieved by regular red cell transfusions every 2–4 weeks, with a post-transfusion haemoglobin target of 130–150 g/L. If venous access is difficult, as is often the case in young children, it is sometimes beneficial to insert a semi-permanent central venous access device, such as a Portacath or Hickman line. The majority of thalassaemia patients are treated with simple top-up transfusions. An alternative involves regular exchange transfusion in which blood is both removed by venesection and transfused; this can be performed either manually or automatically using an apheresis machine. The main advantages are that transfusion can be less frequent, at intervals of up to 6 weeks, and iron loading is significantly less, as blood is also removed. Disadvantages include increased expense and time, increased donor exposure with risk of infection and alloimmunisation, and difficulties with venous access.

Ideally transfusions are with packed red blood cells. Leucodepleted blood reduces the risk of transfusion reactions and cytomegalovirus infection and should be used where available. When the ethnicity of the blood donor population differs from that of the recipient thalassaemia population, as occurs in most of Europe, the USA and Australia, the transfused red cells should be matched for an extended range of blood groups to minimise the risk of alloimmunisation; typically, full matching for all Rh and Kell groups, in addition to ABO, is of benefit. Blood grouping based on DNA analysis offers potential benefits, by identifying variant blood groups that may not be uncovered using serological testing. This is particularly relevant for Rh variants, which are responsible for an increasing proportion of alloantibodies as serological grouping becomes more widespread. On starting transfusions, the patient should be vaccinated against hepatitis B, and ideally also against hepatitis A.

Iron overload

Iron overload inevitably complicates regular blood transfusions and is the source of many serious complications. Each unit of transfused blood contains about 200–250 mg iron, compared with the 1 mg iron normally absorbed each day. Hepcidin is an important negative regulator of iron absorption, but in thalassaemia major and intermedia, hepcidin levels remain inappropriately low, despite increased iron stores. Erythroferrone (ERFE) is a hormone that inhibits hepcidin synthesis and is secreted by differentiating erythroblasts; greatly increased levels of ERFE were found in mice with thalassaemia intermedia, providing an explanation for the inappropriately low hepcidin and increased iron absorption. ERFE, therefore, seems to be the main cause of the low hepcidin levels encountered in β-thalassaemia where there is a large component of ineffective erythropoiesis. Growth differentiating factor-15 (GDF-15) which is produced by erythroid precursors and reaches very high levels in thalassaemia major due to erythroid hyperplasia, has previously been suggested as a pathological suppressor of hepcidin in thalassaemia, but, to date, there is no definitive evidence for its role in suppression of hepcidin (Chapters 11 and 12). Iron is initially stored in macrophages within the liver, and is chaperoned around the body bound to transferrin. As transferrin becomes saturated, labile, more toxic forms of iron appear in cells and plasma, referred to as non-transferrin-bound iron (NTBI). It is thought that NTBI is responsible for most of the iron toxicity, including iron loading into cardiac and endocrine tissues. Once in cells, the iron causes oxidative tissue damage, mostly through the generation of oxidative stress and free radicals.

Iron overload and chelation are discussed in more detail in Chapter 12. Before iron chelation was available, most regularly transfused patients with thalassaemia died in their late teens, mainly from cardiac iron deposition causing cardiac arrhythmias and heart failure. Endocrine failure was also inevitable, with diabetes mellitus, hypothyroidism, hypoparathyroidism, hypogonadism and hypopituitarism. With good iron chelation life expectancy is open-ended, and there is an established link between the efficacy of iron chelation and life expectancy.

The body has no mechanism for excreting iron and iron chelating drugs are necessary to avoid toxic iron accumulation. Iron chelation is usually started after about 1 year of monthly blood transfusions. Ideally, children delay starting chelation until they are 3 years old, as drug toxicity is thought to be highest

in the young; it is usually necessary to start chelation earlier in children who start transfusions in the first year of life, although in general low doses are used initially.

Currently, three drugs are used for iron chelation: desferrioxamine, deferiprone and deferasirox. Desferrioxamine has been in clinical use since the 1970s and is known to be safe and effective; side-effects seem only to occur when the drug is used in high doses or when iron stores are low. Important side-effects include ocular and retinal toxicity, growth impairment and cartilaginous dysplasia. The risk of *Yersinia enterocolitica* infection is increased in iron overload, particularly if desferrioxamine is also in use. Regular use of desferrioxamine has been found to prolong survival in several observational studies. The main problem is that it has to be given by injection; the most commonly used regimen involves overnight subcutaneous infusions given over 8 hours using a syringe driver or balloon-pump. To achieve negative iron balance in a regularly transfused person requires a dose of 40 mg/kg 5 times a week. The subcutaneous route is inevitably a cause of poor adherence to treatment regimens because of the pain and inconvenience. Historically, therefore, many patients have developed life-threatening iron overload despite the availability of desferrioxamine, with median age of death being 30–40 years. Deferiprone was developed in the UK about 30 years ago and was licensed in Europe in 1999, and the USA in 2011. Initial trials demonstrated its efficacy, although subsequent studies suggested that there may be individual variation in response requiring higher dosage up to 100 μg/kg/day instead of 75 μg/kg/day. Arthropathy and agranulocytosis are potentially serious side effects and it is currently recommended that people taking the drug have full blood counts every week. Despite concerns about its safety and efficacy, deferiprone seems to be effective at removing cardiac iron, which is possibly linked to improved cardiac function and reduced mortality. It is increasingly used in combination with desferrioxamine. Deferasirox is a rationally designed oral iron chelator that has been approved in the USA and Europe since the mid-2000s. Large clinical trials have demonstrated its efficacy in thalassaemia. It effectively removes hepatic iron, with increasing evidence that it also removes cardiac iron. Some studies suggest that the different iron chelators can be combined safely and that this may increase efficacy in some cases. Most frequently, deferiprone is combined with desferrioxamine to treat cardiac iron overload, although other small studies have also looked at desferrioxamine-deferasirox and deferiprone-deferasirox combinations, suggesting that they can be safely combined.

It is important to monitor iron stores regularly in transfusion-dependent patients who are receiving iron chelation. Monitoring the volume of transfused blood allows the iron input to be calculated and can be valuable when choosing the dose of iron chelator. Serum ferritin is proportional to the amount of stored iron in the liver and can be used to effectively monitor iron overload, particularly if serial measurements are used. Ferritin is artificially elevated by any inflammatory process, which can cause misleading results, particularly if there is coincidental hepatitis. Liver iron can be accurately assessed using liver biopsy, but this is invasive with a risk of complications. Increasingly, magnetic resonance imaging (MRI) is used to quantitate liver iron, with the R2 method being approved by both European and North American authorities. Cardiac MRI is an important way of identifying those patients with significant cardiac iron, which allows chelation to be targeted to the heart, using either continuous intravenous desferrioxamine or a combination of desferrioxamine and one of the oral iron chelators. Iron monitoring and chelation are very expensive and not easily available to most patients in the world with thalassaemia major.

Monitoring and annual review of patients with thalassaemia major

The aim of regular transfusions is to allow the child to grow and develop normally, and for the quality and quantity of life to be as close to normal as possible. This requires the patient to be regularly monitored, and this is ideally done in a centre with expertise in the condition, often in the form of an annual review. Each year the volume of transfused blood (expressed as mL/kg) should be recorded; if the transfusion requirement is high, exceeding 200–250 mL/kg, this suggests the possibility of hypersplenism. If the spleen is enlarged, splenectomy may significantly reduce the rate of transfusion and iron loading. Splenectomy would not normally be considered before the age of 6 years, and there is emerging concern that it may increase the risk of pulmonary hypertension and other vascular complications in later life.

Growth should be carefully monitored in children, including annual measurement of sitting height to assess spinal growth; desferrioxamine toxicity has been specifically linked to impaired spinal growth. Blood tests should be performed each year to look for endocrinopathy, including fasting glucose, thyroid stimulating hormone, parathyroid hormone, insulin-like growth factor 1 and sex hormone levels. Hepatic and renal function should be monitored regularly, together with hepatitis serology. Cardiac assessment should include an ECG, echocardiogram and increasingly MRI, which can assess both ejection fraction and iron loading; MRI is not usually tolerated by children under the age of 7 years without general anaesthesia or sedation and is not usually justified at this age unless there is strong suspicion of cardiac or other problems. Osteopenia is more common in children and adults with thalassaemia major, and bone densitometry should be monitored regularly from the age of about 10 years. Vitamin D levels should be measured regularly and optimised, with oral supplements of vitamin D being necessary in most countries. There is evidence that bisphosphonates may be effective in preventing and treating osteopenia in adults with thalassaemia, although their role in children is less established, with concern about their effects on growth. Dietary and psychological support are also often beneficial. In general, the organisation and provision of all this care require a multidisciplinary team, including paediatricians, haematologists, cardiologists, endocrinologists, nurse specialists and psychologists.

Haematopoietic stem cell transplantation in severe thalassaemia

Haematopoietic stem cell transplantation (HSCT) is usually the treatment of choice if there is an HLA-identical sibling and it is clear that the child is transfusion dependent. The success of stem cell transplantation is generally reduced as children get older, iron overload increases and iron-related organ damage increases. Under optimal circumstances, the transplant is successful in more than 90% of cases. The main complications are severe infection during the period of transplantation and either acute or chronic graft-versus-host disease. Significantly reduced fertility is also almost inevitable. One limitation of transplantation is the availability of suitable donors; cord blood transplants are potentially useful in this respect. In a small number of cases, preimplantation genetic diagnosis has allowed the selection of HLA-matched embryos to produce siblings who can act as stem cell donors. Increasingly, HSCTs are being performed using alternative sources of stem cells, particularly from haploidentical donors (parents, some siblings), or matched unrelated donors. Outcomes from these alternative donor transplants are improving but still slightly worse than from HLA-identical siblings. Nonetheless, alternative donor transplants offer an important option for some patients at the moment.

Emerging treatments

Gene therapy is starting to emerge as a viable therapeutic option for some patients. Clinical studies using a lentivirus vector to add normal copies of the beta-globin gene to stem cells from patients with severe beta thalassaemia have shown significant therapeutic benefits, increasing the haemoglobin by 20–30 g/L, and abolishing the need for transfusion in some patients who were previously transfusion dependent. This is now a commercially available treatment in some countries, although use is limited by high cost and the need for myeloablative conditioning. Gene editing approaches are still largely experimental, although a large number of different strategies are being developed. Many of these are focused on increasing gamma globin production, to compensate for the lack of beta globin, including reducing the influence of BCL11A on gamma globin transcription and a commercial treatment based on this approach has recently been licensed in Europe, the USA and some other regions. A very small number of patients have so far been treated in this way, with encouraging results. Progress in this area continues to be very rapid, with more precise ways of gene editing being developed, novel targets being identified and new ways of delivering the vectors to erythropoietic tissue to avoid the need for myeloablative conditioning. In the future, it seems likely that stem cell treatment in thalassaemia will involve the in vivo delivery of gene editing tools that can specifically correct the beta-globin variant causing thalassaemia.

Luspatercept is a recombinant protein designed to bind to transforming growth factor-beta ligands to improve red cell maturation, via the inhibition of SMAD2 and SMAD3 signalling. A randomised, placebo-controlled clinical trial in patients with transfusion-dependent beta thalassaemia found that about 20% of patients had a reduction in their transfusion requirements of at least 33% during the study, and 11% of patients became transfusion-independent. There are likely to be similar benefits for patients with thalassaemia intermedia. Luspatercept is approved for use in the EU and USA, although it is not curative and it is not yet clear exactly how it should be used in thalassaemia. It potentially reduces the transfusion requirements of patients, and may reduce iron accumulation, but this has to be balanced against the cost of the drug and its potential side-effects, which include an increased risk of thromboembolism and increased extramedullary haematopoiesis. On-going clinical trials also suggest that pyruvate kinase activators may reduce transfusion requirements in some patients with transfusion dependent thalassaemia.

Prognosis in severe thalassaemia

In theory, with adequate transfusion and effective chelation, survival in thalassaemia major should approach that of the normal population, although historically this has never been the case because of the difficulties patients encounter in adhering to iron chelation regimens, particularly with subcutaneous infusions. In Europe and North America, median survival has improved with each decade since the introduction of desferrioxamine in the 1970s. Most deaths are related to cardiac iron overload and improved survival is primarily related to earlier and more rational use of chelation. Recent studies suggest that deaths from cardiac complications have become much less common in the last 15 years, probably related to improved awareness and treatment of iron-related cardiomyopathy with intravenous desferrioxamine and combination therapy with both desferrioxamine and deferiprone. Earlier detection, using cardiac T2* MRI, and prevention of cardiac iron loading, with oral chelation, seem likely to further improve prognosis. Liver disease, malignancy and infection are becoming relatively more common causes of death.

Heterozygous β-thalassaemia

Carriers for β-thalassaemia are usually symptom-free except in periods of stress such as pregnancy, when they may develop significant anaemia. Transfusion is sometimes necessary during pregnancy, but no other treatment or follow-up is necessary. Palpable splenomegaly is rare. Carriers may have mild anaemia; haemoglobin values are in the range 90–120 g/L. The red cells show hypochromia and microcytosis proportionately greater than the degree of hypochromia seen in iron deficiency. The reticulocyte count is normal. The bone marrow shows mild erythroid hyperplasia with corresponding slight increase in soluble transferrin receptor levels. The characteristic finding is an elevated HbA_2 level, usually greater than 3.5%. There is a slight elevation of HbF in the 1–3% range in about 50% of cases. Silent

or near-silent carriers of β-thalassaemia occur fairly rarely, in which the HbA_2 level is normal with only slight hypochromia; this is typically associated with mild thalassaemic variants in the promoter region of the gene. Failure to identify this state antenatally can result in significant and unexpected thalassaemia in the offspring, if the partner also carries β-thalassaemia. Borderline increases of HbA_2 with variable increases of HbF, but normal red cell indices have also been associated with variants in the *KLF1* gene, but the clinical significance of such variants when coinherited with β-thalassaemia is not clear.

β-Thalassaemia in association with haemoglobin variants

In many populations, because there is a high incidence of both β-thalassaemia and other globin gene mutations, it is quite common for an individual to inherit a β-thalassaemia allele from one parent and a gene for a structural haemoglobin variant from the other. Although numerous interactions of this type have been described, only three are common and significant: HbS/β-thalassaemia, HbC/β-thalassaemia and HbE/β-thalassaemia.

HbS/β-thalassaemia

HbS/β-thalassaemia causes sickle cell disease, with the severity varying from very mild to severe (see also Chapter 15). This interaction does not result in clinically significant thalassaemia. The principal determinant of the severity of sickle cell disease is the nature of the β-thalassaemia mutation, and to what extent β^A is reduced compared with normal. HbS/β^0 -thalassaemia with no HbA present and an average haemoglobin of 70–80 g/L is broadly similar in severity to HbSS. It differs in that red cells are markedly hypochromic and contain excess α-globin chains. Clinically significant splenomegaly is more common than in HbSS, affecting up to 30% of adults. The severity of HbS/β^+-thalassaemia varies from severe to very mild, depending on how much HbA is produced. Some β^+-thalassaemia alleles produce less than 10% of the normal HbA output and result in a clinical picture identical to HbS/β^0-thalassaemia. At the other end of the spectrum, promoter mutations typically reduce HbA output by only 10% and result in a condition that is only marginally more symptomatic than sickle cell carriers. These mild forms of HbS/β^+-thalassaemia occur most often in populations of African origin, whereas the more severe forms are most often found in Mediterranean countries and India.

HbC/β-thalassaemia

HbC is common in parts of West Africa and occurs to a minor extent in populations of North African and southern Mediterranean origins. It is largely asymptomatic and characterized by a mild haemolytic anaemia associated with splenomegaly. The peripheral blood film shows numerous target cells and thalassaemic red cell changes with a moderately elevated reticulocyte count. Haemoglobin electrophoresis shows a preponderance of HbC. The diagnosis is confirmed by finding the HbC trait in one parent and the β-thalassaemia trait in the other, and by DNA analysis where appropriate.

HbE/β-thalassaemia

This is the commonest severe form of thalassaemia in Southeast Asia and parts of the Indian subcontinent. The β^E allele is mildly thalassaemic due to the activation of a cryptic splice site, and when it is inherited together with β^0-thalassaemia, there is a marked deficiency of β-chain production. HbE is slightly unstable *in vitro*, although it is not clear how clinically significant this is. The clinical and haematological features are very variable. There are thalassaemic red cell changes, and the bone marrow shows marked erythroid hyperplasia. There is nearly always anaemia and splenomegaly, with typical thalassaemic bone changes. Haemoglobin values are in the range 40–100 g/L, with an average of 60–70 g/L; in well-resourced countries about half of the patients with this condition are regularly transfused. There are thalassaemic red cell changes and the bone marrow shows marked erythroid hyperplasia.

Although relatively little is known about the natural history of this disorder, it is clear that in many parts of Southeast Asia and India, it causes a very high mortality in early life. Clinically it is indistinguishable from other forms of β-thalassaemia, although the link between genotype and phenotype is less predictable, with some patients having thalassaemia major and others, being non-transfusion dependent, growing and developing with few complications.

The diagnosis is confirmed by finding only HbE and HbF on haemoglobin electrophoresis and by demonstrating HbE trait in one parent and β-thalassaemia trait in the other. In cases of HbE/β^+-thalassaemia, variable quantities of HbA are present and the condition is usually milder. Neonatal diagnosis can be difficult, particularly distinguishing between homozygotes for HbE and HbE/β^0-thalassaemia; family studies and DNA analysis are useful in these circumstances.

Variant forms of β-thalassaemia

Despite the vast heterogeneity of mutations, the increased levels of HbA_2 in β-thalassaemia heterozygotes are remarkably uniform, in the range 3.5–5.5%, and rarely exceeds 6%. Unusually high HbA_2 levels in excess of 6.5% seem to characterise the subgroup caused by lesions (point mutations or small deletions) that affect the regulatory elements in the promoter region of the β-globin gene (see Figure 14.4). The unusually high HbA_2 levels are usually accompanied by higher than usual increases in HbF, resulting in a milder thalassaemia phenotype, despite the absence of HbA in some cases. Otherwise, the haematological picture is identical to the common forms of β thalassaemia.

Some β-thalassaemia heterozygotes have normal HbA_2 levels, despite the typical hypochromic microcytosis. In most cases, this is due to the coinheritance of δ-thalassaemia. Other cases of normal HbA_2 β-thalassaemia are extremely mild forms of β-thalassaemia that is completely silent in heterozygotes and is only identified when it is coinherited with a common form of β-thalassaemia. Heterozygotes do not have any evident haematological phenotype, the only abnormality being a mild imbalance of globin chain synthesis.

β-Thalassaemia occasionally follows a dominant pattern of inheritance, producing symptoms in heterozygotes (see Figure 14.3). The clinical picture is characterised by a moderate degree of anaemia and splenomegaly with marked thalassaemic changes of the red cells, and ineffective erythropoiesis with intracellular inclusion bodies. Although not usually transfusion-dependent, such individuals develop iron overload from hyperabsorption due to ineffective erythropoiesis and may develop liver and/or endocrine damage. The common denominator of these dominantly inherited β-thalassaemias is the synthesis of hyper-unstable β-chain variants, caused by a spectrum of mutations; those resulting from PTCs are typically found in exon 3 of the β-globin gene. Unlike the recessive forms that are prevalent in malarious regions, dominantly inherited β-thalassaemias are rare, occurring in dispersed geographical regions. Most of the dominant β-thalassaemia alleles have been described in single families, many as *de novo* mutations. Dominantly inherited β-thalassaemia should be suspected in any patient with a thalassaemia intermedia phenotype, even if both parents are haematologically normal, and the patient is from an ethnic background where β-thalassaemia is rare. The diagnosis is confirmed by DNA sequence analysis of the β-globin genes.

δβ-Thalassaemia and hereditary persistence of fetal haemoglobin

HPFH and δβ-thalassaemia are much less common than β-thalassaemia and manifest as a range of disorders characterised by decreased or absent HbA production and a variable compensatory increase in HbF synthesis. The distinction between them is subtle and originally made on what appeared to be clear-cut clinical and haematological grounds. However, as more cases became recognised and their underlying mutations delineated, it became evident that there is considerable overlap between the two groups of disorders.

The level of compensatory increase is higher in HPFH compared with δβ-thalassaemia. HPFH heterozygotes have essentially normal red cell indices, normal HbA_2 levels and HbF levels of 10–35%, whereas heterozygotes for δβ-thalassaemia have hypochromic microcytic erythrocytes and normal HbA_2 levels and the HbF increases are lower (5–15%). A distinguishing feature is the heterocellular distribution of HbF in δβ-thalassaemia compared with a pancellular (or homogeneous) distribution in HPFH, although the intercellular distribution of HbF may be a reflection of the magnitude of increase and the sensitivity of the technique used to stain the HbF in the red blood cells (F cells). Clinically, HPFH homozygotes are asymptomatic with slightly reduced or normal MCV and MCH, and compound heterozygotes with β-thalassaemia have very mild disease. Compound heterozygotes of δβ-thalassaemia with β-thalassaemia, and δβ-thalassaemia homozygotes have disease severity that ranges from mild anaemia to transfusion dependence.

Two types of mutations underlie this group of disorders: deletions that remove substantial regions of the β-globin cluster, including the β-globin gene (Figure 14.8), and point mutations in the promoters of either of the γ-globin genes ($^{G}\gamma$ or $^{A}\gamma$). Six deletion forms of HPFH have been described in Africans, Mediterraneans, Indians and Southeast Asians, with deletions ranging from 13 to 86 kb in size. The commonest forms are Black HPFH-1 and HPFH-2, the latter also referred to as Ghanaian HPFH. Included within the HPFH conditions is Hb Kenya, a rare condition found largely in East Africa and characterised by production of a hybrid $^{A}\gamma\beta$-globin chain and increased $^{G}\gamma$-chain (Figures 14.8 and 14.9). The first type of δβ-thalassaemia to be described was Hb Lepore, which consists of hybrid δβ-globin chains produced by misaligned crossing-over between the δ- and β-globin genes (Figures 14.8 and 14.9). Heterozygotes for Hb Lepore have hypochromic microcytic red cells, normal HbA_2 and variably increased HbF. The more common forms of δβ-thalassaemia result from deletions of different lengths in the β-globin gene cluster (Figure 14.8). Deletions that leave both the γ-globin genes intact are called $^{G}\gamma^{A}\gamma$ $(\delta\beta)^0$ -thalassaemias, and they all include parts or all of the δ- and β-globin genes. $^{G}\gamma(^{A}\gamma\delta\beta)^0$ -thalassaemia deletions include part or all of the $^{A}\gamma$-globin gene and hence produce HbF containing only $^{G}\gamma$-chains. A couple of the $(\delta\beta)^0$-thalassaemias include two deletions separated by an inverted region.

Non-deletion HPFH is caused by mutations within the promoters of either of the γ-globin genes and lead to variably increased HbF with a preponderance of only one of the γ-chains. The mutations (single-base substitutions or minor deletions) are clustered in three regions of the promoters, around positions −114, −175 and −200. These regions contain binding sites for ubiquitous and erythroid-specific factors. Altered binding patterns of the transcription factors due to the point mutations are thought to be the cause of the elevated HbF levels, which vary from 5 to 35% in heterozygotes. Deletion and non-deletion HPFH and δβ-thalassaemias are clearly inherited in a Mendelian fashion as alleles of the β-globin gene complex. Heterozygotes have significant elevations of HbF ranging from 10 to 40%.

Inherited increases in HbF have also been reported in families with β-thalassaemia and sickle cell disease; these increases had a modulating effect on the severity of disease and the inheritance appeared to segregate independently of the β-globin gene cluster. Healthy members of the families may also have slight increases in HbF, and historically these individuals were said to have coinherited heterocellular HPFH. Heterocellular HPFH

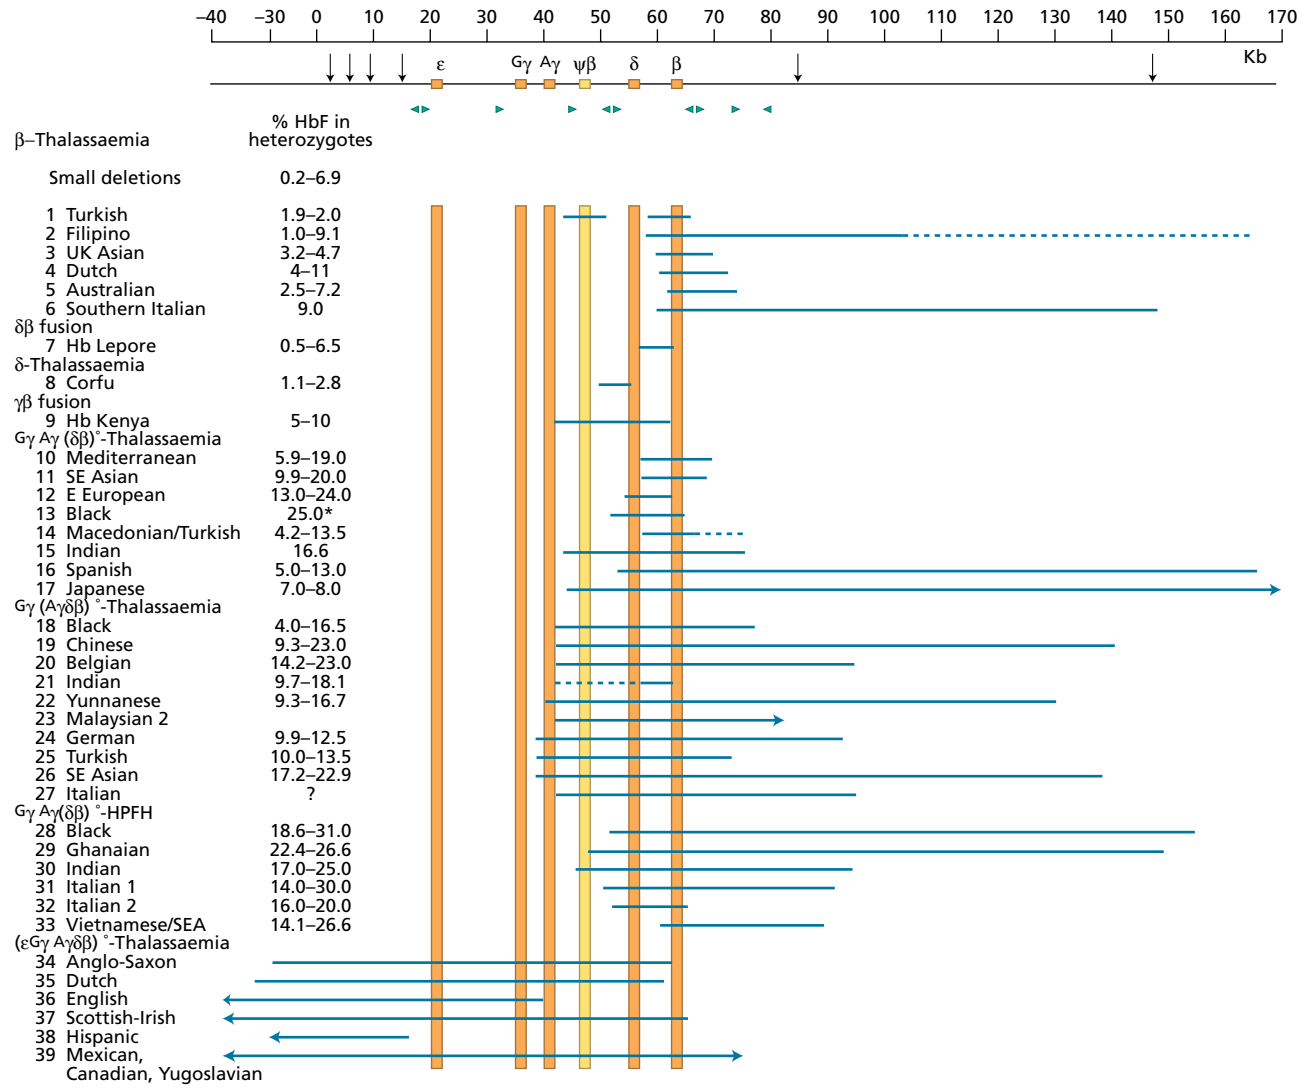

Figure 14.8 The deletions that underlie δβ-thalassaemia and hereditary persistence of fetal haemoglobin. The upper arrows represent DNase I-hypersensitive sites (Source: Weatherall and Clegg 2001. Reproduced with permission of WHO.)

was originally recognised in a group of Swiss army recruits; the HbF elevation was modest and unevenly distributed amongst the erythrocytes, the distinct HbF-carrying red blood cells being termed F cells. Hence Swiss HPFH was also referred to descriptively as heterocellular HPFH. It is now clear that HbF is a highly variable quantitative trait, and that heterocellular HPFH represents the upper tail of the natural continuous distribution that includes approximately 10% of the population with HbF levels between 0.8 and 5%. Unlike the Mendelian forms caused by major deletions or point mutations in the γ-globin promoters, the inheritance of heterocellular HPFH is complex, with an overwhelming genetic contribution. The sequence variant (C→T) at position −158 of the ^{G}γ-globin gene, also referred to as the *Xmn*1-^{G}γ site (or rs74821440), was the first QTL to be implicated through family studies but subsequent studies indicate that rs74821440 is likely to be a surrogate marker for yet to be identified variant(s) in the HBB cluster. Subsequent genetic association studies have confirmed *Xmn*1-^{G}γ as one of the three major QTLs modulating HbF production in adults, the other two being the *HBS1L-MYB* intergenic region on chromosome 6q and *BCL11A* on chromosome 2p. These three QTLs account for a relatively large proportion (20–50%) of the common variation in HbF levels, not only in healthy adults, but also in patients from diverse ethnic groups – Brazilians, African–Americans, African–British, Tanzanians with sickle cell disease. In African–American patients with sickle cell disease, the three loci contribute more than 20% to the HbF variation with a corresponding reduction in frequency of acute pain. Coinheritance of the *Xmn*1-^{G}γ site delays transfusion requirements in β-thalassaemia. A combination of the three HbF QTLs and α-globin genotype

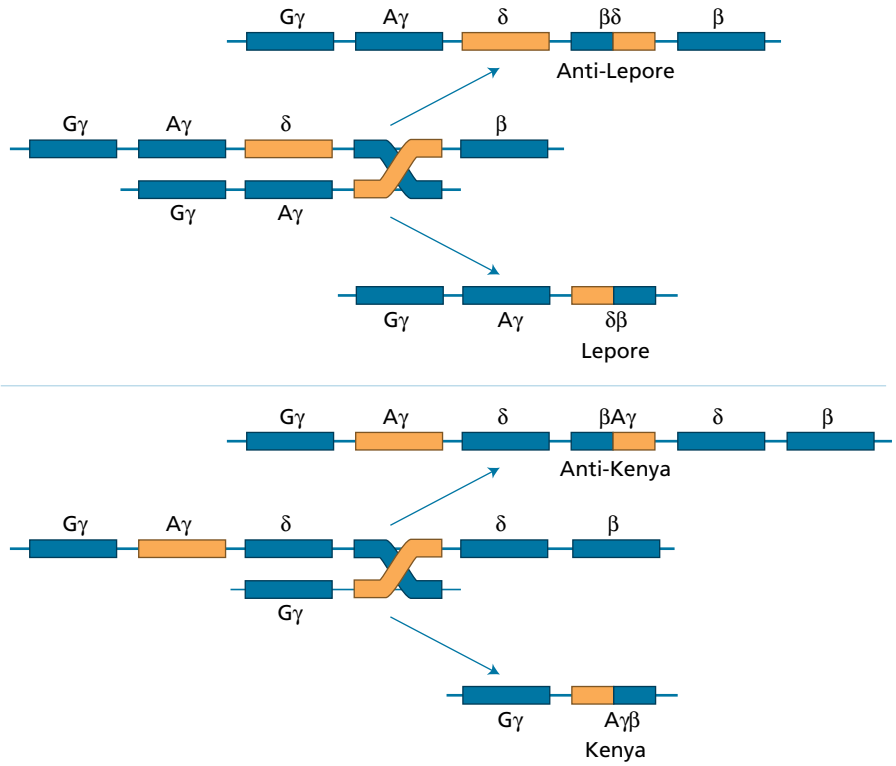

Figure 14.9 The mechanisms for the production of haemoglobin Lepore and related variants.

have also been shown to be predictors of disease severity and transfusion requirements in patients with β-thalassaemia and HbE/β-thalassaemia. HbF increases secondary to *KLF1* variants, either as a primary phenotype or in association with other red cell disorders, such as congenital dyserythropoietic anaemia (CDA type IV), are increasingly noted.

εγδβ-Thalassaemia

These are rare conditions and result from large deletions of the β-globin gene cluster that involve the β-LCR. The deletions fall into two main categories: group I removes all, or a greater part of, the complex including the β-globin gene and the β-LCR, and group II removes extensive upstream regions including the β-LCR but leaving the β-globin gene itself intact. There is no output from the globin genes of the affected cluster. Clearly, the homozygous state would not be compatible with survival. Heterozygotes have severe haemolytic disease of the newborn, with anaemia and hyperbilirubinaemia. The severity of anaemia and haemolysis is variable, even within a family, and in some cases, blood transfusions are necessary during the neonatal period. If they survive the neonatal period, the infants grow and develop normally as compared with infants with typical β-thalassaemia trait. Affected adults have the haematological picture of heterozygous β-thalassaemia, with mild anaemia, hypochromic microcytic red cells and a haemoglobin pattern of normal HbA_2 β-thalassaemia. Using next-generation sequencing (NGS) technology, a novel form of εγδβ-thalassaemia due to an inversion-deletion has recently been characterised in three unrelated English families.

The α-Thalassaemias

Distribution

The α-thalassaemias follow a similar distribution to the β-thalassaemias, extending throughout sub-Saharan Africa, the Mediterranean region, the Middle East, the Indian subcontinent and Southeast Asia, in a line stretching from southern China through Thailand, the Malay Peninsula and Indonesia, to the Pacific Island populations.

In some prevalent areas, carrier frequency for the mild form (α^+) reaches 80% or more. The more severe forms (α^0-thalassaemias) reach their highest frequency in Southeast Asia, where carrier frequency can reach 10%.

Genetic basis of disease: molecular pathology

Normal individuals have four α-globin genes arranged as linked pairs, α2 and α1, at the tip of each chromosome 16, the normal α-genotype being represented as αα/αα (Figure 14.10). The α-thalassaemias can be classified as α^0-thalassaemia, in which no α-chains are produced from the linked pair, and α^+-thalassaemia, in which production of α-chain from the affected chromosome is reduced.

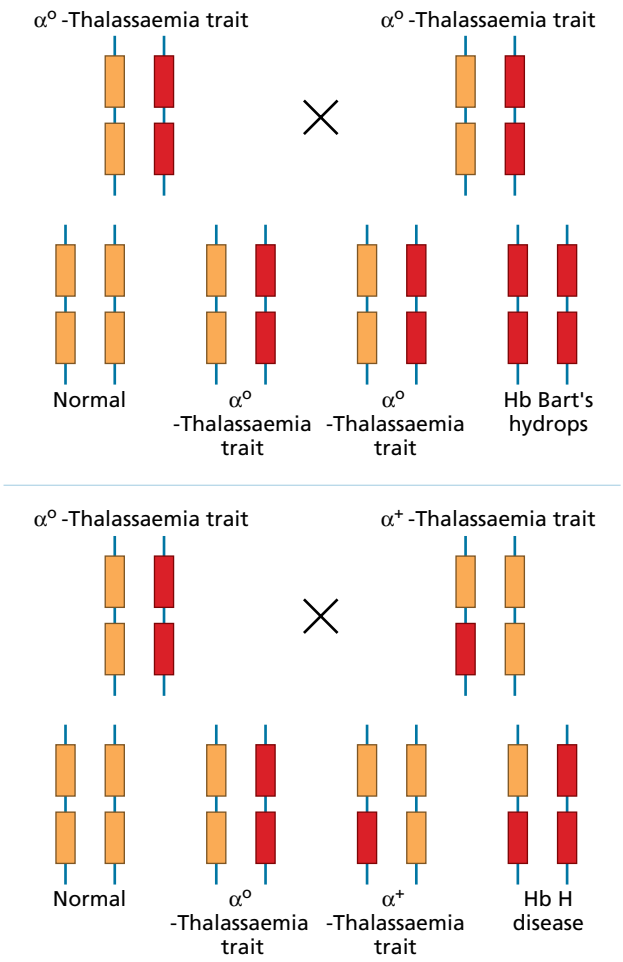

Figure 14.10 The genetics of α-thalassaemia.

The α^0-thalassaemias are caused by deletion of both α-globin genes (Figure 14.11). The deletions vary in size and tend to be geographically isolated, with two particularly common ones in Southeast Asia (/– $-^{SEA}$) and the Mediterranean region (/– $-^{MED}$). Rarely, α^0-thalassaemia can also arise from deletions of the upstream α-globin regulatory elements (MCS) in which the α-globin genes remain intact but completely inactivated. In other cases, more extensive deletions are associated with monosomy for a segment of the tip of chromosome 16p that, when greater than about 1 megabase (Mb), result in the alpha thalassaemia X-linked intellectual disability syndrome (ATR-16). The molecular basis of the α^+-thalassaemias is more complicated; the commonest forms result from deletions that remove one of the linked pairs of α-globin genes, leaving the other intact (–α/αα). The linked α-globin genes are embedded in two highly homologous duplicated units of 4kb within which are three homologous subsegments designated X, Y and Z (Figure 14.12), misalignment and recombination between the Z segments, which are 3.7kb apart, produces chromosomes with one α-globin gene (/$-\alpha^{3.7}$ or *rightward* deletion) and others with three α-globin genes (/ααα$^{anti\text{-}3.7}$). Similarly, crossover between the X boxes, which are 4.2kb apart, produces the *leftward* deletion /$-\alpha^{4.2}$ and the /ααα$^{anti\text{-}4.2}$ allele.

Less commonly, both the α-globin genes are intact and α^+-thalassaemia results from point mutations that partially or completely inactivate one of them ($\alpha^T\alpha/\alpha\alpha$). In contrast to the β-thalassaemias, non-deletional mutations are much less common causes of α-thalassaemia but, like those that cause β-thalassaemia, the non-deletional α-thalassaemia variants act at different stages of gene regulation and expression. The majority of the non-deletional α-thalassaemia (more than two-thirds) are found on the dominant α2 gene, less than one-third on the α1 gene and the others on an /–α-chromosome (/$-\alpha^T$). In general, the non-deletional α^+-thalassaemia variants (/$\alpha^T\alpha$) give rise to a more severe reduction in α-chain output than the single α-gene deletion (/–α) due to the lack of compensatory increase in α-output from the linked α1 gene, as observed in deleted cases. One particularly common form of non-deletional α-thalassaemia found in Southeast Asia is Hb Constant Spring (/$\alpha^{CS}\alpha$), which is due to a single-base substitution (TAA→CAA) in the α_2-globin termination codon. Instead of terminating at the stop codon, mRNA is read through the 3′-UTR until another in-phase termination codon is encountered 31 codons later. This results in an elongated α-globin chain of 172 residues, 31 amino acids from the natural arginine at codon 141. Of the six predicted α_2-chain termination variants, five have been described: Hb Constant Spring (α142 Gln), Hb Icaria (α142 Lys), Hb Koya Dora (α142 Ser), Hb Seal Rock (α142 Glu) and Hb Pakse (α142 Tyr). Hb Constant Spring is by far the most common of these variants, reaching frequencies of up to 4% in Thailand. Finally, non-deletional α-thalassaemia can also arise from single-base substitutions causing structural α-globin variants that are highly unstable, for example Hb Quong Sze α125 Leu→Pro (/α^{QS} α).

Unusual causes of α-thalassaemia

This includes a single case report of α^0-thalassaemia arising from a deletion involving the α1 gene that also inactivated the intact linked α2 gene. Subsequent studies showed that the deletion results in juxtaposition of a downstream gene (*LUC7L*) next to the structurally normal upstream α2 gene. Transcription of antisense mRNA from *LUC7L* led to silencing of the linked α2 gene. Another novel form of non-deletional α-thalassaemia results from a single nucleotide substitution in a non-genic region between the α-globin genes and their upstream regulatory elements. The single-base substitution leads to the creation of a new promoter-like element that interferes with normal activation of all the downstream α-like globin genes, resulting in α^0-thalassaemia.

Pathophysiology

The pathophysiology of α-thalassaemia is different from that of β-thalassaemia. A deficiency of α-chains leads to the production of excess γ- or β-chains, which form Hb Bart's (γ_4) and HbH (β_4),

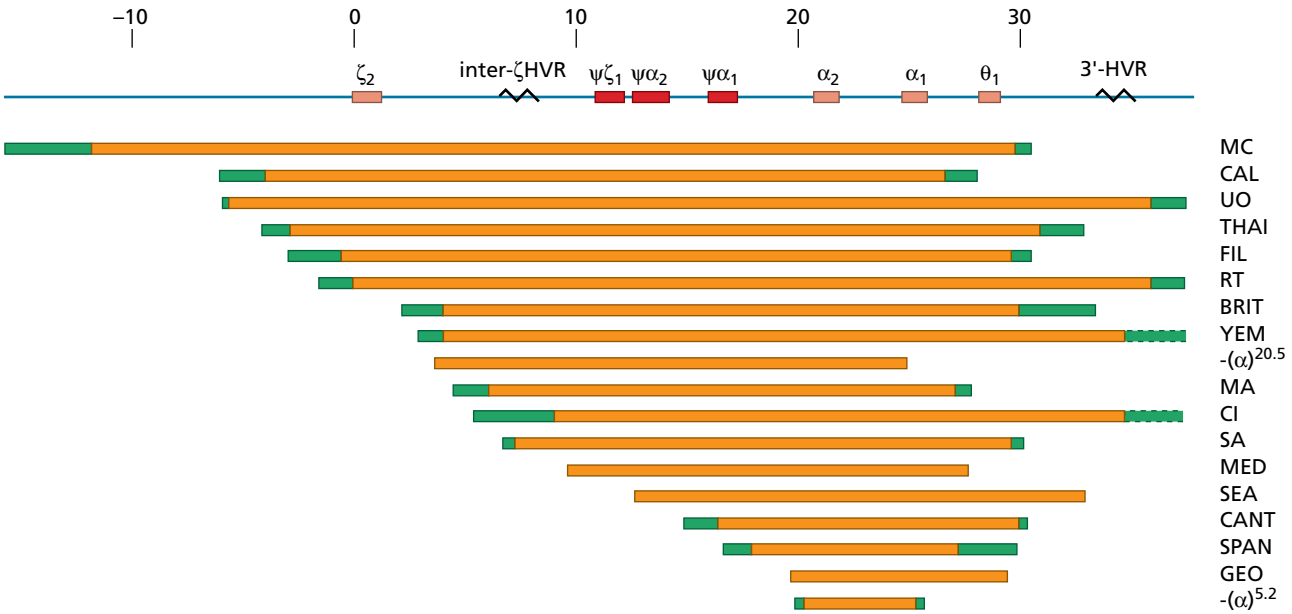

Figure 14.11 The α-globin gene cluster deletions that underlie α^0 thalassaemia (Source: Weatherall and Clegg 2001. Reproduced with permission of WHO.)

respectively. These soluble tetramers do not precipitate extensively in the bone marrow and hence erythropoiesis is more effective than in β-thalassaemia. However, HbH is unstable and precipitates in red cells as they age. The inclusion bodies cause red cell membrane damage and obstruction in the spleen leading to shortened red cell survival. Furthermore, both Hb Bart's and HbH have a very high oxygen affinity and their oxygen dissociation curves resemble myoglobin. Thus, the severe forms of α-thalassaemia are due to defective haemoglobin production, the synthesis of homotetramers that are physiologically useless, and a haemolytic component.

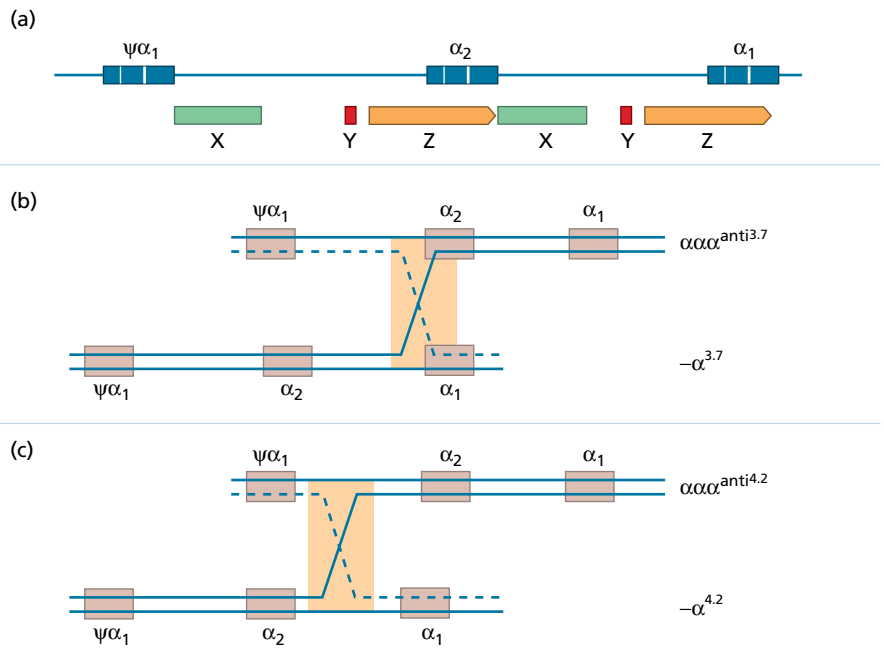

Figure 14.12 The molecular mechanisms that underlie the deletion forms of α-thalassaemia: (a) normal cluster showing X, Y and Z homology boxes. (b) 3.7-kb deletion. (c) 4.2-kb deletion (Source: Weatherall and Clegg 2001. Reproduced with permission of WHO.)

Genotype–phenotype relationship

Loss of one functioning α-gene (αα/−α) is almost completely silent, with normal or only slightly hypochromic red cells. Loss of two α-genes (− −/αα or −α/−α) produces a mild hypochromic microcytic anaemia, the α-thalassaemia trait. Homozygotes for α^0-thalassaemia (− −/− −) have a lethal condition with intrauterine haemolytic anaemia called Hb Bart's hydrops fetalis syndrome (see Figure 14.10). As Hb Bart's hydrops fetalis syndrome follows the homozygous inheritance of α^0 thalassaemia, this condition occurs only in populations in which α^0-thalassaemia is common, notably those of Southeast Asia and the Mediterranean islands. Deficiency of α-chains gives rise to an excess of γ-chains (in fetal life) or β-chains (in adult life), which form γ_4 tetramers (Hb Bart's) or β_4 tetramers (HbH). The presence of Hb Bart's or HbH is thus diagnostic of α-thalassaemia. Due to their very high oxygen affinity, Hb Bart's and HbH are not functional haemoglobins; HbH is unstable and precipitates in older red cells, forming H inclusions.

HbH disease lies between the two ends of the clinical spectrum, the asymptomatic α-thalassaemia trait and Hb Bart's hydrops fetalis As in β-thalassaemia intermedia, HbH disease spans a wide range of clinical and haematological phenotypes, with equally heterogeneous genotypes, varying with the geographic distribution of the different α-thalassaemia variants. HbH disease most commonly results from the interaction of α^0 and α^+-thalassaemia (− −/−α) and thus, similar to Hb Bart's hydrops syndrome, is also restricted to populations where α^0 -thalassaemia is common. Less often, it can result from the interaction of α^0 -thalassaemia with non-deletional forms of α-thalassaemia (/α^Tα) or from homozygous non-deletional α-thalassaemia ($\alpha^T\alpha/\alpha^T\alpha$). HbH disease in Southeast Asia commonly arises from homozygosity or compound heterozygosity for Hb Constant Spring ($\alpha^{CS}\alpha/\alpha^{CS}\alpha$ or $\alpha^{CS}\alpha$/− −).

As the non-deletional forms of α^+-thalassaemia tend to have a more severe phenotype than the deletional forms, in some cases the homozygous state ($\alpha^T\alpha/\alpha^T\alpha$) may be associated with the phenotype of HbH disease. In a small number of cases, HbH can be unusually severe, requiring regular blood transfusion, and rare cases may result in Hb Bart's hydrops syndrome (in particular genotype − −/α^T α).

Haemoglobin Bart's hydrops syndrome

This is an important cause of fetal loss throughout Southeast Asia and the eastern Mediterranean. There is no production of α-chains and hence neither fetal nor adult haemoglobin. The fetus is usually stillborn between 28 and 40 weeks or, if liveborn, takes a few gasping respirations and then expires within the first hour after birth. Affected neonates show the typical picture of hydrops fetalis, with gross pallor, generalised oedema and massive hepatosplenomegaly. Fetal anaemia may be detected from early in the second trimester, with increased blood flow on the fetal middle cerebral artery, as measured by Doppler ultrasound. There is an increased frequency of congenital abnormalities and a very large friable placenta. All these findings are due to severe intrauterine anaemia. The haemoglobin is in the range of 60–80 g/L and there are gross thalassaemic changes in the red cells, with many nucleated erythroid cells in the blood. The haemoglobin consists of approximately 80% Hb Bart's and 20% Hb Portland ($\zeta_2\gamma_2$). Very rarely, Hb Bart's hydrops infants have survived to term because they continue to produce embryonic haemoglobin. Apart from fetal death, this syndrome is characterised by a high incidence of toxaemia of pregnancy and obstetric complications due to the large placenta.

Haemoglobin H disease

This condition is characterised by a variable degree of anaemia and splenomegaly, but it is unusual to find severe thalassaemic bone changes or growth retardation. Patients usually survive into adult life, although the course may be interspersed with severe episodes of haemolysis associated with infection or worsening of the anaemia due to progressive hypersplenism. Parvovirus (erythrovirus) B19 infection, in particular, may cause transient reticulocytopenia with severe anaemia and the need for red cell transfusion. In addition, oxidant drugs may increase the rate of precipitation of HbH and exacerbate the anaemia. Haemoglobin values range from 70 to 100 g/L and the blood film shows typical thalassaemic changes. There is a moderate reticulocytosis and, on incubation of the red cells with brilliant cresyl blue, numerous inclusion bodies are generated by precipitation of HbH under the redox action of the dye. Extramedullary haematopoiesis can be a problem, particularly in more severe forms associated with non-deletional variants. After splenectomy, large preformed inclusions can be demonstrated on incubation of blood with methyl violet. Haemoglobin analysis reveals 5–40% HbH, together with HbA and a normal or reduced level of HbA_2.

α-Thalassaemia traits

α^0-Thalassaemia trait is characterised by very mild hypochromic anaemia with red cell indices similar to those of β-thalassaemia trait; the MCH is less than 25 pg and the HbA_2 level is normal. Occasional HbH bodies may be present in the red cell on supravital staining. There are no diagnostic tests with which to identify this condition with certainty except DNA analysis. Deletional α^+-thalassaemia carriers have near-normal haematological findings. The heterozygous states for the non-deletional forms of α^+ -thalassaemia are sometimes associated with very mild hypochromic anaemia; the type associated with Hb Constant Spring can be identified by the presence of trace amounts of the variant on haemoglobin electrophoresis at an alkaline pH. α^0-Thalassaemia carriers can be identified with more certainty in the neonatal period when they have 5–10% Hb Bart's, which disappears over the first few months of life and is not replaced by HbH. Some α^+-thalassaemia

carriers have slightly increased levels of Hb Bart's, in the 1–3% range, but its absence does not exclude the diagnosis.

Other forms of α-thalassaemia

There are several other forms of α-thalassaemia that are completely unrelated in their pathogenesis and distribution to the conditions described in the previous sections. They comprise the α-thalassaemia with intellectual disability syndromes and the association of α-thalassaemia with myelodysplasia.

α-Thalassaemia with X-linked intellectual disability syndromes

There are two forms of α-thalassaemia associated with intellectual disability, one arising from mutations on chromosome 16 (ATR-16) the other, on the X chromosome (ATR-X). ATR-16 results from large chromosomal rearrangements and extensive deletion of 1–2 Mb from the subtelomeric end of the short arm of chromosome 16. Affected children usually have a relatively mild degree of intellectual disability and no dysmorphic features. Because the *ATR-X* gene is on the X-chromosome and X-linked, it affects boys, and is associated with widespread dysmorphic features and severe intellectual disability. The condition results from many different mutations of the *ATRX* gene. The ATRX protein has many features in common with DNA helicases, transcription factors that are involved in the modelling of chromatin and gene regulation. ATRX also appears to play an important role in the transcription of the α-globin genes and undoubtedly many other genes during early development. The *ATRX* gene has also been reported to be involved in a considerable number of X-linked intellectual disability syndromes without an α-thalassaemia phenotype.

α-Thalassaemia associated with myelodysplasia

An α-thalassaemic phenotype is also found in association with forms of myelodysplasia in elderly patients. The blood films of such patients show dimorphic features, with populations of red cells containing HbH inclusion bodies and a variable level of HbH in peripheral blood. Acquired mutations in the *ATRX* gene have been identified in the blood cells of patients with this syndrome. The relationship of the mutations in *ATRX* to the neoplastic phenotype remains to be determined.

Thalassaemia intermedia (non-transfusion-dependent thalassaemia)

Definition and molecular pathology

The term thalassaemia intermedia is used to describe patients with the clinical picture of thalassaemia which, although not transfusion dependent, is associated with a more severe degree of anaemia than is found in carriers for α- or β-thalassaemia. It is increasingly referred to as non-transfusion-dependent thalassaemia (NTDT), particularly in literature discussing iron chelation. Whether a patient is classified as having thalassaemia intermedia or thalassaemia major depends on a doctor deciding that the patient would benefit from regular blood transfusions; this decision is based not only on the clinical evidence mentioned in the section on thalassaemia major, but also on more complex factors such as the availability of safe blood transfusions, the experience of the clinician and the wishes of the patient. Many different genotypes underlie thalassaemia intermedia, as mentioned earlier, with HbE/β-thalassaemia perhaps being the commonest (Table 14.2). HbH disease is sometimes considered as a type of thalassaemia intermedia, but its pathophysiology is quite different to that caused by β-thalassaemia.

Table 14.2 Molecular basis of β-thalassaemias intermedia.

Homozygous or compound heterozygous state for β-thalassaemia
Inheritance of mild β-thalassaemia alleles (homozygous or compound heterozygotes)
Compound heterozygosity for a mild and a more severe allele
Coinheritance of α-thalassaemia
Increased HbF response
β-Globin gene promoter mutations (deletional or non-deletional)
Coinheritance of HbF quantitative trait loci
Linked: Xmn1- $^{G}\gamma$ polymorphism
Unlinked: *BCL11A* gene (chromosome 2p), *HBS1L-MYB* intergenic polymorphisms (chromosome 6q) *KLF1,* variants
Heterozygous state for β-thalassaemia
Coinheritance of extra α-globin genes as triplicated (/ααα) or quadruplicated (/αααα) globin complexes or segmental duplication of entire α-globin cluster
Dominantly inherited β-thalassaemia (hyper-unstable β-globin chain variants)
Compound heterozygosity for β-thalassaemia and β-chain variants
HbE/β-thalassaemia
Compound heterozygosity for β-thalassaemia and HPFH or δβ-thalassaemia
Homozygosity for δβ-thalassaemia

Clinical and haematological changes

At one end of the spectrum are individuals who, except for mild anaemia, are symptom-free. At the other, there are patients who have haemoglobin values of 50–70 g/L and who develop marked splenomegaly, osteopenia and skeletal deformities due to expansion of bone marrow. Iron absorption is increased because of the expanded erythron causing high levels of GDF-15, ERFE or other proteins, with suppression of hepcidin production. A wide range of other problems are particularly associated with

thalassaemia intermedia, including pulmonary hypertension, hypercoagulability, pseudoxanthoma elasticum and other connective tissue disorders, hypersplenism, leg ulceration, folate deficiency, extramedullary haemopoietic tumour masses in the paraspinal regions and skull, gallstones and a marked proneness to infection. Many of these problems worsen with age, due to iron loading and cardiovascular impairment, and increasing numbers of patients become transfusion dependent. Because of the heterogeneity of these disorders, management is highly dependent on the clinical picture that evolves in an individual patient rather than any particular genotype or other biomarker; all patients should be followed up very carefully from early childhood. The haemoglobin constitution of β-thalassaemia intermedia depends on the contributing genotypes, and in many cases is similar to that found in the major forms.

Treatment

Intermittent blood transfusions are often necessary due to falls in haemoglobin caused by fever and infection, particularly with parvovirus (erythrovirus) B19, which causes reticulocytopenia. It can be difficult to decide who would benefit from more regular blood transfusions and when to start them. In countries with a ready supply of safe blood, there is an increasing tendency to start regular transfusions even in children, maintaining the haemoglobin at greater than 80 g/L in order to avoid the emerging complications of skeletal deformities, pulmonary hypertension and osteopenia. There is also some evidence that this improves the quality of life for many patients. This intensive approach is not possible in much of the world and management consists of reserving transfusion for severe symptomatic anaemia.

Even in the absence of regular erythrocyte transfusions, significant levels of iron accumulate through increased gastrointestinal absorption. Clinical trials with iron chelators have shown that it is possible to remove this excess iron safely, and this is increasingly practised (Chapter 12). However clinical complications of iron overload are relatively uncommon in thalassaemia intermedia, and it is less clear when chelation should be started.

Pharmacological treatment to increase HbF and total haemoglobin levels is potentially applicable to thalassaemia intermedia, in that relatively small increases in haemoglobin levels with a corresponding reduction in ineffective erythropoiesis could help a patient thrive who would otherwise require regular transfusions. Hydroxycarbamide (hydroxyurea) is the most widely used drug in this context, and while some patients undoubtedly benefit, in general, results are disappointing. Butyrate and other short-chain fatty acids also promote HbF synthesis and have been used with limited clinical success in thalassaemia intermedia. A number of newer drugs are being developed that may boost HbF to a greater extent, most notably the new generation of short-chain fatty acid derivatives and immunomodulatory drugs such as pomalidomide and lenalidomide. Thalidomide is quite widely used in some countries in combination with hydroxyurea to increase haemoglobin levels. It is currently unclear how useful luspatercept will be in managing these patients, but it is likely to have some role in high-income countries. Another promising approach for both alpha and beta thalassaemia is activating pyruvate kinase which increases glycolytic flux and reduces oxidative stress. Mitapivat and etavopivat are currently under clinical development. Gene therapy is available in some countries, but currently has a very small role to play in the management of thalassaemia, although it is likely to become increasingly important over the next decade.

Screening for thalassaemia

Preconception, antenatal and neonatal screening programmes are important in the clinical care and public health management of haemoglobinopathies. Thalassaemia is prevalent in many middle- and low-income countries, where either treatment is not available or the cost of regular blood transfusions and chelation is a major drain on limited medical resources. In other countries, including parts of Europe, Australia and North America, it is important to identify the antenatal risk of having a baby with thalassaemia to provide informed parental choice. Apart from haemopoietic stem cell treatments, there is no definitive treatment, and many countries in which the disease is common are putting a major effort into programmes for its prevention.

Premarital and preconception screening

Ideally, individuals know their thalassaemia status before they decide to have children, and potentially use this information to choose a suitable partner. Some programmes therefore concentrate on screening teenagers at school. Other countries insist that a couple are screened for thalassaemia status before they can get married; this latter approach has been successful in Cyprus and parts of the Middle East, such as Bahrain, where social pressures have reduced the number of at-risk partnerships.

Antenatal screening, prenatal diagnosis and preimplantation genetic diagnosis

Many screening programmes concentrate on identifying pregnant women who are thalassaemia carriers in the first trimester of pregnancy. This is done by varying combinations of blood tests and the identification of women at high risk of carrying thalassaemia based on their ethnic origin. The latter approach is potentially effective in areas with a low prevalence of thalassaemia in the native population, such as northern Europe, although increasing ethnic diversity is reducing the feasibility of such selective screening. If a woman is found to be a carrier, screening is then offered to her partner, and if both are carriers, they are counselled about the risk of the fetus inheriting a severe form of thalassaemia and offered prenatal diagnosis (PND).

PND of the thalassaemias was first carried out by fetal blood sampling, between 18 and 20 weeks of gestation, and was based on measuring relative rates of globin chain synthesis. Fetal blood sampling has now been replaced by fetal DNA analysis obtained at 11–12 weeks' gestation by chorionic villus sampling or amniocentesis. DNA analysis is now based largely on direct sequencing of the globin genes and specific techniques to detect large deletions, such as multiplex-ligation-dependent probe amplification. This produces rapid results, typically taking 48–72 hours, with accuracy of greater than 99%.

Couples can use this information to make an informed choice as to whether to continue the pregnancy if the fetus is affected. Some couples find PND helpful in preparing for the birth of a potentially ill child, even though they would not contemplate termination. The main complication of invasive PND is the increased risk of miscarriage of about 1%. This has led to research to develop non-invasive methods of PND based on maternal blood sampling. Maternal blood contains small numbers of fetal cells and also cell-free fetal DNA, both of which could potentially be used to diagnose fetal thalassaemia. The low concentration of fetal material relative to maternal has made this technically very difficult, although advances in methods of DNA analysis and sequencing platforms are starting to make this feasible.

Some couples want to avoid having a fetus with thalassaemia, but find PND and selective termination unacceptable. Preimplantation genetic diagnosis involves the use of *in vitro* fertilisation techniques to generate 5–15 embryos; at the eight-cell stage, one embryonic cell can be removed and tested for thalassaemia alleles; it is then possible to only implant embryos without thalassaemia. Whilst appealing, it is a difficult, stressful and expensive procedure, with fewer than 50% couples taking home a baby. Advances in reproductive biology and DNA technology are making this more applicable, and it is available in an increasing number of countries.

Neonatal screening

It is possible to detect the majority of babies with severe thalassaemia by neonatal testing, either on cord blood or blood taken directly from the baby. Many neonatal screening programmes involve testing dried blood spots on pieces of filter paper, usually made from a heel-prick blood sample when the baby is 5–7 days old. This blood spot is also used to screen for other serious neonatal disorders, including phenylketonuria, congenital hypothyroidism and cystic fibrosis. If haemoglobin analysis shows HbF only, with no HbA or other haemoglobin variants, it is likely that the baby has inherited a severe form of β-thalassaemia and may be transfusion dependent; less severe possibilities include thalassaemia intermedia and homozygosity for HPFH. Babies identified in this way can then be followed up closely rather than waiting until they present following a period of prolonged illness. Parents can also be tested and given advice concerning the risk to future pregnancies.

Table 14.3 Diseases due to structural haemoglobin variants.

Sickle cell disease
Sickle cell anaemia, with homozygosity for the sickle mutation (HbSS)
Compound heterozygosity for HbS with other β-haemoglobin variants (HbS/C, HbS/D Punjab, HbS/O Arab)
Compound heterozygosity for HbS with β-thalassaemia (HbS/β-thalassaemia)
Haemolytic anaemia
Unstable haemolytic variants
Congenital polycythaemia
High-oxygen-affinity haemoglobin variants
Congenital cyanosis
Low-oxygen-affinity haemoglobin variants
M haemoglobins
Hypochromic microcytic anaemia (thalassaemia phenotype)
Variants with inefficient synthesis due to alternative splicing, e.g. HbE
Lepore haemoglobins
Unstable chain termination variants, e.g. Hb Constant Spring
Drug-induced haemolysis
e.g. Hb Zurich

Structural haemoglobin variants related to thalassaemia

The unstable haemoglobin disorders

The unstable haemoglobin disorders are a group of rare inherited haemolytic anaemias that result from structural changes in the haemoglobin molecule, which cause its intracellular precipitation with the formation of Heinz bodies (Table 14.3). Their true incidence is not known and there have been several well-documented instances in which patients with one of these variants have had no affected relatives, suggesting that they have arisen by a new mutation. Unlike more common globin gene mutations, there is no obvious ethnic or geographical variation. Haemoglobin Koln (β98, Val→Met) is perhaps the most common.

Molecular pathology and pathogenesis

Most of the unstable haemoglobins result from single amino acid substitutions or small deletions. For example, substitutions in or around the haem pocket can disrupt its anatomy and allow in water, with subsequent oxidative damage to haem, leading to precipitation of haemoglobin. Some substitutions, such as those involving proline residues, cause a marked disturbance of the secondary structure of globin chains. A few variants result from deletions of either single amino acids or several residues. For example, in Hb Gun Hill, five amino acids are missing,

including the haem-binding site. As the unstable haemoglobins precipitate in the red cells or their precursors, they produce intracellular inclusions (Heinz bodies) which, together with oxidant damage to their membranes, make the cells more rigid and hence cause their premature destruction in the microcirculation.

Clinical features

Unstable haemoglobins are characterised by a chronic, non-spherocytic haemolytic anaemia and splenomegaly. Like all chronic haemolytic anaemias, there is an increased incidence of pigment gallstones with their associated complications; the risk is particularly high if there is coinheritance of Gilbert syndrome (polymorphic variant in the promoter of the *UGT1A1* gene). The condition may become worse during periods of infection causing fever, and, in the more severe forms, such episodes are associated with life-threatening anaemia and the need for blood transfusion. Some oxidant drugs may increase the rate of haemolysis, and parvovirus (erythrovirus) B19 infection may cause temporary reticulocytopenia. Apart from icterus and splenomegaly, there are no characteristic physical findings.

Laboratory diagnosis

The peripheral blood film shows typical features of haemolysis, but the red cell morphology may be normal. Occasionally, there is mild hypochromia and microcytosis. Supravital staining with dyes such as methyl violet shows Heinz bodies in the peripheral blood, particularly after splenectomy. The most characteristic feature of the unstable haemoglobins is their heat instability. If a dilute haemoglobin solution is heated at 50 °C for 15 min, the unstable haemoglobins precipitate as a dense cloud. A similar effect can be induced by isopropanol at lower temperatures. The isopropanol heat sensitivity test is more sensitive and specific than simple heat instability. Some of these variants can be seen on haemoglobin electrophoresis, but others are electrophoretically silent, because they result from a neutral amino acid substitution; these can be demonstrated only by the heat precipitation test. DNA analysis can provide more definitive diagnosis, typically by sequencing of the α- or β-globin genes, and this is increasingly used at an early stage as sequencing gets faster and cheaper.

Treatment

Splenectomy seems to be beneficial in some cases, although experience is inevitably limited. Intermittent blood transfusions may be necessary. If haemolysis is very severe, the patient may benefit from regular blood transfusions and bone marrow transplantation should be considered.

High-oxygen-affinity haemoglobin variants

Some haemoglobin variants cause increased oxygen affinity, which results in varying degrees of polycythaemia. These are rare and occur sporadically; haemoglobin Chesapeake (α92, Arg→Leu) was the first one identified in 1966.

Molecular pathology

Some high-oxygen-affinity haemoglobin variants result from single amino acid substitutions at critical parts of the haemoglobin molecule that are involved in the configurational changes which underlie haem–haem interaction and the production of a sigmoid oxygen dissociation curve at the junctions between the α- and β-subunits. Others involve the amino acids concerned with the binding of 2,3-DPG to haemoglobin. Reduced 2,3-DPG binding moves the oxygen dissociation curve to the left, reducing the P_{50} and causing the haemoglobin to hold on to oxygen more avidly than normal. This causes functional anaemia, with tissue hypoxia, which in turn causes an increased output of erythropoietin and an elevated red cell mass.

Clinical features

Most affected individuals are completely healthy and are identified only when a routine haematological examination shows an unusually high haemoglobin level or haematocrit. There is no splenomegaly and, apart from a raised red cell mass, there are no associated haematological findings. Although it might be expected that a high-oxygen-affinity haemoglobin would cause defective oxygenation of the fetus, none of the reported families has a history of such problems.

Diagnosis

The condition should be suspected in any patient with a pure red cell polycythaemia associated with a left-shifted oxygen dissociation curve. Erythropoietin levels will typically be inappropriately high for the haematocrit. The absolute reticulocyte count may be slightly elevated, although the reticulocyte percentage should be normal. The erythron is expanded, as shown by high plasma concentrations of soluble transferrin receptor. The diagnosis can be confirmed by haemoglobin analysis, mass spectrometry, and increasingly DNA analysis.

Treatment

In asymptomatic individuals, no treatment is necessary. The difficulty arises if there is associated vascular disease, particularly coronary or cerebral artery insufficiency. As these patients require a high haemoglobin level for oxygen transport, venesection should be carried out with caution. Venesection is undertaken because of increased risk of vascular complications, and

typically the aim is to keep the haematocrit below 0.55, although there is little evidence to support this.

Low-oxygen-affinity haemoglobin variants

More than 50 haemoglobin variants with reduced oxygen affinity have been identified, often associated with other abnormal properties such as instability. The first to be described, Hb Kansas (β102 Asn→Thr), was found in a mother and son with unexplained cyanosis. The subjects were asymptomatic and had normal haemoglobin levels without any evidence of haemolysis. Like many of the high-affinity haemoglobins, the amino acid substitution in this variant was at the interface between the α- and β-globin chains. For reasons that are not clear, some substitutions in this region give rise to variants with a relatively low oxygen affinity. This condition should be thought of in any patient with unexplained congenital cyanosis.

Congenital methaemoglobinaemia due to haemoglobin variants

Several α- and β-globin variants associated with methaemoglobinaemia have been discovered. These are usually referred to as M-haemoglobins, for example haemoglobin M-Boston (α58, His→Tyr). These disorders, unlike the genetic methaemoglobinaemias due to enzyme defects, follow a dominant pattern of inheritance. The patients are blue in colour and may have mild polycythaemia as methaemoglobin does not carry oxygen. Diagnosis is based on detecting high methaemoglobin levels, which are increasingly measured by blood gas analysers and some pulse oximeters. Increased methaemoglobin levels should be confirmed on formal laboratory analysis using spectrophotometry. Subsequently haemoglobin analysis using electrophoresis or mass spectrometry is performed, or sequencing of the α- and β-globin genes.

Acknowledgement

Parts of the present chapter are based on the corresponding previous edition chapter, and for this, we acknowledge the contribution of the late Professor Sir David Weatherall.

CHAPTER 15

Sickle cell disease

15

Neha Bhasin and Elliott P Vichinsky

Department of Pediatrics, Division of Hematology, UCSF Benioff Children's Hospital Oakland, Oakland, CA, USA

Introduction

Sickle cell disease (SCD) is an inherited chronic haemolytic anaemia whose clinical manifestations arise from the tendency of the haemoglobin (HbS or sickle haemoglobin) to polymerise and deform red blood cells into the characteristic sickle shape. This property is due to a single nucleotide change in the β-globin gene leading to substitution of valine for glutamic acid at position 6 of the β-globin chain ($\beta^{6glu \rightarrow val}$ or β^{s}). The homozygous state (HbSS or sickle cell anaemia) is the most common form of SCD, but interaction of HbS with thalassemia and certain variant haemoglobins also leads to sickling. The term 'sickle cell disease' is used to denote all entities associated with sickling of haemoglobin within red cells (Table 15.1).

Geographic distribution of sickle mutation

Several distinct β-globin gene haplotypes are associated with the sickle mutation, and their distribution provides evidence for origin of the mutation in several locations within Africa (the Senegal, Benin and Bantu haplotypes) and Asia (the Arab–Indian haplotype). The sickle trait bestows survival benefits in areas endemic for *falciparum* malaria, and the distribution of SCD historically paralleled this disease. The sickle haemoglobin-containing red cells inhibit proliferation of *P. falciparum* and are more likely to become deformed and removed from the circulation. In recent times, the dissemination of the sickle mutation in different areas of the world took place from the movement of populations via trade routes and the slave trade (Table 15.2). The prevalence of SCD varies tremendously amongst ethnic and tribal groups within a geographic area. The ethnic groups represented in the California newborn population during a 3-year interval showed that 93% of sickle cell anaemia cases (HbSS) was reported in Black newborns. However, a large proportion of HbS/β-thalassaemia cases (12.5%) was observed in the Hispanic population.

Pathophysiology

Molecular basis of sickling

Deoxygenation of HbS leads to a conformational change that exposes a hydrophobic patch on the surface of the β^{s}-globin chain at the site of β^{6} valine (Figure 15.1). Binding of this site to a complementary hydrophobic site on a β-subunit of another haemoglobin tetramer triggers the formation of large polymers. The polymers consist of staggered haemoglobin tetramers that aggregate into 21-nm diameter helical fibres, with one inner and six peripheral double strands. The polymerisation proceeds after a delay, the length of which is extremely sensitive to the intracellular deoxy-HbS concentration. Even a small increase in deoxy-HbS concentration, such as might occur with cellular dehydration, profoundly shortens the delay time and augments sickling. The haemoglobin tetramers first aggregate into a nucleus, which rapidly expands into a fibre. The newly formed fibre provides nuclei on its surface for aggregation of haemoglobin tetramers to form several more fibres.

The polymerisation of HbS in the circulating red cells is influenced by the oxygenation status, the intracellular haemoglobin concentration and the presence of non-sickle haemoglobins. Acidosis and elevated levels of 2,3-diphosphoglycerate (2,3-DPG) promote polymer formation by reducing the oxygen affinity of haemoglobin. The presence of HbA within the red

cells, as in sickle trait, inhibits polymerisation by diluting HbS. The inhibitory effect of fetal haemoglobin, HbF, on polymerisation of HbS is more profound owing to the greater amino acid disparity between the β^s and γ-globin chains.

Effect on erythrocytes

Red cells acquire the sickle or elongated shape upon deoxygenation as a result of intracellular polymerisation of HbS, a phenomenon that is reversible on reoxygenation. Even in the normally shaped red cells, however, the presence of HbS polymer reduces deformability, with consequent increase in blood viscosity. HbS has reduced oxygen affinity compared with HbA which further exacerbates HbS polymerisation, further decreasing oxygen affinity. In addition, 2,3-diphosphoglycerate (2,3-DPG), a glycolytic intermediate, is physiologically present at very high levels in sickle erythrocytes and reduces Hb oxygen affinity even further.

Haemolysis

Repeated or prolonged sickling progressively damages the red cell membrane, which is a phenomenon of primary importance in the pathophysiology of SCD and leads to haemolysis. The red cell survival, measured by ^{51}Cr assay, is 4–25 days, with dense cells surviving for a considerably shorter time than red cells containing some HbF (F cells). Patients have greatly expanded bone marrow space, but the serum erythropoietin level is lower than expected for the extent of anaemia because of the decreased oxygen affinity of HbS. Individuals with concomitant deletion of one or two α-globin genes, or the Senegal or Arab–Indian haplotypes, have higher baseline haemoglobin levels.

Oxidised erythrocyte membrane proteins reveal antigens that bind to existing antibodies and membranes expose phosphatidylserine (PS). Both these processes promote phagocytosis of erythrocytes by macrophages, a pathway of *extravascular haemolysis. Intravascular haemolysis* of erythrocytes releases two factors that interfere with nitric oxide synthase (NOS) activity. The enzyme *arginase 1* competes with NOS for L-arginine, the substrate required for NO production by NOS. This process facilitates cell proliferation and vascular remodelling. *Asymmetric dimethylarginine* (ADMA) is an endogenous NOS inhibitor and is abundant in erythrocytes and is released during

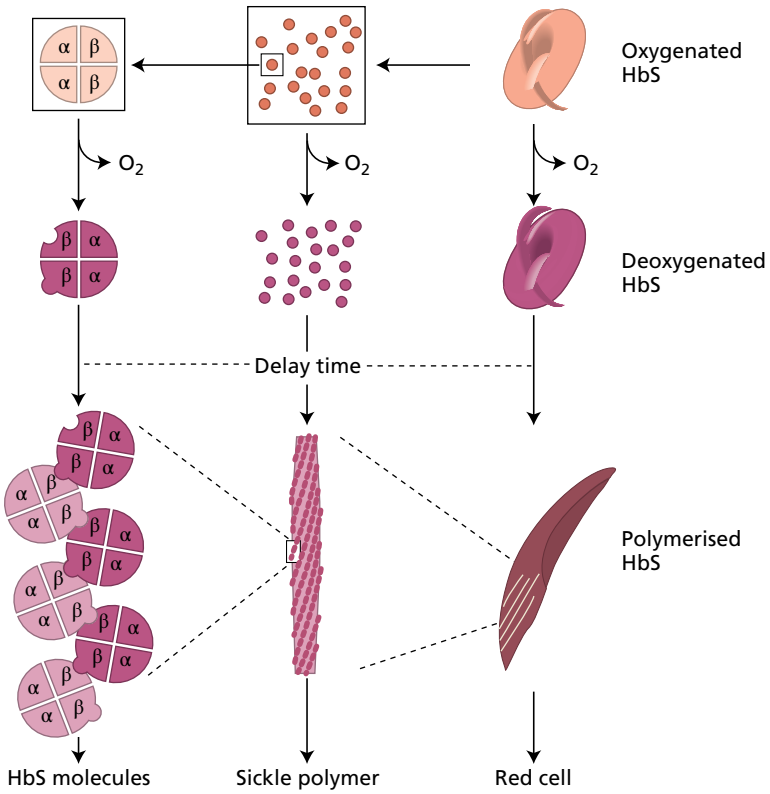

Figure 15.1 Induction of red cell sickling. As red cells traverse the microcirculation, oxygen is released from oxy-HbS (red circles), generating deoxy-HbS (purple circles). Conformational change exposes a hydrophobic patch at the site of the β^6 -valine replacement, shown as a projection (left column), which can bind to a complementary hydrophobic site on a subunit of another haemoglobin tetramer, shown as an indentation. Only one of the two β^6 -valine sites in each HbS tetramer makes this contact. The middle column shows the assembly of deoxy-HbS into a helical 14-strand fibre, shown as a twisted rope-like structure. The delay time is inversely proportional to the intracellular haemoglobin concentration raised to the 15th power. As deoxy-HbS polymerises and fibres align, the red cell is distorted into an elongated banana or 'sickle' shape (right column) (Source: Bunn, 1997 [*New Engl J Med* **337**: 762–9]. Reproduced with permission of Massachusetts Medical Society.)

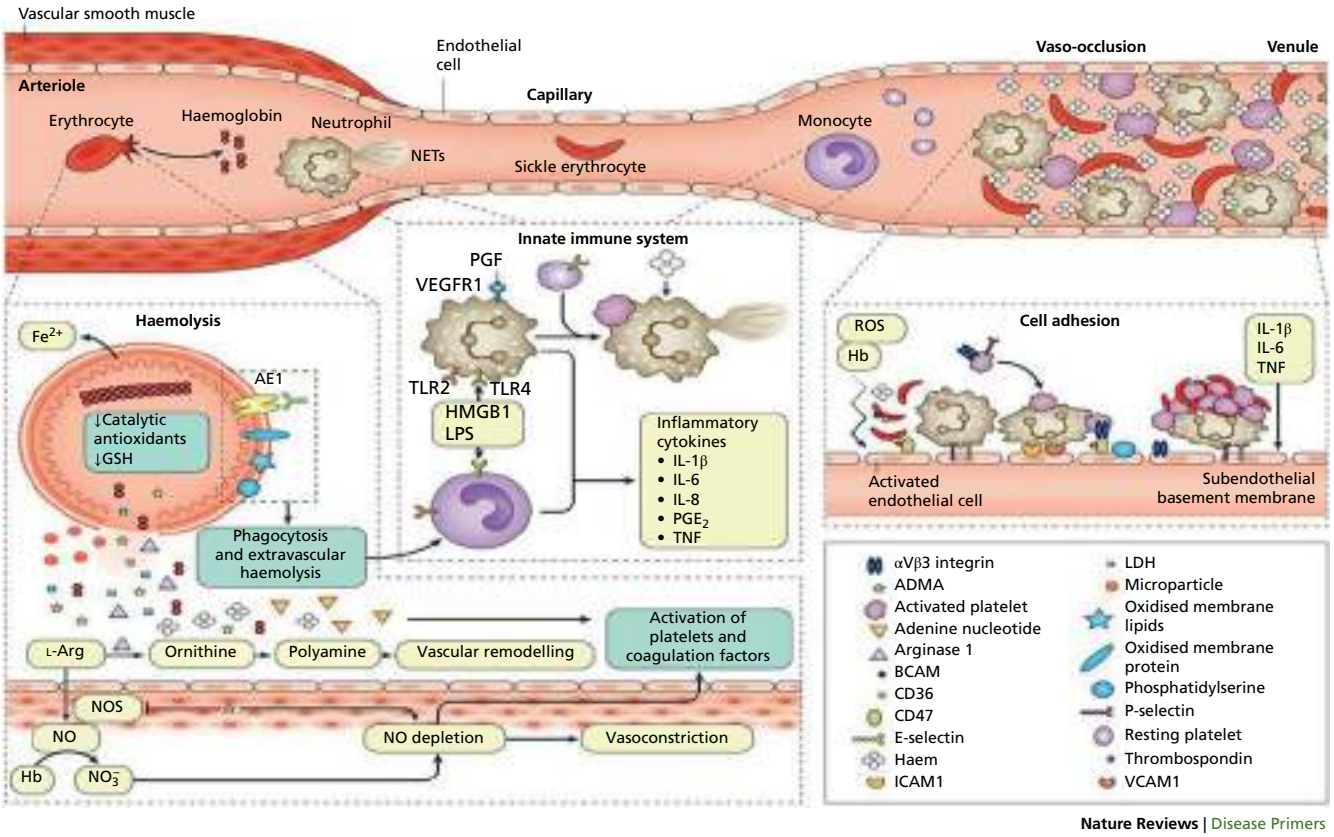
haemolysis. Both ADMA and depletion of L-arginine by arginase 1 could contribute to uncoupling of NOS, which then produces reactive oxygen species (ROS) instead of NO. ROS further depletes NO, leading to vasoconstriction and vascular remodelling, especially in the lung. NO deficiency promotes platelet activation and activation of blood clotting proteins.

Vaso-occlusion

Several processes contribute to development of vaso-occlusion in SCD. Slowing of blood flow arises from abnormal regulation of vascular tone as a result of diminished nitric oxide (NO)-induced vasodilatation. This is aggravated by increase in blood viscosity, resulting from less deformable red cells, a phenomenon called abnormal rheology. Vaso-occlusion is initiated by adhesion of young deformable red cells to the vascular endothelium and is followed by trapping of rigid irreversibly sickled cells. In postcapillary venules, activated endothelial cells that express P-selectin and E-selectin can bind rolling neutrophils. Haemolysis activates the innate immune system including monocytes, macrophages and cytokines which promote an inflammatory state and activate endothelial cells promoting platelet and neutrophil adhesion and formation of neutrophil extracellular traps (NETs). (Figure 15.2). Even reticulocytes and deformable erythrocytes (i.e. erythrocytes that have not become permanently sickled) are substantially more adhesive than the irreversible and dense sickle erythrocytes. Platelets play an important part in the pathophysiology of SCA and are in an activated state, with high levels of P-selectin and activated αIIbβ3 integrin. Platelets are found in the circulating heterocellular aggregates of neutrophils and red blood cells (mainly reticulocytes) in the blood from individuals with SCA. Platelets could also act as accessory cells of the innate immune system by releasing cytokines.

Clinical manifestations

Clinical symptoms vary tremendously between patients with SCD. The disease is more severe in patients with HbSS or HbS/β^0-thalassaemia than in those with HbS/β^+ -thalassaemia



Nature Reviews | Disease Primers

Figure 15.2 Mechanisms of erythrocyte haemolysis, vaso-occlusion, cell adhesion and immune system activation in sickle cell disease.

or HbSC disease. However, for increasingly recognised reasons, the disease severity varies enormously, even within the subgroup of patients with HbSS. Genetic modifiers that influence both laboratory and clinical parameters in part explain the phenotypic heterogeneity of SCD. Some of the genetic modifiers known to impact disease phenotype include coinheritance of α-thalassaemia trait, β-globin haplotype, modifiers of endogenous haemoglobin F production, *UGT1A1* promoter polymorphisms and genes that have shown protection against stroke. The coinheritance of one or two α-gene deletions results in lower MCV, MCH, total bilirubin and absolute reticulocyte counts. The Senegal and Arab–Indian β-globin haplotypes produce less severe clinical disease than the other African haplotypes. The high HbF level observed in hereditary persistence of fetal haemoglobin (HPFH) is associated with very mild disease. Certain *BCL11A* single nucleotide polymorphisms known to positively affect endogenous fetal haemoglobin production have been shown to have favourable laboratory profiles and may serve as potential targets for gene editing of haemopoietic stem cells. Specific promoter mutations within the *UTG1A1* gene as seen in Gilbert syndrome, encoding an enzyme necessary for bilirubin conjugation, are correlated with increased bilirubin levels and a propensity to develop cholelithiasis. Mutations within the *GOLGB1* and *ENPP1* genes have been shown to have a protective effect against stroke in SCD. These and other genetic modifiers help to explain the phenotypic heterogeneity observed in this monogenic disease. Genome-wide genetic association studies and identification of epigenetic phenomena are likely to identify other potential modifiers of disease severity.

In countries with inadequate healthcare, SCD is associated with high mortality in the first 3 years of life as a result of sepsis and splenic sequestration. In the developed world, the typical patient with SCD has moderately severe anaemia, leads a relatively normal life interrupted by 'crises' as a result of vaso-occlusion, and has a life expectancy of over 45 years.

Anaemia

The underlying β-globin genotype primarily determines the baseline haemoglobin value in SCD, but exacerbation of anaemia can occur for numerous reasons. Patients with more severe anaemia at baseline have a greater probability of developing stroke and renal dysfunction. On the other hand, a higher haemoglobin level is associated with a higher incidence of painful episodes, avascular necrosis and acute chest syndrome. Infants with SCD have lower than normal haemoglobin levels after the

neonatal period, and the decline continues until it reaches a nadir between 12 and 15 months of age. Boys are slightly more anaemic than girls in the first decade, whereas adult men have higher haemoglobin values than women. Gradual exacerbation of anaemia is observed in both sexes beginning in the fifth decade.

A gradual decrease in haemoglobin level from the baseline value may indicate an underlying folate or iron deficiency. In older patients, however, inadequate erythropoietin production due to chronic renal insufficiency is the most important aetiology of worsening anaemia. Many such patients will become transfusion dependent, although recombinant human erythropoietin therapy can improve the anaemia.

Acute exacerbations of anaemia are observed with aplastic crises and splenic sequestration. The transient arrest of erythropoiesis and the resultant reticulocytopenia in aplastic crisis is most often due to parvovirus (erythrovirus) B19 infection. The reticulocytopenia begins 5 days after exposure, lasts for 7–10 days and is followed by recovery with reticulocytosis and normoblasts in peripheral blood. Blood transfusion is often required in the short term. Parvovirus B19 infection is followed by development of lifelong protective immunity.

Splenic sequestration is a serious complication in young children whose spleen has not yet undergone fibrosis due to recurrent vaso-occlusion. The peak incidence of the first episode of sequestration is between 6 and 12 months of age and affects 30% of all patients. Approximately 15% of patients die during the acute episode and the condition recurs in half of the survivors. Episodes may be triggered by a viral illness and the rapid acute enlargement of the spleen traps a significant proportion of the blood volume. Clinically, the child presents with acutely worsening anaemia (>20 g/L fall in haemoglobin), reticulocytosis, enlarging spleen and hypovolaemic shock. Prompt restoration of the blood volume and correction of anaemia is required. Splenectomy is recommended following a sequestration crisis that is life-threatening or for recurrent splenic sequestration episodes. Chronic transfusion therapy is sometimes used in infants with life-threatening anaemic episodes. Parent education to detect splenic enlargement and seek early medical attention significantly reduces the risk of death from sequestration crisis.

Acute painful episode

An acute episode of pain due to vaso-occlusion is the most frequent symptom for which patients with SCD seek medical attention. Painful episodes are more common in young adults and tend to diminish in older patients. One-third of patients with SCD rarely experience pain, whereas a small subgroup of patients suffer from recurrent episodes. When patients maintain a pain diary, painful events are noted on up to half of the days, but are not severe enough to require visit to a physician. Painful episodes vary in intensity and generally last for a few days. The majority of the episodes have no identifiable cause, although some attacks are precipitated by cold, dehydration, infection, stress or menses. There are no physical or laboratory findings that can determine whether a patient with SCD is having a pain episode or not.

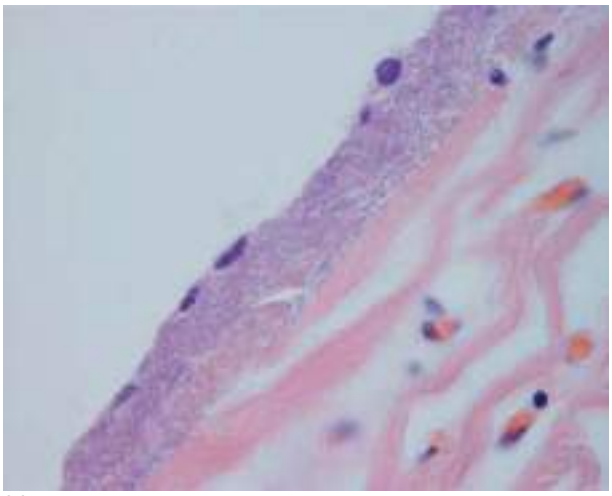
In young children, the initial pain episode typically presents as dactylitis or hand–foot syndrome, with swelling over the dorsal surface of hands and feet. It arises from bone infarction affecting the small bones and the swelling subsides over 1–2 weeks. The radiographs show thinning of cortex and destructive changes of the affected small bones several weeks after onset. In older children and adults, the common sites of pain are the back, chest, extremities and abdomen. Chest pain is of special significance as it can precede development of acute chest syndrome. Frequent incapacitating painful episodes that are inadequately managed have adverse psychosocial consequences and stress the physician–patient relationship.

Growth and development

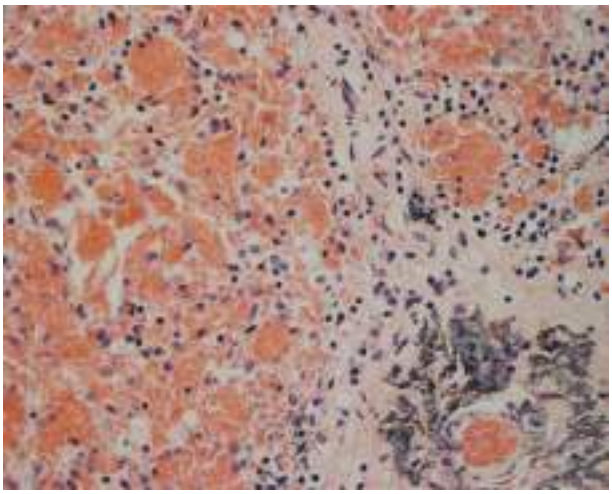
Children with SCD are born with normal weight but fall behind other children by the end of the first year. The weight deficit persists through adulthood and imparts a thin habitus to the typical patient, although obesity is seen in some cases. The rate of growth is lower than normal in SCD patients, and the pubertal growth spurt is delayed by 1–2 years, but the final adult height is normal. Delays also occur in skeletal maturation and onset of puberty, and female patients achieve menarche 1–2 years later than their peers.

Infections

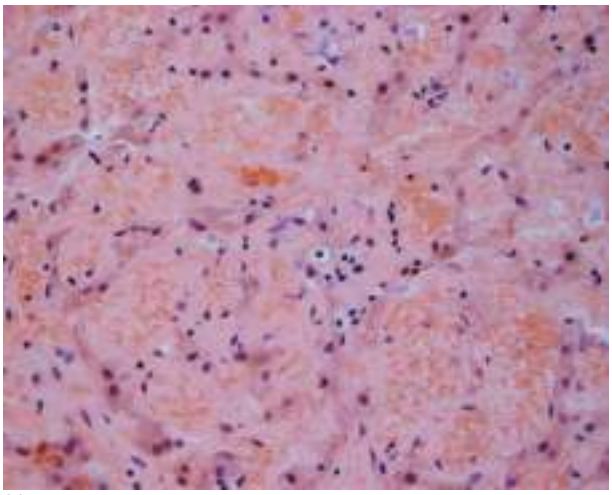
Early loss of splenic function from recurrent vaso-occlusion and the inability to make specific IgG antibodies to polysaccharide antigens increases the risk of fulminant sepsis. Pneumococcal infection is a serious problem in SCD, particularly in children under 3 years (Figure 15.3). Meningitis can accompany pneumococcal sepsis, and the overall mortality rate is 20–50%. Patients who have had previous pneumococcal sepsis are at increased risk for recurrent episodes and must remain on lifelong penicillin prophylaxis. *Haemophilus influenzae* type B is the next most common organism and affects older children. There is considerable variation in the relative incidence of bacterial organisms causing sepsis in young children with SCD in various regions of the world. In Africa, *Salmonella* spp., *Klebsiella* spp., *Escherichia coli* and *Staphylococcus* spp. are more commonly isolated from the blood of febrile children than *Streptococcus pneumoniae*. The incidence of pneumococcal and *H. influenzae* sepsis has declined as a result of penicillin prophylaxis and vaccination of infants. The risk of death during septic episodes has decreased considerably owing to empirical use of antibiotics to treat fever in SCD.



(a)



(b)



(c)

Figure 15.3 Overwhelming pneumococcal sepsis in a 7-year-old child. (a) Numerous bacteria in the blood adjacent to the right ventricular wall. Massive sequestration of the spleen (b) and the liver (c).

Of the other infections, pneumonia is particularly common in SCD and can be difficult to differentiate from non-infective causes of acute chest syndrome. The most frequent organisms responsible for pneumonia are *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *S. pneumoniae* and *H. influenzae*. Lung infections can also arise due to respiratory viruses. In adults, bacteraemia and urinary tract infections due to *E. coli* and other Gram-negative organisms are more frequent. Patients with SCD are susceptible to osteomyelitis caused by bone infarction resulting from vaso-occlusion. The infection is typically due to *Salmonella* spp. or *Staphylococcus aureus*.

Recently COVID-19 infections were shown to have a high mortality in sickle cell patients especially those with underlying chronic kidney disease, pulmonary hypertension, congestive heart failure and history of stroke. Children with SCD with history of pain and renal and heart or lung problems were shown to have worse outcomes with COVID-19 infection. Patients presented with vaso-occlusive pain during the pandemic and several of them developed acute chest syndrome.

Neurological complications

Stroke, silent cerebral infarcts (silent strokes), and cognitive morbidity are the most common permanent sequelae of SCD. The risk of stroke is increased with lower baseline haemoglobin, low HbF level, high leucocyte count or high systolic blood pressure. A large prospective cohort study demonstrated that by 40 years of age, ~20% and ~10% of adults with phenotype haemoglobin SS (HbSS) or HbSC had a cerebrovascular accident respectively. For most children with HbSS living in low-middle-income settings, ~11% will have a stroke by 18 years of age. Stroke due to infarction is more frequent in young children and those over 30 years of age, whereas haemorrhage is more common between 20 and 30 years. Stroke is rare in infants, increases to 1 in 100 patients per year between 2 and 9 years, and then diminishes to half that incidence in older patients. The incidence of stroke is 5–10 times greater in HbSS compared with HbSC, HbS/β^+ -thalassaemia or HbS/β^0 thalassaemia.

Focal seizures or transient ischemic attacks are common presenting symptoms of overt stroke, followed by hemiparesis, coma and speech or visual disturbances. However, the most common cause of permanent neurological injury in children and adults with HbSS and HbSβ^0 thalassaemia is a silent cerebral infarct, occurring in ~39% of children by age 18 years of age and >50% of adults by age 30 years of age. Both stroke and silent cerebral infarcts are associated with significant cognitive impairments that may significantly alter educational attainment, employment status and quality of life. The site of bleeding in haemorrhagic stroke is frequently subarachnoid, and these patients present with severe headache, vomiting and coma. Death can occur during the acute event, particularly with haemorrhagic stroke.

Patients with neurological symptoms should be evaluated initially with a computed tomography (CT) to rule out

haemorrhage and acute mass effect followed by magnetic resonance imaging (MRI) as CT alone is not sensitive for ischaemic stroke. Immediate exchange transfusion to lower the HbS level to less than 30% is required. Patients with haemorrhage may require surgical intervention to ligate accessible aneurysms.

Moyamoya disease in non-SCD patients is a rare progressive cerebrovascular disorder caused by blocked arteries at the base of the brain in the basal ganglia. The name 'moyamoya' means 'puff of smoke' in Japanese and describes the look of the tangle in tiny vessels formed to compensate for the blockage. Vascular damage in SCD results from elevated cerebral blood flow velocities and interaction of rigid or adherent sickle cells with the vessel wall. Angiography demonstrates stenosis or occlusion of vessels in the circle of Willis and internal carotid arteries, sometimes with aneurysm formation or development of moyamoya disease (Figure 15.4b). Surgical vascular bypass procedure with extracranial arteries (encephalodural synangiosis) should be considered in children with SCD and moyamoya disease.

Prevention, early detection and treatment of neurologic complications are important. Transcranial Doppler (TCD) ultrasonography has been shown to be an effective screening tool for identification of stroke risk. TCD screening should begin at 2 years of age and continue annually into the late teenage years up to a minimum of 16 years of age. Increased blood flow velocity due to stenosis can be detected by TCD ultrasonography in asymptomatic patients, and flow rates in excess of 200 cm/s correlate with a high risk of stroke. Development of first stroke in children at risk, who are identified by elevated cerebral Doppler blood flow velocity, can be prevented effectively through regular transfusions. A randomised controlled trial (TWiTCH) comparing the effectiveness of hydroxycarbamide as an alternative to transfusion for primary stroke prevention in 2016 showed that for high-risk children with sickle cell anaemia and abnormal TCD velocities, after 4 years of transfusions and without severe MRA vasculopathy, hydroxycarbamide therapy can substitute for chronic transfusions to maintain TCD velocities and help prevent primary stroke. In patients who have already had a stroke, a prospective randomised controlled trial comparing transfusion to hydroxycarbamide for secondary stroke prevention was undertaken (SWiTCH trial) but was terminated early due to a high prevalence of events in the hydroxycarbamide arm. Patients treated with transfusions had fewer neurologic as well as non-neurologic sickle-cell-related serious adverse events. Though hydroxycarbamide has been shown to lower the incidence of pain and acute chest syndrome, its efficacy in the prevention and progression of cerebral vascular disease is less effective. Blood transfusions are therefore still considered the standard of care for secondary stroke prevention and initial therapy for primary stroke prevention in patients with abnormal TCD velocities. In a recent randomised single-blind clinical trial of children with silent cerebral infarcts (SITS trial), regular blood transfusion therapy significantly reduced the incidence of the recurrence of cerebral infarcts in children with sickle cell anaemia.

Cognitive impairment is very common amongst children and adults with sickle cell anaemia. In the most comprehensive meta-analysis to date, children with HbSS with normal MRIs of the brain, silent cerebral infarct and strokes had a mean full-scale intelligence quotient (FSIQ) of 91, 84 and 73 respectively. Few comprehensive cognitive studies in adults with sickle cell anqemia have been done that include assessment of FSIQ, employment status and assessment of cerebral infarct status. Optimal strategies to screen and implement rehabilitation for cognitive impairment have not been established for sickle cell anaemia. The use of formal screening tools improves the ability to detect developmental delays or cognitive impairment compared with informal observational methods. Identification of developmental or cognitive delays increases likelihood of access to remediation services. Vascular cognitive impairment is of particular concern in adults with SCD and requires ongoing efforts to identify cognitive symptoms and medical risk factors to help patients and families understand the cause of functional deficits and discuss the prognosis to plan for future needs. Outpatient services such as speech therapy, occupational therapy or rehabilitation psychology may be indicated and available depending on the results of a full evaluation.

Pulmonary complications

Acute and chronic pulmonary complications are the leading cause of death in older patients. The acute chest syndrome is characterised by hypoxia, tachypnoea, fever, chest pain and pulmonary infiltrate on chest radiography (Figure 15.4c). Acute chest syndrome often follows a painful event, particularly in adults (Table 15.3). The pathogenesis of acute chest syndrome involves vaso-occlusion, infection or embolisation of bone marrow fat. Infections due to *Mycoplasma*, *Chlamydia*, *Legionella*, pneumococcus, *H. influenzae* and other viruses are more likely in children. Recently, COVID-19 illness was shown to occur more frequently in children if they had frequent vaso-occlusive events prior to the infection or underlying heart and lung disease related to SCD. Fat-laden pulmonary macrophages in the airways due to fat embolisation from the bone marrow are present in half of the cases. Hypoxia due to acute chest syndrome can result in widespread sickling and vaso-occlusion, with risk of multiorgan failure. Patients should receive supplemental oxygen, incentive spirometry and antibiotic therapy directed towards the common organisms. Most patients have a bronchoreactive component and should receive bronchodilator therapy. Patients require close monitoring for persistent hypoxia or worsening lung consolidation for which blood transfusion should be provided. Exchange transfusion and mechanical ventilation are sometimes needed in rapidly progressive cases. NO and steroids may be beneficial in life-threatening cases.

Figure 15.4 Complications of sickle cell disease: (a) Stroke; (b) Moyamoya transformation; (c) Acute chest syndrome; (d) Avascular necrosis of hip joint; (e) Chronic leg ulcer.

Table 15.3 Presenting symptoms of acute chest syndrome.

Symptom	Children (%)	Adults (%)
Fever	86	70
Shortness of breath	31	58
Chest pain	27	55
Extremity pain	22	58
Rib pain	14	30

Adults are more likely than children to have pain preceding the onset of pulmonary symptoms.

Chronic pulmonary problems seen in SCD are obstructive and restrictive lung disease, pulmonary hypertension and hypoxia. Asthma, a form of obstructive lung disease, has a multifactorial pathophysiology in SCD and is influenced by genetic factors, environmental factors, the presence of a chronic underlying inflammatory state, and haemolysis-induced arginine–nitric-oxide dysregulation. Asthma has been shown to be an independent predictor of morbidity and mortality and may be missed during a physical examination. Screening for asthma with formal pulmonary function testing should be considered. Sleep-disordered breathing, diagnosed by formal sleep polysomnography, may have significant consequences for outcomes in children and potentially, adults with SCD. Sleep-disordered breathing is defined by abnormal respiratory patterns such as apnoeas and/or hypopnoeas and hypoventilation during sleep resulting in daytime sleepiness or fatigue that interferes with an individual's ability to function and reduces quality of life. Despite its utility, polysomnography as a screening tool for asymptomatic individuals with SCD is not clear but should be considered for symptomatic patients.

Pulmonary hypertension is another independent predictor of mortality and morbidity in SCD. The diagnosis of pulmonary hypertension is associated with a 10-fold increase in relative risk of dying compared with patients who have normal pulmonary artery systolic pressure. Echocardiography can detect an elevated tricuspid regurgitant velocity (>2.5 m/s), which is observed in 20% of paediatric patients. Right heart catheterisation is necessary to confirm the diagnosis (pulmonary artery pressure >25 mmHg). The prevalence of right heart catheter-confirmed pulmonary hypertension is approximately 10%. Pulmonary hypertension is more frequent amongst patients with high rates of chronic haemolysis, reflected by marked elevation in plasma lactate dehydrogenase (LDH). Disease-modifying therapeutics and/or chronic transfusion therapy should be strongly considered in SCD patients with pulmonary hypertension. Severely affected patients have been treated with regular transfusions, anticoagulation and oxygen inhalation. Current data do not support the use of targeted pulmonary arterial hypertension pharmaceuticals in SCD unless obstructive sleep apnoea, significant lung disease and left heart failure have been ruled out. A pulmonary hypertension expert must be involved in the patients' care if there are concerns for pulmonary hypertension. Lastly, hypoxia, both daytime and nocturnal, has been associated with the development of pain and acute chest syndrome and can be prevented with effective treatment.

Hepatobiliary complications

The liver can be affected by hepatic sequestration, intrahepatic cholestasis, transfusion-acquired infection and transfusional haemosiderosis. Episodes of cholestasis due to intrahepatic sickling can lead to liver failure in rare instances. Pigmented gallstones are seen in two-thirds of patients, particularly those with HbSS, and can occur in young children. Patients with abdominal symptoms attributable to gallstones should undergo cholecystectomy, although the management of asymptomatic gallstones is less clear. Laparoscopic cholecystectomy can be safely performed but associated common duct bile stones first require endoscopic retrograde cholangiopancreatography. As patients with SCD are living longer into adulthood, cirrhosis and liver failure are becoming increasingly prevalent disease-related sequelae. Sickle cell intrahepatic cholestasis syndrome (SCIC) is an uncommon but potentially fatal complication of SCD with a high death rate, observed mainly in patients with homozygous sickle cell anaemia. Its presentation ranges from a benign hyperbilirubinaemia to a fulminant hepatic failure and is characterised by abdominal pain in the upper right quadrant, enlarged liver, acholic or light stools, marked hyperbilirubinaemia and variable elevation of aminotransferases (AST and ALT) levels. In severe cases, renal dysfunction and alteration of coagulation tests can be observed. The diagnosis requires exclusion of viral hepatitis and cholecystitis/cholelithiasis. Treatment patterns are not well established and range from supportive care to exchange transfusion. Early recognition of severe cases and aggressive exchange transfusion is crucial for these patients. Vigilance for hepatic dysfunction, aggressive iron chelation in transfused patients and prompt recognition and treatment of hepatobiliary disease in children may prevent development of hepatic end-organ dysfunction in adults. Chelation therapy can also be associated with liver and kidney dysfunction that needs close monitoring.

Pregnancy

People with SCD are at risk for having a child affected with SCD if their partners have SCD, β-thalassemia trait or are carriers of other abnormal haemoglobin such as HbC. Women whose partners carry one of these traits can avoid an affected pregnancy by undergoing preimplantation genetic diagnosis (PGD). PGD is testing performed on an embryo during an *in vitro* fertilisation cycle. Alternatively, after spontaneous conception, prenatal diagnosis of SCD is possible by chorionic villus sampling in the first trimester or by amniocentesis in the second trimester of gestation.

Women with SCD are frequently exposed to blood products. The fetuses of women who are alloimmunised are at risk of significant haemolytic anaemia or mortality. The fetuses are at an increased risk of growth restriction, preterm delivery and stillbirth amongst women with SCD. Fetal surveillance, which includes growth ultrasounds and antepartum testing (nonstress tests, biophysical profiles and contraction stress tests), may lead to planned early delivery and can reduce but not eliminate risks. For women who require chronic opioid therapy during pregnancy, there is an increased risk of neonatal withdrawal in their newborns.

The steady-state haemoglobin level falls in SCD during pregnancy, similar to the decline in haemoglobin observed in normal pregnant women. Folate deficiency can exacerbate the anaemia and supplements should be provided throughout pregnancy. Compared to women without SCD, women with SCD are more likely to experience preeclampsia, venous thromboembolism, infections and maternal mortality during pregnancy. During pregnancy, 40–50% of women with SCD require at least one hospital admission. The presence of pulmonary hypertension increases the cardiopulmonary demands of gestation. Painful episodes become more common in the last trimester. Prophylactic transfusions during pregnancy or the type of delivery do not alter the outcome for mother or newborn however, prophylactic transfusions at regular intervals at the onset of pregnancy should be considered for women with a history of severe SCD-related complications to reduce recurrent pain episodes, acute chest syndrome or if the patient has a high-risk pregnancy from additional comorbidities such as other medical conditions or nephropathy.

In women with SCD, regular use of contraception can decrease the health risks associated with an unintended pregnancy. Hormonal contraceptives may also decrease menstrual blood flow, leading to higher haemoglobin levels. Use of progestin-only hormonal contraceptives lowers the risk of thromboembolism compared to use of oestrogen-containing contraceptives and has been shown to be safe for women with SCD. Intrauterine devices (IUDs) and intrauterine implants carry modest risks associated with the insertion procedure. Progestin-only contraceptives (pills, injections and implants), levonorgestrel IUDs, and barrier methods should be used as first-line contraceptive methods in women with SCD. If the benefits are considered to outweigh the risks, combined hormonal contraceptives (pills, patches and rings) may be used in women with SCD as second-line therapy.

Renal complications

There is increasing recognition that renal disease affects morbidity and mortality in individuals with SCD age. The hypoxic, acidotic and hypertonic renal medulla favours vaso-occlusion, leading to destruction of the *vasa recta* and hyposthenuria in the first year of life. It presents clinically as enuresis or nocturia, and patients are susceptible to dehydration in hot weather. Haematuria as a result of papillary necrosis usually originates from the left kidney. Management is generally by bed rest and hydration, although sometimes blood transfusion and ε-aminocaproic acid are required. SCD patients tend to have a lower systemic BP than age and ethnic-matched controls. Therefore, it is important to be aware of relatively 'normal' BP in patients whose baseline BP readings are typically low – this may indicate significant hypertension. Blood pressure goal for SCD patients should be ≤120–130/80 mmHg.

Proteinuria due to glomerular injury precedes development of nephrotic syndrome and eventual chronic renal insufficiency in one-quarter of adults. Individuals with SCD can develop proximal and distal renal tubular acidosis (RTA) that is characterised by low carbon dioxide (CO_2) and abnormal potassium levels, and occasionally hyperchloraemia. In addition, iron-chelating agents may cause Fanconi syndrome (generalised proximal tubular dysfunction), which may affect calcium and phosphate levels in the blood and urine. All patients should have annual screening starting at age 8 years for proteinuria with urinalysis and urine albumin-to-creatinine ratio and should have correction of their acidosis with bicarbonate as well as appropriate treatment for the RTA. The progression to renal failure can be delayed by angiotensin-converting enzyme inhibitors. Careful control of blood pressure, avoidance of non-steroidal anti-inflammatory drugs (NSAIDs) and aggressive treatment of urinary tract infection and anaemia are important objectives for patients with chronic renal insufficiency. Patients with end-stage renal disease are treated with dialysis and renal transplantation. Some renal complications, such as hyposthenuria and haematuria, are also observed in individuals with sickle trait, as is the rare renal medullary carcinoma.

Priapism

Priapism occurs in two-thirds of males with SCD, with a peak incidence in the second and third decades. Males do not reveal this often during regular history so early counselling is important during regular visits. It is caused by vaso-occlusion leading to obstruction of venous drainage from the penis. It typically affects the *corpora cavernosa* alone, resulting in a hard penis with a soft glans. Episodes can be brief (stuttering) or prolonged, when they last for longer than 3 hours. Recurrent priapism leads to fibrosis and eventual impotence. Young boys require explanation of symptoms and the need to seek early help for priapism. At the onset of priapism, patients should drink extra fluids and attempt to urinate. An oral dose of pseudoephedrine or terbutaline can be given. Persistent priapism requires intravenous hydration and opioid analgesia. If priapism persists for more than 2–3 hours, aspiration and irrigation of the corpora with dilute phenylephrine or etilefrine solution should be performed.

A simple intracavernosal injection with these agents tried early may induce detumescence and avoid the need for aspiration and irrigation. For patients with recurrent episodes, daily sildenafil or daily alpha-adrenergic agonist may be used. Antiandrogens, 5α-reductase inhibitors and gonadotropin-releasing hormone agonists with or without intermittent self-administration of sympathomimetic agents for acute episodes have been shown to be successful medical management options for some patients with stuttering priapism. As anti-androgenic agents, these therapies can negatively affect sexual function and physical composition. Therefore, they are not recommended in young patients who have not reached puberty or adult stature, and they should not be used in men desiring fertility. Priapism lasting for more than 4–6 hours is a urologic emergency because it represents a compartment syndrome of the penis. In these cases, urology should consider aspiration of blood from the corpus cavernosum with or without saline irrigation followed by injection of an alpha-adrenergic agonist to cause detumescence and in turn allow oxygenated blood to re-enter the cavernosa. For patients with recurrent episodes despite being on hydroxycarbamide, chronic transfusion therapy with a goal HbS <50% should be started.

Ocular complications

Vaso-occlusion of retinal and other vascular beds in the eye can lead to grave complications. Patients with SCD can develop abnormal (comma-shaped) conjunctival vessels, iris atrophy, retinal pigmentary changes and retinal haemorrhages. However, much more serious is neovascularisation causing proliferative retinopathy, appearing as a 'sea fan', with its potential for vitreous haemorrhage and retinal detachment. Such patients are treated with laser photocoagulation or vitrectomy. The incidence of proliferative changes is substantially higher in HbSC and HbS/β^+ thalassaemia patients than in HbSS. All patients with SCD should have annual ophthalmological evaluation, beginning in the second decade.

Sudden change in vision in a patient with SCD is an ocular emergency. Central retinal artery occlusion requires immediate treatment with hyperoxygenation and reduction of intraocular pressure, but the prognosis for vision is poor. Hyphaema, which can arise after minor trauma, leads to glaucoma due to sickling of blood in the anterior chamber. The elevated intraocular pressure causes ischemic optic atrophy and retinal artery occlusion. Individuals with sickle trait are also vulnerable to this complication. Urgent surgical attention is required to wash out blood from the anterior chamber.

Bone complications

The chronic haemolytic process results in expansion of the medullary space. Bone infarction due to vaso-occlusion produces tenderness, warmth and swelling, which can be difficult to distinguish from osteomyelitis. In such cases, cultures from blood and direct aspiration of the joint involved are negative and radiography later shows patchy sclerosis and cortical thickening. Collapse of vertebral end plates due to infarction produces the codfish appearance. Patients are managed with analgesia and hydration until resolution of symptoms.

Avascular necrosis of the femoral head is a serious complication that is difficult to treat and leads to chronic disability and pain (Figure 15.4d). Patients with coexisting α-thalassaemia have a higher incidence of osteonecrosis at a younger age. The condition also affects the humeral head but with fewer functional consequences. Aggressive physical therapy or combination of early core decompression followed by physical therapy can postpone the need for additional surgical intervention. Hip arthroplasty may be required for patients with severe symptoms.

The majority of children ages 9–19 years of age with severe manifestations of SCD have significant reduction in their bone density. Deficits in calcium and vitamin D occur in a majority of patients, which might contribute to low bone density, therefore vitamin D should be optimised in these patients.

Leg ulcers

Chronic leg ulcers are frequent in adult patients with SCD, particularly affecting males with the HbSS genotype (Figure 15.4e). Ulcers arise near the medial or lateral malleolus and may be single or multiple. Occlusion of skin microvasculature from sickle red cells predisposes to ulcers, which are made worse by trauma, infection or warm climate. Ulcers are always colonised with pathogenic bacteria (*Pseudomonas aeruginosa*, *S. aureus* and *Streptococcus* spp.) and acute infection can occur. The ulcers are painful and resistant to healing, and although bed rest and elevation of the leg are efficacious, they may not be practical, owing to the chronic nature of the problem. Treatment requires debridement, elastic dressings, zinc sulfate, and in some cases, red cell transfusions and skin grafting. Topical lidocaine is used for local treatment as with any leg ulcer in addition of NSAIDs and opioid therapy. Oedema related to superficial or deep venous insufficiency is usually seen. Venous compression is therefore recommended to relieve pain, reduce oedema and promote wound healing. Nitric oxide plays an essential role in chronic wound healing by increasing the production of extracellular matrix and stimulating keratinocyte proliferation and angiogenesis. A phase I study in 2014 on topical sodium nitrite, which produces NO, showed a significant reduction in the surface area of leg ulcers and in SCD patients. A recent study using the disease modifying agent voxelotor in patients with SCD and leg ulcers showed some improvement or resolution of the ulcers in the majority of patients on voxelotor therapy compared to patients on placebo. The resolution of ulcers was associated with increased haemoglobin levels in these patients.

Variant sickle cell syndromes

Sickle cell trait

Sickle cell trait (HbAS) is a benign condition that has no haematological manifestations and is associated with normal growth and life expectancy. The ratio of HbA to HbS is 60:40, owing to the greater affinity of α-globin chains for β^A-globin chains. Sickle cell trait affects 8–10% of African–Americans and up to 25–30% of the population in West Africa. Sickle trait reduces the risk of severe *falciparum* malaria, but not the prevalence of parasitaemia. There appears to be no effect on infections with other forms of malaria. Impaired urine-concentrating ability and haematuria can occur and an increased incidence of urinary tract infection is observed in pregnant women with sickle cell trait. Splenic infarction is possible at very high altitudes. A slight risk of sudden death during exercise has been reported. Sickling and vaso-occlusion under extreme circumstances can lead to rhabdomyolysis, acute kidney injury and cardiac arrhythmias. Like all people, individuals with sickle cell trait are advised to gradually increase exercise intensity, to avoid dehydration and to stop physical activity with the onset of muscle cramp or fatigue. Recent data shows some concerns for higher risk of venous thromboembolism, specifically pulmonary emboli, in people with sickle cell trait compared to non-sickle cell trait patient but further data is needed to clarify this risk. Treatment of sudden collapse consists of rapid intravenous hydration and oxygen supplementation.

Genetic counselling should be provided to individuals with sickle cell trait. It is important to note that some patients with HbS/β^+ may be misdiagnosed as having sickle cell trait. Therefore, it is important to look at the haemoglobin electrophoresis/high-performance liquid chromatography of patients to confirm the diagnosis. A rare compound heterozygote for haemoglobin S and haemoglobin Quebec-Chori may present as sickle cell trait on electrophoresis but have clinical and laboratory evidence of mild-to-moderately-severe SCD. Therefore, careful examination of the peripheral blood film and of a complete blood count, including a reticulocyte count, is needed to establish a diagnosis of sickle cell trait. When sickle forms are seen in the peripheral blood smear, the patient has evidence of haemolytic anaemia, and when atypical symptoms suggestive of SCD occur in a patient with an apparent sickle cell trait, an evaluation for an electrophoretically silent haemoglobin variant is indicated.

HbSC disease

HbC is found amongst individuals of African descent and the compound heterozygous state HbSC accounts for 25–50% of patients with SCD. The vaso-occlusive complications seen in patients with HbSC resemble those seen in patients with HbSS but are less severe. Splenomegaly and the risk of sequestration can persist into adult life. Of particular note is the higher incidence of proliferative retinopathy in HbSC beginning in the second decade. The haemoglobin level (100–120 g/L) is higher than in HbSS, and the red cells are relatively microcytic with a higher mean corpuscular haemoglobin concentration (MCHC). Peripheral blood smear reveals frequent target cells, intraerythrocytic crystals and rare sickle cells. Equal amounts of HbS and HbC are present in the red cells and the solubility test for sickle haemoglobin is positive. The electrophoretic appearance of HbSC, HbSE and HbSO Arab at pH 8.4 is similar, but a distinction can be made based on ethnicity and by performing isoelectric focusing or agar gel electrophoresis at pH 6.5. Fat embolism syndrome (FES) is a rare clinical entity that results from the release of fat globules into the circulation, causing respiratory and neurologic damage, cutaneous and haematological manifestations and can occur in individuals with HbSC disease. People with haemoglobin C trait have red blood cells and do not have health problems related to having the trait. However, they can pass haemoglobin C trait to their children and combined with HbS trait can have a child with HbSC disease.

Sickle cell/β-thalassaemia

Sickle cell/β-thalassaemia compound heterozygotes account for less than 10% of patients with sickle syndromes in the US. The majority of these patients have the β^+-phenotype, with the proportion of HbA ranging from 3 to 25%. The clinical phenotype is mild and disease severity correlates with the amount of HbA present. The clinical manifestations of the less frequent HbS/β^0-genotype are similar in severity to those of HbSS. The red cells are microcytic and hypochromic, and variable numbers of target cells and sickle cells are observed. Reticulocytosis (10–20%) is present and the level of HbA_2 is elevated.

Sickle cell anaemia with coexistent α-thalassaemia

Coinheritance of αα-thalassaemia (−α/αα or −α/−α) with SCD is common, and such patients have less severe anaemia and demonstrate hypochromia and microcytosis. In general, the clinical severity is similar to that seen in HbSS patients with a normal complement of α-globin genes.

Sickle cell/HPFH

Approximately 1 in 100 patients with HbSS has an elevated HbF level due to deletional or non-deletional mutations that maintain γ-globin gene expression after birth. Such individuals have 20–30% HbF and less than 2.5% HbA2. In most newborn screening techniques, HbS/HPFH appears identical to severe HbSS disease. Therefore, DNA globin gene testing or family studies looking at both parents' sickle cell trait is necessary to make this diagnosis. The haemoglobin level is normal, with microcytosis,

and target cells are observed in the peripheral smear. The clinical course is benign, and vaso-occlusive complications are rare because of the inhibition of sickling by elevated HbF.

Other sickling syndromes

Sickle cell/Hb Lepore disease

Coinheritance of Hb Lepore with the sickle cell mutation produces a clinical picture similar to that of HbS/β-thalassaemia, but with a low HbA_2 level.

Sickle cell/HbD disease

Of all the D or G haemoglobins, HbD Punjab (D Los Angeles) alone interacts with HbS to produce moderately severe haemolytic anaemia in compound heterozygotes. Target cells and irreversibly sickled cells are observed in the peripheral smear, and the clinical manifestations resemble mild sickle cell anaemia.

Sickle cell/HbO Arab disease

HbO Arab resembles HbC on alkaline electrophoresis and produces a moderately severe haemolytic anaemia in association with HbS. The disease is more severe than HbSC, and numerous sickled erythrocytes are observed on the peripheral smear.

Sickle cell/HbE disease

HbSE disease causes mild haemolysis and no remarkable abnormality of red blood cell morphology. HbE comprises only 30% of the total haemoglobin because of the thalassaemic nature of the mutation. Patients are generally asymptomatic, although occasionally significant vaso-occlusive complications and anaemia have been observed.

Diagnosis

Peripheral blood findings

The peripheral blood picture depends on the type of sickle cell syndrome. The haemoglobin level is normal in the newborn period, but anaemia develops and sickle or cigar-shaped irreversibly sickled cells can be observed in the peripheral blood by 3–4 months of age as HbF declines. In HbSS disease, the red cells are normocytic and normochromic, with polychromasia, many irreversibly sickled cells (ISCs) and fewer target cells (Figure 15.5a). The average reticulocyte count is 10% (4–20%) and normoblasts may be observed. Red cells are microcytic in the presence of coexisting α-thalassaemia or iron deficiency. In HbS/β-thalassaemia, ISCs, target cells and hypochromic microcytic red cells are prominent. The red cell morphology in HbSC disease is characterised by predominant target cells and rare ISCs. The occasional Howell–Jolly body, indicative of loss of splenic function in SCD, may be observed. The white cell count is elevated ($12–20 \times 10^9$/L) as a result of an increase in mature neutrophils. The platelet count is also elevated to $300–500 \times 10^9$/L as a result of decreased splenic function.

Other laboratory tests

Serum levels of unconjugated bilirubin, reticulocyte counts and lactate dehydrogenase (LDH) are elevated, and haptoglobin and haemoglobin levels are decreased in patients with haemolysis related to SCD. SCD alters other organ functions including the coagulation system, renal and cardiac functions.

Haemoglobin electrophoresis

HbS can be identified by cellulose acetate electrophoresis at pH 8.4 (Table 15.1 and Figure 15.5b). HbD and HbG have the same electrophoretic mobility with this method, but can be distinguished using citrate agar electrophoresis at pH 6.2 or thin-layer isoelectric focusing. Distinction cannot be made between HbSS and HbS/β^0 -thalassaemia on electrophoresis. The diagnosis of HbS/β^0 -thalassaemia is suggested by microcytosis and elevated HbA_2, and confirmed by finding β-thalassaemia trait in one of the parents. HbA and HbS are observed upon electrophoresis in both sickle cell trait and HbS/β^+ -thalassaemia; however, the HbA fraction is greater than 50% in the former, but ranges from 5 to 30% in the latter. The level of HbF is variably elevated, with higher levels observed in patients with the Arab–Indian and Senegal haplotypes.

High performance haemoglobin liquid chromatography, or capillary electrophoresis, is widely used in lieu of gel electrophoresis and provides qualitative and quantitative estimations of haemoglobin fractions in an automated fashion. Globin gene testing is being increasingly used for the diagnosis of SCD given its increased specificity and decreasing costs.

Other tests to detect sickle haemoglobin

Sickling of red cells can be induced by sealing a drop of blood under a coverslip to exclude oxygen or by adding 2% sodium metabisulfite. The solubility test for HbS utilises a reducing agent such as sodium dithionite, which is added to the haemolysate. Deoxy-HbS is insoluble and renders the solution turbid. Both these tests are unable to distinguish sickle cell trait from sickle cell anaemia and cannot be used for primary diagnosis. They are useful aids in the identification of an abnormal electrophoretic band as HbS and for identifying sickle cell trait in units of red cells prior to transfusion.

Newborn screening

Universal newborn screening is recommended for identifying SCD in the neonatal period. The efficacy of penicillin prophylaxis in preventing death from early sepsis in SCD provided the rationale for development of screening programs. Blood samples

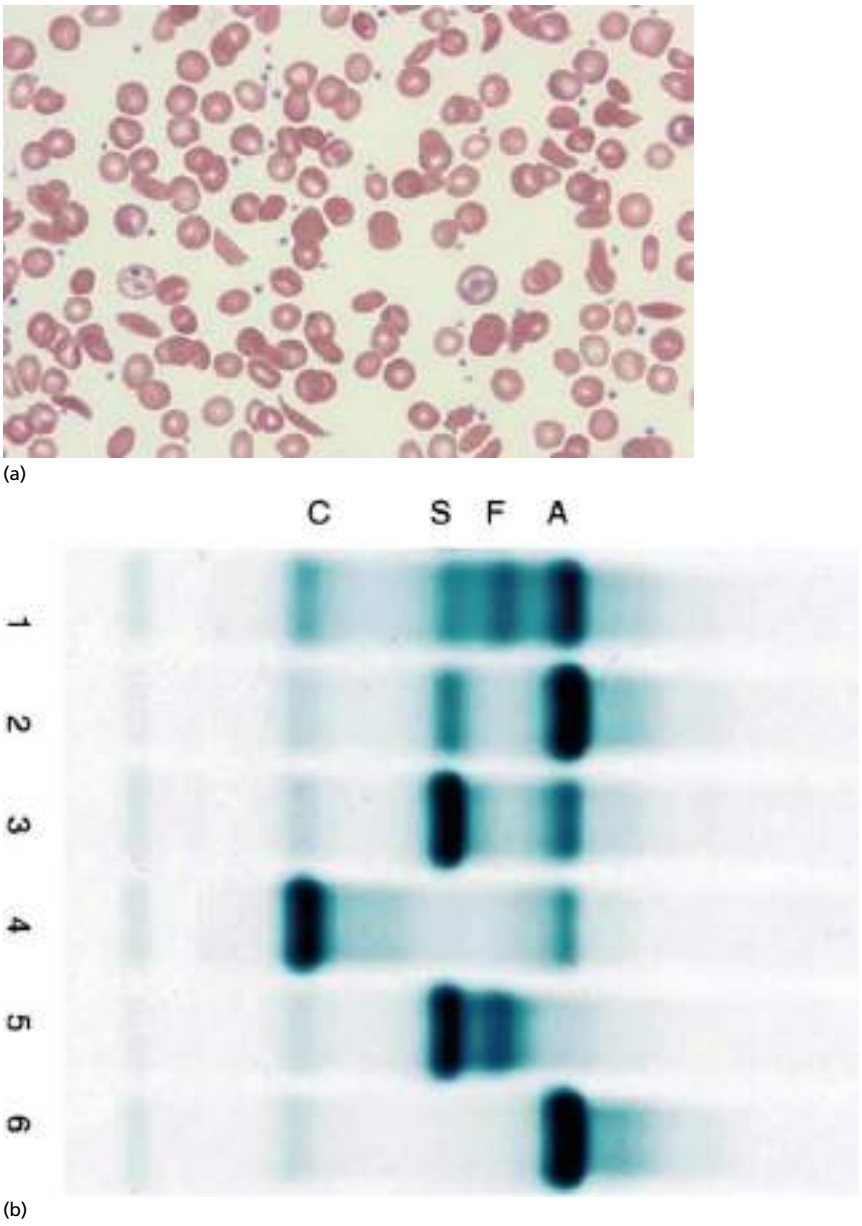

Figure 15.5 (a) Peripheral smear from an individual with sickle cell anaemia (Source: American Society for Clinical Pathology / https://www.ascp.org/patient-champion/resources/sickle-cell-disease / last accessed on November 22, 2024). (b) Haemoglobin Electrophoresis showing Lane 1 as control; Lane 6 as normal adult HbAA; Lane 5 as an infant with HbSS and residual HbF production; Lane 4 as HbCC disease; Lane 3 as HbSS prior to transfusion; and Lane 2 is the same patient after transfusion (Source: Menon & Frei-Jones (2021) / Springer Nature).

obtained by heel prick are spotted onto filter paper and tested by electrophoresis or chromatography. Neonates with HbSS disease and HbS/β^0-thalassaemia have an FS pattern (the order of haemoglobins indicates their relative abundance in the sample). In sickle cell trait, the haemoglobin pattern is FAS, whereas newborns with HbS/β^+-thalassaemia have an FSA pattern. Finally, the presence of the FSC pattern suggests HbSC disease. Family studies help to make the definitive diagnosis and, when both parents are unavailable, DNA-based testing is useful.

Prenatal diagnosis

Prenatal diagnosis is available through direct detection of the GAG→GTG mutation responsible for SCD in fetal cells. Chorionic villus sampling is recommended given its reliability in making an early prenatal diagnosis with minimal risks. Preimplantation diagnosis and selection of healthy embryos may offer some hope in minimising disease burden in the future. All patients with abnormal newborn screening results

should receive genetic counselling in addition to follow-up with a provider to assess their clinical and laboratory outcomes and severity of disease that is not evident on newborn testing alone.

Therapy

This section discusses general issues in the management of SCD. The treatment of specific complications is addressed in the section on clinical manifestations.

Routine healthcare

All adults and children with SCD require specialised care at an experienced centre with expertise in taking care of these patients.

The level of healthcare available to patients with SCD varies tremendously in different countries. Where resources are limited, the primary focus should be on penicillin prophylaxis, vaccination, education and analgesia for painful episodes. Recent studies have shown that hydroxycarbamide and TCD screening for stroke can be successfully implemented in low-resource settings with success. Where comprehensive care is available, both medical and psychosocial needs should receive attention (Figure 15.6). Sickle cell centres should have specialists in several fields who are available to address complications that may affect different organs.

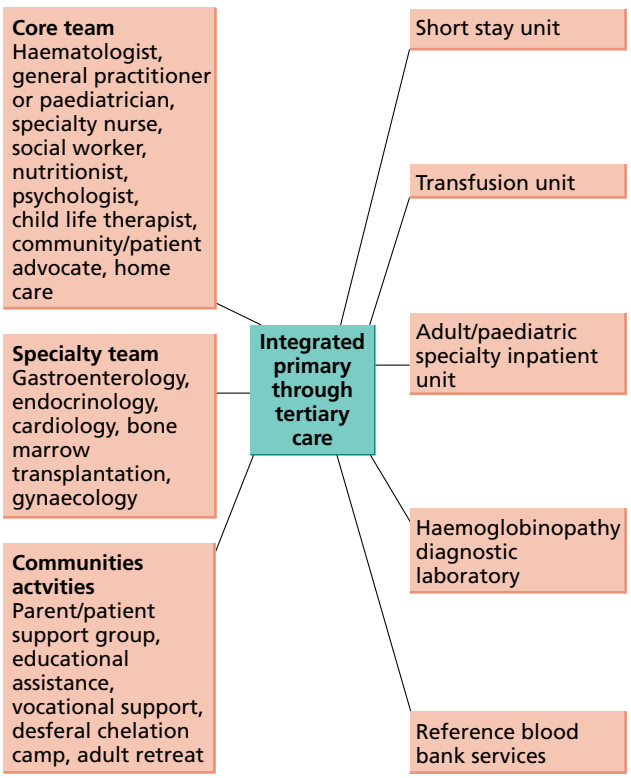

Figure 15.6 Comprehensive care of patients with sickle cell disease.

In cases when diagnosis is made on newborn screening, the infant should be seen within 1–2 months to instruct parents about infections and splenic enlargement. Routine immunisation should include pneumococcal, *H. influenzae*, hepatitis B and influenza vaccines. All children receive prophylactic penicillin; evidence for its continuation after the age of 5 years in the absence of any episode of pneumococcal sepsis or splenectomy is unclear and practices vary. Folic acid supplementation (1 mg daily) is recommended. Evaluation of cerebral blood flow by transcranial Doppler should be performed on all children after 2 years to identify those at risk for stroke. Annual retinal examination is begun at 10 years. Sexually active women should have routine pelvic examinations and receive advice about birth control.

Infections

Fever in children with SCD requires urgent attention in the clinic or emergency department. A complete blood count, blood and urine cultures and chest radiographs should be obtained, and lumbar puncture should be performed if meningitis is suspected. Very young children with fever or older children with apparent sepsis should be hospitalised for intravenous antibiotics. The choice of antibiotics depends on causative agents prevalent locally and the pattern of resistance. In the USA, cefuroxime or ceftriaxone are preferred, whereas high-dose penicillin is used in several other countries. Many patients older than 2 years who do not look septic or seriously ill can be managed at home after receiving parenteral antibiotics in the emergency department. Antibiotics should continue for 1 week when bacteraemia is documented. In the presence of pneumonia, a macrolide should be added to cover *Mycoplasma* or *Chlamydia*. Antibiotics for osteomyelitis should provide coverage for *Salmonella* and *S. aureus* and are given for a period of 4–6 weeks.

Transfusion therapy

Blood transfusion in SCD is used to treat severe anaemia or to reduce the amount of circulating sickle haemoglobin. Only sickle-negative blood, which can be identified by negative sickle solubility test, is used for transfusions. The blood should also be leuko-depleted and matched for common minor E, C and Kell antigens. A simple transfusion is used to treat severe anaemia that is often associated with aplastic crisis and splenic sequestration. Older patients with chronic kidney injury may also need transfusions for declining haemoglobin level.

Dilution of circulating sickle haemoglobin can be accomplished by simple transfusion if the baseline haemoglobin level is low. Exchange transfusion is required to prevent hyperviscosity from the significant rise in haemoglobin when the patient has high baseline haemoglobin or when a greater reduction in

HbS is desired. The final haemoglobin level should not exceed 120 g/L after simple or exchange transfusion. Conditions in which a reduction in the proportion of HbS is required include stroke, progressive acute chest syndrome, persistent priapism or preparation for general anaesthesia longer than 1 hour. Longer-term reduction in HbS through regular transfusions is advocated to prevent recurrence of stroke and sequestration, and in selected patients with leg ulcers or chronic pain. Routine blood transfusion is not needed for pain episodes, infections, minor surgery or uncomplicated pregnancy.

It is possible to eliminate most complications of SCD with the use of chronic transfusions to suppress endogenous sickle haemoglobin production. However, alloimmunisation, iron overload and transmission of viruses are significant risks that limit the use of transfusions for the management of severe complications. In addition, because of the limited availability and decreased safety of blood, criteria for transfusion are more stringent in less developed countries. The high incidence of alloimmunisation from minor blood group incompatibility (Rh, Kell, Duffy and Kidd) between donors and recipients can be avoided by use of phenotypically matched units. Genomic analysis of RH alleles can improve the precision of blood matching and decrease the incidence of alloimmunisation. Patients on long-term transfusions develop iron overload, which requires chelation with deferoxamine, deferasirox or deferiprone. The prevalence of iron-induced organ damage appears to be lower in SCD compared with thalassaemia, despite similar amounts of iron burden. MRI and, rarely, liver biopsy are necessary to measure iron burden because the serum ferritin is unreliable. Because iron accumulation can be reduced or prevented by erythrocytapheresis (red cell exchange), this technique is now preferred when venous access is available.

Pain management

Prompt management of pain is essential, given its frequent occurrence and potential adverse psychological consequences. Patients with recurrent pain are best managed in a familiar ambulatory setting rather than the emergency department (ED). When ED management is necessary, utilization of pain management protocols can improve the delivery of care. Pain management protocols have been shown to expedite the administration of pain medications and facilitate timely reassessment of pain withing 30 minutes of triage in the ED. The patient should be evaluated for potential infectious, traumatic or surgical causes of pain. Pain assessment tools are available for young patients and are also helpful in older patients to follow the response to therapy. Adequate analgesia using opioids and NSAIDs should be provided. Several narcotic agents are available for oral and parenteral use and the choice of medicine depends on local experience, as well as the patient's preference. Even though no opioid alternatives are available, ketamine has shown some promise in its effects on pain and narcotic-sparing effects. The use of incentive spirometry reduces the potential for developing hypoxia and acute chest syndrome secondary to hypoventilation. Under-treatment of pain can be avoided by using patient-controlled analgesia, which has the added benefit of reducing apparent drug-seeking behaviour. Narcotic addiction is no more frequent in sickle cell patients than in others requiring analgesia. NSAIDs improve pain control with or without narcotics. Providing psychosocial support and reassurance, and allaying anxiety, are important goals. Individualised pain plans should be developed for all patients with SCD with the participation of the patient and their family and should be available to be used in acute settings when patients present with an acute pain event. Chronic pain is rare in SCD and may require long-acting pain management with the support of a pain specialist. It is important to note that overuse of NSAIDs can lead to renal dysfunction in SCD patients at risk for renal complications and should be monitored.

Disease-modifying therapies

Hydroxycarbamide

Hydroxycarbamide is a tremendously important drug in the management of patients with SCD who have severe clinical manifestations. Hydroxycarbamide inhibits ribonucleotide reductase, leading to S-phase arrest of replicating cells, and is used in SCD because of its ability to stimulate production of HbF. Hydroxycarbamide increases HbF as a result of stress erythropoiesis induced by its myelosuppressive effect. Patients show variable response in the degree of rise in HbF, and some experience no change from the baseline value. Other biological effects of hydroxycarbamide play an equally significant role in the beneficial clinical effects observed during therapy. Erythrocytes of patients on hydroxycarbamide have increased water content and deformability and decreased adherence to vascular endothelium. There is elevation of the haemoglobin level, mean corpuscular volume (MCV), HbF and F cells, whereas total white cell and neutrophil count, reticulocyte count and the number of dense sickle cells decrease. Patients on hydroxycarbamide experience 50% reduction in the incidence of acute painful episodes and acute chest syndrome. Transfusion needs, frequency of hospital admissions and the risk of death are also decreased. Hydroxycarbamide does not improve leg ulcers, while the effect on priapism is unclear. It may reduce the risk of stroke, and its role in children with elevated cerebral blood flow velocities is under intense study.

The efficacy of hydroxycarbamide therapy is now well established in adults and children as young as 9 months of age. Prospective trials in paediatrics demonstrated a reduction in both painful episodes and acute chest syndrome.

The overall benefit of hydroxycarbamide to the patient is closely related to compliance, for which monitoring in the clinic and psychological support should be provided. Patients

should be made aware that 3–6 months may elapse before clinical benefits are realised. Hydroxycarbamide should be offered to all patients ages 9 months and above with HbSS and HbSβ0 disease regardless of their incidence of pain crises and acute chest syndrome episodes, and symptomatic patients with other genotypes of sickle cell anaemia. It is started at a dose of 20 mg/kg per day and increased by 5 mg/kg every 2–3 months until the absolute neutrophil count is close to 2.5×10^9/L. Compliance with prescribed dose should be ascertained before each dose escalation, up to the maximum dose of 35 mg/kg or 2000 mg/day. Patients require frequent monitoring of blood counts, as well as renal and hepatic function. Myelosuppression is the most commonly encountered side-effect and temporary cessation of therapy and dose reduction is required for neutropenia, thrombocytopenia, reticulocytopenia or fall in haemoglobin. Dose modification is necessary for patients with renal dysfunction. Skin pigmentation affecting the nails, palms and soles is commonly observed. There may be a temporary decline in sperm production amongst men while on hydroxycarbamide treatment. Despite concerns about the leukaemogenic and teratogenic effects of hydroxycarbamide, no convincing increase has been reported in SCD. Men and women should practise contraception while taking hydroxycarbamide, and women who become pregnant should stop the drug. No decrease in growth rate is observed in children over 5 years using hydroxycarbamide, while the growth effects of the drug in younger children are under evaluation. Overall, the risks associated with hydroxycarbamide therapy are low. A recent study in children with sickle cell anaemia in sub-Saharan Africa treated with hydroxycarbamide showed its feasibility and safety in this population and reduced incidence of vaso-occlusive events, infections, malaria, transfusions and death. This study supports the need for wider access to treatment for sickle cell anaemia.

L-Glutamine (Endari)

L-Glutamine may be used for SCD for patients with recurrent pain episodes despite being on hydroxycarbamide or who could not tolerate hydroxycarbamide therapy. It contributes to NAD+ synthesis for the regeneration of glutathione, which is depleted when reactive oxygen species are circulating. It has been shown to reduce the number of annual vaso-occlusive episodes, hospitalisations and acute chest syndrome when used with hydroxycarbamide therapy. This therapy is currently approved for patients ages 5 years and older with HbSS and HbSβ0 with symptoms not adequately controlled with hydroxycarbamide alone.

Voxelotor

Voxelotor is a first-in-class small molecule that forms a reversible covalent bond with alpha-globin which stabilises dexoxygenated haemoglobin in the relaxed state, thus preventing polymerisation. This medication may be used for patients aged 12 years and over and has been shown to increase the haemoglobin lifespan and reduce haemolysis. No long-term safety or efficacy outcomes have been measured yet for this drug. However, long-standing anaemia is a known risk factor for many chronic complications of SCD including pulmonary hypertension, chronic kidney disease, cerebrovascular accidents and mortality, so correction of anaemia with voxelotor has potential to preserve long-term organ function. This therapy can be used in conjunction with hydroxycarbamide by mouth and is especially beneficial for patients who have low baseline haemoglobins.

Crizanlizumab

P-selectin is an adhesion molecule present on endothelial cells and platelets that facilitates interactions between endothelial cells, WBC, RBCs and platelets. P-selectin is known to be upregulated in inflammatory conditions including SCD. Crizanlizumab binds to P-selectin glycoprotein ligand and blocks adhesion and has been shown to decrease the incidence of vaso-occlusive pain episodes, longer time to first and second crises. It has not been shown to decrease any markers for haemolysis. This therapy may be used for patients with all genotypes of SCD aged 16 years and over. It is delivered intravenously every 4 weeks.

In young patients with severe disease, matched-sibling stem cell transplantation should be discussed as an alternative to chronic transfusions or long-term disease-modifying therapies listed above.

New therapeutic modalities

A better appreciation of the pathophysiology of SCD will make it possible to exploit new therapeutic mechanisms (Table 15.4). There are several agents in clinical trials that are promising.

Haemopoietic stem cell transplantation

Allogeneic haemopoietic stem cell transplantation (HSCT) from a matched sibling donor cures 93% of children with SCD less than 16 years of age and 81% of patients over 16 years or older. The 5-year probability of graft versus host disease-free survival is 86% for patients younger than 16 years and 77% for patients 16 years or older. Both bone marrow and umbilical cord blood from related donors are suitable sources for the stem cells (Figure 15.7). Studies are underway to evaluate the use of unrelated donors or reduced-intensity conditioning regimens. Additional long-term risks after HSCT are infertility and second malignancy. Selection of candidates for HSCT is complex owing to the uncertain long-term course of the disease. HSCT should be considered in children (age <16 years) with SCD (any genotype) who have a human leucocyte antigen (HLA)-identical related donor and evidence of target organ damage involving

Table 15.4 Summary of disease-modifying therapies currently available.

Drugs	Approved for ages	Mechanism of action	Major side effects	Administration	Good for..
Hydroxycarbamide	>9 months	Ribonucleotide reductase inhibitor: ↑HbF, ↓WBC, retic	Cytopenia	Oral liquid or capsule	All patients with HbSS or HbSβ0 or other genotypes with severe phenotype
L-glutamine	≥ 5 years	Repletes glutathione to reduce oxidative stress	Nausea, abdominal discomfort	Oral powder for reconstitution	Persistent pain on HU
Voxelotor	≥12 years	Stabilises HbS in deoxygenated state and reduces polymerisation	Headache, abdominal discomfort	Oral tablet	Low Hb, HU not effective or tolerated
Crizanlizumab	≥16 years	Binds to PSGL-1 and prevents P-selectin mediated adhesion of WBC, sickled RBCs and platelets to endothelium and each other	Arthralgias, Nausea	IV infusion	Inflammatory phenotype, frequent pain crises, HU not effective or tolerated

Table 15.5 Advances in the management of sickle cell disease.

Category	Intervention
Newborn screening	Counselling
	Comprehensive care
Infection	Prophylactic penicillin. Immunisation
Brain injury	Screening with TCD, MRI
	Neurocognitive testing, Behavioural health screening
	Chronic transfusions
Transfusion safety and iron overload	Phenotypically or genotypically matched red blood cells
	Erythrocytapheresis
	Iron chelation
Lung injury	Incentive spirometry
	Antibiotics (including macrolides)
	Transfusion
	Echocardiographic screening for pulmonary hypertension
	Prevention with hydroxycarbamide
Surgery/anaesthaesia	Preoperative transfusion for sedation >1 hour
Avascular necrosis	Physical therapy
	Hip joint replacement
Priapism	Adrenergic agonist
	Anti-androgen therapy
Pain	Prevention with hydroxycarbamide
	Patient-controlled analgesic devices
	Non-steroidal anti-inflammatory drugs
Renal	ACE inhibitors for proteinuria
	Improved renal transplantation
Gallbladder disease	Laparoscopic cholecystectomy
Severe disease	Allogeneic bone marrow transplantation
	Chronic transfusions
	Hydroxycarbamide, Voxelotor, Crizanlizumab, L-Glutamine

ACE, angiotensin-converting enzyme; MRI, magnetic resonance imaging; TCD, transcranial Doppler.

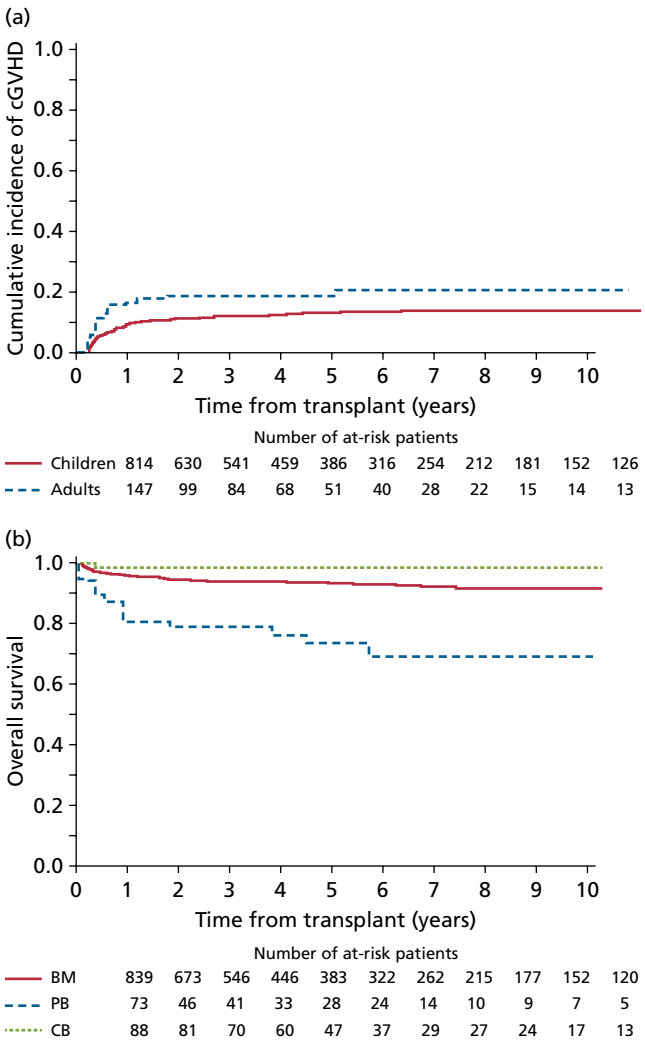

Figure 15.7 Outcomes after HSCT for SCD (a) Unadjusted chronic graft versus host disease, according to age; and (b) overall survival, according to stem cell (Source Gluckman E, *et al.* 2017/ with permission of Elsevier. *Blood.*)

the brain, lungs, kidneys or eyes. Children who are placed on long-term blood transfusions for any indication should also be evaluated for HSCT. Although it is clear that high-risk patients benefit from this treatment, the role of HSCT in asymptomatic children is not defined. Severe organ dysfunction increases the risks from the procedure, and hence discussion for HSCT should be started early when eligible indications are identified.

Gene therapy

Correction of SCD by gene therapy requires efficient insertion of a gene into repopulating haemopoietic cells and regulated expression in erythropoietic lineages. An anti-sickling haemoglobin, constituting 20–30% of the total haemoglobin, would be enough to produce clinical response. Mouse models of SCD have considerably helped in the effort to develop gene therapy and correction of the sickling phenotype has been demonstrated in such animals. Early ongoing clinical trials for gene therapy using CRISPR gene editing technique are very promising.

Psychosocial issues

Recurrent pain and the unpredictable course of the illness place SCD patients at higher risk of depression and anxiety with poor family relationships. Despite this, with integrated medical care and social support most patients with SCD are well-adjusted. Addiction to narcotics is an uncommon phenomenon and is the result of social influences rather than analgesic therapy. Attention to psychological wellbeing as well as educational and vocational support are important components of the care provided to SCD patients.

Haemolysis

Definitions

Haemolysis indicates that the destruction of red cells is accelerated. Normally, in adults, the bone marrow output is well below its maximal capacity. Red cell production can be increased more than 10-fold in the adult by increasing the cellularity of existing haemopoietic marrow, as well as by expansion of haemopoietic marrow into the long bones. In the newborn, and during infancy, marrow expansion depends on expanding the medullary cavity of bones, leading to thinning of cortical bone. These bony changes are most extreme in the β-thalassaemia syndromes, but some skeletal changes, usually some bossing of the frontal bones, may be seen in more extreme hereditary haemolytic anaemias of other causes. Increased red cell destruction is often completely matched by increased production, resulting in compensated haemolysis. When the rate of haemolysis exceeds the maximum erythropoietic capacity of the bone marrow, or when the latter is limited (e.g. because of inadequate supply of iron or folate or by ineffective erythropoiesis), the result is haemolytic anaemia.

General features of haemolysis

The clinical and laboratory aspects of haemolysis depend on the consequences of increased red cell destruction and production as well as the main process by which destruction takes place. Increased red cell destruction leads to an increase in unconjugated bilirubin from increased haemoglobin turnover. Unconjugated bilirubin does not appear in the urine, although there will be an increase in urinary urobilinogen. The bilirubin level is usually not more than 2–3 times normal because the normal liver is able to increase excretion to compensate for at least some of the increased production. Jaundice is usually mild in hereditary haemolytic anaemias although there are important exceptions.

In the neonate, particularly premature infants, liver function is not fully developed and more severe jaundice requiring urgent therapeutic intervention may occur. A rare but potentially confusing problem is the coinheritance of Gilbert syndrome, which comprises a group of congenital liver enzyme deficiencies that impair bilirubin conjugation. On its own, Gilbert syndrome does not produce clinical jaundice except when there is inadequate calorie intake, but in conjunction with haemolytic anaemia the hyperbilirubinaemia may be considerable. The increased bilirubin of haemolysis does increase the risk of gallstones and cholecystitis, which in turn may lead to an increase in serum bilirubin.

In the degradation of haemoglobin, the molecule is broken down into two constitutive subunits, α and β globin, which are bound to haptoglobin, the complex being rapidly internalised in the hepatocyte after binding to the haptoglobin complex receptor. In the presence of haemolysis, serum haptoglobin levels are

Hoffbrand's Postgraduate Haematology, Eighth Edition. Edited by Adam J Mead, Michael A Laffan, Graham P Collins, Deborah Hay, and A Victor Hoffbrand (Consulting Editor).

Companion website: www.wiley.com/go/mead/HPH8e

greatly reduced or absent. However, haptoglobin is an acute-phase protein and levels will increase in the presence of inflammation. Haemopexin is another haem-binding protein produced by the liver that is decreased in haemolysis. Chronic haemolytic anaemia may increase the iron content of the body through increased iron absorption as a consequence of anaemia coupled to the retention of the haem iron following binding to haptoglobin and haemopexin. In rare cases of inherited haemolytic anaemia, this iron overload may be sufficient to produce clinically important effects, particularly if there is coinheritance of a haemochromatosis gene. In most haemolytic anaemias, owing to membrane defects, the destruction of red cells takes place extravascularly in the reticuloendothelial system, particularly in the spleen, and the iron is retained. When destruction is intravascular, free haemoglobin will be released into the plasma, producing haemoglobinaemia and methaemalbuminaemia, and will pass through the glomerulus to produce haemoglobinuria and haemosiderinuria. Iron deficiency is thus more likely than overload in intravascular haemolysis.

Increased red cell production leads to expansion of the red cell precursor compartment of the bone marrow, as described above. There are also changes in the structure of the marrow as a consequence of the chronic anaemia, which allows the early release of reticulocytes and, in more marked cases of haemolytic anaemia, nucleated erythroblasts and even myelocytes. In the peripheral blood, the polychromasia and macrocytosis of reticulocytosis are the result of this increased throughput and release. The increased cell production requires an increased supply of folate which, at least theoretically, can produce folate deficiency unless supplements are given. It is usual to give folic acid (400 µg daily or 5 mg once weekly) to people with chronic haemolytic anaemia. The main features of haemolytic anaemia are summarised in Table 16.1.

Table 16.1 Main features of haemolytic anaemia.

Increased red cell destruction
Unconjugated hyperbilirubinaemia
Mild jaundice
Increased risk of gallstones
Increased urinary and faecal urobilinogen
Decreased serum haptoglobin and haemopexin
Extravascular changes
Increased iron stores
Splenomegaly
Intravascular changes
Haemoglobinaemia and haemoglobinuria
Haemosiderinuria
Methaemalbuminaemia
Decreased iron stores
Increased red cell production
Marrow expansion: bone changes
Increased erythropoiesis: ↓ myeloid/erythroid ratio
Reticulocytosis: polychromasia
Increased folate requirements: macrocytosis

Classification

Because of the unique structural and functional specialisation of the mature red cell, the impact on it of a wide range of exogenous or endogenous changes is relatively uniform: the cell will be destroyed prematurely. According to the site of the primary change, haemolytic disorders have been traditionally classified as being due either to intracorpuscular or to extracorpuscular causes. According to the nature of the primary change, haemolytic disorders have also been classified as inherited or acquired. These two classifications correlate almost completely with each other, in that extracorpuscular causes are usually acquired, whereas intracorpuscular causes are usually inherited. One notable exception is paroxysmal nocturnal haemoglobinuria, a disease in which an intracorpuscular defect is acquired as a result of a somatic mutation (see Chapter 31).

Although in every cell all molecules and organelles are naturally interdependent, it is convenient to consider the red cell as a conveyance for a large amount of haemoglobin contained in a plasma membrane, the stability of which is maintained by appropriate metabolic machinery and structural organisation of the proteins. Unfavourable genetic changes in any of these components may cause haemolysis. Accordingly, inherited haemolytic disorders can be classified into three major groups: (i) genetic disorders of haemoglobin (see Chapters 14 and 15); (ii) abnormal membrane (including the cytoskeleton) and (iii) abnormal metabolism (enzymopathies).

Red cell membrane disorders

The red cell membrane

The red cell membrane, like all other cell membranes, consists of a lipid bilayer that is stabilised and given specific properties by the proteins, glycolipids and other specialised molecules and structures with which it is associated. The lipid bilayer consists of approximately equal molar quantities of phospholipids and cholesterol molecules. The charged phosphatidyl groups of the phospholipids are hydrophilic and form the outer and inner surfaces of the bilayer. The interior of the membrane is formed by hydrophobic bonding of the acyl chains and cholesterol, which form the internal parts of the two leaflets (Figure 16.1). The arrangement is energy efficient but the two leaflets are not symmetrical. The outer leaflet consists mainly of phosphatidylcholine and sphingomyelin, the inner leaflet of phosphatidylethanolamine and phosphatidylserine (Figure 16.2). Maintenance of the asymmetry and the proper function of the membrane requires energy. In mature red cells, this is provided by adenosine triphosphate

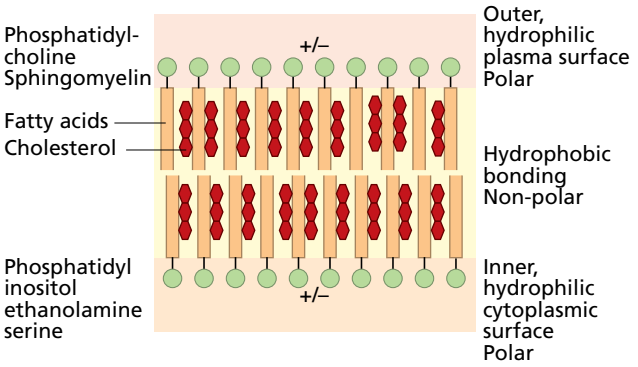

Figure 16.1 Arrangement of membrane lipids. The acyl chains of the diacylphosphatidylglycerides are hydrophobic non-polar domains and they form hydrophobic bonds with the acyl groups of the opposite layer. Cholesterol is present in roughly equimolar amounts and determines the fluidity of the membrane.

(ATP) from the glycolytic pathway and reducing power mainly in the form of glutathione.

The normal biconcave shape and function of the red cell membrane are determined by the membrane proteins and their interactions with the lipid bilayer and with each other. There are two main sorts of protein–membrane associations. The integral proteins have strong hydrophobic domains that are associated with the hydrophobic part of the bilayer. Many of these integral proteins span the membrane and provide channels between the plasma and cytosolic compartments. The cytosolic inner domains of these proteins interact with each other and with the second main group, the proteins of the membrane skeleton. The integral proteins that provide the

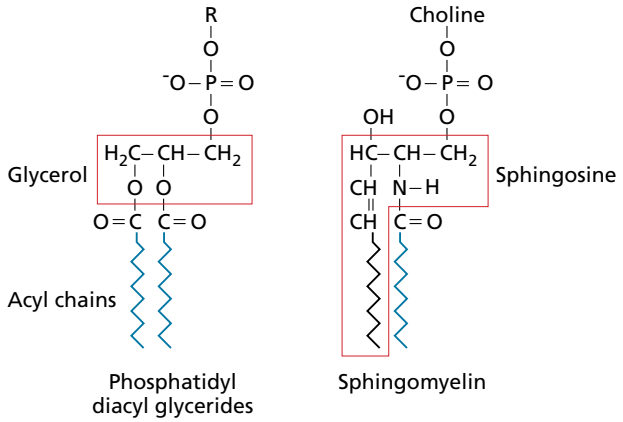

Figure 16.2 Main lipids of the red cell membrane. The outer, plasma, layer contains mostly neutral lipids, sphingomyelin and phosphatidylcholine (lecithin). The inner, cytoplasmic, layer contains mostly acidic groups, phosphatidylserine, phosphatidylethanolamine and phosphatidylinositol. R may be choline, serine, ethanolamine or inositol.

links between the lipid bilayer and the membrane skeleton have conveniently been referred to as 'vertical connections', whereas the proteins of the membrane skeleton that comprise the inner network of the cell membrane are characterised as 'horizontal connections'. Genetic abnormalities that produce spherocytosis mainly have mutations affecting the vertical connections. Mutations of the horizontal system usually produce elliptocytosis or more bizarre-shaped changes. The main proteins are listed in Table 16.2, and their arrangement is shown schematically in Figure 16.3.

In addition to the compartments mentioned so far, there are numerous surface proteins that provide the main interface with the plasma, including the blood group systems and other receptors. Many of these molecules are heavily glycosylated, as are the integral proteins, the glycophorins; sialic acid, which comprises the main side-chain of the glycophorins, contributes the most to the negative surface charge of the erythrocyte. Some of these surface proteins are linked to the membrane by the glycosylphosphatidylinositol (GPI) anchor, which provides the hydrophobic domain required for association with the inner hydrophobic part of the membrane. Somatic mutations in the gene for phosphatidylinositol glycan A (*PIGA*) leads to a failure to produce the anchor and to paroxysmal nocturnal haemoglobinuria (discussed in Chapter 31).

The integral proteins and vertical interaction

The two major integral proteins that span the lipid bilayer are band 3 (the anion channel protein) and glycophorin C. Band 3 and associated molecules, 4.2 (pallidin) and ankyrin (2.1), form one major vertical interactive pathway with binding to the β-chain of the spectrin tetramer through ankyrin. Glycophorin C and protein 4.1 also provide a vertical interaction, but the association with spectrin is through a link with actin, which is a key part of the horizontal network. The band 3–4.2–ankyrin– spectrin complex is a central part of the organisation of the lipid bilayer and loss of part of this complex leads to loss of membrane, thereby reducing the surface-area-to-volume ratio of the red cell and leading to the characteristic spherocytes of hereditary spherocytosis.

The main protein of the membrane skeleton is spectrin, consisting of two subunits, α and β, which associate side by side to produce a heterodimer. The dimers associate head-to-head to form tetramers which when fully extended are ~200 nm long. The tail end of the dimer makes contact with a short actin filament composed of 14 monomers; the interaction between spectrin and actin is stabilised by protein 4.1, adducin and dematin. Binding of spectrin dimers to actin filaments produces the more or less hexagonal network of spectrin tetramers on the inner surface of the membrane associated with the lipid bilayer. Spectrin–actin–4.1 interactions provide much of the flexibility of the red cell membrane. Spectrin qualitative defects that affect these horizontal interactions

† Periodic acid–Schiff stain: bands seen only on PAS-stained gels.

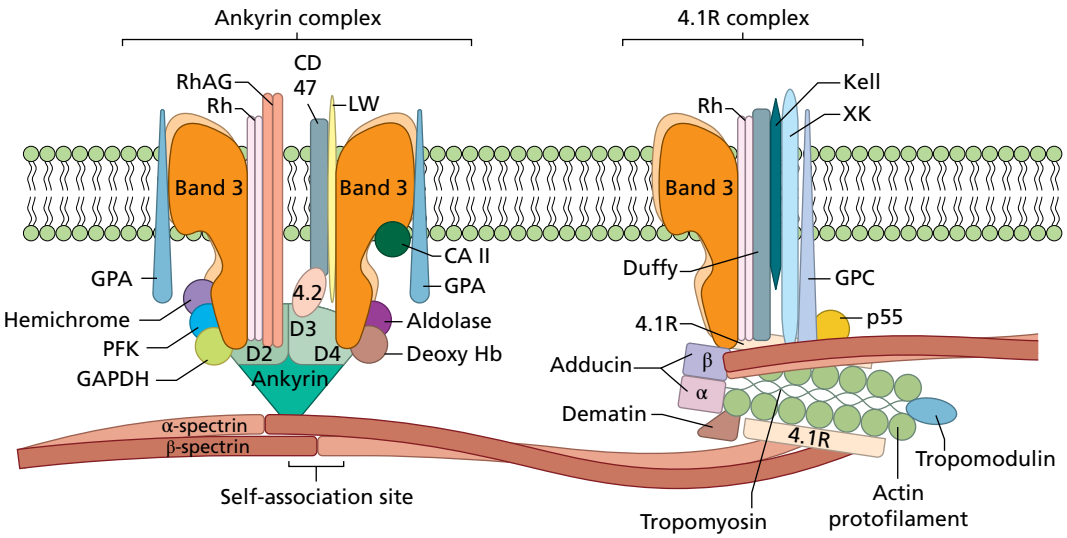

Figure 16.3 A schematic model of the structural organisation of the red cell membrane. The membrane is a composite structure in which the lipid bilayer is linked to the spectrin-based membrane skeleton. The linking of the lipid bilayer to the membrane skeleton is mediated by band 3-ankyrin-protein 4.2– β-spectrin interactions and by glycophorin C–protein 4.1R interaction (vertical interactions).
The horizontal interactions in the spectrin network involve spectrin dimer–dimer interaction and spectrin–actin–protein 4.1 interaction.

tend to induce a loss of structural stability of the membrane and elliptocytosis.

The clinical phenotypes of hereditary membrane disorders

Mutations in the genes that control the proteins of the membrane and their interaction mainly produce changes in the shape of red cells, which is characteristic of any individual. Many of the conditions are inherited as autosomal dominant disorders, homozygosity for major defects mainly being lethal. Severe, bizarre or unexpected red cell morphology is often produced by double heterozygosity or inheritance of more than one defect of the membrane proteins. Mutations affecting the red cell membrane are many and heterogeneous, but the effect on the phenotype can be classified in five main categories: (i) hereditary spherocytosis; (ii) hereditary elliptocytosis and hereditary pyropoikilocytosis (severe form of elliptocytosis); (iii) Southeast Asian ovalocytosis; (iv) hereditary acanthocytosis and (v) hereditary stomatocytosis.

Hereditary spherocytosis

As the name implies, hereditary spherocytosis (HS) is a genetically determined haemolytic anaemia characterised by the spherical shape of the affected red cells. The spherical shape produces a characteristic appearance in the stained blood film of round cells with smaller than normal diameter, which lack the area of central pallor of the normal biconcave discs (Figure 16.4). The disorder is generally inherited as a dominant condition with a wide spectrum of severity. The usual clinical picture is of mild to moderate haemolytic anaemia, but varies from severe neonatal haemolysis with kernicterus (rare) to clinically silent and asymptomatic (usual) haemolysis. Autosomal recessive inheritance occurs in a few mutations, often producing severe haemolysis. In detailed analysis of white populations, HS is one of the most common haemolytic anaemias due to membrane defects, with a prevalence of clinically apparent disease of 200–300 per million population. The occurrence of clinically silent cases probably means that the overall prevalence is likely higher. However, it has been reported in all regions of the world.

Clinical features

The commonest forms of HS present as mild anaemia and jaundice, with a modestly enlarged spleen. However, the genetic heterogeneity of HS (see below) is reflected in the clinical presentation. As the main site of increased red cell destruction in HS is the spleen, it is not surprising that the size of the spleen tends to reflect the severity of the haemolysis, although splenomegaly is rarely marked, enlargement below the umbilicus being very uncommon. When HS presents in adolescence or adult life, it needs to be distinguished from other causes of spherocytosis, particularly warm autoimmune haemolytic anaemia.

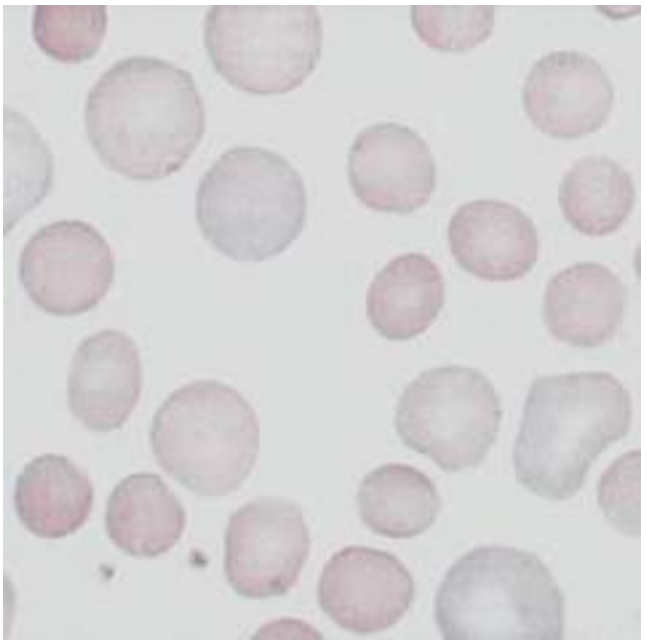

Figure 16.4 Hereditary spherocytosis, peripheral blood. Small spherocytic red cells lack area of central pallor. Large polychromatic red cells (reticulocytes) result in normal MCV, although MCHC may be increased.

HS may present at birth. The functions of the spleen become mature only after birth, so severe anaemia *in utero* is rare. Erythropoiesis is highly active before birth, but enters a phase of reduced activity in the neonatal period. Severe anaemia, developing over 5–30 days post delivery and requiring transfusion, may result from this double physiological development of reduced production and increased destruction, but the anaemia may greatly reduce during the first year of life as compensatory erythropoiesis develops. Decisions about splenectomy do not need to be taken during this time.

Molecular pathology

About 60% of HS cases result from a defect in the ankyrin–spectrin complex, with the genes for ankyrin (*ANK1*) and the α- and β-subunits of the spectrin dimer (*SPTA1*, *SPTB*) being implicated in different genetic types (Table 16.2). A further 25% involve deficiency in band 3, the anion channel. In the remainder of the dominantly inherited HS families, there is a deficiency of protein 4.2 or no abnormality has yet been identified. Deficiency of protein 4.2 is particularly common in Japanese families with HS (Table 16.2). The rare cases of Rh null also present with spherocytosis and mild anaemia. These defects involving spectrin– ankyrin–band 3 interactions affect the vertical interactions.

Laboratory diagnosis

The typical findings of extravascular haemolysis are present in HS (Table 16.1). The diagnosis is usually made on the basis of red cell morphology, backed up where possible with a family history. The mean corpuscular haemoglobin concentration (MCHC) is often increased above 350 g/L, but the presence of macrocytic reticulocytes usually results in a low normal mean corpuscular volume (MCV) rather than true microcytosis. These changes result not only from the reduction of the surface-area-to-volume ratio, but also from the slight dehydration of HS cells. A number of variants of the typical HS features have been described, usually the more severe forms that may have denser and less perfectly round cells in the peripheral blood. In infancy, the morphology may be more difficult to interpret. The effect of immature splenic function and the macrocytosis and anisocytosis of infancy combine with the HS phenotype to produce red cell appearances not typical of the developing HS. Family studies can assist in the diagnosis.

Osmotic fragility test

The osmotic fragility test, which measures the sensitivity of red cells to lysis *in vitro* to swelling caused by incubation in increasingly hypotonic saline solutions, is the most appropriate test to diagnose HS, although its sensitivity decreases in milder cases. In normal red cells with the biconcave disc shape, 50% lysis occurs when the saline solution reaches about 0.5% sodium chloride. The HS cells have less ability to swell and so lyse at higher salt concentrations, producing a right-shifted osmotic fragility curve. One of two patterns may be seen in HS: a generally right-shifted curve, which is the more common finding, and one where there appears to be a 'tail' of lysis-sensitive cells. Incubation of blood for 24 hours at 37 °C accentuates the fragility (Figure 16.5). An alternative to the osmotic fragility test is to measure the extent of membrane surface area loss by flow cytometry following labelling with eosin-5-maleimide (EMA binding test). EMA binds to band 3, which is selectively lost during loss of membrane surface area in red cells from HS patients. The EMA binding screening test has to be used in conjunction with morphology because Southeast Asian ovalocytosis, congenital dyserythropoietic anaemia type II, and cryohydrocytosis also give reduced fluorescence because they can create a long-range modulation effect on the dye binding site in band 3 protein.

Identification of protein abnormalities or gene defects

Methods that identify the defective gene or its product are the most specific for membrane defects but are beyond the scope of most routine haematology laboratories. The original identification of membrane proteins using sodium dodecyl sulfate-solubilised polyacrylamide gel (SDS-PAGE) electrophoresis has led to the classification according to the banding system indicated in Table 16.2 The identification of specific genetic abnormalities may be important in compound haemolytic syndromes, but requires specialised laboratories.

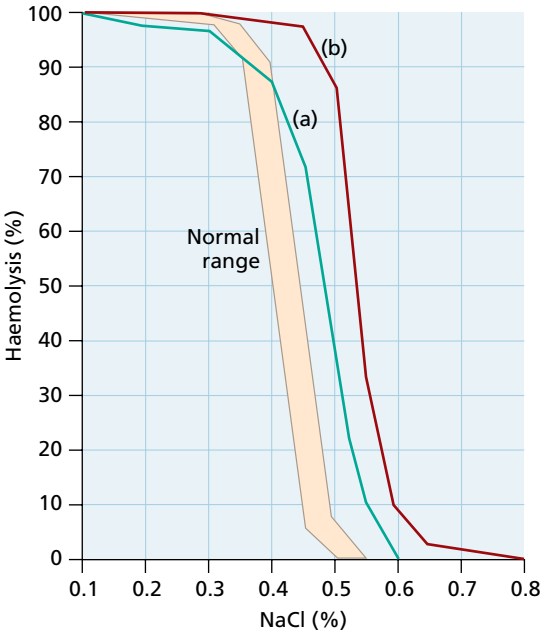

Figure 16.5 Osmotic fragility test in hereditary spherocytosis. Osmotic fragility is increased in the microspherocytes (right shift), but there is also a small population of resistant cells due to increased reticulocytes (a). After splenectomy, the microspherocytes remain, but the proportion of reticulocytes is reduced to normal values and the resistant cells are not seen (b).

Clinical course and complications

In most kindreds, the course of the disorder is similar in affected members although, as with most inherited defects, there is some variable penetrance and it is not rare to find a very mildly affected parent with more severely affected offspring. As with all congenital haemolytic anaemias, the anaemia may be aggravated by environmental factors. This may be consequent of an increase in the red cell destruction or a decrease in production. Increased jaundice may occur during viral infections or bacterial sepsis, the anaemia also being aggravated by a decrease in production consequent on the effects of the acute-phase response or the inhibition of erythropoiesis by interferon (IFN)-γ.

Primary infection with parvovirus (erythrovirus) B19 produces a specific and marked inhibition of erythropoiesis, often characterised as an aplastic crisis. In patients with shortened red cell survival, severe anaemia may be produced by the inhibition, which lasts for some 4–7 days. In normal individuals with a red cell lifespan of 120 days, such an inhibition produces no clinical effect. The anaemia associated with parvovirus infection in HS may require urgent transfusion.

The diagnosis is made by finding absent parvovirus antibodies with subsequent appearance of IgM antibodies. The presence of IgG antibodies at the time of the anaemia excludes the diagnosis.

Acute anaemia due to splenic sequestration is a relatively uncommon complication of HS in childhood. The pathogenesis is probably increased splenic size and activity leading to increased trapping of HS cells within the spleen. This complication may also require urgent transfusion. Malnutrition may increase anaemia because of folate deficiency, but also from increased jaundice through the effect of low-calorie input on unconjugated bilirubin levels in the blood. The anaemia of pregnancy may aggravate a haemolytic anaemia and hence bring the condition to the attention of clinicians and patients. Classical HS is not a risk to mother or child in pregnancy.

Gallstones are an expected complication in HS, as in other chronic haemolytic anaemias. Silent gallstones require no intervention. Recurrent cholecystitis or biliary colic may require cholecystectomy accompanied by splenectomy (see below). Leg ulcers are a rare but well-recognised complication of HS, as with other chronic haemolytic anaemias. Extramedullary haemopoietic masses, usually paravertebral, occur rarely in more severe HS.

Management

Patients with well-compensated haemolysis and no transfusion requirements need no treatment other than reassurance and folic acid supplements (e.g. 400 µg daily or 5 mg weekly). For people with a well-balanced and adequate diet, folic acid supplements are probably unnecessary, but custom dictates the practice should be continued. Radiolucent gallstones, if detected by chance on ultrasound, are common and need no treatment unless complications arise. Gallstones without recurrent inflammation are not a risk factor for carcinoma of the gallbladder. Recurrent cholecystitis or obstruction would be an indication for cholecystectomy, which would also be an indication for splenectomy.

Splenectomy

For the great majority of patients with autosomal dominant forms of HS, splenectomy increases the lifespan of the HS red cells to near normal and alleviates the haemolysis and hyperbilirubinaemia, since the spleen is responsible for the removal of spherocytic red cells with reduced surface area. However, splenectomy carries short- and long-term risks that must be weighed against the benefits in any individual patient. After splenectomy, the blood film continues to show spherocytosis together with common changes associated with splenectomy. The osmotic fragility remains increased.

Risks of splenectomy

The immediate risks associated with splenectomy include those of any abdominal operation together with an increased risk of thrombosis, associated with a marked rise in platelet count that occurs promptly after splenectomy. In HS, in which the erythropoietic drive returns to normal following splenectomy, the platelet count also returns to normal and the risk diminishes. In conditions where haemolysis persists, the platelet count remains elevated, sometimes markedly, and the increased risk of thrombosis continues.

The major hazard of splenectomy is the long-term susceptibility to severe infection, so-called overwhelming postsplenectomy infection (OPSI). The spleen plays an important role in filtering and phagocytosing bacteria and removing parasitised erythrocytes from the blood. The spleen is the major source for mounting the rapid, specific IgM response to organisms that enter through the gut. The main organisms of this class are the encapsulated organisms, *Streptococcus pneumoniae*, *Haemophilus influenzae* type B and *Neisseria meningitidis*. Pneumococcal infection is responsible for about 70% of OPSI and has a 60% mortality. Lack of a spleen greatly increases the virulence of the infection, with progression from the first feeling of fever and non-specific flu-like symptoms to irreversible endotoxic shock occurring in a matter of hours. Patients may present with purpura, evidence of disseminated intravascular coagulation, multiorgan failure, hypotension and peripheral limb ischaemia. Diarrhoea and vomiting are common prodromes. It is this speed of progression that makes the prophylaxis of this fortunately uncommon complication so important. Prophylaxis depends on education and awareness for the patient, specific measures to reduce the risk from particular organisms and the provision of information concerning the splenectomy for healthcare workers (Table 16.3). There is no direct evidence that phenoxymethylpenicillin (e.g. 250 mg twice daily) reduces the risk of OPSI in splenectomised patients, but good evidence that it does so in homozygous sickle cell patients who have functionally inactive spleens. It is on this evidence that such antibiotic prophylaxis (or erythromycin 250 mg b.d. for those sensitive to penicillin) is recommended. The actual incidence of OPSI is difficult to calculate. The overall risk has been stated as 0.04 per 100 patient-years for patients without added immunosuppression, but considerably higher for those immunocompromised by malignancy or chemotherapy. The risk is greatest in the first 2 years after splenectomy but continues lifelong. Children under the age of 5 years are particularly susceptible and splenectomy should be avoided in this group if at all possible.

Indications for splenectomy

Patients with marked haemolysis producing symptoms or requiring transfusion should be splenectomised, although preferably not before the age of 5 years (later if possible). Recurrent aplastic crises are also an indication. Attacks of cholecystitis or biliary colic warrant cholecystectomy and splenectomy, but symptomless gallstones are not a necessary indication. In small children with severe anaemia, partial splenectomy has been used to decrease the extent of anaemia, but

Table 16.3 Guidelines for prevention and management of infection in the splenectomised patient.

It is essential to educate patients regarding the risk and the importance of prompt recognition and treatment of infections. Leaflet card for patients to alert health professionals to risk of OPSI.
All patients should receive polyvalent pneumococcal, *Haemophilus influenzae* type b and meningococcal vaccination.
Vaccines should ideally be given 2 weeks prior to splenectomy or 2 weeks after splenectomy.
Pneumococcal immunisation
- Infants <2 years*: should be immunised with three doses at the national schedule with polyvalent-PCV vaccination. One dose of PPV at 2 years should also be offered.
- Children 2–5 years: one dose of PPV or PCV13 followed by PPV depending on previous routine childhood vaccinations.
- Children >5 years and adults: irrespective of immunisation status should continue to receive one dose of PPV by measuring antibody response.
- Responders should be revaccinated with PPV at 5-year intervals.

Haemophilus influenzae b (Hib) vaccination
- Infants <2 years: should complete their vaccination according to the national schedule.
- Children >2 years and adults: should be offered one dose of Hib-containing vaccine irrespective of their previous immunisation status.
- Meningococcal vaccination (Men)
- The quadrivalent MenACWY conjugate vaccine is recommended in preference to the plain polysaccharide meningococcal vaccine for all age groups.
- Infants <2 years, if immunised or partially immunised: 3 and 4 months of age; MenC conjugate vaccine at 12 months of age as well as quadrivalent MenACWY no earlier than 1 month later. At 2 years an additional booster of Hib/MenC should be given at second birthday.
- Children >2 years and adults: should receive one dose of MenC conjugate vaccine plus a single dose of quadrivalent MenACWY conjugate vaccine 1 month later.
- Travellers to endemic areas should receive quadrivalent MenACWY conjugate vaccine before travelling.

All patients should receive yearly influenza vaccination.
Lifelong prophylactic antibiotics (oral phenoxymethylpenicillin or an alternative).
Patients developing infection despite measures should receive systemic antibiotics and be admitted urgently to hospital.
Awareness of risks of malaria and scrupulous prophylaxis if at risk.

PCV, vaccination pneumococcal conjugate vaccines; PPV, pneumococcal polysaccharide vaccine; PCV13, 13-valentPCV.
* Age at which splenectomy is performed.

the performance of this procedure requires special surgical skills and there is need for careful long-term follow-up.

Hereditary elliptocytosis

Deficiency of spectrin tetramers, the horizontal links of the cytoskeleton, produces a wide spectrum of disease from fully compensated haemolysis with mildly elliptocytic red cells to severe and life-threatening anaemia with grossly distorted cells. When the morphological characteristic is a relatively uniform elliptical shape, the condition is referred to as hereditary elliptocytosis (HE). Haemolytic anaemia associated with the more distorted forms, which are also heat labile, was previously called hereditary pyropoikilocytosis (HPP). Recent evidence implies that HPP is a severe form of HE. Within a family, HE and HPP may both be present, the more severely affected individuals having both spectrin deficiency as well as a relative deficiency of spectrin tetramers. This may be caused by coinheritance of a low-expression allele for α-spectrin, compound heterozygosity for two HE alleles or HE homozygosity. A number of families have been described in which mutations involving the protein 4.1 gene result in failure to produce the protein. In heterozygotes with this variant, elliptocytosis occurs without haemolysis; in homozygotes, there is a severe haemolysis with extensive cell fragmentation.

Clinical features

As with HS, haemolytic anaemia in HE has a heterogeneous clinical presentation and molecular basis. The anaemia can range from very mild to severe with splenomegaly and few cases of hydrops fetalis have been reported. The clinical management of HE parallels that of HS.

Mild common hereditary elliptocytosis

Frequently, HE is discovered by chance from a blood film (Figure 16.6) or the presence of marginally raised bilirubin. Some affected people have no evidence of shortened red cell survival, whereas others have a well-compensated haemolytic anaemia.

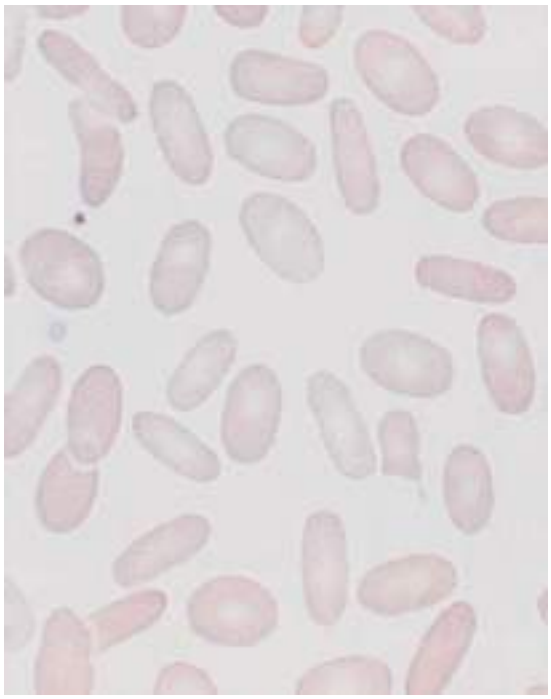

Figure 16.6 Hereditary elliptocytosis, peripheral blood. Characteristic elliptocytes of mild common hereditary elliptocytosis (Source: Haemolytic Anaemia.)

No treatment is required, although the blood film of partners should be examined if there is consanguinity, making homozygosity in offspring possible. For patients with mild haemolysis, anaemia may increase during infections, in pregnancy, with folate deficiency or with other conditions likely to enhance anaemia.

Silent carriers: low-expression genes

Mutations that produce low expression of α-spectrin may lead to no haematological abnormality because of the normal overexpression of α-spectrin in red cells compared with β-spectrin. However, when these defects are inherited in *trans*, on the other allele from an HE gene, HPP may result. Several mutations have been described, particularly commonly in codon 28, which produces low-expression genes. A common polymorphism, intron 45C→T, is spectrin α^{LELY} (LELY denoting 'low-expression allele Lyon').

Haemolytic hereditary elliptocytosis

The characteristics of haemolytic HE previously termed HPP are densely contracted and fragmented cells (Figure 16.7), moderate to severe haemolysis and heterogeneity of manifestations within a family. In general, patients with haemolytic HE have spectrin deficiency in addition to the abnormalities of spectrin–spectrin contacts resulting in tetramer deficiency. One parent of an HE propositus may have normal haematology

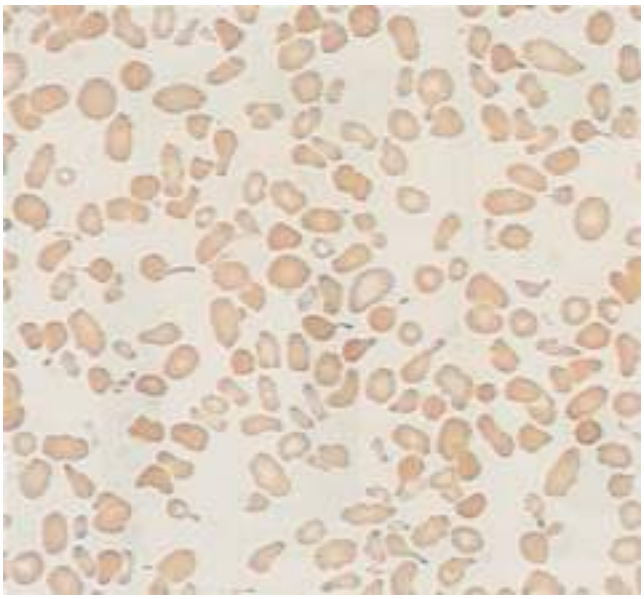

Figure 16.7 Hereditary pyropoikilocytosis, peripheral blood. Marked anisocytosis and poikilocytosis from a child with homozygous hereditary elliptocytosis.

but carry a mutation in *trans*, which leads to spectrin deficiency. The affected cells show thermal lability and fragmentation at lower temperatures than normal, and erythrocytes are mechanically unstable.

Hereditary elliptocytosis and poikilocytosis in the neonate

In the neonate, the manifestations of HE may be a more marked poikilocytosis resembling HPP, with more fragmented red cells. These red cells are susceptible to fragmentation above 46 °C, whereas normal cells only fragment above 50 °C. The morphological changes and haemolysis gradually decrease over the first year until the typical picture of mild HE remains. Treatment of neonatal poikilocytosis is required only if the anaemia is such as to warrant transfusion.

Laboratory investigation

The standard approach to the diagnosis of HE is the identification of haemolysis, coupled to a careful examination of the blood film of the patient and as many first-degree relatives as possible. Examples of blood films are shown in Figures 16.6 and 16.7. Other acquired causes of elliptocytic or fragmented red cells need to be excluded, including iron, folate or vitamin B_{12} deficiency and the microangiopathic haemolytic anaemias. Congenital dyserythropoietic anaemia and thalassaemia intermedia also need to be excluded.

As with the investigation of HS, appropriate gel electrophoresis assays may reveal protein abnormalities, although more specific

identification requires a sophisticated approach beyond the abilities of most haematology laboratories.

Treatment

Patients with chronic haemolysis should be given folate supplements. Splenectomy is indicated for severe haemolytic anaemia in patients with haemolytic HE. Response in HE may not be complete, but the anaemia is usually markedly alleviated. As with HS, there may be an increased risk of increased thrombotic tendency. The precautions against OPSI are the same as for HS.

Hereditary stomatocytosis and related disorders

Stomatocytes are so-called from the mouth-like slit or 'stoma' that appears on blood films (Figure 16.8). Stomatocytes are leaky to cations. There are other variations with Na^+ or K^+ leaks that are clinically similar to stomatocytosis without the obvious morphological changes. All these conditions are inherited in autosomal dominant fashion and mostly produce moderate haemolytic anaemia (haemoglobin 100 g/L or above) and macrocytosis. There are two main variants: over-hydrated hereditary stomatocytosis associated with mutations in *RHAG* gene, in which MCHC is low, and dehydrated hereditary stomatocytosis, with an increased MCHC; this latter including hereditary xerocytosis due to abnormalities of mechanosensitive channel *PIEZO1* and Gardos channelopathy (*KCNN4* variants). Other rare variants of stomatocytosis are pseudohyperkalaemia and cryohydrocytosis with neurological impairment, respectively due to defects in *ABCB6* or *SLC2A1* genes.

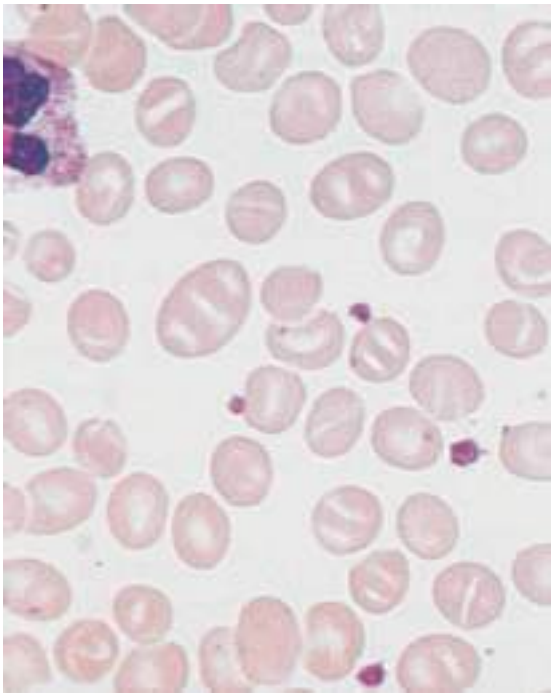

Figure 16.8 Hereditary stomatocytosis, peripheral blood.

Table 16.4 Features of hereditary stomatocytosis and related disorders.

Characteristic	Expression	Group affected
Haemolytic anaemia	Mild to moderate	All variants
	Absent	Hereditary pseudohyperkalaemia
Morphology	Macrocytosis	All variants
	Stomatocytosis	Variable
MCHC	Decreased	Over-hydrated HSt (hydrocytosis)
	Increased	Dehydrated HSt (hereditary xerocytosis, desiccocytosis)
Serum [K^+]	Raised *in vitro*	Pseudohyperkalaemia Dehydrated HSt Cryohydrocytosis
Thrombotic tendency	Post splenectomy	All variants
Fluid balance	Perinatal oedema	Dehydrated HSt

The blood film may show stomatocytosis, but more commonly the film is unremarkable, apart from macrocytosis and polychromasia. The group is rare, estimates suggesting that 1 in 10,000–1 in 100,000 of the population are affected. However, associated features make the conditions important beyond their rarity (Table 16.4). Pseudohyperkalaemia may occur because K^+ leaks rapidly from the red cells at room temperature. In some individuals, there is no evidence of haemolysis, only macrocytosis and pseudohyperkalaemia. Unless the cause of the apparent hyperkalaemia is diagnosed, unnecessary, and even dangerous, investigation and treatment may be undertaken. In some families, the K^+ leak is greatly increased *in vitro* by cold (cryohydrocytosis). In dehydrated hereditary stomatocytosis, there may be marked perinatal ascites that resolves spontaneously over the first year of life, but which again can lead to extensive unnecessary investigation. The third problem with hereditary stomatocytosis, both over-hydrated and dehydrated varieties, is that splenectomy is followed by very marked thrombotic tendencies such that splenectomy should not be performed.

Laboratory investigations

Tests for haemolysis and examination of the blood film of the patient and close relatives are the first steps in diagnosis.

The finding of a raised serum potassium, together with macrocytosis, especially with some evidence of haemolysis, indicates the pseudohyperkalaemia of dehydrated hereditary stomatocytosis. Additional studies involve the measurement of intracellular [Na^+] or [K^+] and their flux through the membrane at different temperatures. Four subgroups have been defined according to the intracellular sodium concentration (normal 5–10 mmol/L). Patients with the pseudohyperkalaemia of dehydrated hereditary stomatocytosis may have normal or slightly high sodium concentrations (12–18 mmol/L); in families with cryohydrocytosis, (temperature-sensitive leak) the sodium concentration is 20–50 mmol/L, and in over-hydrated hereditary stomatocytosis, the sodium concentration is 60 mmol/L or more.

Osmotic gradient ektacytometry analysis that provides simultaneous information on RBC geometry, cytoplasmic viscosity, volume regulation and fluidity of the membrane has been considered for many years the gold standard for the diagnosis of this group of disorders. By this technique, dehydrated stomatocytosis due to *PIEZO1* gene mutations is characterised by a left-shifted profile, and over-hydrated stomatocytosis by a right-shifted profile. Of note, in Gardos Channelopathy, most patients display a normal ektacytometric curve.

Recently the molecular basis of hereditary stomatocytosis has been elucidated, and the genes involved (Table 16.5) are usually included in targeted-next generation sequencing diagnostic panels of hereditary haemolytic anaemias. Consequently the identification of the molecular lesion is now considered mandatory to confirm the diagnosis.

Treatment

There is rarely a need for measures to raise the haemoglobin, and splenectomy should be avoided because of the risk of thrombosis, including hepatic and portal vein thrombosis. If splenectomy is necessary, lifelong anticoagulation should be considered.

Southeast Asian ovalocytosis

A dominantly inherited ovalocytosis is found in parts of Southeast Asia, where Plasmodium *falciparum* malaria is common, particularly in Papua New Guinea, Borneo, Southern Thailand and the Philippines. The red cell morphology is ovalocytic rather than elliptocytic. Stoma-like slits may be present and transverse banding in the red cells is seen (Figure 16.9). Most individuals have no haemolysis except in the neonatal period but, in a few, mild anaemia may be present. The molecular defect is a deletion of nine amino acids at the transmembrane cytosol junction of band 3; the defect possibly limits the mobility of band 3 within the membrane. Homozygosity is rarely found and is presumably lethal *in utero*.

Abnormalities of membrane lipids

Acanthocytosis

Acanthocytes, or spur cells, show prominent, somewhat regular projections on the surface, best demonstrated by scanning electron microscopy. They are formed when the outer lipid layer of the membrane acquires additional lipid. Acanthocytosis is an acquired characteristic of severe liver disease, usually end stage, and the result of interaction of altered plasma lipids.

Table 16.5 Molecular basis of hereditary stomatocytosis and related disorders.

Disease	Defective protein	Gene	Chromosome	Clinical phenotype
Hereditary xerocytosis	FAM38A Mechanosensitive ion channel	*PIEZO1*	16q24.3	Haemolytic anaemia mild-moderate Polycythaemia
Gardos channelopathy	KCa3.1 – Gardos channel	*KCNN4*	19q13.31	Haemolytic anaemia mild-moderate
Overhydrated stomatocytosis	Rh associated glycoprotein	*RHAG*	6p21.1-p11	Haemolytic anaemia
Cryohydrocytosis	Glucose transporter 1 – GLUT1	*SLC2A1*	1p35-p31.3	Haemolytic anaemia Neurologic symptoms (rare cases)
Familial pseudohyperkalaemia	ATP binding cassette subfamily B	*ABCB6*	2q.36	Pseudohyperkalaemia No anaemia
Sitosterolaemia	ATP binding cassette subfamily G	*ABCG5* *ABCG8*	2p.21	Sitosterols accumulation Haemolytic anaemia Macrothrombocytopenia
South East Asian Ovalocytosis	Anion exchange channel – Band 3	*SLC4A1*	17q21.31	Haemolytic anaemia mild/ compensated

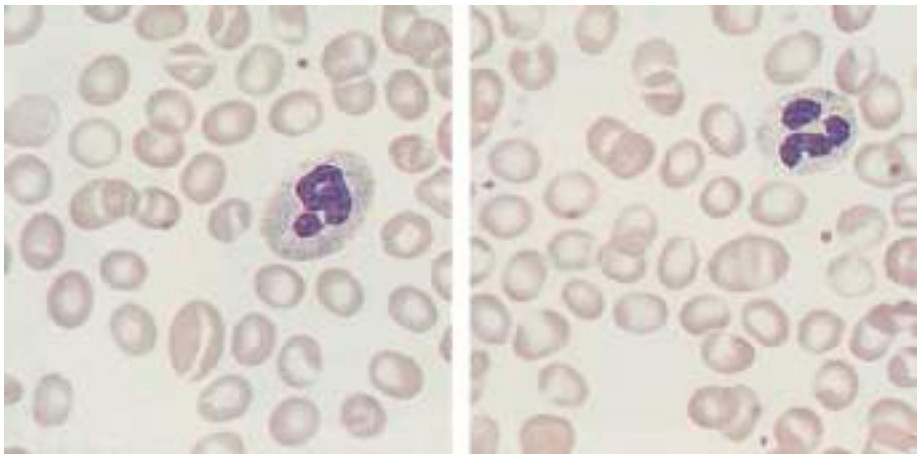

Figure 16.9 Southeast Asian ovalocytosis, peripheral blood films. Mild ovalocytosis and some stomatocytosis. Some cells have apparent transverse ridge.

Abetalipoproteinaemia

Abetalipoproteinaemia is a rare inherited defect with absent β-apolipoprotein, which results in low serum cholesterol, but increased sphingomyelin, which enters the cell membrane and produces the acanthocytes. The main clinical features are retinitis pigmentosa, fat malabsorption and hepatic encephalopathy.

McLeod phenotype

In the McLeod phenotype, acanthocytosis occurs (Figure 16.10), together with decreased expression of the Kell antigen. The defective gene is on the X chromosome (Xp21), close to the genes for Duchenne muscular dystrophy and retinitis pigmentosa, conditions with which the phenotype has been linked. The gene codes for the Kx protein and is linked to the Kell blood group protein in the membrane. There may be mild anaemia.

Defects of red cell metabolism

The main function of the red cell is to carry haemoglobin around the circulation in high concentration and in a functional state so that gas exchange may occur efficiently in the lungs and in the tissue capillaries. In order to fulfil its function, the red cell needs a supply of energy in the form of ATP and a source of reducing power.

Mature red cells contain no DNA or RNA and hence are incapable of protein synthesis, and the only source of energy as ATP is derived from anaerobic glycolysis, the linked reducing system of the hexose monophosphate shunt (pentose phosphate pathway) and the glutathione cycle. ATP is required to maintain the membrane in its deformable state, with asymmetric lipid layers, and to regulate ion and water exchange. Reducing power is required to reduce methaemoglobin to its functional state of deoxyhaemoglobin and to counteract the strong oxidative stresses which a circulating cell carrying molecular oxygen encounters. The main process that reduces methaemoglobin utilises reduced nicotinamide adenine dinucleotide (NADH), produced from nicotinamide adenine dinucleotide (NAD^+) by the glycolytic

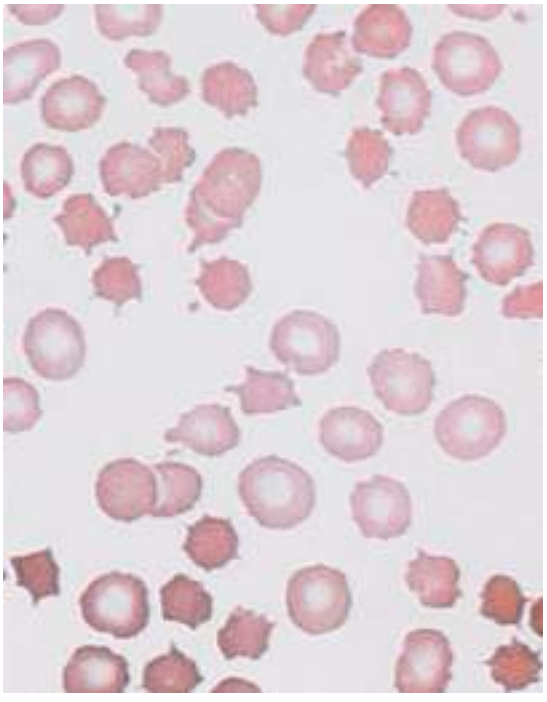

Figure 16.10 McLeod syndrome, peripheral blood. Note the marked acanthocytosis.

pathway. Reduction and detoxification of free oxygen radicals and hydrogen peroxide produced during reactions to infection are provided by reduced nicotinamide adenine dinucleotide phosphate (NADPH) generated by the first steps of the pentose phosphate pathway, catalysed by glucose-6-phosphate dehydrogenase (G6PD) and the linked enzyme 6-phosphogluconate dehydrogenase. NADPH drives the glutathione cycle, glutathione (GSH) being the major reducing agent within the red cell.

The lack of protein synthesis in the mature red cell means that none of the enzymes in the metabolic pathways can be replaced during the red cell's lifespan. Over the 120 days of normal red cell survival, enzyme activities decline at variable but predictable rates. This decline probably contributes to the ageing process of the red cell. Many of the abnormalities that affect red cell metabolism provoke haemolytic anaemia.

The glycolytic pathway (Embden–Meyerhof pathway)

Glycolysis is the process by which glucose is converted to pyruvate through a number of steps, with a net gain of two molecules of ATP generated for each molecule of glucose metabolised. Glucose is derived from the plasma by facilitated transfer through the membrane. Pyruvate and lactic acid are in equilibrium determined by the redox potential of the cell (NAD^+/NADH) and can diffuse out of the cell. The internal milieu of the cell, with its high K^+ concentration and presence of other cations, such as magnesium, necessary for efficient glycolysis, is maintained through the activity of various ion channels in the membrane. The glycolytic pathway also provides the redox reaction to convert methaemoglobin to deoxyhaemoglobin by utilising NADH in a reaction catalysed by methaemoglobin-NADH reductase (cytochrome b_3). The various products and functions of glucose metabolism are shown schematically in Figure 16.11 and in detail in Figure 16.12.

The Rapoport–Luebering shunt

One of the essential roles of erythrocyte metabolism is also to provide sufficient 2,3-diphosphoglycerate (2,3-DPG) to regulate the oxygen affinity of haemoglobin. 2,3-DPG is produced from 1,3-DPG under the influence of the enzyme diphosphoglycerate mutase in linked reactions that form the Rapoport–Luebering shunt: 2,3-DPG is broken down to 3-phosphoglycerate by a phosphatase and thus re-enters the glycolytic pathway. It should be noted that when metabolism takes place via the Rapoport–Leubering shunt, there is bypass of the stage of ATP production (Figure 16.12). The shunt thus not only provides the 2,3-DPG for interaction with the haemoglobin tetramer, but also acts as an energy control mechanism for glycolysis.

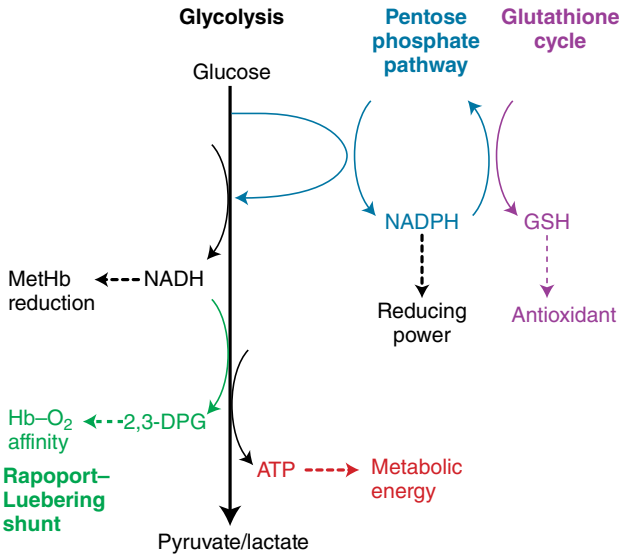

Figure 16.11 Principal pathways of energy production in the mature red cell. The glycolytic pathway provides energy in the form of ATP. Under normal conditions, methaemoglobin (MetHb) is reduced by the coupled reaction with $NADH^+$. The Rapoport–Luebering shunt provides 2,3-diphosphoglycerate (2,3-DPG) for control of haemoglobin oxygen affinity. Reducing power is produced by the pentose phosphate pathway and is linked to redox reactions through the glutathione cycle.

Disorders of the glycolytic pathway

Mutations of most of the enzymes in the glycolytic pathway have been described in association with congenital non-spherocytic haemolytic anaemia (CNSHA), as the result of a failure to produce sufficient ATP. However, when the defective enzyme is expressed throughout the body, other non-haematological symptoms may occur.

Pyruvate kinase deficiency

Pyruvate kinase (PK) is one of the dominant controlling steps in glucose metabolism (together with hexokinase and phosphofructokinase). It catalyses the final steps of the glycolytic pathway with the conversion of phosphoenolpyruvate to pyruvate, with the concomitant phosphorylation of ADP to ATP, leading to overall net gain of ATP from this pathway. There are four tissue-specific isoenzymes codified by two separate genes. The *PKM2* gene, on chromosome 15, produces *PKM1* and *PKM2* through differences in post-transcriptional splicing. *PKM1* is present in skeletal muscles, *PKM2* in leucocytes, kidneys, adipose tissue and lungs. The *PKLR* gene, on chromosome 1, gives rise to PKL in the liver and PKR in red cells, controlled by tissue-specific promoters. The active enzymes are homotetramers. *PKM2*, PKR and PKL demonstrate marked allosteric reactions with several ligands; *PKM1*, on the other hand, has no allosteric interactions.

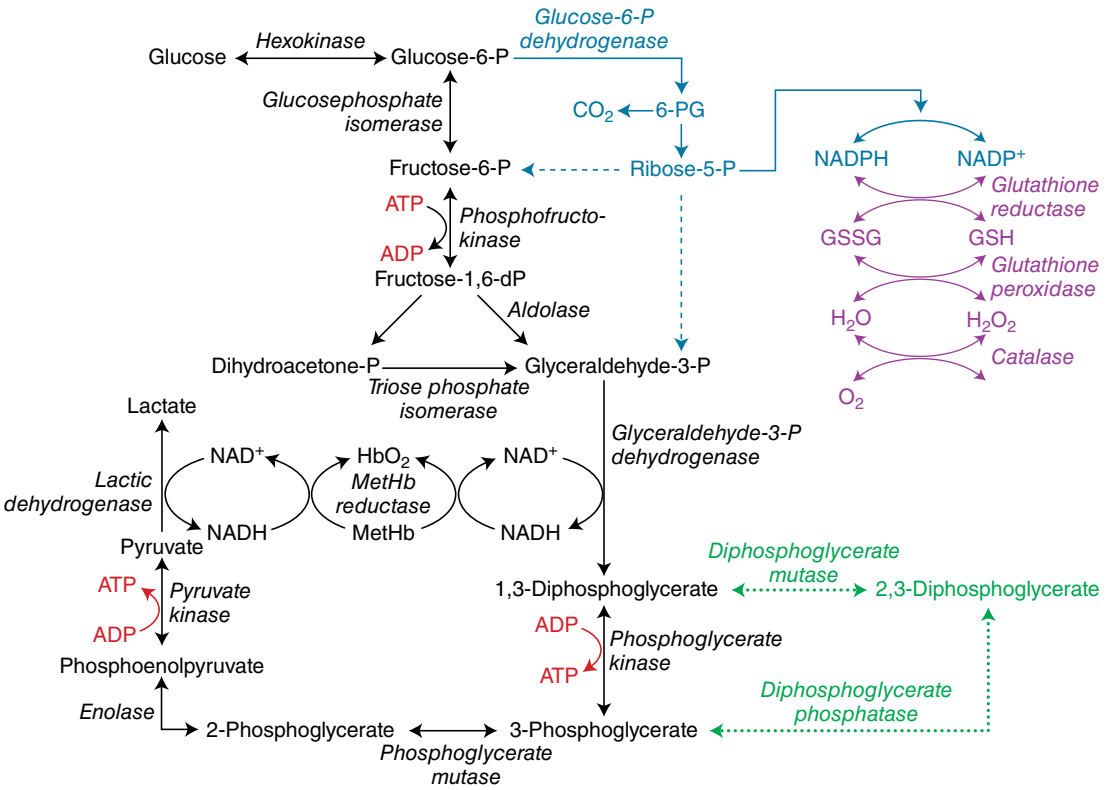

Figure 16.12 The glycolytic pathway and interactions with the other metabolic pathways.

PK deficiency is the most common enzymopathy of the glycolytic pathway inherited in an autosomal recessive form. The prevalence of this disease, as assessed by gene frequency studies, has been estimated to be 1:20,000 in the general white population. More than 250 different mutations have been described in *PKLR* gene, the majority involving missense mutations, a few deletions or mutations in the promoter region. Many individuals are compound heterozygotes. Not surprisingly, there is enormous genetic heterogeneity between affected individuals, reflected in the multiplicity of quantitative and kinetic defects. Because PKR is a homotetramer, the genotype–phenotype correlations are difficult to predict, although by the analysis of an extensive large series of 257 PK deficient patients, it has been shown that patients with homozygous or compound heterozygous non-missense variants (e.g. stop-codon, frameshift and splicing variants) have lower haemoglobin levels, higher numbers of lifetime transfusions and higher rates of complications including iron overload. The comparison of recombinant mutants of human PKR with wild-type enzymes has revealed the effect of amino acid replacements on the molecular properties of the enzyme. However, the clinical manifestations of red cell enzyme defects are not merely dependent on the molecular properties of the mutant protein but rather reflect the complex interactions of additional factors, including genetic background, concomitant functional polymorphisms of other enzymes, post-translational or epigenetic modifications, ineffective erythropoiesis and differences in splenic function.

Deficient PK activity leads to accumulation of substrates further up the pathway, including 2,3-DPG. The increased concentration of 2,3-DPG in PK-deficient red cells shifts the oxygen dissociation curve to the right, indicating low oxygen affinity. It has been reported that PK-deficient patients tolerate apparent anaemia well because the lower haemoglobin content will deliver the same amount of oxygen to the tissues as normal haemoglobin, at least under normal conditions, though oxygen reserves would be limited.

Reticulocytes have alternative means of producing energy in the form of ATP via the oxidative respiratory pathway of the remaining mitochondria. They can also synthesise enzyme in those variants characterised by enzyme instability in mature red cells. Reticulocytes thus have a metabolic advantage over mature red cells in PK deficiency.

Clinical features

The genetic heterogeneity is reflected by the wide variation in the phenotype. The presenting features may vary from severe neonatal jaundice and anaemia, rarely even presenting with hydrops fetalis, severe chronic non-spherocytic haemolytic anaemia requiring repeated transfusions, moderate haemolysis with exacerbation during infections or pregnancy, to symptomless

compensated haemolysis with only a minor apparent anaemia. The majority of reported cases have presented in childhood. PK deficiency does not usually have an adverse effect on the outcome of pregnancy, although occasionally transfusion may be required to compensate for the added dilutional anaemia.

Jaundice, as with other congenital haemolytic anaemias, may be exacerbated by coinheritance of other genes, as in Gilbert syndrome. The haemolysis is nearly always extravascular, though rare examples with some intravascular haemolysis have been detected, particularly in infancy. Gallstones are common in PK deficiency and may lead to bouts of cholecystitis and biliary colic. Jaundice may also be increased by administration of drugs that affect bile excretion. As with other cases of congenital haemolytic anaemia with extravascular haemolysis, excess iron accumulation may occasionally develop, even in the absence of transfusion or coinheritance of a haemochromatosis gene.

The spleen is usually palpable in cases with significant haemolysis, though in milder cases it may only be evident by ultrasound or other imaging techniques.

Laboratory diagnosis

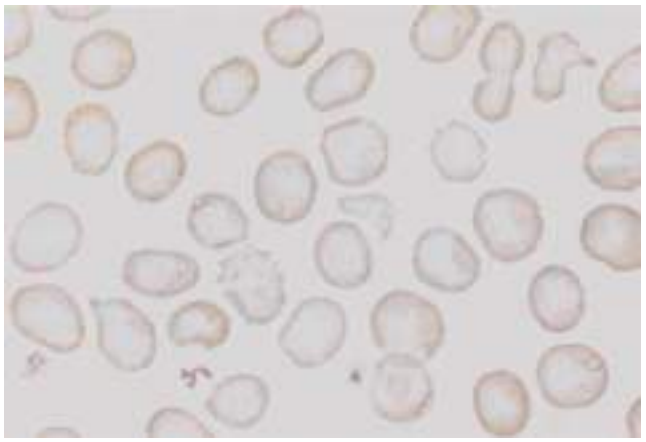
The haematological features of PK deficiency are common to other hereditary non-spherocytic haemolytic diseases; for this reason, the diagnosis ultimately depends on the exclusion of other causes of haemolytic anaemia, upon the demonstration of low enzyme activity and the confirmation at DNA level.

The blood count reveals normochromic anaemia with reticulocytosis, sometimes producing a slight macrocytosis. An increased mean corpuscular haemoglobin concentration is occasionally seen in severe cases due to dehydration brought about by ATP deficiency. Red cell morphology is commonly unremarkable, displaying anisocytosis and a variable portion of spur cells or acanthocytes (which are not specific), particularly after splenectomy. A further increase of reticulocytes postsplenectomy is typically observed (Figure 16.13a–c).

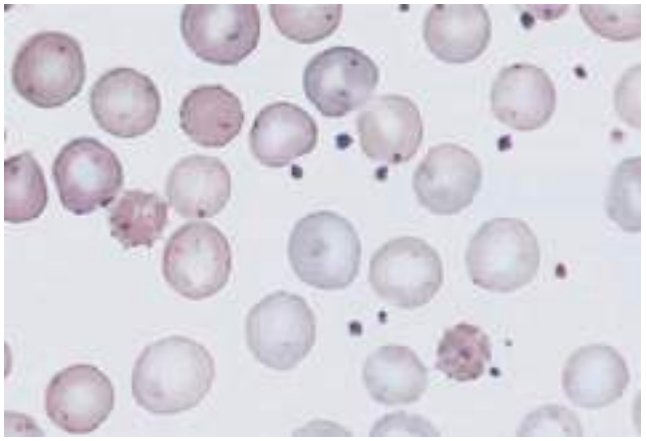
The decreased enzyme activity is associated with an elevated 2,3-DPG level (2–3 times normal). Meaningful enzyme levels can only be achieved after total removal of leucocytes, which have up to 300 times the PK activity of red cells; the effect of reticulocytes also has to be taken into account. No correlation has been described amongst the residual PK activity, degree of haemolysis and clinical severity of PK deficiency.

Management

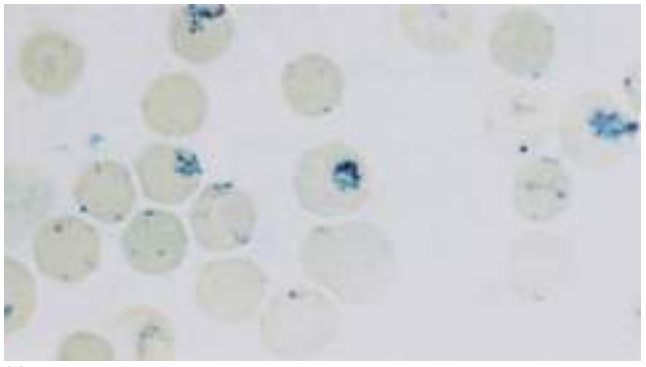
Red cell transfusions may be required in severely anaemic cases, particularly in the first years of life; the haemoglobin then tends to stabilise in many cases at about 60–80 g/L, and transfusions are no longer necessary unless the anaemia is exacerbated by infections, pregnancy or other conditions. Because the delivery of oxygen to tissues is highly efficient due to the high 2,3-DPG content, the decision to transfuse a PK-deficient patient should be based on the clinical conditions rather than on the haemoglobin levels.



(a)



(b)



(c)

Figure 16.13 PK deficiency, peripheral blood. (a) Red cell anisocytosis and poikilocytosis before splenectomy. (b) After splenectomy showing acanthocytes or 'prickle' cells. (c) Gross reticulocytosis after splenectomy (supravital new methylene blue stain) (Source: europeanmedical.info.)

Splenectomy does not arrest haemolysis and should be reserved for severely affected young patients who need regular blood transfusions and to patients who do not tolerate anaemia. It usually results in an increase of 10–30 g/L in haemoglobin,

reducing or even eliminating transfusion requirement. Indications and risks of splenectomy, particularly the risk of overwhelming sepsis, are the same reported for red cell membrane disorders. Aplastic or haemolytic crises may still occur after splenectomy. As with all chronic haemolytic anaemias, folic acid 5 mg per week or 400 μg daily is a sensible supplement. Iron chelation may be required since iron overload is not uncommon in PK deficiency, even in non-transfused patients. Bone marrow transplantation has been performed in a limited number of cases and should be considered an investigational treatment: the analysis of 16 PK-deficient patients known to be transplanted to date, showed a three-year overall survival of 65%. Significantly better survival was observed for patients transplanted before the age of ten.

Recently novel therapeutic approaches have been proposed: a small molecule allosteric activator of PK has been developed with safety and efficacy demonstrated in clinical trials. A gene therapy clinical trial for PK deficiency was launched in 2020.

Other defects of the enzymes of the glycolytic system

Compared with PK deficiency, other defects of the glycolytic pathway are very rare. The main features of these disorders are summarised in Table 16.6.

Hexokinase deficiency

Hexokinase catalyses the phosphorylation of glucose to glucose-6-phosphate (G6P), the first step in the glycolytic pathway. The erythrocytic isoenzyme, derived from alternative splicing, differs from that in nucleated cells, which have oxidative respiration, by lacking a porin-binding domain that links the enzyme to the mitochondrial membrane. The enzyme provides a major rate-limiting step in glycolysis and has extensive allosteric interactions: it is highly pH sensitive and its activity is regulated by its products, G6P, P_i, 2,3-DPG and disulfide compounds. The enzyme activity decays predictably with age of the normal red cell and may be used as a comparator for other enzyme activities where absolute levels may be difficult to interpret because of the age distribution of the red cells.

Hexokinase deficiency has been recorded in about 20 cases characterised by molecular and phenotypic heterogeneity. Most patients have moderately reduced activity and complete hexokinase deficiency is probably lethal. The enzyme deficiency results in moderate, mild anaemia, but some cases present with severe anaemia and death in neonatal period. Typically, reduced hexokinase activity is associated with a low concentration of 2,3-DPG within the cells. Patients have less exercise tolerance for a given level of haemoglobin than would be expected because of the left shift in the oxygen dissociation curve.

Glucose phosphate isomerase deficiency

Glucose phosphate isomerase (GPI) catalyses the second step of glycolysis, the interconversion of G6P to fructose-6-phosphate (F6P). The enzyme is also known as phosphohexose isomerase, phosphoglucose isomerase, autocrine motility factor and neuroleukin, indicating that the protein has other actions in other cells.

GPI deficiency is one of the commonest causes of CNSHA after G6PD and PK deficiency. About 30 different mutations have been identified, underlying the molecular heterogeneity and consequently the heterogeneity of the clinical picture. Most reported cases present with mild to moderate haemolytic anaemia; hydrops fetalis may occur. In T lymphocytes, GPI acts as neuroleukin, a lymphokine that induces the formation of antibody-secreting cells. GPI is also expressed in neutrophils, but there is no increase in infections in deficient subjects. In some deficient patients, neurological impairment or intellectual disability has been reported, thought to be related to hypoxia or ischaemia *in utero* rather than to direct metabolic effects.

Phosphofructokinase deficiency

Phosphofructokinase (PFK) catalyses a reaction in which F6P is phosphorylated to fructose-1,6-diphosphate, ATP being the donor of the phosphate group. Under normal physiological conditions, this may be the major rate-limiting step in glycolysis in the red cell. Erythrocytic PFK is a tetramer composed of M or L subunits encoded by two separate genes; there may be five isoenzymes composed of different numbers of L and M subunits. PFK is a homotetramer of M subunits (M4) in muscle and of L subunits (L4) in liver. A third subunit is found in platelets. Deficiency of the M subunit leads to glycogen storage disease type 7 (Tarui disease). It is characterised by muscle cramps and myoglobinuria on exertion. Shortened red cell viability may be a minor component of this disease. Evidence of haemolysis may be accompanied by mild erythrocytosis as a result of decreased production of 2,3-DPG.

Fructose diphosphate aldolase A deficiency

Fructose-1,6-diphosphate aldolase A (ALDOA) catalyses the conversion of fructose-1,6-diphosphate to Ga3P and dihydroxyacetone phosphate (DHAP). There are three aldolase isoenzymes in human tissues, A, B and C; A isoenzyme is expressed in red cells. ALDOA is produced in the developing embryo and also forms the bulk of the enzyme in muscle, where it may be as much as 5% of the total cellular protein. In the red cell, the reaction catalysed by the enzyme is virtually irreversible.

This enzyme deficiency is extremely rare, with only six patients described so far. The defect presents with anaemia, which may be associated with intellectual disability, dysmorphic features or myopathy. In one patient, rhabdomyolysis occurred.

Table 16.6 Main features of red cell enzyme deficiencies.

	Transmission	Gene	Chromosome	No. cases	No. mutations	Haematology	Other symptoms
Embden–Meyerhof pathway							
Hexokinase	AR	*HK1*	10q22.1	20 cases	5	CNSHA	
Glucose-phosphate isomerase	AR	*GPI*	19q13.11	>50 fam	31	CNSHA	Intellectual disability?

AD, autosomal dominant; AR, autosomal recessive; fam, families; CNSHA, congenital non-spherocytic haemolytic anaemia; HA, haemolytic anaemia.

Triose phosphate isomerase deficiency

Triose phosphate isomerase (TPI) catalyses the interconversion of DHAP and Ga3P. In red cells, all DHAP is converted to Ga3P, which is then metabolised down the glycolytic pathway, providing the ultimate two molecules of ATP for each molecule of glucose metabolised. The enzyme is a homodimer present in all tissues that is catalytically active only in its dimeric form. In tissues other than the red blood cell, DHAP is an important precursor for the biosynthesis of lipids. More than 50 cases of TPI have been reported. This produces a severe syndrome, present from birth, consisting of CNSHA, a progressive neurological disorder with spasticity and central nervous system (CNS) degeneration. Cardiac failure and sudden death due to arrhythmias are also features. Death occurs usually at about 5 years of age, likely because of the formation of toxic protein aggregates, induced by misfolded TPI. A number of point mutations have been identified that lead to the syndrome; the most predominant is Glu104Asp, linked by common haplotypes suggesting descent from a common ancestor.

Phosphoglycerate kinase deficiency

Phosphoglycerate kinase (PGK) catalyses the reversible conversion of 1,3-DPG to 3-phosphoglycerate, generating one molecule of ATP for each molecule of 1,3-DPG metabolised. The active enzyme in the red blood cell is encoded by the *PGK1* gene on the X chromosome. The enzyme is monomeric and is expressed in all tissues. PGK deficiency shows a wide clinical phenotype: it may present with chronic haemolysis, neurological impairment (intellectual disability and ataxia) and myopathy (exercise intolerance or muscle weakness). A few affected individuals suffer the full spectrum of symptoms, whereas some cases are described with myopathy without haemolysis.

Defence against oxidative stress: the production of reducing power

As with all cells, but perhaps more urgently, red blood cells need to be protected against the effects of free radicals, hydrogen peroxide and other highly oxidative material to maintain membrane integrity and functional activity. In addition, haemoglobin has to be maintained in its functional state, and the steady production of methaemoglobin reversed to deoxyhaemoglobin, which is able to combine reversibly with oxygen. The major generator of reducing power within the red cell is the pentose phosphate pathway, which generates reducing power in the form of NADPH from $NADP^+$ coupled to the oxidation of G6P to 6-phosphogluconate (6PG) and the subsequent oxidation of 6PG to ribose-5-phosphate, by the action of G6PD and 6-phosphogluconate dehydrogenase (Figure 16.14).

GSH is important for protecting cells from oxidative damage by these free radicals and the effects of infection, maintaining protein sulfydryl groups in the reduced state and maintaining membrane transport. GSH is provided by the glutathione cycle linked to the pentose phosphate pathway through the action of glutathione reductase (Figure 16.15).

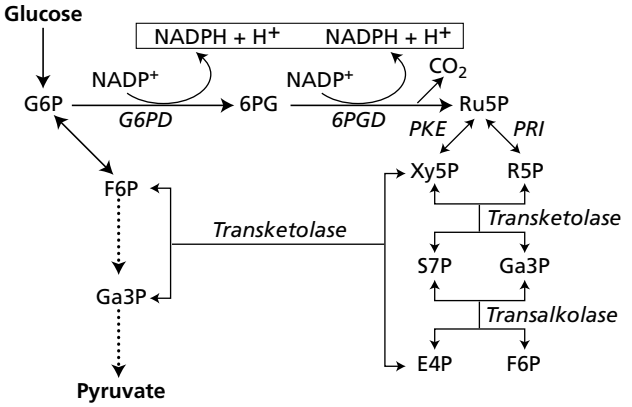

Figure 16.14 The pentose phosphate pathway. Substrates: G6P, glucose-6-phosphate; 6PG, 6-phosphogluconate; Ru5P, ribulose-5-phosphate; R5P, ribose-5-phosphate; Ga3P, glyceraldehyde-3-phosphate; F6P, fructose-6-phosphate; Xy5P, xylose-5-phosphate; S7P, septulose-7-phosphate; E4P, erythrose-4-phosphate. Enzymes: G6PD, glucose-6-phosphate dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; PKE, phosphoketoepimerase; PRI, phosphoribose isomerase.

Oxidative stress that exceeds the reducing power of the red cell leads to intravascular haemolysis following denaturation of haemoglobin with precipitation as Heinz bodies and peroxidation of the red cell membrane. Methaemoglobinaemia may occur. The resulting clinical features – acute intravascular haemolysis, Heinz body haemolytic anaemia or methaemoglobinaemia – depend on the nature of the oxidative stress and the size of the imbalance between the stress and the redox potential.

Pentose phosphate pathway (hexose monophosphate shunt)

The pentose phosphate pathway, schematically shown in Figure 16.12 and in detail in Figure 16.14, is essential for the production of ribose and its incorporation into RNA. In red cells, its only function is the production of reducing power in the form of NADPH. The first step of the pathway, catalysed by G6PD, utilises G6P as substrate. G6P is also a substrate for glycolysis. About 10% of glucose is metabolised by the pentose phosphate pathway which is controlled by the availability of NAD^+ and the feedback inhibition of ATP. Under conditions of oxidative stress, the flux through the pentose phosphate pathway can be greatly increased. The products of the pathway re-enter the glycolytic pathway through F6P or Ga3P. The most frequent defect of the pentose phosphate pathway is G6PD deficiency. However, other enzymes can be important in acquired

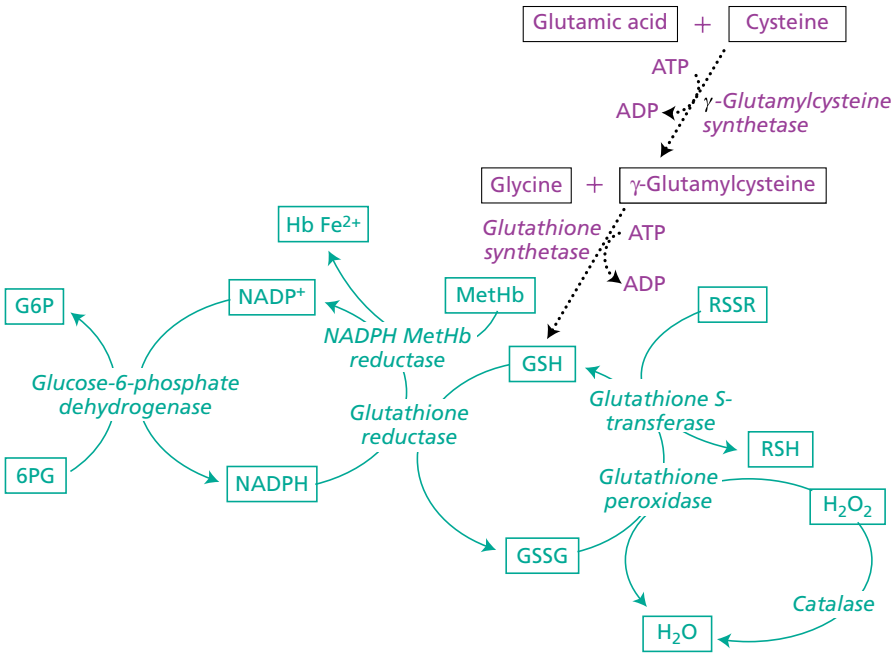

Figure 16.15 The glutathione (GSH) cycle and synthetic pathways. Redox control is exercised by the glutathione cycle linked to the NADPH of the pentose phosphate pathway by glutathione reductase.

disorders, some steps of the pathway being inhibited by drugs, including oestrogen/progesterone contraceptive pills.

Glucose-6-phosphate dehydrogenase deficiency

G6PD is the enzyme controlling flux through the availability of $NADP^+$. Conversion of G6P to 6PG is accompanied by the reduction of $NADP^+$ to NADPH (Figure 16.14); the oxidation of 6PG to ribose-5-phosphate produces a second molecule of NADPH. $NADP^+$ availability is determined by the glutathione cycle, which is linked to the pentose phosphate pathway through the activity of glutathione reductase (Figure 16.15).

The gene encoding for G6PD is located on the X chromosome at Xq28. The protein is assembled to produce an equilibrium of dimers and tetramers. Each monomer has an $NADP^+$-binding domain and a large domain with the active site between the two. The gene is highly conserved throughout evolution and is expressed in all cells, with an essential role in the production of RNA in nucleated cells. Complete inactivity of the enzyme in nucleated cells would be lethal. The clinical consequences of G6PD deficiency are virtually confined to the erythrocyte, with occasional evidence of leucocyte malfunction in some variants. Most mutations affect the stability of the enzyme so that its activity rapidly declines in the mature enucleated red cell as it ages. G6PD deficiency is the commonest genetically determined enzyme deficiency in the world, with an estimated 400 million people being affected. More than 180 different variants associated with deficient enzyme activity have been described and at least 35 of them are polymorphisms. The G6PD variants have been classified into five classes according to their activity relative to the wild-type G6PD type B (Table 16.7). In Africa, the variant G6PD type A^- is the predominant polymorphism, with equivalent activity to G6PD type B.

G6PD deficiency is widely found in people whose ethnic heritage relates to Africa, the Mediterranean basin, the Middle East, Southeast Asia and the Indian subcontinent. G6PD-A^- is common in Africa; the Mediterranean variant is common in Southern Italy, Sardinia and other Mediterranean regions and G6PD-Canton is common in Southern China. These variants are only the most common amongst many different mutations in these areas and throughout the rest of the affected world. This distribution of the deficiency equates with areas where *Plasmodium falciparum* malaria is common, and this is thought to be the evolutionary drive that has produced such widespread polymorphisms. It has subsequently been confirmed that G6PD deficiency does indeed protect against lethal *falciparum* malaria, particularly in childhood, and this protection, especially in hyperendemic areas, more than outweighs the haematological problems associated with deficiency.

There are four main syndromes associated with G6PD deficiency differing in their clinical presentations: neonatal jaundice, favism, chronic non-spherocytic haemolytic anaemia and drug-induced haemolytic anaemia. In all four, haemolysis is

Table 16.7 World Health Organisation classification of G6PD deficiency (1989).

Class	Enzyme activity (% normal)	Examples	Clinical effects
I	Severe (usually <2)	Santiago de Cuba (Gly447Arg)	CNSHA, acute exacerbations
II	<10	Mediterranean (Ser188Phe) Canton (Arg459Leu) Orissa (Ala44Gly)	Favism, acute intravascular haemolysis (drug-induced), neonatal jaundice
III	Moderate (>10, <60)	A– (Val68Met, Asn126Asp)	Acute intravascular haemolysis (drug-induced), neonatal jaundice
IV	100	B (wild type) A (Asn126Asp)	None None
V	150	//	None

CNSHA, congenital non-spherocytic haemolytic anaemia.

aggravated or promoted by exposure to oxidative stress through infection or ingestion of oxidative foods or drugs. Age always modifies the clinical effects, not always as might be expected.

The neonatal jaundice syndrome has been described in class I, II and III variants, favism mainly, though not exclusively, in class II, CNSHA in class I, and the drug-induced haemolytic anaemias mainly in class III. While G6PD deficiency is most common in males, the prevalence of the gene in many parts of the world means that female homozygotes are not uncommon and heterozygous females are often susceptible to oxidative stress because of the effects of X-inactivation and marked lyonisation resulting in a significant population of G6PD-deficient red cells.

Neonatal jaundice and G6PD deficiency in infancy

Neonatal jaundice is a severe manifestation of G6PD deficiency and is a major source of potential morbidity from kernicterus. Most common variants have been associated with the syndrome, including the A^- and Mediterranean variants. In parts of the world where G6PD is common, it is the most prevalent cause of neonatal jaundice. The jaundice probably starts *in utero* during the perinatal period, but the clinical problem only becomes apparent on about the second or third day after birth. Phototherapy or exchange transfusion may be required to prevent neurological sequelae. Anaemia is not a feature, and it is thought that jaundice is a manifestation of liver enzyme deficiency coupled perhaps to the physiological underdevelopment of neonatal liver function or the coinheritance of Gilbert's syndrome. Acute haemolytic crises may occur in infants, usually through exposure to oxidative stress, including nitrites or nitrates in water or the ingestion of fava beans by the mother, but in some cases of severe acute haemolysis, even fatal, no cause has been obvious.

Favism

Favism is the term given to the G6PD syndrome where acute intravascular haemolysis may be precipitated by exposure to the broad bean *Vicia fava*, ingested in any form, usually about 24 hours after the exposure (Table 16.9). The offending agent is divicine, or its aglycone isouramil, which can produce free oxygen radicals on autoxidation. Divicine is not present in peas or beans of other types, which may be eaten without effect. The amount of haemolysis is dose-related, which may explain the marked variation in susceptibility not only in different subjects, but also in the same individual at different times. In children, acute haemolysis, sometimes life-threatening, is common, but renal failure is uncommon, although there may be systemic symptoms of fever and loin pain. Acute kidney injury occurs more often in adults, possibly because of comorbidity. Favism is usual in class II variants, for example Mediterranean and Canton, but may occur in others, including the African A^- variant. Acute haemolysis after eating fava beans has also been described in glutathione reductase deficiency. Some other compounds with which affected individuals may come in contact can cause acute haemolysis, including topical henna and some of the pulses used to make local sweetmeats.

Between attacks of favism or exposure to oxidising substances, the blood count is normal with no evidence of haemolysis. The cooccurrence of infection, which promotes the formation of hydrogen peroxide following the oxygen burst in neutrophils and macrophages with ingestion of oxidising substances, even mild ones such as chloramphenicol, may promote haemolysis, even though the drug on its own does not.

Chronic non-spherocytic haemolytic anaemia

Sporadic cases of CNSHA are found with underlying G6PD deficiency. Many of the mutations that cause CNSHA occur on exon 10 and affect the formation of dimers or tetramers.

Table 16.8 Characteristic features of haemolytic attack in G6PD deficiency.

Phase	Clinical	Laboratory
Acute	Abrupt onset	
	Malaise, prostration	
	Pallor	Anaemia, Heinz bodies, reticulocytosis, G6PD deficient
	(Abdominal pain)	
	Fever	Leucocytosis
	Dark urine	Haemoglobinuria, haptoglobin absent
	Haemoglobinaemia	
	Methaemalbuminaemia	
	Jaundice	Hyperbilirubinaemia
	(Renal failure)	↑ Urea, ↑ creatinine
Recovery	Gradual but rapid cessation of haemolysis	Reticulocytes peak days 5–8
	Urine clears in few days	G6PD increases (rarely to normal range)
	Jaundice clears in 1–2 weeks	

The haemolysis is extravascular, although additional oxidative stress may provoke an acute intravascular episode.

Drug-induced acute haemolysis

The introduction of primaquine and its derivative pamaquine as antimalarials to replace quinine during the Pacific phase of the Second World War and the later Korean War revealed that a proportion of men exposed, particularly in the black population, suffered from severe acute intravascular haemolysis. Studies by Carson and others from the University of Chicago, working at the Statesville Penitentiary Malaria Project, identified the problem as G6PD deficiency and identified that young red cells and reticulocytes had sufficient activity to withstand the oxidative stress so that haemolysis lessened as the reticulocyte level rose. It became apparent that many other drugs could also produce haemolysis. The common African A^- variant is the main example of class III mutations producing this type of haemolysis.

The haemolysis is dose-related and may be self-limiting. Although it is important to recognise which drugs are likely to produce haemolysis (Table 16.9), it is also important to realise that the disease for which the drugs may be needed, for example *falciparum* malaria, may be fatal, and thus the concern for haemolysis is a lesser problem.

Laboratory diagnosis

Acute intravascular haemolysis raises the suspicion of G6PD deficiency. Red cell morphology shows contracted haemoglobin in 'ghost' membranes (Figure 16.16). Haemoglobinuria may be gross, producing almost black urine without red cells in the centrifuge deposit. Several screening tests have been devised to identify G6PD deficiency in red blood cells. These tests can reliably distinguish between deficient and non-deficient individuals but are not reliably quantitative. The gold standard is the quantitative assay of G6PD activity. Since G6PD activity is red blood cell age-dependent the measurement of enzyme activity might yield false-normal results in the presence of reticulocytosis, (i.e. during haemolytic attack). The diagnosis of heterozygous females can be especially difficult; in extreme cases, it can only be done by family studies. However, the probability of clinically significant haemolysis in a heterozygote roughly correlates with the proportion of G6PD-deficient red cells in her blood. Therefore, if a normal level of G6PD activity is found in a heterozygote, she is unlikely to be at risk of G6PD-related haemolysis. DNA analysis is the most effective way of identifying heterozygotes, in particular in regions where G6PD has a high prevalence and the main variants are known.

Management

Management is mostly dictated by the symptoms and signs in patients, although education in the avoidance of oxidising substances is important (Table 16.8). In many populations, the condition is well known and the need for avoidance is recognised. Neonatal jaundice may need urgent therapy to prevent neurological damage. Extreme hyperbilirubinaemia can be prevented by administration of Sn-mesoporphyrin if the diagnosis is known at birth. Acute intravascular haemolysis may require transfusion, but the anaemia is often self-limiting. High fluid intake should be encouraged to prevent renal damage. CNSHA may be severe enough to warrant active treatment and splenectomy may be helpful.

Glutathione

GSH is the major intracellular thiol in aerobic cells and is equally important in the red cell. It has a number of critical functions: protecting cells against oxidative damage, participation in

Table 16.9 Drugs to be avoided in G6PD deficiency.

Category of drug	Predictable haemolysis	Possible haemolysis
Antimalarials	Dapsone Primaquine Methylene blue	Chloroquine Quinine
Analgesics/Antipyretic	Phenazopyridine	Aspirin (high doses) Paracetamol (Acetaminophen)
Antibacterials	Cotrimoxazole Sulfadiazine Quinolones (including nalidixic acid, ciprofloxacin and ofloxacin) Nitrofurantoin	Sulfasalazine
Other	Rasburicase Toluidine blue	Chloramphenicol Isoniazid Ascorbic acid Glibenclamide Vitamin K Isosorbide Dinitrate

Similar tables have also been published previously (e.g., Betke *et al.* 1967; Cappellini and Fiorelli, 2008; Luzzatto, 2012). The *Predictable haemolysis* column includes all seven drugs listed in a recent evidence-based review (Youngster *et al.* 2010). We consider that even a single case of AHA must be taken seriously if the clinical picture is well documented and if AHA is unlikely to have had another cause (e.g. infection): therefore, in addition to those seven drugs, we have retained in this column cotrimoxazole (of the two chemicals present in cotrimoxazole, sulfamethoxazole rather than trimethoprim is likely to be the culprit); sulfadiazine; and quinolones. The *Possible haemolysis* column is based on older literature (see for instance Burka *et al.* 1966; WHO Working Group, 1989). As examples of the causal role of some of these drugs in causing AHA in G6PD-deficient persons see Sicard *et al.* (1978) for chloroquine, Meloni *et al.* (1989) for aspirin, Mehta *et al.* (1990) for ascorbic acid, Meloni and Meloni (1996) for glibenclamide
(*Source:* Luzzatto and Seneca, 2014. Reproduced with permission of Wiley.)

detoxification of foreign compounds, maintenance of protein sulfhydryl groups in a reduced state and possibly transport of amino acids. In red cells, its main function is as an antioxidant. GSH is synthesised from glutamate, cysteine and glycine by the link reactions of two enzymes, γ-glutamylcysteine synthetase and glutathione synthetase (Figure 16.15). GSH exerts its function in preserving thiol groups and reducing hydrogen peroxide and free oxygen radicals through reactions catalysed by glutathione-*S*-transferase and glutathione peroxidase, respectively. Oxidised glutathione (GSSG) is reduced to GSH by the action of glutathione reductase, the hydrogen donor being NADPH. Failure to maintain the GSH level leads to chronic haemolytic anaemia and increased susceptibility to oxidative stress.

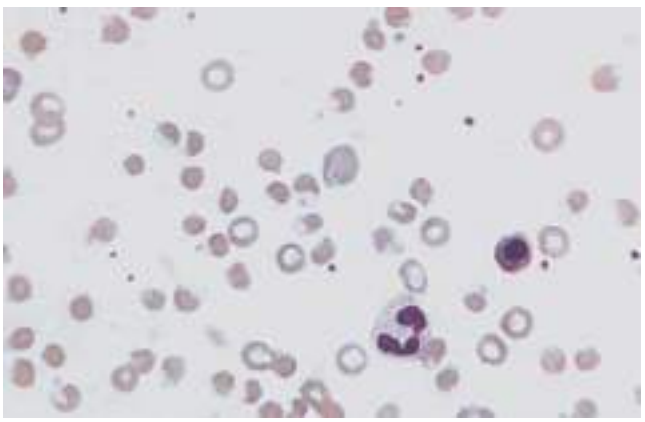

Figure 16.16 G6PD deficiency. Peripheral blood film following acute oxidant drug-induced haemolysis shows an erythroblast and damaged red cells, including 'blister' and 'bite' cells.

Complete loss of GSH synthesis is probably lethal. Severe deficiency leads to 5-oxoprolinuria, metabolic acidosis and intellectual disability. A milder deficiency limited to red cells is associated with haemolytic anaemia aggravated by oxidative stress. Low levels of GSH caused by γ-glutamylcysteine synthetase or glutathione synthetase deficiency, with CNSHA, have been described (Table 16.5). Haemolytic anaemia due to deficiency of glutathione reductase has also been reported.

Nucleotide metabolism

Adenosine nucleotides, ATP (85–90%), ADP (10–12%) and AMP (1–3%) comprise the main nucleotide pool in mature

red cells. The cell has no mechanism for making nucleotides once the RNA of the reticulocytes has been degraded, and it has an effective salvage mechanism for maintenance of the adenine pool, with the enzymes adenosine deaminase (ADA) and adenylate kinase involved in regulation. Deficiency of the enzymes in the salvage pathway does not usually lead to haemolysis. ADA deficiency is associated with severe combined immunodeficiency and excess activity is found in Diamond–Blackfan anaemia. During maturation of reticulocytes the RNA is broken down to pyrimidine and purine nucleotides, which are dephosphorylated to nucleosides that can diffuse out of the cell. The purine nucleotides enter the salvage pathway. Deficiency of pyrimidine 5′ -nucleotidase leads to accumulation of pyrimidine nucleotides that interferes with the adenine nucleotide pool, producing haemolysis (Table 16.5).

Pyrimidine 5′-nucleotidase

Pyrimidine 5′-nucleotidase (P5N), catalyses the dephosphorylation of the pyrimidine 5′-monophosphates uridine monophosphate (UMP) and cytidine monophosphate (CMP) to corresponding nucleosides (Figure 16.17). In red cells, there are two isoforms, type 1 (P5N1), which has a high affinity for UMP and CMP, and type 2 (P5N2), which hydrolyses deoxypyrimidine nucleotide monophosphates. P5N1 deficiency leads to haemolytic anaemia. The gene (*NT5C3*, also named P5′ N1), codifies for the two isoforms by exon 2 alternative splicing. The enzyme is strongly inhibited by lead.

P5N1 deficiency is not uncommon, it is probably the third most common enzyme deficiency causing CNSHA. It is characterised by marked basophilic stippling in the red cells (Figure 16.18), similar to that seen in lead poisoning, and accumulation of high concentrations of pyrimidine nucleotides. The haemolysis is usually mild to moderate, although more severe cases have been reported. Splenectomy usually results in stabilisation of the haemoglobin to higher levels (median increase 32 g/L).

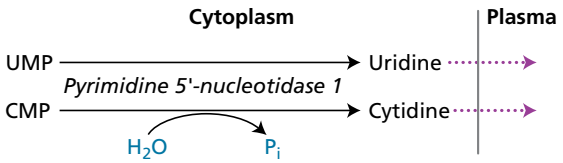

Figure 16.17 Pyrimidine nucleotide catabolism in the reticulocyte. Pyrimidine 5′ -nucleotidase converts the nucleotides to monophosphates, which diffuse out of the cell.

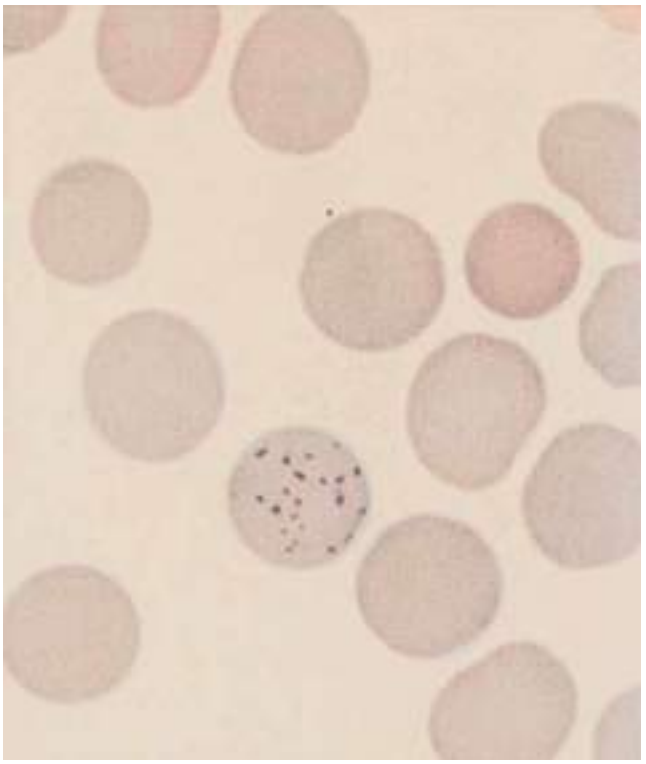

Figure 16.18 Peripheral blood film in pyrimidine 5′ -nucleotidase deficiency showing basophilic stippling.

CHAPTER 17

Acquired haemolytic anaemias

17

Rachel Kesse-Adu and Anietie Ekong

Guy's and St Thomas' Hospital, Great Maze Pond, London, UK

Introduction

Haemolytic anaemias result from significant shortening of the red cell life span and can result from either acquired or inherited causes. The acquired haemolytic anaemias are divided into two main categories based on the mechanism by which premature destruction of red blood cells is produced. In the immune haemolytic anaemias, antibodies are the main agents of destruction, while the non-immune acquired haemolytic anaemias result from diverse causes and mechanisms.

Immune haemolytic anaemias

Antibody-mediated haemolysis is an important cause of acquired haemolytic anaemia. These antibodies may be autoantibodies produced by a patient's immune system and directed against epitopes of their own red cell antigens, or they may more rarely be alloantibodies. Alloantibodies may be produced by the patient and directed against antigens either introduced by blood transfusion of donor red cells or secondarily acquired as in drug-induced haemolysis. Alloantibodies directed against the patient's red cell antigens might also be introduced from outside the patient, as occurs from the mother in haemolytic disease of the fetus and newborn. A simple classification of immune haemolytic anaemias is given in Table 17.1.

Immune haemolytic anaemias are distinguished from the non-immune by detecting antibody on the surface of red cells using the direct antiglobulin test (DAT).

Autoimmune haemolytic anaemia

Autoimmune haemolytic anaemia (AIHA) is a rare disease with an incidence of 1–2 cases per 100,000 per year, it has a highly variable clinical course ranging from mild disease to severe life-threatening haemolysis. About half of AIHA cases are classed as primary when no underlying or associated disorder is found, the rest are classed as secondary, related to an underlying cause that may be malignant (e.g. chronic lymphocytic leukaemia, CLL), autoimmune (e.g. systemic lupus erythematosus SLE), infective (including SARS-CoV2) or drug-induced (e.g. cephalosporins). AIHA can also occur in the context of solid organ or haematopoietic stem cell transplantation.

AIHA is a heterogeneous disorder which can be serologically divided into warm AIHA (wAIHA), accounting for two-thirds of cases; cold agglutinin disease (CAD), the second most common cause, affecting patients commonly in their 7th and 8th decades of life; mixed AIHA; paroxysmal cold haemoglobinuria (PCH), a rare condition that typically affects children; and atypical AIHA, a recently defined subgroup of DAT negative AIHA which may be driven by IgA or warm IgM.

Pathogenesis of AIHA

The pathogenesis of AIHA is complex and not yet fully elucidated, but as with other autoimmune disorders, its development is associated with the presence of autoreactive T and B cells as well as the dysregulation of self-tolerance. T helper type 17 cells (Th17) cells are engaged in autoimmunity and the development of inflammation, whereas CD4+ and CD25+ T regulatory cells (Tregs) inhibit the development of autoimmunity and contribute to self-tolerance by suppressing

Table 17.1 Classification of immune haemolytic anaemias.

Antigen type	Antibody	Diseases	Associations
Autoimmune	Warm antibody	Primary Secondary	Idiopathic Autoimmune diseases (ITP, SLE, Rheumatoid arthritis) Lymphoproliferative disorders Infections (EBV, SARS-CoV2) Ovarian carcinoma and some other cancers
	Cold antibody	Cold agglutinin disease (CAD) Cold antibody syndromes	Drugs Infections (*M. pneumoniae*), lymphoproliferative disorders
	Donath–Landsteiner antibody	Paroxysmal cold haemoglobinuria (PCH)	Post viral, syphilis
Alloimmune	Induced by red cell antigens	Haemolytic transfusion reactions Haemolytic disease of the fetus and newborn (HDFN) Post haematopoietic stem cell transplant	
	Drug dependent	Antibody/macrophage-mediated Antibody/complement-mediated Membrane modification Autoimmune	

EBV, Epstein–Barr virus; ITP, immune thrombocytopenia; SLE, systemic lupus erythematosus.

auto-reactive T cells. In AIHA, there is an imbalance due to an increase in the Th17 compartment.

There is also a breach of the normal interaction between several other components of the immune system including antibody-dependent cell-mediated cytotoxicity (ADCC) mediated by macrophages, cytotoxic T cells, NK cells and autoantibodies. Interactions between cytokines, B cells and reactive oxygen species (ROS) have also been implicated, as have reticulocytes which some models have shown to be a target for pathogenic autoantibodies. There is gathering evidence on the role of shear stress in the induction and progression of AIHA, as well as genetic pre-disposition; next generation sequencing has revealed recurrent *KMT2D* mutations in CAD patients for example.

The risk of acquiring AIHA increases significantly with age, and this age-related effect is likely contributed to by immunosenescence (age-related decline of the immune system) or an age-related accumulation of epigenetic abnormalities in the haematopoetic stem cell.

Characteristics and specificity of red cell autoantibodies

Autoantibodies typically show reactivity against a number of antigens and are not as specific as alloantibodies. In AIHA, the antibody type and its thermal characteristics influence both the site and intensity of red cell destruction. The direct antiglobulin test (DAT) is the cornerstone of diagnosis in AIHA and is used to evaluate the anti-red cell antibodies using routinely available multi- and mono-specific anti-human globulin reagents which detect IgG, IgM, IgA and the complement components C3c and C3d. The most frequent patterns detected by DAT on the red cell surface in AIHA are IgG alone, IgG and complement, and complement alone. True DAT-negative AIHA is rare: some initial apparently DAT-negative cases will be due to low-affinity antibodies which can be overcome by low ionic strength solution or cold washing. Newer, more sensitive assay methods including flow cytometry may be useful. Despite extensive work-up a small fraction of AIHA cases remain DAT negative, but this is a diagnosis that can only be made after excluding many other causes of haemolysis.

Warm-acting antibodies

WAIHA autoantibodies bind to red cells more strongly at 37 °C and have decreased affinity at lower temperatures; they are polyclonal and IgG antibodies predominate. Complement activation is seen when the antibody titre is markedly raised or when IgG1 or IgG3 subclasses are involved. These antibodies may be detected in the serum by the indirect antiglobulin test (IAT) in about 50–60% of patients, rising to more than 90% of cases when the red cell membrane of the reagent cells is modified with papain or another proteolytic enzyme. In most cases of warm-type AIHA, the antibody detected in the patient's serum is pan-reacting with all cells in a routine group O panel. Where specificity of the antibody can be determined, it is most commonly in the Rh blood group complex, with 10–15% showing specificity for either anti-e, anti-D or anti-c.

A greater proportion shows specificity by reacting with all cells except –/– Rh^{null} cells. Other rare specificities against high-frequency antigens include anti-En^a, anti-Wr^b or anti-U.

Cold-acting antibodies

Cold-acting antibodies are predominantly IgM and are most actively bound to antigen in the cold (4 °C), with little affinity at physiologic temperatures. These antibodies act both as agglutinins and lysins *in vitro*; the two functions may have different thermal ranges. The clinical significance of the antibody is not related to the titre of the cold antibody, but depends on the thermal range of its activity and how the antibody binds to red cells at or near 37 °C. IgM antibodies active against the I (auto) antigen at 4 °C can be a normal finding and, although they have a wide range of thermal activity, they produce no clinical disturbance above 32 °C. *In vitro*, the IgM antibodies elute off the red cell membrane, leaving bound complement to be detected by anti-C3d in the DAT.

According to a recent international AIHA consensus document, primary cold agglutinin disease (CAD) is defined as an AIHA characterised by a monospecific DAT strongly positive for complement fragment C3d, usually negative for IgG (although it may be weakly positive in up to 20% of cases). There is usually an underlying indolent B-cell lymphoproliferative disorder that produces the cold agglutinin (CA) which initiates the haemolysis. CA are usually a monoclonal IgM (κ) with an optimum temperature of reaction at 4 °C (thermal range 4–34 °C), which determines their pathogenicity. They bind to red cells in the cooler peripheral circulation, which can result in agglutination of the red cells leading to acrocyanosis or Raynaud's disease in some patients. After binding, the IgM-antigen complex initiates the classical complement pathway resulting in opsonisation of the red cell by C3b. Once warmed in the central circulation the IgM detaches from the red cells allowing agglutinated cells to separate, but C3b remains bound to the red cell membrane. C3b opsonised red cells are prone to phagocytosis; on the red cells that survive this process, the surface C3b is further cleaved to C3d which can be detected by DAT.

Secondary cold agglutinin syndrome (CAS) is a similar to CAD, but the associated clinical disease may be an aggressive lymphoma or an infection with *Mycoplasma pneumoniae* or Epstein Barr virus. It may also occur secondary to an autoimmune disorder or malignancy. The cold agglutinin associated with infection and autoimmune diagnoses tends to be a polyclonal IgM, however, CAS cases associated with an overt (clinical or radiological) lymphoma will be monoclonal. Polyclonal CA may also be detected in low titres in a proportion of the adult population without any haemolysis or clinical symptoms.

These cold agglutinins (IgM antibodies) tend to have specificity for the I/i blood group system. I predominates from 18 months age onwards hence most patients' cold agglutinins are specific for the I antigen. Very occasionally, there is specificity for other antigens including anti-Pr, anti-P, anti-M or anti-N.

The antibodies in a subtype of cold AIHA, paroxysmal cold haemoglobinuria (PCH), are of IgG type and bind to antigen below 20 °C. When the temperature is raised to 37 °C in the presence of complement, lysis occurs. This biphasic reaction is the basis of the Donath–Landsteiner reaction. In PCH, the specificity of the autoantibody is anti-P.

Complement activation

Antibody binding to two adjacent sites on the red cell membrane is required to activate the C1 complement component by the classical pathway. IgM molecules are pentameric and a single molecule can bind adjacent sites whilst IgG molecules can only activate complement if they form a 'doublet'. IgG1, IgG2 and IgG3 can activate complement, whereas IgG4 and IgA do not. In AIHA, complement activation usually stops at the C3 stage where C3b is bound to the membrane and further proteolysed to form the inactive component C3d, which is detected by the appropriate DAT. Complement activation beyond the C3 stage may lead to the formation of the membrane attack complex resulting in intravascular haemolysis. AIHA due to IgG2 alone is very rare and that due to IgG4 or IgA alone is uncommon. It is interesting that in the rare case of IgA AIHA, complement does become activated on the cell surface, although the mechanism is obscure as IgA does not itself fix complement. In general, when there is more than one class or subclass of antibody on the cell surface, the haemolysis is more intense and may be intravascular.

Mechanisms for immune red cell destruction

There are two main mechanisms of red cell destruction *in vivo:* first, cell-mediated, predominantly extravascular haemolysis, and second complement-mediated intravascular haemolysis. Haemolysis in AIHA is mainly extravascular: the red cells are commonly coated with IgG only and preferentially destroyed in the spleen. In the cases where they are coated with a combination of IgG and complement or complement alone, the main site of destruction is the liver, however, intravascular haemolysis may also occur. The site and severity of red cell destruction depend on the structural and functional characteristics of the antibody and the efficiency of the mechanism of destruction, while the degree of anaemia depends on the rate of destruction versus the capacity of the bone marrow to compensate.

Cell-mediated immune destruction of antibody-coated red cells is carried out by macrophages of the reticuloendothelial system within the spleen, liver and bone marrow. These cells have cell-surface receptors for the Fc portion of IgG and the antigenic determinants present on activated C3. Macrophages have Fc receptors for IgG1 and IgG3 molecules, but not for IgG2, IgG4, IgM or IgA. Hence only IgG-coated red cells are

destroyed in this way. It is the main method of haemolysis in warm AIHA where 70–75% of autoantibodies are IgG. Phagocytosis and antibody-dependent cell-mediated cytotoxicity are the major Fc receptor-dependent modes of antibody-coated cell destruction.

Role of the spleen

The splenic vasculature is adapted to provide an efficient filter for particles such as effete red cells, bacteria and immune complexes. As blood passes through the central arteries towards the red pulp, the branches of these arteries have a plasma-skimming effect that raises the haematocrit of the blood as it passes towards the splenic cords. There, red cells come into close contact with splenic macrophages. The low plasma content and the relative lack of free plasma IgG molecules allow red-cell-bound IgG to interact preferentially with macrophage Fc receptors, leading to phagocytosis of coated red cells. When phagocytosis is partial, so that only portions of the cell membrane are removed, the remaining circulating red cell becomes spherocytic, although the somewhat rigid spherocytes may themselves be trapped in the splenic sinusoids and destroyed. The spleen is therefore the major site of red cell destruction when IgG alone is the main Fc-binding protein on the red cell surface.

Role of the liver

Macrophages that are present in the liver sinusoids (Kupffer cells) express Fc receptors on their surface. Blood flow through the sinusoids is rapid and compared with the spleen and there is no plasma-skimming effect so IgG-coated red cells are not preferentially destroyed in this situation, instead, there is competition for the Fc receptors from circulating IgG and red cell destruction is more dependent on cells being coated with C3.

Two types of C3 receptor have been identified in macrophages: CR1 and CR3. CR1 is specific for an antigenic site in the C3c region of activated C3b, and its breakdown product iC3b which is the only ligand for CR3. Immune adherence of C3b-coated red cells to macrophages occurs mainly through CR1, whereas CR3 binding triggers phagocytosis. The largest concentration of C3b-binding macrophages is found in liver sinusoids, and hence the liver is the major site for trapping and phagocytosing C3b-coated red cells. There is no competition for complement receptor sites from non-activated C3 in the plasma. When markedly enlarged, the spleen also becomes an important site of cell destruction.

Complement-mediated intravascular haemolysis

Complement-mediated intravascular haemolysis is a minor mechanism for red cell destruction in most patients with AIHA, however in a small proportion of patients when more than one class or subclass of immunoglobulin is present on the red cell surface, such a mechanism may predominate and produce severe intravascular haemolysis.

In warm AIHA, complement-induced intravascular haemolysis has been reported with IgA-coated red cells, although the mechanism is obscure, as IgA does not itself fix complement.

In cold AIHA syndromes, intravascular haemolysis may be precipitated by exposure to cold. In such cases, lytic as well as agglutinating antibodies with a high thermal range may be demonstrated *in vitro*, a pattern that may be found in cold AIHA associated with *Mycoplasma pneumoniae* infection. Acute intravascular haemolysis is the usual presentation in PCH, where the antibody is IgG in type.

Other factors influencing red cell destruction and production

The bone marrow's function and capacity to increase erythropoiesis following significant red cell destruction may be impaired by autoantibodies that bind to and destroy reticulocytes and erythroblasts as well as the mature red blood cells. Red cell production may also be reduced by acute folate deficiency secondary to increased demand. In lymphoproliferative disorders, red cell production can be impaired by bone marrow infiltration.

Reticuloendothelial function plays an important role because the severity of cellular immune red cell destruction depends largely on macrophage function. Reticuloendothelial function may be reduced in SLE by the clearance of immune complexes, a process known as reticuloendothelial blockade. In methyldopa-induced AIHA, the drug has been shown to reduce reticuloendothelial clearance of IgG-coated red cells, a possible explanation for the fact that many patients with a strongly positive DAT due to methyldopa have little or no haemolysis.

Hypocomplementaemia or a relative complement deficiency may result from continuous complement activation such as occurs in patients with chronic CHAD. Hypocomplementaemia is common in SLE and there is a strong association between SLE and the occurrence of null alleles for the C2 and C4 genes, which causes a genetically determined complement deficiency.

Clinical features of warm AIHA

Warm-type AIHA affects all age groups and accounts for up to 70% of AIHA cases. The haemolysis is caused by high-affinity IgG antibodies produced by reactive polyclonal B cells. An underlying or associated disorder can be identified in 50–70% of cases and there is a preponderance of female patients in both idiopathic and secondary AIHA.

The clinical presentation is variable and depends on the speed with which anaemia develops, the capacity of the bone marrow to compensate, and the effects of any associated disease. Typically, the onset is insidious, with gradual awareness

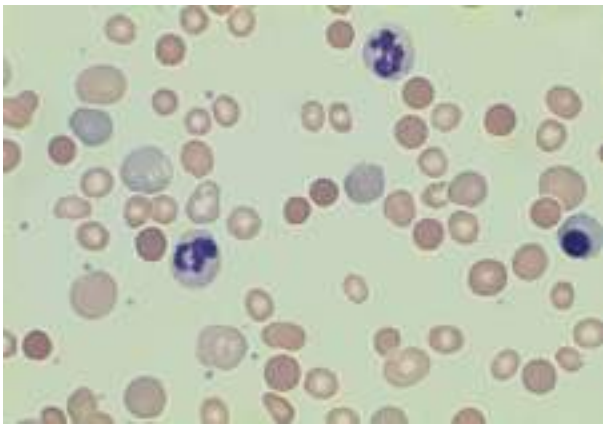

Figure 17.1 Warm autoimmune haemolytic anaemia. Blood film showing spherocytosis (arrows), polychromasia and a nucleated red blood cell (×40).

of symptoms of anaemia or observation of pallor or mild icterus by friends or relatives. Occasionally, the onset is acute, with rapidly developing anaemia and, in older patients, the risk of heart failure. Rarely, severe fulminant haemolysis may occur, resulting in life-threatening anaemia. A moderate increase in unconjugated serum bilirubin and excess urinary urobilinogen occurs as a result of extravascular haemolysis. Where intravascular haemolysis occurs, patients pass very dark urine caused by haemoglobinuria. More marked icterus (bilirubin >90 μmol/L) suggests coexisting liver disease or biliary tract obstruction due to pigment gallstones or biliary sludge. Mild splenomegaly is common, rarely more than 2–3 cm below the costal margin; marked splenomegaly suggests the possibility of an underlying lymphoproliferative disorder.

Anaemia with marked reticulocytosis is present and the peripheral blood film is characterised by polychromasia, spherocytes (Figure 17.1), circulating nucleated red cells and, in some cases, red cell agglutination. Rarely, there may be reticulocytopenia associated with a positive DAT. There is an increase in lactate dehydrogenase (LDH) due to red cell lysis, but other liver function tests are normal unless there is associated liver or biliary tract disease. The DAT is positive, commonly with IgG alone (mainly IgG1 and IgG3 subclasses) or with IgG and complement (the latter pattern commonly seen in SLE). Autoantibody in the serum may show specificity within the Rh system (e.g. auto anti-e), but in most cases is pan-reactive with all red blood cells. The autoantibody reacts at 37 °C. In very rare cases, the amount of antibody remaining on the red cell surface is insufficient to be detected by the conventional DAT.

Idiopathic warm AIHA

Idiopathic warm AIHA with no underlying cause or associated disorder accounts for approximately 30% of patients with a DAT-positive haemolytic anaemia. It may occur at any age; peak incidence occurs in infancy and early childhood with a second rise during the third decade and the majority of cases occurring after the fifth decade. In infancy, the onset is often acute, typically precipitated by infection and transient. However, anaemia may be profound and difficult to control. There is a male preponderance in the childhood setting in contrast to females in adult cases. IgG antibodies can be transferred from an affected mother across the placenta, producing haemolysis in the newborn. A careful drug history should be taken in all cases to exclude haemolysis induced by drugs or by chemical exposure. In girls, AIHA may precede clinical or immunological evidence of SLE which should not be excluded on account of initial negative serology. Clinical presentation may vary from gradual onset of symptomatic anaemia to an acute, fulminating and life-threatening haemolytic process. Systemic symptoms include pallor, jaundice and mild splenomegaly (1.5–5 times normal size). Marked splenomegaly suggests a secondary cause.

Evans syndrome

Evans syndrome is defined as the combination of AIHA and immune thrombocytopenia (ITP) in the absence of any underlying disorder. The onset of thrombocytopenia may coincide with haemolysis or may arise separately. The platelet and red cell antibodies are distinct and do not cross-react. Rarely, episodes of immune neutropenia or pancytopenia have also been described in association with a positive DAT. The diagnosis is important because there appears to be a higher incidence in these cases of underlying conditions including immunodeficiency or autoimmune lymphoproliferative disease (ALPS) in children and of SLE or T-cell lymphoma in adults. Typically, the condition runs a chronic course characterised by relapses and remissions.

Warm AIHA associated with other autoimmune diseases

This is well described in patients with SLE, especially in young women, and in other autoimmune or presumed autoimmune diseases, notably rheumatoid arthritis, Sjögren syndrome and ulcerative colitis. Warm AIHA is also part of the spectrum of autoimmune diseases associated with agammaglobulinaemia. Autoantibodies are usually IgG, and both IgG and C3d are found on the red cell surface. Occasionally, the DAT may be positive because of immune complexes adsorbed onto the red cell surface. The spleen is important for clearing such coated cells and splenectomy should be avoided if possible. Otherwise, treatment is as for idiopathic AIHA (see below).

Lymphoproliferative diseases

Lymphoproliferative diseases, including chronic lymphocytic leukaemia (CLL) and other forms of low-grade B-cell non-Hodgkin lymphoma are well described in association with cases of warm AIHA. The AIHA may precede the diagnosis of lymphoma by

months or years, may occur simultaneously with onset of the lymphoma, or occur afterwards. Antibody response is thought to be due to immune dysregulation rather than direct production by the malignant clone. Antibodies are polyclonal and have no distinct pattern of type or specificity. Refractory autoimmune cytopenias are also well described following the use of therapeutic agents for lymphoma including fludarabine and alemtuzumab, probably the result of their powerful effect on the immune system.

Drug-related warm AIHA

Antibody-induced haemolytic anaemia caused by drugs is rare with an estimated incidence of approximately 1–4 cases per million individuals per year, but it can result in an acute, brisk and potentially life-threatening haemolysis. More than 130 drugs have been implicated, most commonly antibiotics, especially the second- and third-generation cephalosporins, and platinum-based chemotherapies.

Drugs typically have a molecular weight that is too low to be immunogenic (hapten), unless they are conjugated with a larger carrier molecule such as a protein, which then allows them to elicit an immune response. Haemolysis results from antibodies directed against self-antigens induced by a drug and these divide into two broad mechanisms. The first is via drug-dependent antibodies that activate the immune response only while the drug is present; the second is due to drug-independent antibodies, which create an autoimmune response in the absence of the drug. The first mechanism is more common. How these drugs induce autoantibody formation has not been elucidated and a variety of mechanisms have been postulated; however, the same drug at different doses or repeated usage may activate different mechanisms and there are recent suggestions that membrane modification may underlie most of the mechanisms.

Drug adsorption and extravascular haemolysis:

Penicillin is the prototype drug for this mechanism, although other penicillin derivatives and cephalosporins have also been implicated. These drugs form hapten–carrier complexes with plasma proteins enhancing drug-specific antibody production such that an estimated 90% of individuals receiving penicillin will produce clinically insignificant IgM anti-penicillin antibodies. When high-dose intravenous penicillin is administered, the drug is adsorbed onto the red cell surface and becomes non-specifically attached to cell-surface proteins. A minority of patients on high-dose intravenous penicillin therapy (>l million units daily) develop high-titre IgG anti-penicillin antibodies that attach to the drug bound to the red cell surface causing predominantly extravascular haemolysis. Typically, mild to moderate haemolysis occurs, but if unrecognised and large doses of drug are continued in the presence of increasing antibody levels, complement fixation and acute intravascular haemolysis may occur. The DAT, due to IgG on the red cell surface, becomes positive some weeks following treatment. When the drug is stopped, haemolysis stops and the DAT rapidly becomes negative. Antibody in the patient's serum or eluate from the red cells will react with normal red cells only in the presence of the drug. The clinical and serological features are shown in Table 17.2.

Immune complex and complement-activated acute intravascular haemolysis:

Several drugs have been reported to cause immune haemolytic anaemia by this mechanism. Most frequently reported are rifampicin, phenacetin, quinine and, more recently, intravenous cephalosporins and diclofenac (see below). Hapten–carrier complexes are formed between these drugs and plasma proteins, leading to the production of drug-specific antibodies. Once drug antibodies are present, reintroduction of the drug causes

Table 17.2 Drug-induced immune haemolytic anaemias: clinical and serological features.

	Drug adsorption mechanism	Immune complex mechanism	Autoimmune mechanism	Membrane modification mechanism
Examples	Penicillin, Cephalosporins	Third-generation cephalosporins, Quinidine, Diclofenac	Methyldopa, Procainamide, Mefenamic acid, Fludarabine*, Cladribine*	Cephalosporins, Cisplatin, Carboplatin
Dose/duration	Large therapeutic doses/ prolonged	Very low dose on second or subsequent exposure/short	Therapeutic/ about 6 weeks	Therapeutic
Haemolysis	Extravascular Subacute	Intravascular Acute	Extravascular Mild/ subacute	Rare
DAT	IgG ± C3	C3 only	IgG only	IgG
Serum reaction	To drug-treated cells	Only in presence of drug or metabolite	To normal cells	To drug-treated cells
Eluate reaction	To drug-treated cells	Non-reactive	To normal cells	To drug-treated cells

* May change T-cell regulation.

the formation of immune complexes that are adsorbed onto the red cell membrane and activate complement. Classically, haemolysis occurs on the second or subsequent exposure to the drug and may develop within minutes or hours of drug ingestion. Severe intravascular haemolysis may occur with fever, rigors, and, in extreme cases, acute kidney injury. Several groups have reported fatal immune haemolysis with the third-generation cephalosporin, ceftriaxone, whilst others from the same group such as cefotaxime and ceftazidime have also been implicated.

Membrane modification:
Cephalosporins may cause a positive DAT by modifying red cell membrane components, resulting in a positive DAT, without causing haemolysis. Cisplatin, carboplatin and ribavirin in combination with interferon-α (IFN-α) or with pegylated IFN-α can all cause haemolytic anaemia by membrane modification. Ribavirin enters cells, is phosphorylated to ribavirin triphosphate and hydrolysed back to ribavirin in nucleated cells, which leaves the cells as the serum level declines. Red cells lack hydrolysing enzymes so the triphosphate accumulates, altering the membrane and prompting extravascular haemolysis. With ribavirin monotherapy, haemolysis may be compensated by increased marrow activity, but in combination with IFN-α, bone marrow suppression by the latter agent inhibits the compensatory response. In this setting, management involves dose reduction or supportive therapy with recombinant erythropoietin (epo), which may allow continuation of therapy in 10–30% of patients.

Autoimmune mechanism:
Methyldopa was the paradigmatic drug in drug-induced AIHA. There is a delay of some 6 weeks before the DAT becomes strongly positive due to IgG on the red cell surface. Haemolysis may be absent or trivial, although this is not true with some other drugs that produce haemolysis by this route, notably mefenamic acid (Ponstan). The antibodies usually show no Rh specificity when tested against Rh_{null} cells. It is important to note that some drugs produce haemolysis by both the immune complex and autoimmune mechanisms, depending on the circumstances.

The diagnosis of drug-induced immune haemolytic anaemia should be made in three stages: (i) diagnosis of a DAT-positive haemolytic anaemia, (ii) careful drug history and (iii) serological demonstration of drug-specific antibody, which interacts with red cells.

Carcinoma-related warm AIHA

Carcinoma-related warm AIHA has been recorded with a number of malignancies, but it remains unclear whether there is a true association between the tumour and onset of haemolysis. Reports exist in patients with ovarian cysts where the cystic fluid has been found to contain the agglutinin and in patients with ovarian carcinoma.

Viral infections

Viral infections may precede warm AIHA in children, but rarely in adults; the haemolysis is usually brisk, but self-limiting. Hypotheses include alteration of the red cell membrane by the virus, thereby generating 'auto' antibodies against altered antigens or formation of antiviral antibodies that cross-react with membrane antigens. A third possibility involves the formation of immune complexes between the virus and specific antibodies, which are secondarily adsorbed onto the red cell surface, leading to immune destruction.

Clinical management

The indication for treatment of AIHA is symptomatic anaemia, however, treatment in AIHA is largely not evidence-based.

Supportive therapy

Blood transfusion must be given if the clinical situation demands it, if the haemoglobin continues to fall or heart failure develops, despite the impossibility of achieving a satisfactory crossmatch in the presence of a positive DAT. The least incompatible grouped blood should be used and transfused slowly. Some authors recommend the use of blood-lacking antigens to which the autoantibodies react, but others point out that specificity is rarely absolute and that there is a risk of provoking an alloantibody response.

Intravenous immunoglobulin (IVIg) has been used in AIHA, particularly when IgG is the main component on the red cell surface. This is given at the same dose as used for ITP, typically 0.4 mg/kg daily for 5 days or 1 g/kg daily for 2 days. However AIHA responds less frequently to IVIg. Side effects of IVIg include headache, fever–chill reactions and a small but present risk of viral transmission. Folic acid supplements should be given to all patients with chronic haemolysis.

First-line treatment

Corticosteroids are effective in warm AIHA: 70–80% of patients will respond to prednisolone given at a dose of 1 mg/kg body weight once daily for 10–14 days. If parenteral administration is preferred, an equivalent dose of methylprednisolone can be used. In patients who respond, the dose should be reduced steadily using laboratory tests, including Hb and LDH as a guide, it is important not to stop steroids too quickly as this may result in relapse. Although 70–80% of patients improve their Hb initially on corticosteroid treatment only 30% maintain this response long term. Response rates may be improved when steroids are used in combination with rituximab, a chimeric murine–human monoclonal antibody that binds to CD20 antigen on B cells and immature plasma cells. The only two prospective randomised trials of treatment for warm AIHA both

compared prednisolone to prednisolone plus rituximab first line both showed improved responses in the combination arm at 75% versus 31 and 36% at 1 year. However neither study was powered nor had long enough follow-up to address whether the combination reduced the need for other treatments and improved long-term remissions. Rituximab remains unlicensed in AIHA treatment.

Corticosteroids, in general, are well-tolerated by patients, especially over the short term. However, when given for a prolonged period a number of side effects including weight gain, hypertension, diabetes, cardiovascular disease, osteoporosis and immunosuppression may be present. The use of pneumocystis prophylaxis is sometimes considered in patients on long-term steroid therapy.

Second-line treatments

Rituximab remains the most commonly used second-line treatment (when not used up-front). The overall response rate for rituximab from meta-analysis is around 79%, with a median time to response around 3–6 weeks, but 30% of patients who receive it first line relapse after 3 years. Re-treatment of relapsed patients gives similar results. Half the patients in reported studies received concomitant corticosteroids. Rituximab is generally well tolerated, immediate side effects are minimal and mainly infusion-related. It is associated with significant B-cell depletion which causes hypogammaglobulinaemia and prolonged immunosuppression. This can lead to infections such as reactivation of hepatitis B, hence pre-administration screening for hepatitis B is required. A further rare but significant infection risk is with JC virus which may lead to development of multifocal leukoencephalopathy – a rare and usually fatal condition.

Treatment with cytotoxic immunosuppressive drugs is reserved for steroid-refractory patients, and relapse following steroid withdrawal. The mechanism of action of these agents is relatively non-selective, resulting in significant systemic toxicity, including bone marrow suppression, renal toxicity and the potential long-term risk of malignancy. It should be emphasised that there are no controlled trials to prove the worth of cytotoxic drugs in AIHA, but there are small case reports of success with each agent. Response to these drugs is not usually seen for 4–6 weeks and they should be continued for at least 3 months before being deemed ineffective.

Azathioprine has response rates of around 55–60% in warm AIHA and it has significant steroid-sparing action at a dose of 2–2.5 mg/kg daily. Danazol has been used, both in combination with corticosteroids as a first-line treatment and in the refractory setting, with mixed results in AIHA. Other agents include cyclophosphamide 1.5–2.0 mg/kg daily and ciclosporin, starting at 2.5 mg/kg twice daily to achieve trough plasma levels of 100–200 mg/L. There are small case reports of the use of mycophenolate mofetil, an immunosuppressive agent, and of vincristine, a cytotoxic agent with powerful antitumor effect, with some success in severe refractory AIHA. Small case series have also reported some effectiveness with Bortezomib, a proteasome inhibitor used primarily in myeloma therapy.

Splenectomy

Patients with predominantly IgG on the red cell surface respond best to splenectomy, while those with complement respond poorly. Of a selected group of patients post splenectomy, about 40% achieve a complete remission and do not require steroids, and a third will show no or only transient response before relapse; the rest will have reduced steroid requirement. There is no certain way to determine clinical response to splenectomy.

Splenectomy is associated with an increased risk of overwhelming sepsis, therefore all patients should receive pneumococcal, meningococcal and *Haemophilus influenzae B* vaccination at least 2 weeks before the procedure, and prophylactic penicillin indefinitely.

Prognosis

The prognosis of warm AIHA depends on a number of variables, including age, associated diseases and severity of haemolysis. AIHA can be a serious and potentially life-threatening disease with reported estimates of mortality of idiopathic AIHA in adults of 10% at 5 years to 40% at 7 years. Increased mortality typically occurs in patients over 50 years with deaths in the first 2 years after diagnosis usually related to underlying clinical disorders or treatment side-effects. Most children with AIHA recover completely, and mortality is much lower, probably about 5%. Treatment-related side-effects, particularly prolonged high-dose steroid therapy, can result in considerable morbidity.

Cold agglutinin disease

Cold agglutinin disease (CAD) is a relatively uncommon disorder accounting for only 15–30% of AIHA; it occurs mainly in the elderly and typically runs a chronic course. CAD is mostly benign, but the clinical features can be disabling and distressing.

Clinical features of cold agglutinin disease

The clinical features of the cold agglutinin haemolytic anaemia vary with the pathogenesis of the disorder. Symptoms resulting from red cell agglutination are present in most patients and can be problematic, including purplish skin discoloration which is maximal over the extremities (acrocyanosis), most notably present in cold weather. Acrocyanosis occurs due to stasis in the peripheral circulation secondary to red cell agglutination. On warming the skin, the colour returns to normal or there is transient erythema.

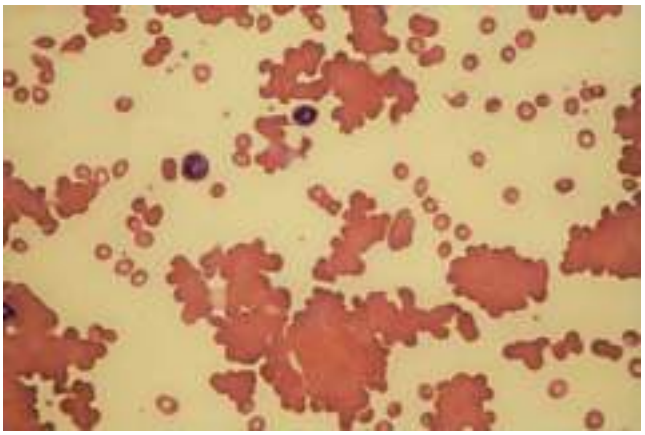

Figure 17.2 Cold haemagglutinin disease. Blood film showing gross haemagglutination (×20).

In the laboratory, spontaneous agglutination of red cells is frequently observed, both macroscopically and on the peripheral blood film if this is made at room temperature (Figure 17.2). Automated blood cell counters detect agglutinates and record erroneously high mean corpuscular volume and low Hb values, unless the sample is tested at 37 °C.

DAT is positive with only C3d on the red cell surface; IgM cold agglutinins are not detected because they elute from the cell surface *in vitro*. The serological characteristics of the antibodies found in these syndromes are shown in Table 17.3. Cold agglutinins are monoclonal IgM κ, with heavy chain variable regions encoded by the *IGHV4*–34 gene segment, but serum electrophoresis may not reveal a monoclonal band because the concentration of the protein is too low.

Traditionally defined by the absence of an underlying disorder, recent studies using sensitive tests including flow cytometry and immunohistochemical assessments have demonstrated a monoclonal CD20-positive κ-positive B-lymphocyte population in the bone marrow of 90% of patients with CAD. Therefore some authorities consider CAD a premalignant B-cell disorder that becomes clinically overt due to the specificity of the antibody for red cell surface antigens. The prognosis is usually that of the underlying lymphoproliferative disease.

Cold agglutinin syndrome

These are usually secondary to either aggressive lymphoma or specific infections, most commonly *M. pneumoniae*, or infectious mononucleosis. Rare cases following *Listeria* or *Toxoplasma* infections have also been reported. These antibodies are mostly polyclonal IgM in type, but occasional IgG cold antibodies are found. The antibodies develop in response to the infectious organism and cross-react with red cell antigens; haemolysis occurs 2–3 weeks after the infection and is usually mild and self-limiting. Acute and potentially fatal episodes of intravascular haemolysis have been reported in association with *M. pneumoniae* infection. Urgent blood transfusion through a blood warmer may be required.

Management of CAD

The management of cold haemagglutinin syndromes may be challenging and is summarised below.

Supportive therapy

The majority of patients with CAD can be managed supportively. All patients should avoid exposure to cold; the use of electrically heated gloves and socks should be encouraged in the winter months. Patients should be nursed in a warm environment, which may include measures such as special blankets during surgical procedures. In the context of infections, the anaemia may be worsen, but this can often be managed with short-term transfusion support

Table 17.3 Serological characteristics of cold-acting antibodies in the cold agglutinin syndromes.

Disorder		Antibody characteristics	
		Specificity	**Clonality and subtype**
Primary	Idiopathic (CHAD)	Anti-I Rarely Anti-P	Monoclonal IgM κ Monoclonal
Secondary	Lymphoproliferative disease	Anti-I Rarely Anti-I	Monoclonal IgM κ/λ (IgG) Monoclonal
	Mycoplasma pneumoniae	Anti-I	Polyclonal
	Infectious mononucleosis	Anti-I Anti-i	Polyclonal
Paroxysmal cold haemoglobinuria		Anti-P Donath–Landsteiner (biphasic)	Polyclonal IgG

CAD, cold agglutinin disease.

without committing to long-term systemic therapy. Blood transfusions should be given with due regard to the difficulty in cross-matching in the presence of cold haemagglutinins. Blood should be given through an in-line blood warmer.

Plasma exchange (therapeutic apheresis) can be used to control severe symptoms by temporarily lowering the titre of cold agglutinins, but it has no effect on the underlying disease. If patients are severely symptomatic despite supportive treatment then they may require systemic therapy (see below).

Management of secondary CAS is usually supportive. Transfusions are given when indicated with the same precautions as in primary CAD. The rest of the management strategy aims at treatment of the underlying condition where possible.

Folic acid supplements should be given to patients with chronic haemolysis.

Drug treatments

Unlike warm-type AIHA, corticosteroids are rarely of use in CAD and should only be used in exceptional circumstances when antibodies are present in low titres and have a high thermal range. Rituximab, the anti-CD20 monoclonal antibody has been shown to be effective in idiopathic CAD and in cold agglutinin syndromes (CAS) associated with LPD. Response rates of up to 50% have been reported in phase II studies, but with a short duration of response around 11 months. Longer response is seen with a combination of rituximab and fludarabine, with remission in 75% of patients and median duration of over 66 months. However, significant side-effects including grade 3–4 neutropenia make this regimen unsuitable for elderly patients. Rituximab and bendamustine in combination also resulted in improved response rate of 71% (40% complete remission and 31% partial remission), and only 20% had neutropenia suggesting that this regimen is more widely applicable to the older patient population.

Anaemia in CAD is caused by complement-mediated red cell lysis and complement inhibition in the treatment of CAD has shown promise. The classical pathway components responsible for extravascular haemolysis in CAD occur at the C3 level. Eculizumab is a humanised monoclonal antibody that inhibits cleavage of C5 into C5a and C5b preventing the formation of the terminal complement system including the formation of the membrane attack complex. Eculizumab will not inhibit the C3b-mediated extravascular haemolysis and therefore blockade of C5, but it was the first complement inhibitor to be used in the treatment of severe CAD, and a small trial demonstrated significant reductions in LDH, haemoglobin stabilisation and transfusion avoidance.

Blockade at the C3 level is more promising. Sutimlimab is a humanised monoclonal antibody that inhibits C1s to stop complement-mediated haemolysis and is in phase 3 trials. Similarly, Pegcetacoplan, a subcutaneously administered peptide molecule that binds C3 and C3b thereby reducing both extravascular and intravascular haemolysis, is also under investigation in CAD.

Paroxysmal cold haemoglobinuria (PCH)

This rare syndrome occurs in children following acute viral infections or childhood immunisations. A history of cold exposure is not always present and presentation is acute with significant intravascular haemolysis resulting in pallor, dark urine (haemoglobinuria), abdominal pain and sometimes collapse. The original cases were described by Donath, Landsteiner and Ehrlich in congenital and tertiary syphilis. The cold antibody is a biphasic polyclonal IgG antibody (Donath–Landsteiner antibody) that reacts with the P antigen on red cells below 20 °C in the peripheral circulation, with subsequent lysis by complement activation on rewarming to 37 °C in the central vessels. Treatment involves strict avoidance of cold and keeping the patient warm, preferably at an ambient temperature of 37 °C until the self-limiting pathological process subsides.

On the rare occasions where there is brisk haemolysis causing symptomatic anaemia such that blood transfusion is required, obtaining compatible P-negative or pp donor red blood cells for transfusion is difficult, as the P antigen is a high incidence antigen and most blood donors are P positive. Despite this *in vitro* serologic incompatibility, there are several case reports of successful transfusion of P-positive red cells to patients with PCH who then achieve a rise in Hb level without precipitation of further haemolysis. In emergency cases associated with symptomatic anaemia despite supportive measures, transfusion of ABO- and Rh-compatible P-positive blood should be used. It is important that the blood is transfused using a blood warmer or where this is not available, that the patient is kept warm and transfused slowly.

There are case reports of chronic or refractory disease, particularly in adults, where rituximab has been used successfully, and eculizumab has also been used with some success in refractory paediatric cases.

Alloimmune haemolytic anaemia with anti-D

Severe, acute intravascular haemolysis has been reported in some patients, 1–24 hours following treatment with a number of intravenous anti-D immunoglobulin preparations, which have been licensed for treatment of ITP in unsplenectomised RhD-positive patients. In this setting, higher doses are used than for prevention of haemolytic disease of the fetus and newborn. The mechanism of action is thought to be inhibition of platelet destruction by the spleen due to phagocytosis of coated red cells. Intravascular haemolysis may lead to oliguria and disseminated intravascular coagulation (DIC) and a number of deaths have been reported. The reaction is similar to that seen following mismatched transfusion reactions (see Chapter 19), but so

far no culpable antibodies other than anti-D have been detected in different batches of the anti-D preparations tested. The reaction does not happen at the doses used to prevent Rh sensitisation in pregnancy.

Non-immune acquired haemolytic anaemias

Haemolysis and haemolytic anaemia may be the consequence of a wide variety of acquired conditions that do not lend themselves to a precise and logical classification. Classification tends to be based on causes rather than mechanisms, although there are some common pathogenic mechanisms that lead to red cell destruction. The main groups of agents causing haemolysis are infections, vascular disorders (mechanical disorders), chemical and physical agents and disorders affecting the red cell membrane. A classification is shown in Table 17.4.

Infections causing haemolytic anaemia

A variety of infections may produce haemolysis through several different pathways. Haemolysis may be a consequence of direct invasion of the red cell by a microorganism or may arise from alterations in the microcirculation, leading to mechanical haemolysis. The intracellular organisms tend to produce the more severe haemolysis.

Malaria

Some degree of haemolysis is seen in all types of malarial infection, but the most severe abnormalities are found in *Plasmodium falciparum* infection (Figure 17.3). *Plasmodium falciparum* infection is one of the most common causes of anaemia in the world. Many factors may contribute to the anaemia, including marrow suppression, dyserythropoiesis, folate deficiency, hypersplenism and red cell sequestration, as well as haemolysis. The condition has two main components: extravascular destruction

Table 17.4 Non-immune acquired haemolytic anaemias.

Cause	Mechanisms	Examples
Infections	Intracellular organisms	*Falciparum* malaria Babesiosis *Bartonella*
	Endotoxin-induced DIC	Meningococcal sepsis Pneumococcal sepsis Gram-negative sepsis
	Haemophagocytic syndromes	Atypical mycobacterial infections HIV Viruses
	Enzyme toxins	*Clostridium perfringens* Snake, spider bites
Chemical and physical agents	Oxidative damage	Drugs Industrial/domestic substances
	Heat	Burns
	Osmotic lysis (fresh water), dehydration of red cells (salt water)	Drowning
	Enzyme inhibition	Lead poisoning Copper (Wilson disease)
Fragmentation (mechanical)	Lysis on prosthetic surfaces	Cardiac haemolysis Perivalvular leak
	Vasculitis, endothelial cell swelling, fibrin shear	Microangiopathic haemolytic anaemia March haemoglobinuria
Acquired membrane disorders	Lipid or cholesterol changes Somatic mutation	Liver disease Paroxysmal nocturnal haemoglobinuria (PNH)

DIC, disseminated intravascular coagulation.

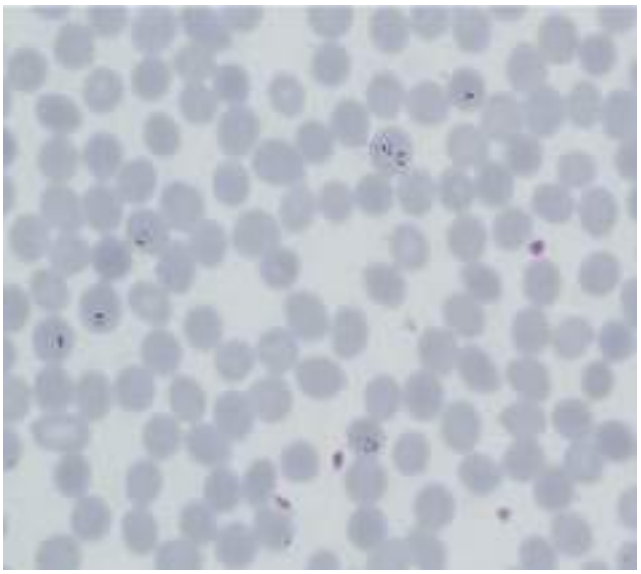

Figure 17.3 *Falciparum* malaria infection (Giemsa × 100) (Source: Dr Robin Ireland. Reproduced with permission).

of parasitised cells in the reticuloendothelial system, particularly the spleen, and intravascular lysis when the sporozoites break out of the red cells into the circulation. In most patients, the systemic symptoms of malaria dominate the clinical picture, but occasionally, acute intravascular haemolysis is the presenting problem. Haemolysis in malaria may be associated with a positive DAT.

Blackwater fever

This is an uncommon, but well-described and feared complication of *falciparum* malaria with an acute and potentially fatal episode of intravascular haemolysis leading to the passing of black or dark-red urine. Occurring after a few days of malaria fever, the patient presents with further fever and rigors, loin pain and appearance of black urine. Acute hypovolaemia and hypotension may result in oliguric acute kidney injury if not promptly managed, and in some cases, pulmonary and cerebral symptoms may develop. The condition is reported in all ethnic populations in endemic areas and does not seem to be confined to non-immune individuals. In indigenous populations, glucose-6-phosphate dehydrogenase (G6PD) deficiency may play a part in the pathogenesis in addition to quinine exposure. The spread of chloroquine-resistant malaria in the Far East led to increased use of quinine and subsequently, to an increase in the incidence of blackwater fever.

The degree of parasitaemia is very variable, and the red cell count may fall to 1×10^{12}/L within 24 hours of the start of the haemoglobinuria. There is usually a rise in fibrin degradation products in the serum, but this rise is not often marked and is compatible with a degree of kidney injury. Intravascular coagulation does not seem to play a major role in the pathogenesis.

Immediate treatment includes correction of fluid and electrolyte loss, transfusion support and eradication of the parasite. Renal dialysis may be required and it is important to note that renal supportive therapy may need to continue for a period of weeks before renal function returns. Subsequent attacks of *falciparum* malaria may produce further episodes of blackwater fever making adherence to prophylaxis mandatory in susceptible individuals.

Babesiosis

Infection with the intracellular protozoan *Babesia* is uncommon and symptomatic disease is mostly confined to splenectomised patients. *Babesia* is a tick-borne organism; the tick in Europe, *Ixodes ricinus*, is associated with cattle, whilst in North America *Ixodes dammini* is carried by rodents and deer. Transmission can also occur by blood transfusion. In splenectomised patients, the disease has an acute onset and in the European variety, can be fatal. A period of malaise for 1–3 days may be followed by vomiting, diarrhoea, high fevers, rigors, jaundice, acute intravascular haemolysis, haemoglobinuria, acute kidney injury and death. In North America, unsplenectomised patients tend to experience a milder self-limiting haemolytic anaemia. The diagnosis is made from identification of the parasites, very similar to *P. falciparum*, within the red cells in the peripheral blood film. A history of tick bite or exposure to potential vectors should be sought. Treatment is difficult. Clindamycin and quinine are standard therapy, whilst red cell exchange transfusion and renal support may be required in severely affected patients.

Bartonella (Oroya fever)

Bartonella bacilliformis is an arthropod-transmitted infection found only in the western Andes of Peru and neighbouring countries. The diagnosis is made from the peripheral blood film. The organism is an intracellular Gram-negative rod during the acute attack, which becomes coccoid in recovery. In non-immune individuals, presentation is with anaemia which occurs partly through intravascular haemolysis and partly through erythrophagocytosis as well as splenomegaly. The organism is rapidly killed by chloramphenicol, tetracyclines, penicillin and aminoglycosides.

Clostridium perfringens

Clostridium perfringens septicaemia causes an intense intravascular haemolysis with prominent microspherocytosis and ghost cells in the peripheral blood film. The spherocytosis is the result of membrane destruction by lipases and proteases produced by the organism. Although the organism is sensitive to a variety of antibiotics, the appearance of intravascular haemolysis is usually a harbinger of death because of the toxaemia.

Toxoplasmosis

Infection with *Toxoplasma gondii* acquired *in utero* may produce haemolysis and a syndrome similar to haemolytic disease of the newborn. In adults, toxoplasmosis is not associated with haemolysis, except perhaps in the immunocompromised host.

Bacterial infections

Intravascular coagulation produced by bacterial infection may be accompanied by some degree of intravascular haemolysis with fragmentation of red cells. Septicaemia from meningococcal or pneumococcal infection may result in haemolysis, which is not as clinically significant as the other effects of the septicaemia.

Haemorrhagic fevers

The haemorrhagic fevers may be accompanied by haemolysis. These include dengue fever, which is present worldwide, yellow fever, and West African haemorrhagic fevers, which are mainly found in Africa.

Fragmentation haemolysis: mechanical haemolytic anaemias

Fragmentation haemolysis may occur in the presence of prosthetic materials, due to altered flow following cardiovascular surgery, due to trapping or adherence of red cells in arteriovenous malformations and as a result of the destruction of red cells in pathologically altered small blood vessels (microangiopathic haemolytic anaemia). Characteristic features of fragmentation haemolysis are the appearance of the blood film (Figure 17.4) and the presence of intravascular haemolysis. Depending on the underlying vascular pathology, there may be a reduction in the platelet count and evidence of DIC. The rate of red cell destruction also varies according to the pathogenesis, so the signs of intravascular haemolysis vary from absence of haptoglobin, elevated LDH and minimal haemosiderinuria to acute intravascular destruction with haemoglobinaemia and haemoglobinuria. The major causes of fragmentation haemolysis are shown in Table 17.5.

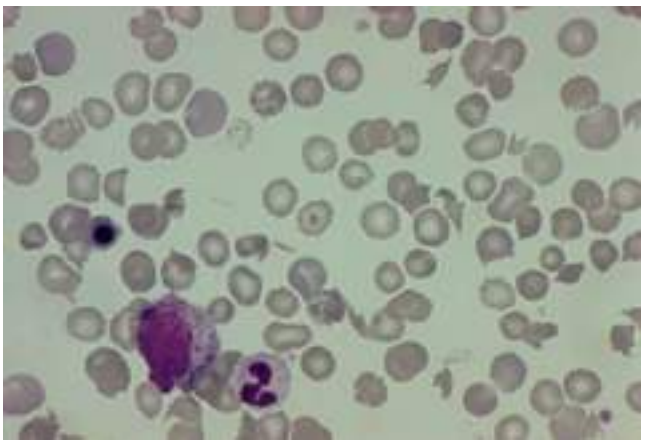

Figure 17.4 Microangiopathic haemolytic anaemia. Blood film from a patient with carcinoma and bone marrow metastases. Note fragmentation of red cells, low platelets and leucoerythroblastic changes (circulating nucleated red cell and metamyelocyte) suggestive of underlying disseminated intravascular coagulation (×40).

Table 17.5 Classification of anaemias caused by fragmentation haemolysis.

Vascular origin	Pathogenesis	Platelets
Cardiac haemolysis	Prosthetic heart valves	Normal
	Patches, grafts	
	Periprosthetic or perivalvular leaks	
Arteriovenous malformations	Kasabach–Merritt syndrome	Very low
	Malignant haemangioendotheliomas	
Microangiopathic (see also Table 17.6)	TTP/HUS	Low
	Malignant disease	Normal/low
	Vasculitis	Normal/low
	Pre-eclampsia, HELLP	Low
	Renal vascular disorders	Normal/low
	Disseminated intravascular coagulation	Low

HELLP, haemolysis with elevated liver function tests and low platelets; HUS, haemolytic–uraemic syndrome; TTP, thrombotic thrombocytopenic purpura.

Haemolysis associated with cardiac surgery

Cardiac haemolytic anaemia was a term coined to describe haemolysis following cardiac surgery that involved the insertion of prosthetic valves, patches or grafts. Mechanical trauma to red blood cells is the primary cause of haemolysis in this setting and is mainly due to increased turbulent flow resulting in excessive shearing forces on the surface of the red cells. Secondary physiologic mechanisms include pressure fluctuations, intrinsic abnormalities of the red cell membrane (largely due to fragile, iron-poor red cells in iron-deficient patients), interaction with foreign surfaces and unfavourable flow characteristics of valves. Clinical situations in which cardiac haemolysis may be of considerable importance include:

- *Periprosthetic or perivalvular haemolysis* – following insertion or repair of a heart valve, a leak occurs around the valve or through a suture track, which may cause severe intravascular haemolysis without haemodynamic distress. Laboratory diagnosis may be difficult because red cell fragmentation may not be prominent on the blood film, although spherocytes may be present.

The diagnosis is made by exclusion of an autoimmune haemolysis in a patient who experiences intravascular haemolysis following recent cardiac surgery. The haemolysis can only be cured by further surgery.

- *Ambulatory haemolysis* occurs when a patient who has undergone valve replacement shows evidence of mild haemolysis while in hospital but experiences significant anaemia after discharge. The higher cardiac output associated with greater exercise following discharge from hospital produces greater turbulence and results in red cell fragmentation. A similar mechanism may occur if the patient becomes iron deficient as a result of chronic intravascular haemolysis. Iron replacement and advice about slowly increasing exercise levels may prevent the need for further surgery.
- *Cardiopulmonary postperfusion syndrome* – acute intravascular haemolysis may occur in patients who have undergone cardiopulmonary bypass surgery. The haemolysis may be accompanied by neutropenia and pulmonary distress. Although clearly relevant to patients with cardiac pathology, this syndrome is not strictly classified as cardiac haemolysis since the haemolysis seems to be caused by complement activation and binding of the membrane attack complex to the red cell surface. The blood film shows ghost red cells rather than fragmentation. The condition is self-limiting and the patient requires only supportive care.

Arteriovenous malformation

Fragmentation of red cells may be seen in Kasabach–Merritt syndrome, in which platelets are trapped in the vascular network of giant arteriovenous malformations, sometimes with evidence of a consumption coagulopathy. The bleeding disorder that ensues is of greater significance than haemolysis in these patients. A similar pattern is seen in malignant haemangioendothelioma, in which the tumour invades and grows alongside veins resulting in a consumptive coagulopathy with laboratory evidence of DIC.

Microangiopathic haemolytic anaemias (MAHA)

These are conditions in which intravascular haemolysis with fragmentation of red cells is caused by their destruction in an abnormal microcirculation. Proof of microangiopathy may be lacking in those not subjected to a post-mortem examination, and MAHA should be considered a clinical syndrome. The three main pathological lesions that give rise to MAHA are deposition of fibrin strands, often associated with DIC, platelet adherence and aggregation, and vasculitis. The vessel abnormalities may be generalised or confined to particular sites or organs. In most cases, haemolysis is of less consequence than the underlying cause of the microangiopathy, but fragmentation of red cells helps to confirm the diagnosis. Some of the disorders producing MAHA are given in Table 17.6 and the more well-defined clinical syndromes are described in detail here.

Table 17.6 Causes of microangiopathic haemolytic anaemia.

Disease	Microangiopathy
Haemolytic–uraemic syndrome	Endothelial cell swelling, microthrombi in renal vessels
Thrombotic thrombocytopenic purpura	Platelet plugs, microaneurysms, small-vessel thrombi
Renal cortical necrosis	Necrotising arteritis
Acute glomerular nephritis	
Malignant hypertension	
Pre-eclampsia	Fibrinoid necrosis
HELLP	
Polyarteritis nodosa	Vasculitis
Granulomatosis with polyangiitis	
Systemic lupus erythematosus	
Homograft rejection	Microthrombi in transplanted organ
Mitomycin C	Uncertain
Ciclosporin	Renal vessel anomalies
Carcinomatosis	Abnormal tumour vessels, intravascular coagulation (disseminated or localised)
Primary pulmonary hypertension	Abnormal vasculature
Cavernous haemangioma (Kasabach–Merritt)	Local vascular changes, thrombosis

HELLP, haemolysis with elevated liver function tests and low platelets.

MAHA and malignant disease

Fragmentation of red cells with chronic intravascular haemolysis may occur in malignant disease. Clinically significant anaemia may occur, especially when the tumour invades large blood vessels, as occurs in haemangiopericytoma, but more commonly haemolysis is trivial or well-compensated. Other malignancies closely associated with MAHA include mucin-secreting tumours and acute leukaemia, particularly, but not exclusively, acute promyelocytic leukaemia, where acute intravascular coagulation occurs and dominates the clinical picture. A blood film showing evidence of MAHA together with leucoerythroblastic changes may be suggestive of malignant disease with secondary deposits in the bone marrow (Figure 17.4).

MAHA and infection

Infections, particularly septicaemia, may provoke intravascular coagulation and MAHA. Generally, the coagulation changes and septic shock overshadow the mild fragmentation, but occasionally infections produce a chronic state of partially compensated intravascular haemolysis and marked red cell

fragmentation. Haemolytic–uraemic syndrome (HUS) may be precipitated by infection, particularly *Escherichia coli* O157.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP) is an acute syndrome characterised by fever, neurological signs, haemolytic anaemia with fragmented red cells and profound thrombocytopenia (Chapter 46). There is severe deficiency of von Willebrand factor cleaving protease (also known as *ADAMTS13*) to less than 10% of normal activity due to formation of auto-antibodies directed against it. The diagnosis is made on the basis of the clinical presentation and evidence for haemolytic anaemia with fragmented red cells and thrombocytopenia.

March haemoglobinuria

Haemoglobinuria following running has been documented for about 100 years. Its origin is mechanical, with destruction of red cells occurring in the feet. It can be cured by wearing soft shoes or running on soft ground. The disorder may arise in joggers and is benign except that it may lead to extensive invasive investigations unless recognised. The blood film does not show any red cell fragmentation or consistent abnormality. Occasionally, haemoglobinuria after running is accompanied by nausea, abdominal cramps and aching legs and enthusiastic athletes with this condition may exhibit mild splenomegaly and jaundice.

Chemical and physical agents

Oxidative haemolysis

Oxidative substances may cause haemolysis in people with normal red cell metabolism and normal HbA if the oxidative stimulus is large enough. The major causes of oxidative haemolysis in normal subjects are shown in Table 17.7. The clinical features of this condition are dependent on the main sites of oxidative attack: whether on the membrane of the red cell (intravascular haemolysis), the globin chains (Heinz body formation) or the haem group (methaemoglobin accumulation).

Dapsone and sulfasalazine (Salazopyrin) will cause oxidative intravascular haemolysis in normal subjects if taken in sufficiently high dosage. Normal doses will cause significant oxidative haemolysis when given to G6PD-deficient patients. The blood film shows polychromasia, macrocytosis and the classical 'bite' abnormality of the chemically damaged cell (Figure 17.5). Heinz bodies appear on the blood film when G6PD haemolysis occurs in hyposplenic individuals, but they are absent or scanty in patients with an intact spleen. Haemolysis is usually well-compensated and there is no need to stop the treatment unless the anaemia is severe. Methaemoglobinaemia is uncommon unless the patient is partially deficient in NADH methaemoglobin reductase.

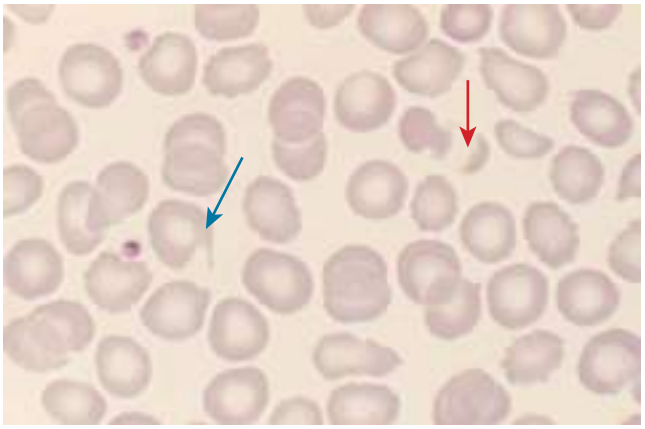

Figure 17.5 Oxidative haemolysis caused by drug (phenacetin). Note red cells with bite cells (blue arrow) and contracted haemoglobin (red arrow).

Table 17.7 Substances causing oxidative haemolysis and/or methaemoglobinaemia in people with normal red cell metabolism.

Substance	Use	Remarks
Dapsone	Leprosy, dermatitis herpetiformis	Chronic haemolysis; slow acetylators more susceptible
Maloprim	Antimalarial	Methaemoglobinaemia in NADH methaemoglobin reductase-depleted subjects
Sulfasalazine	Ulcerative colitis	Chronic intravascular haemolysis
Phenazopyridine	Analgesic in urinary tract infections	Methaemoglobinaemia
Menadiol	Water-soluble vitamin K analogue	Haemolysis/kernicterus in infants
Nitrites	Fertiliser; present in well water, some vegetable juices	Methaemoglobinaemia in infants
Nitrates	Amyl nitrate, butyryl nitrite; abused recreationally	Methaemoglobinaemia/haemolysis
Chlorate	Weed-killer	Acute intravascular haemolysis; acute kidney injury; >30 g fatal
Arsine	Gas produced in smelting and other industrial processes	Acute intravascular haemolysis; renal failure

Methaemoglobinaemia

Methaemoglobinaemia may be caused by nitrites in water and by vegetable juices in infants with physiological impairment of the reducing systems. Well water that comes from land with an excess of nitrites and which is used to reconstitute artificial feeds has produced cyanosis in infants. Cases have also been described following the enthusiastic feeding of juice from carrots grown on organically fertilised land and of spinach juice (spinach has a high concentration of nitrogen-fixing bacteria on its leaves). Nitrate drugs, for example, amyl nitrate, also produce methaemoglobinaemia and have proved fatal when taken in sufficiently high dosage for 'recreational' purposes. Water-soluble analogues of vitamin K (menadiol sodium diphosphate) cause haemolysis with or without methaemoglobinaemia in infants and *in utero* if given to the mother during the third trimester. Fat-soluble vitamin K preparations must be used if required in these situations. Methaemoglobinaemia due to oxidative drugs rarely causes problems with oxygen delivery, but severe cases (>40% methaemoglobin) may be treated with intravenous methylene blue 1–2 mg/kg. Ascorbic acid by mouth may also be used. These measures are ineffective in G6PD-deficient patients and when very strong oxidant substances are implicated. In these circumstances, methylene blue should be avoided because it acts as an oxidant and makes the condition worse.

Methaemoglobinaemia following exposure to strong oxidising substances may cause acute intravascular haemolysis and acute kidney injury. These substances are found mainly in industrial or horticultural settings and include sodium chlorate, a weed-killer, and arsine, a gas produced in various industrial situations such as dross removal in smelting procedures and drain clearance where arsenic is a contaminant. Acute intravascular haemolysis and haemoglobinuria develop 1–24 hours after exposure, depending on the dose. The serum becomes brown, often very dark, so that blood cells cannot be seen in anticoagulated preparations, due to the presence of methaemalbumin, methaemoglobin and free haemoglobin. Vomiting, abdominal pain and oliguric acute kidney injury usually develop over about 24 hours. The blood film shows microspherocytosis, ghost cells and bizarre forms. Urgent treatment is required with red cell exchange and renal dialysis, methylene blue is ineffective.

Thermal injury

Normal red cells when heated *in vitro* to 46 °C for 1 hour show no changes, however they show temperature- and duration-dependent changes above 47–50 °C. Some hereditary membrane defects produce red cells that have increased thermal fragility.

Severe burns

Severe burns may be accompanied by intravascular haemolysis with haemoglobinuria. The intravascular haemolysis is related to the extent and severity of the burns. The gross haemoglobinuria occurs over the first 24 hours after the burns and ceases thereafter. The blood film shows spherocytosis and schistocytes, the morphological abnormalities reflecting the thermal damage and the amount of lysis. Prolonged anaemia after burning is related to inflammation, occult blood loss and infection rather than haemolysis.

Lead poisoning

Haemolysis is an important contributor to the anaemia associated with excessive lead exposure. Lead is a potent inhibitor of pyrimidine 5′-nucleotidase 1 (P5N1). This is the prime mechanism of lead-induced haemolysis, producing the same gross basophilic stippling of the red cells as seen in the inherited deficiency of the enzyme (see Chapter 16). P5N1 activity is a good surrogate marker for lead exposure.

Acquired disorders of the red cell membrane

The most common acquired disorder is paroxysmal nocturnal haemoglobinuria (PNH), caused by somatic mutation of the phosphatidylinositol glycan A (*PIGA*) gene on the X chromosome, which leads to failure to produce the glycosylphosphatidylinositol (GPI) anchor needed to transport and attach many proteins to the red cell membrane. Intravascular haemolysis occurs through the unchecked action of activated complement.

Some degree of shortening of red cell survival occurs in most cases of acute hepatitis, cirrhosis and Gilbert disease, but anaemia is not present and there is only a slight rise in reticulocytes. Biliary obstruction is associated with the appearance of target cells and fulminant hepatitis with acanthocytosis, both due to changes in plasma lipid composition.

The mature red cell does not have the capacity to repair its membrane, the lipids of the membrane are in equilibrium with the lipids of the plasma and changes in the ratio of free cholesterol to phospholipids in plasma may affect red cell shape and, in some instances, lead to haemolysis. Although most commonly seen in liver disease, other inherited lipid disorders may also affect the red cell secondarily.

Zieve syndrome

Zieve syndrome is an uncommon disorder seen mainly in individuals with alcohol use disorder. It comprises intravascular haemolysis and acute abdominal pain in patients with jaundice and cirrhosis. The cause is unknown but is probably related to lipid changes in the blood. Spherocytes are seen in the peripheral blood.

Wilson disease

Wilson disease may present as acute intravascular haemolysis. This is probably not a membrane disorder but is consequent on the high levels of copper ions in the blood. The haemolysis may antedate development of hepatic or neurological features, but Kayser–Fleischer rings are usually present. The blood film may show spherocytosis. The diagnosis is made once the condition is suspected. Apart from caeruloplasmin deficiency, patients have a specific aminoaciduria.

Hereditary acanthocytosis (abetalipoproteinaemia)

This rare inherited deficiency of low-density lipoproteins is characterised by retinitis pigmentosa, steatorrhoea, ataxia and intellectual disability. The haemolysis that occurs is of minor importance to such patients, but the blood film may indicate the diagnosis, with the red cells showing marked acanthocytosis.

Vitamin E deficiency

Deficiency of vitamin E may occur in premature and other infants who are fed a commercial formula that is rich in polyunsaturated fatty acids. Vitamin E is an antioxidant and oxidative damage to the red cell membrane is thought to be the cause of the haemolysis. Clinically, generalised oedema associated with haemolytic anaemia is reported in association with low levels of vitamin E in premature infants aged between 4 and 8 weeks. There is laboratory evidence of haemolysis with contracted red cells and a thrombocytosis, all of which are corrected following adequate vitamin E replacement therapy.

Introduction

Red cell immunohaematology is the study of the interactions between blood group antigens and their corresponding antibodies, both *in vivo* and *in vitro*, and of the presence or absence of clinical consequences following those interactions. It encompasses: (i) determination of the phenotype of red cells from donors and patients, defined by antibodies, (ii) the search for and identification of antibodies in patients' sera, with red cells of known phenotype, (iii) in the presence of clinically significant antibodies, compatibility testing of patients' sera against selected cell samples from ABO compatible donor units and (iv) investigation of adverse effects due to incompatibility.

The aim of this chapter is to provide an introduction to blood group serology, to include aspects of immunology, biochemistry and molecular genetics that contribute to our understanding of blood group antigens, antibodies and antigen–antibody reactions, and to provide some details on the blood group systems of most relevance to blood transfusion.

Blood group systems

The International Society of Blood Transfusion recognises 393 red cell surface antigens, 366 of which belong to one of 47 blood group systems (Table 18.1). Each system represents either a single gene or two or three very closely linked homologous genes. Each system is genetically discrete from all others. In addition, there are 27 antigens that have not been included in systems, owing to inadequate genetic evidence. Most blood groups are inherited as Mendelian characteristics, although environmental factors may occasionally affect blood group expression. The 47 systems represent a total of 52 genes: MNS contains 3 loci, Rh, Xg and Ch/Rg 2 loci each, and the other 43 systems each contain a single gene. The majority of the genes are autosomal, except for *XG*, *XK*, and *ATP11C* which are on the X chromosome, and *CD99*, which is located on both the X and Y chromosomes. All 52 genes have been identified and sequenced.

The red cell membrane and chemistry of blood group antigens

The red cell membrane is composed of about 40% (w/w) lipids and up to 10% carbohydrates, the remainder being protein. Blood group antigens may be integral proteins or glycoproteins of the red cell membrane, or they may be membrane glycolipids. In proteins and glycoproteins, blood group polymorphisms and variants may represent differences in the amino acid sequence (e.g. Rh and Kell blood group systems). In glycoproteins and glycolipids, the blood group activity may reside in the carbohydrate moiety and polymorphism is associated with differences in the oligosaccharide sequence (e.g. ABO). In some glycoproteins, blood group polymorphism may be caused by amino acid substitutions, but antigen expression is also dependent on glycosylation of the polypeptide.

The integral proteins of the red cell membrane penetrate the lipid bilayer and, in some cases, are bound to the membrane skeleton or cytoskeleton. Cell-surface proteins are not necessarily discrete units within the cell membrane; they may congregate

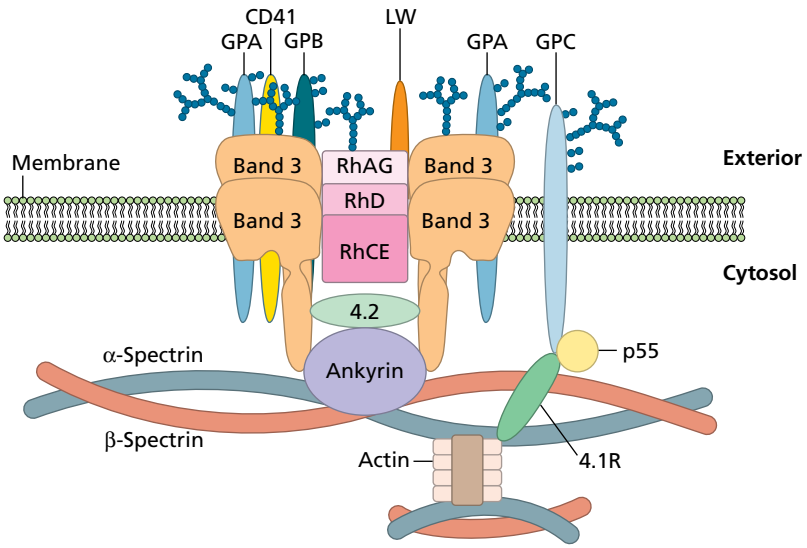

Figure 18.1 Diagrammatic representation of some integral red cell membrane proteins, including the band 3/Rh macrocomplex and components of the membrane cytoskeleton.

together in lipid rafts or might be part of complexes of proteins in which the components contribute to the function of the whole (Figure 18.1). There are four types of integral proteins in the red cell membrane. Type 1 glycoproteins, typified by the glycophorins, carrying the MNS antigens, cross the membrane once, with the amino-terminal domain on the outside and the carboxy-terminal domain in the cytosol. The Kell glycoprotein is a type 2 structure. It also crosses the membrane once but has the carboxy-terminal domain on the outside and the amino-terminal domain in the cytosol. Type 3 glycoproteins are polytopic: they cross the membrane several times giving rise to a series of extracellular loops, one of which is usually glycosylated. These N-glycans express ABO, H and Ii blood group activity. In most of these type 3 proteins, both terminal domains are cytosolic (e.g. Rh proteins, band 3, glucose transporter, Kidd glycoprotein), but the Duffy glycoprotein has an extracellular amino-terminal domain. Type 5 membrane glycoproteins, which include the Dombrock and Cromer glycoproteins, reside in membrane microdomains rich in cholesterol known as lipid rafts and are attached to the lipid bilayer by a glycolipid, the glycosylphosphatidylinositol (GPI) anchor. There are no Type 4 proteins in the red cell membrane.

On the inside of the lipid bilayer is a network of glycoproteins that comprise the cytoskeleton, which is responsible for maintenance of the shape and integrity of the red cell as it squeezes through the tiniest capillaries. The main components of the membrane skeleton are the α- and β-subunits of spectrin, which form long flexible rods, plus actin, ankyrin, proteins 4.1R and 4.2, and several other glycoproteins. Band 3, the anion exchanger and Diego blood group protein, has an extended N-terminal domain attached to the membrane skeleton through ankyrin and proteins 4.2 and 4.1R. Glycophorin (GP) C and GPD, the Gerbich glycoproteins, have C-terminal domains attached to the membrane skeleton through protein 4.1R and p55. In addition, there is evidence that several other integral membrane proteins interact with components of the membrane skeleton. Absence or reduced levels of these integral membrane proteins that interact with the membrane skeleton often result in some degree of abnormal red cell morphology (see Chapter 16).

ABH and Ii antigens are found predominantly on the carbohydrate moieties of the major red cell glycoproteins band 3 (anion exchanger) and on the glucose transporter, although they are also present on type 3 and some other minor glycoproteins and on the carbohydrate portions of membrane glycolipids. P, P1 and P^k antigens are expressed on the carbohydrate of glycolipids. The M and N antigens arise from interactions between the carbohydrate and polypeptide in glycophorin A. In addition to the antigens on integral membrane components, the Lewis and Chido/Rogers antigens are not of erythroid origin, but are adsorbed from the plasma.

Blood group antibodies

Several terms have been used in the past and are still sometimes used to describe different types of blood group antibodies, including 'naturally occurring' and 'immune' antibodies, and 'cold' and 'warm' antibodies. They are described below and an attempt is made to correlate these terms with the class of immunoglobulin involved.

Naturally occurring and immune antibodies

Antibodies are naturally occurring when they are produced without any obvious immunising stimulus, such as pregnancy or transfusion. These antibodies are not present at birth and, in the case of anti-A,B anti-A and anti-B, start to appear in the serum at about 3–6 months of age. ABO antibodies are probably

produced in response to antigens of bacteria, viruses and other substances that are inhaled or ingested. Despite this probable antigenic stimulus, the term 'naturally occurring' is retained for these 'non-red-cell-induced' antibodies. 'Immune' red cell or alloantibodies are only produced after pregnancy or following transfusion or injection of blood or blood group substances.

Cold and warm antibodies

Cold antibodies give higher agglutination titres at low temperatures (0–4 °C), and many of them will not agglutinate red cells at 37 °C. Most naturally occurring antibodies are cold-reacting. Some, such as naturally occurring anti-A,B have a wide thermal range and will react at 37 °C, activating complement and leading to red cell lysis. However, the titre will be much higher at 0–4 °C. Cold antibodies that fail to react above 30 °C are of no clinical significance and can be ignored for blood transfusion purposes.

Immune antibodies have a thermal optimum of 37 °C. Any red cell antibody reacting above 30 °C should be considered potentially capable of destroying red cells *in vivo*.

IgM and IgG

IgM antibodies agglutinate red cells suspended in saline. They are often called saline or directly agglutinating antibodies. Conversely, IgG antibodies do not usually agglutinate saline-suspended red cells. However, lack of agglutination does not mean that the antibodies have not bound to their antigen, and it can be shown that they have reacted by using antiglobulin reagents, which facilitate agglutination of antibody-coated cells (see below). Most naturally occurring antibodies are IgM and preferentially cold-reacting, whereas most immune antibodies are IgG and warm-reacting, although some may be IgM. Exceptionally, very potent IgG antibodies may be directly agglutinating.

Monoclonal antibodies

Monoclonal antibodies have increased the repertoire of well-standardised blood grouping reagents of guaranteed quantity, quality and potency. By fusing the spleen cells of immunised mice or rats with drug-sensitive myeloma cells and selecting for drug-resistant hybrids, it has been possible to establish permanently growing cloned cell lines in tissue culture that secrete antibodies of desired specificities. Several murine hybrids secreting potent human blood-group-specific monoclonal antibodies have now been established, many of which were raised using immunogens other than intact red cells (e.g. anti-A, -B, -Le^a, -Le^b, -M and -N).

Human monoclonal antibodies specific for D, other Rh antigens, Jk^a, Jk^b, and several other antigens, have been obtained by transformation of isolated peripheral blood lymphocytes from immunised individuals with Epstein–Barr virus or by fusion of human lymphocytes with mouse myelomas to form heteromyelomas.

Monoclonal antibodies of murine and human origin have widely replaced polyclonal blood grouping reagents in everyday ABO and D grouping. The future of blood grouping may lie in DNA-based array technology, which is able to provide a means of accurate extended typing of both patients and donors, where suitable serological reagents are currently unavailable.

Lectins

Lectins are sugar-binding proteins, mostly extracted from plants and lower vertebrate animals. They are useful tools for routine and experimental blood group serology. They combine with simple sugars (e.g. fucose, galactose and *N*-acetylgalactosamine) present on the glycolipids and glycoproteins of cell membranes and body fluids. The three most commonly used blood-group-specific lectins are extracts from *Dolichos biflorus*, *Vicia graminea* and *Ulex europaeus*, which have anti-A1, -N and -H specificities, respectively. Several other lectins have proven valuable in investigating red cell polyagglutinability. Lectins are also used for determining ABH secretor status and for partially purifying and identifying blood-group-active membrane glycoproteins.

Clinical significance of red cell antibodies

The clinical significance of red cell antibodies depends partly on their destructive capacity *in vivo* and partly on their frequency. ABO and D antibodies are by far the most significant. Several factors influence immune red cell destruction *in vivo*:

1 *Plasma concentration and avidity of the antibody*.

2 *Thermal amplitude of the antibody*. Only antibodies reacting at 37 °C can cause haemolysis *in vivo* because complement can only be fixed at such a temperature and because antibody binding to Fc receptors can only take place at 37 °C.

3 *Immunoglobulin class and subclass*. The complement-fixing ability of most warm-reacting IgM antibodies, such as anti-A,B, anti-A and anti-B, makes them clinically significant. Of the IgG subclasses, IgG1 and IgG3 have clinical importance because of their capacity to bind to the Fc receptors of mononuclear phagocytic cells, the effector cells of extravascular immune red cell destruction. In addition, some IgG1 and IgG3 antibodies can fix complement up to C3b.

4 *Antibody specificity*. Several warm-reacting antibodies are incapable of causing *in vivo* red cell destruction (e.g. anti-Ch, -Rg, -Cs^a, -Kn^a, -Xg^a and most examples of anti-Yt^a).

5 *Antigen density on the red cell membrane*. The likelihood and degree of sensitisation of a red cell with antibody and/or complement increases with the number of antigen sites on the surface. There are many more A sites than D sites on red cells.

6 *Volume of incompatible red cells transfused*. A small volume of incompatible red cells will be destroyed more rapidly than a large volume from the same donor. If antibodies are not very potent, larger volumes of cells may exhaust the circulating antibody available and saturate the mononuclear phagocytic system.
7 *Presence of antigen in donor plasma*. Lewis antigens (Le^a and Le^b) and the Ch/Rg antigens are primarily in plasma and are only secondarily adsorbed onto red cells. ABH antigens are present on red cells and plasma. The free antigen in plasma of transfused red cells can react with part of the recipient's antibody and inhibit its binding to red cells.
8 *Activity of cells of the mononuclear phagocyte system*. The ability of macrophages to remove sensitised red cells varies between individuals. Splenectomy and drugs such as corticosteroids and immunosuppressants will decrease the clearance of IgG-sensitised cells.
9 *Sensitivity of red cells to complement*.
10 *Extent of complement activation*. Some antibodies regularly bind complement and others do so rarely or not at all. Of the complement-binding antibodies, IgM (e.g. anti-A,B, -A, -B, -Le^a and -$PP1P^k$) will activate the complement cascade through to C9, resulting in intravascular haemolysis, but with IgG antibodies, such as anti-Fy^a, -Jk^a and -K, the cascade is interrupted at the C3 stage. Red cells coated with IgG and C3b will be destroyed extravascularly in the liver. As a rule, Rh antibodies do not fix complement.

Detection of red cell antigen–antibody reactions

Agglutination techniques

There are various ways of detecting antigen–antibody reactions *in vitro*, either manually or with automated methods. In manual methods, tubes, microplates or gels can be used. The most widely used methods employ the following techniques.

Direct agglutination

Most IgM antibodies will directly agglutinate saline-suspended red cells of the appropriate phenotype. This method is used routinely for ABO grouping with polyclonal or monoclonal antibodies and RhD typing with monoclonal antibodies.

Indirect agglutination

Apart from ABO, antibodies against most blood group antigens are IgG and generally will not produce direct agglutination of red cells. Such antibodies can be detected by the antiglobulin technique or with the aid of agents that enhance agglutination, for example proteases, such as papain, albumin and other colloids, aggregating agents such as polybrene and polyethylene glycol (PEG), and low ionic strength solutions (LISS).

Antiglobulin test

The antiglobulin test is used to detect IgG antibodies that do not cause direct agglutination of saline-suspended red cells. The technique can be used to test directly, with an antiglobulin reagent, for the presence of antibodies or complement components that are bound to the red cells *in vivo*, as in autoimmune haemolytic anaemia, haemolytic transfusion reactions (HTRs) or haemolytic disease of the fetus and newborn (HDFN); this is the so-called direct antiglobulin test (DAT). Alternatively, the test can be used before transfusion to detect IgG antibodies in a patient's serum by adding the appropriate screening test red cells and then, after incubation and thorough washing (except in microcolumn tests), adding an antiglobulin reagent that will agglutinate cells coated *in vitro* with antibody or complement components; this is the indirect antiglobulin test (IAT). If IgG antibodies are found, these will be identified by IAT with an extended red cell panel. The IAT will then be used with the appropriate antigen-negative cells in the crossmatch, to ensure compatibility between the patient's serum and donors' red cells. IATs are also used with many reagent antibodies, such as anti-K, -Fy^a, and -Jk^a for determining blood group phenotypes (Figure 18.2).

The first step in the antiglobulin test is the antibody uptake during the incubation of antibody with red cells carrying the antigen (Figure 18.2). When an IAT is undertaken with red cells suspended in normal-ionic-strength saline (NISS) solution, maximum antibody uptake, and hence maximum sensitivity, is achieved within 60–90 minutes incubation. The incubation phase can be reduced to 10–15 minutes by using low-ionic strength saline (LISS) solutions. When the DAT and IAT are performed in tubes or microplates, it is essential that, after the antibody uptake, the red cells are washed 3 or 4 times with a large volume of saline before adding the antiglobulin reagent, as any free IgG or complement will neutralise the anti-IgG or anticomplement reagent and lead to false-negative reactions. With microcolumns containing a matrix of either a gel or glass beads, the wash phase has been eliminated.

Antibodies against IgG and complement should always be present in polyspecific antiglobulin reagents. The anti-IgG component is essential for pretransfusion antibody screening and cross-matching, as the vast majority of clinically significant antibodies, apart from anti-A,B, -A and -B, are IgG. The anti-complement component is needed for the detection of occasional examples of weak complement-binding antibodies (e.g. some anti-Jk^a) and for the detection of *in vivo* complement coating of red cells (i.e. in the DAT). Antiglobulin reagents are generally produced from polyclonal antibodies to IgG, made in experimental animals, and with monoclonal antibodies to C3d.

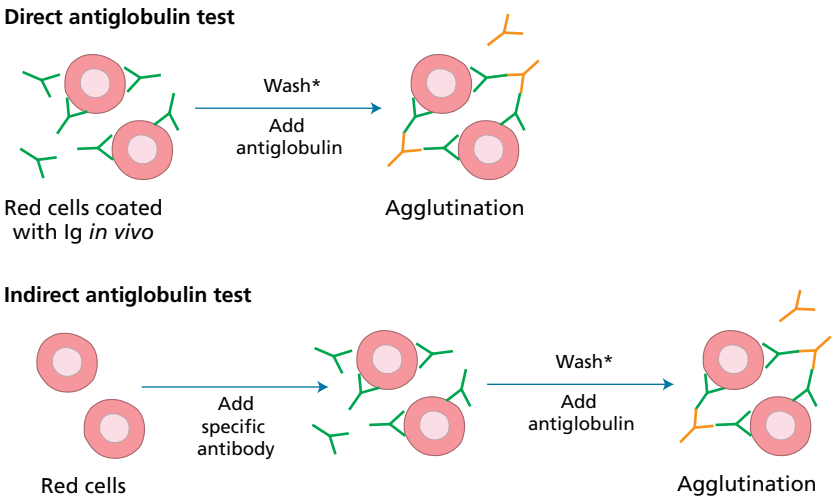

Figure 18.2 Direct and indirect antiglobulin tests. Antiglobulin antibodies are shown in red.*Washing is not required in microcolumn technology.

Inhibition of agglutination

Expected agglutination reactions with known antigens and antibodies can be neutralised by soluble antigens of the appropriate specificity. For example, the saliva of group A secretors inhibits the agglutination of group A cells by anti-A. Hydatid cyst fluid with $P1P^k$ activity can be used to confirm the presence of anti-P1 in sera. Soluble antigens produced by recombinant DNA technology are useful in reference laboratories as aids to sorting out complex serological problems. Certain soluble antigens lend themselves to be more useful than others, either because of the lack of a suitable monospecific serological typing reagent (Dombrock-specific soluble antigen) or the need to inhibit clinically insignificant pan-reactive alloantibodies (CR1 soluble antigen). Additionally, they may be used to inhibit therapeutic monoclonal antibodies, which are increasingly used to treat a range of haematological malignancies, and can interfere with pre-transfusion compatibility testing (for example; anti-CD38).

Haemolysis

After the incubation of red cells with fresh serum, red cell lysis indicates a positive antigen–antibody reaction mediated by IgM complement-fixing antibodies. A pink- or red-coloured supernatant after settling or centrifugation of red-cell–antibody mixtures is an indication of haemolysis.

Adsorption and elution tests

Specific antibodies can be removed from serum by adsorption on red cells carrying the corresponding antigen. Bound antibodies can be subsequently recovered from the washed, sensitised red cells by elution with heat treatment, freeze-thawing, low pH or chloroquine treatment.

Specialised antiglobulin techniques

Flow cytometry and less commonly used enzyme-linked immunosorbent assays (ELISAs) may be used for the estimation of the number of antigen sites on red cells, for the quantitation of anti-D in pregnant women and when more sensitive antiglobulin techniques are required. The essence of these approaches is the use of a labelled antiglobulin: in flow cytometry, which is the most commonly used methodology, fluorescent anti-IgG is used (or antibodies can be directly coupled with a fluorescent dye); in the case of ELISA, enzymes are attached covalently (i.e. conjugated) to the antiglobulin (Figure 18.3).

In these assays, antibody-coated cells or particles are incubated with the labelled antiglobulin reagent. After incubation, excess unbound antiglobulin is washed away and bound labelled antiglobulin is then measured. For flow cytometry, a cytofluorimeter is used to measure fluorescence of each cell. For ELISA, the bound enzyme conjugate is detected through the enzyme's ability to modify its substrate, usually effecting a colour change. The colour intensity of the modified substrate is then measured with a spectrophotometer.

Microcolumn tests (gel and beads)

The principle of microcolumn tests is the separation of agglutinated from non-agglutinated red cells by centrifugation through a miniature filtration column. For blood grouping, red cells are layered on microcolumns impregnated with blood grouping sera; for antibody screening and identification, phenotyped panel red cells are mixed with patients' sera within the incubation chamber of the microcolumn. After centrifugation, agglutinated red cells are retained towards the top of the microcolumn because the agglutinates are trapped by the column matrix,

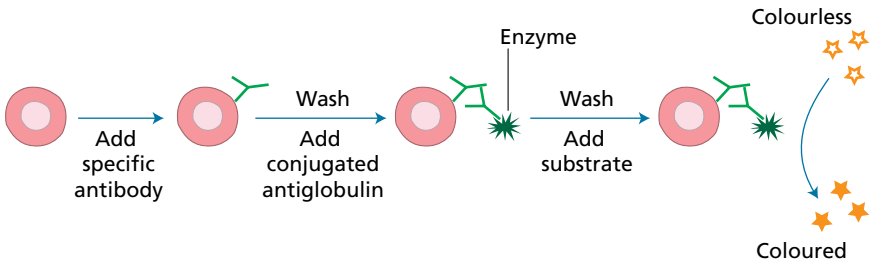

Figure 18.3 Enzyme-linked immunosorbent assay (ELISA) for cell-bound antibodies. Enzyme substrate is represented by open and closed stars, for colourless and coloured derivatives respectively.

whereas unagglutinated red cells form a button at the bottom of the column (Figure 18.4).

Antiglobulin tests can be performed by centrifuging the preincubated mixture of red cells and patient's serum through a column impregnated with anti-IgG or polyspecific antiglobulin. Any red cells coated with IgG will be agglutinated by the free anti-IgG in the matrix of the column, giving a positive result. No washing of sensitised cells is required, as IgG in the serum does not penetrate the column, as it is less dense than the matrix, and so does not neutralise the anti-IgG in the column. The advantages of microcolumn techniques are the ease of reading and reproducibility, and the fact that the tests can be stored for later examination, checking, photocopying or photographing. These systems can be automated and the agglutination results evaluated by image analysis.

Microplate techniques

Semi-automated blood grouping and antibody screening can be performed in microtitre plates, which can also be used for extended phenotyping of red cells, antibody identification and large-scale screening for rare red cells and antibodies.

Figure 18.4 Results of a gel microcolumn test. The subject is group B D-negative. Red cells remaining at the top of the gel represent a positive result; red cells collected at the bottom of the tube represent a negative result.

A single microplate is equivalent to 96 short test tubes and the same basic principles of discrete analysis of agglutination apply. Several commercial microplate-based blood grouping systems are available, using bar codes to identify samples, automated liquid handling of samples and reagents, and plate readers linked to computers for easy and accurate record-keeping.

Solid-phase microplate systems, with antigen or antibody adhered to the surface of the plastic, reduce the variability between tests, inherent in liquid-phase systems when undertaken by different operators, and easily lend themselves to automated reading of results. Blood grouping (e.g. for ABO and D groups) can be accomplished with U-shaped microplate wells coated with the relevant antibody (e.g. anti-A, -B, -D); suspensions of patients' or donors' red cells are added to the wells and then centrifuged. Positive results appear as a carpet of cells coating the bottom of the well. Negative results appear as a tight pinhead of unattached cells in the centre of the well.

In antibody screening and identification by solid-phase, the microplates are coated with a panel of phenotyped red cell ghosts. The wells are incubated with patient serum and LISS, washed and then anti-IgG is added. Anti-IgG will bind to those wells where the patient's IgG antibody has bound to the relevant red cell ghost; bound anti-IgG is then easily detected by adding indicator red cells coated with IgG (e.g. D-positive cells coated with anti-D), followed by brief centrifugation, as described above.

Automated techniques

Fully automated walk-away blood grouping and antibody screening, using microcolumn techniques or microplates, is widely used in transfusion centres, where large numbers of donor samples are tested daily, and in-hospital transfusion laboratories where large numbers of patient samples are tested. In microplate automated systems, test samples are mixed with typing sera or screening cells in individual wells of a special microplate with a terraced surface at the bottom of the well. After incubation and settling of the red cells, agglutination patterns are distinguished either on the basis of light transmission or by image analysis with the aid of a computer-controlled camera.

Blood grouping reagents

In pretransfusion testing, it is essential to determine, as a minimum, the correct ABO and D groups of donors and recipients. To avoid potential fatalities resulting from errors, it is essential that the ABO and D typing reagents have suitable potency and comply with the European Directive on *in vitro* diagnostic devices and the associated Common Technical Specifications and carry the 'CE' mark to show they are in conformance and/or show the equivalent UKCA (UK Conformity Assessed) mark.

IgM monoclonal reagents are generally used for ABO, Rh and K typing. Such reagents are extensively tested prior to release and are generally free of unwanted contaminating antibodies. Blood grouping reagents from polyclonal antisera are more likely to have unwanted antibodies and should have been exhaustively tested with an extensive panel of cells to exclude common and rare specificities before they are issued for routine use.

Antibody screening and identification

For all patients who may require a transfusion, sera should be screened against unpooled group O cells from selected individuals known to carry the following antigens between them: D, C, E, c, e, M, N, S, s, P1, Le^a, Le^b, K, k, Fy^a, Fy^b, Jk^a and Jk^b. Ideally, one cell sample should be R_1R_1 (DCe/DCe), or $R1^WR1$ and the other R_2R_2 (DcE/DcE), so that the Rh antigens all have double dose expression (i.e. homozygous). A minimum double dose expression of Fy^a, Fy^b, Jk^a, Jk^b, S and s should be present on the red cells used for antibody screening and identification. It is generally possible to meet these requirements with two screening cell samples, but if more antigens with double dose expression are required, three cell samples might be needed. Zygosity can be checked by molecular genetic methods.

Antibody screening of patients' sera need only consist of a well-controlled sensitive IAT, using a low ionic strength solution (LISS), commonly with microcolumns. If the antibody screening is positive, antibody identification against a panel of 8–12 fully phenotyped red cells should be performed. For identification, in addition to the IAT, a second sensitive technique (e.g. using enzyme-treated cells, PEG or manual polybrene test), is recommended. Saline tests are not essential for antibody screening or identification and all tests should be performed at 37 °C, as antibodies reacting at lower temperatures only are generally of no clinical importance.

Molecular techniques for blood grouping

It is possible to predict blood group phenotypes from DNA with a high degree of accuracy. This is usually performed when a blood group phenotype is required but a suitable red cell sample is not available. Currently, the most important application is the antenatal determination of fetal blood groups. When a pregnant woman has a blood group antibody with the potential to cause severe HDFN, it is beneficial to determine whether her fetus has the corresponding antigen and consequently, whether it is at risk from HDFN. Hence, molecular typing for D antigen by targeting the *RHD* gene is usually required, but typing for c and K antigens (*RHCE* and *KEL* genes) may sometimes be needed. The standard source material for fetal genotyping is the small quantity of cell-free fetal DNA present in the maternal plasma. In some countries, fetal *RHD* typing is applied to all D-negative pregnant women in order to avoid giving antenatal Rh immunoglobulin prophylaxis unnecessarily when the fetus is predicted D-negative.

Molecular methods for analysis of blood group genes are useful in transfusion-dependent patients, where serological methods are not possible because of the presence of transfused red cells in the patient's blood. Such tests are carried out on DNA isolated from whole blood of the transfused patient. Genotypes can be determined for all clinically important blood group polymorphisms, usually by analysing the relevant single nucleotide variants (SNVs) in blood group genes, such that matched blood can be provided to prevent the patient from making multiple red cell alloantibodies. Another group of patients who would benefit from blood group genotyping are those with autoimmune haemolytic anaemia, whose red cells are coated with immunoglobulin, thus making serological typing difficult.

Several types of tests, ranging from low to high-throughput, are commonly used in blood group genotyping. Most of these are available commercially:

1 Amplification of a portion of a blood group gene by polymerase chain reaction (PCR) to determine its presence. This only applies to *RHD*.

2 PCR amplification of a portion of a gene followed by detection of the restriction fragment length polymorphism with restriction endonuclease enzymes (PCR-RFLP).

3 Selective amplification of a specific allele by the use of an allele-specific primer (allele-specific PCR).

4 PCR amplification of a portion of a gene followed by Sanger sequencing of the amplified product.

5 Allelic discrimination by PCR, incorporating allele-specific fluorescently labelled probes, in which relative quantities of a pair of alleles are measured.

6 Medium/high-throughput methods based on targeting multiple blood group-related SNPs, such as microarray technology, usually involving coloured microbeads, in which numerous polymorphisms can be tested from a relatively small quantity of DNA.

7 Next-generation sequencing (NGS), including whole genome sequencing (WGS), whole exome sequencing (WES) or the targeted sequencing of blood group-related genes. These methods substantially increase sample throughput and the amount of data generated, which enables accurate detection of all known and novel variants in the genes of interest in a single test.

Testing of large numbers of blood donors for multiple blood groups by medium and high-throughput methods is beginning to be introduced in order to establish a database of donors typed for all clinically significant groups. This would be a valuable resource, especially for transfusion-dependent patients, and microarray technology and NGS are now being introduced for such testing.

The ABO system

ABO was the first system to be recognised and remains the most important in transfusion and transplantation. Almost everybody over the age of about 6 months has clinically significant anti-A and/or anti-B in their serum if they lack the corresponding antigens on their red cells. Thus, if we consider the incidence of ABO blood groups in the UK (Table 18.2), transfusions given without regard to ABO would result in a major incompatibility (patient has the antibody and the antigen is on the transfused red cells) about once in every three cases.

Antigens of the ABO system

The blood of the majority of humans can be grouped into six main ABO phenotypes (Table 18.2), although several rare weak variants can be distinguished serologically. The incidence of ABO groups varies very markedly in different parts of the world and in different races.

A_1 and A_2 variants

The distinction between the A_1 and A_2 variants is usually made by using anti-A1, which will agglutinate A_1, but not A_2, red cells. There are several sources of anti-A_1: (i) by absorbing anti-A (from group B people) with A_2 red cells, (ii) in the serum of some A_2 and A_2B persons (Table 18.3), (iii) from a saline extract of the seeds of the hyacinth bean *Dolichos biflorus* and (iv) mouse monoclonal anti-A1. Anti-A1 is not used routinely as it is not necessary to distinguish A_1 from A_2 red cells for most transfusion recipients. There is no specific antibody for A_2 red cells; if anti-A is absorbed with A_1 cells, all the antibody is removed. Group B serum can therefore be thought of as containing two antibodies: anti-A, which agglutinates both A_1 and A_2 red cells, and anti-A1, which agglutinates only A_1 red cells. The anti-A component of group O serum also has both antibodies.

Table 18.2 Incidence of ABO groups in the UK.

Phenotype	Frequency (%)	
O		44.9
A_1	30.8	41.1
A_2	10.3	
B		10.1
A_1B	2.7	3.9
A_2B	1.2	

The difference between the A_1 and A_2 variants is partly quantitative: the red cells of A_1 and A_1B subjects have more A antigen sites than A_2 and A_2B subjects, respectively. For practical purposes, A_2 can be regarded as a weaker form of A. When both A and B antigens are present, there are fewer sites for each than when either is present alone. The practical importance of this lies in the fact that the A antigen of A_2B red cells may give an extremely weak reaction with anti-A, which could be missed in routine grouping tests if reagents of inadequate potency are used. Moreover, if the same person's serum contains anti-A_1 and is tested in the reverse grouping only with A_1 and not A_2 red cells, he/she will be grouped as B. For this reason, potent anti-A reagents reacting with A_2B cells must be used in routine blood grouping. This is now possible with the widespread use of monoclonal antibodies in routine testing.

There is also a qualitative difference between A_1 and A_2, but this must be very subtle because A_2 red cells can absorb all the anti-A

Table 18.3 ABO blood grouping.

Agglutination of test cells with				Agglutination of test serum of			ABO group of test sample	Possible genotype
Anti-A	Anti-A_1	Anti-B	Anti-A, B*	A cells	B cells	O cells		
−	−	−	−	+	+	−	O	*O/O*
+	+	−	+	−	+	−†	A_1	A^1/A^1, A^1/O, A^1/A^2
+	−	−	+	−/+‡	+	−	A_2	A^2/A^2, A^2/O
−	−	+	+	+	−	−	B	*B/B*, *B/O*
+	+	+	+	−	−	−†	A_1B	A^1/B
+	−	+	+	−/+‡	−	−	A_2B	A^2/B

* Anti-A,B (group O serum) is not generally used in routine laboratories.
† Some group A_1 and A_1B individuals may have weak anti-H in their plasma.
‡ Serum from a proportion of A_2 (1–8%) and A_2B (22–35%) individuals contains anti-A1.

from group B serum if the absorption is carried out at 0–4°C for sufficient time. The chemical basis is unresolved, but A-active oligosaccharide structures called type 4A are only present on A_1 cells.

H antigen

Group O cells have no antigens of the ABO system but do possess H antigen, the precursor upon which the products of the *ABO* genes act. The H gene (called *FUT1*) is on chromosome 19, whereas *ABO* is on chromosome 9. The H antigen is present to some extent on almost all red cells, regardless of the ABO group, but the amount of H antigen varies with the ABO group as follows: O > A_2 > A_2B > B > A_1 > A_1B.

Individuals with the rare Bombay phenotype are homozygous for inactive *FUT1* alleles (*h/h*). Their red cells are not agglutinated by anti-A or anti-B, regardless of *ABO* genotype, but are not group O as they are also not agglutinated by anti-H. The serum of Bombay subjects contains potent anti-H, anti-A and anti-B that will only allow transfusion with red cells of the scarce Bombay phenotype.

Distribution of the A, B and H antigens

ABH antigens are often referred to as histo-blood group antigens because they are widely distributed in the body. They are therefore very important in transplantation. They are present on white cells, platelets and epidermal and other tissue cells. They are also present in the plasma, regardless of ABH secretor status, and in the saliva and other secretions of ABH secretors (see later).

ABO variants

Rare ABO variants (often termed ABO subgroups) are usually disclosed because an expected ABO antibody is missing. A sample typed as group O that has anti-B but no anti-A will usually prove to be a weak A variant. The presence of weak A or B antigens can be demonstrated either by using potent monoclonal antisera or by adsorption and elution. A variety of A and B variant phenotypes exist with the symbols A_3, A_x, A_{end}, A_m A_{el}, B_3, B_x, B_m and B_{el}. All are rare, and are usually recognised by their variable reactions with anti-A and/or anti-A,B reagents, and arise from mutations in the coding or regulatory regions of the *ABO* gene.

Acquired weakening of the A antigen can also occur in acute myeloid leukaemia. The A antigen may revert to almost normal in remission. Similar weakening of B, H and I antigens has also been described.

B-like antigens may be acquired by group A individuals who are suffering from bowel infections, usually associated with carcinoma or strictures of the large bowel. Red cells with an acquired B antigen are agglutinated by some anti-B, including some monoclonal anti-B, but not by the patient's own anti-B. Bacterial deacetylases convert *N*-acetylgalactosamine, the immunodominant sugar of the A antigen, into galactosamine, a structure similar to galactose, the immunodominant sugar of the B antigen.

Antibodies of the ABO system

Anti-A, anti-B and anti-A,B

It is likely that 'naturally occurring' ABO antibodies arise in response to A- and B-like antigens present on bacterial, viral or animal molecules. Titres of ABO antibodies vary considerably with age, reaching a peak in young adults and then declining in old age.

Sera taken from people over the age of about 6 months that do not contain the expected A and B antibodies (Table 18.3) are very rare. They should always be investigated thoroughly; often, some interesting explanation will be found, for example a rare subgroup of A, a blood group chimera or congenital absence of IgM.

Anti-A and anti-B have a wide thermal range. Although they are active at 37°C, they react better at lower temperatures. ABO antibodies always have some IgM component and, in group A and B persons, they are almost entirely IgM. Antibodies from group O individuals, even before immunisation, usually have some IgG anti-A,B, an antibody that cross-reacts with both A and B structures.

Following immunisation with red cells or blood group substances, the thermal characteristics of the antibodies change, but group A and B subjects continue to produce antibodies that are mainly IgM. Most group O persons, however, will produce IgG as readily as IgM anti-A,B. Consequently, mothers of children with ABO HDFN are almost always group O. Immune anti-A,B are mainly IgG2, which does not cause HDFN because there are no Fc receptors for IgG2 on the cells of the mononuclear phagocyte system. When the maternal serum contains potent IgG1 and/or IgG3 ABO antibodies, HDFN may occur, although this is comparatively milder than HDFN caused by antibodies to Rh blood group antigens (see Chapter 19). Some IgA anti-A or anti-B may be produced following immunisation with A or B substances.

Group O as a universal donor

Group O red cells can be transfused to A, B or AB recipients and group O donors were formerly, and inappropriately, called 'universal donors'. Group O donors have anti-A, anti-B and anti-A,B in their plasma, which will react with the recipient's A or B cells. Normally, if group A, B or AB recipients are transfused with a relatively small number of group O units of whole blood, the anti-A or anti-B that is transfused will be diluted out and neutralised by the plasma of the adult recipient, especially as red cells in additive solution are now used. The use of whole blood in trauma is becoming increasingly popular, firstly in use by the military, it is now being used in some civilian trauma and pre-hospital emergency settings. Components used are typically a combination of leucodepleted,

platelet poor group O RBC and Gp O plasma of low ABO haemolysin titre to mitigate against any ABO antibody-mediated haemolysis.

There is usually a shortage of group O blood, and not infrequently a surplus of group A blood. In the vast majority of cases, including emergencies, there is enough time to perform a rapid ABO group on the patient's cells, which will allow the transfusion of group-specific blood. If there is no time to do an ABO group before transfusion, group O red cells in optimal additive solution, devoid of plasma, should be given until the patient's blood group is known. The practice of transfusing group O platelets to non-O patients should be discouraged as the dose of adult platelets will contain approximately 300 mL of donor plasma, unless part of it has been replaced by platelet-additive solution. Group O fresh-frozen plasma and cryoprecipitate should only be given to group O recipients.

Anti-A1

Anti-A1, reactive at room temperature (18–22 °C), can be found in the serum of 1–8% of group A_2 and 22–35% of group A_2 B persons. Most of these antibodies are not of clinical importance because they do not agglutinate A_1 red cells at 30 °C and above. Very rarely, anti-A1 able to react at 37 °C may lead to significant destruction of A_1 red cells *in vivo*. Group A or group O red cells, crossmatch compatible by IAT, should be provided in these rare instances.

Anti-H

Several forms of anti-H exist:

1 Clinically significant 'true' anti-H occurs in the serum of very rare individuals with the Bombay phenotype (O_h) blood. It is active at 37 °C and only O_h blood may be transfused.

2 Anti-HI, commonly found in the serum of group A_1, B and A_1B persons, reacts much more strongly with adult than with cord red cells. Anti-HI does not usually agglutinate O cells above 30 °C. Very occasionally, anti-HI may cause rapid destruction of at least some of the transfused O red cells *in vivo*. However, these antibodies will not interfere with red cell survival if ABO identical units, i.e. A_1, B or A_1B units, are transfused to A_1, B or A_1B recipients, respectively.

ABH secretor status

About 80% of Caucasian populations, ABH secretors, have H antigen, plus A or B according to their ABO genotype, in a water-soluble form in their body secretions. The remaining 20% are non-secretors.

Biochemistry and biosynthesis of ABH antigens

ABH antigens

A, B and H antigens on red cell membranes (Figure 18.1) are predominantly glycoproteins, the majority being on the N-glycans of the anion exchanger (band 3) and the glucose transporter (GLUT1). ABH antigens on red cells are also expressed on glycosphingolipids. Soluble ABH antigens are glycoproteins. Differences in the terminal sugars of the glycoproteins and glycolipids determine the specificity of these antigens: L-fucose (Fuc) for H, L-fucose plus *N*-acetyl-D-galactosamine (GalNAc) for A and L-fucose plus D-galactose (Gal) for B.

Two major types of carbohydrate chain endings serve as acceptors for the fucosyltransferases that synthesise H antigen: type 1 and type 2 chains have Gal joined to *N*-acetylglucosamine (GlcNAc) through 1 → 3 and 1 → 4 linkages, respectively. A- and B-transferases transfer GalNAc and Gal, respectively, from their donor substrates UDP-GalNAc and UDP-Gal to the terminal galactosyl residue of type 1 H and type 2 H, creating A and B epitopes and masking H specificity (Figure 18.5).

Secretory glycoproteins possess both type 1 and type 2 linkages, whereas red cells synthesise type 2 chains only. Other chains, called type 3 and 4, are also present in low numbers on red cells, but probably only on glycolipids.

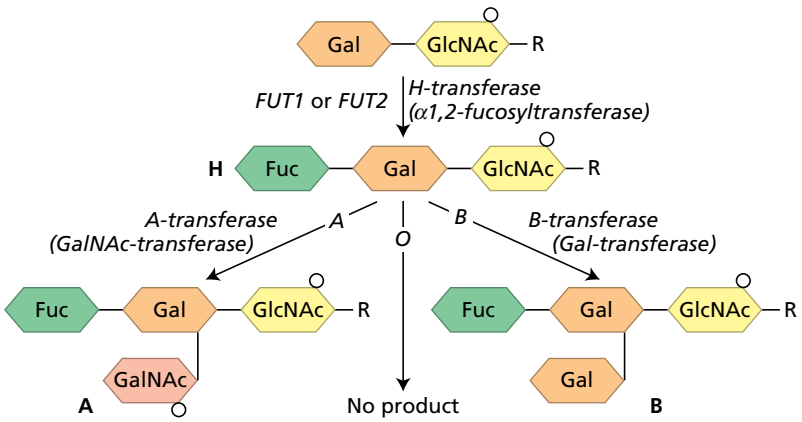

Figure 18.5 Biosynthetic pathway of H antigen from its precursor, and of A and B antigens from H. In group O subjects, H remains unconverted in the absence of *A* or *B* gene products. R, remainder of molecule.

ABO genes

ABO is located on the long arm of chromosome 9, comprises seven exons and encodes the A and B glycosyltransferases. Products of the *A* and *B* alleles differ by four amino acids encoded by exon 7, two of which determine whether the enzyme has GalNAc-transferase (A) or Gal-transferase (B) activity.

The majority of *O* alleles (called O^1) resemble *A*, but have a single-base deletion in exon 6, which creates a shift in the reading frame, truncating any putative polypeptide. About 3% of *O* alleles (called O^2) have a single-nucleotide polymorphism (SNP) that changes one of the vital amino acids in the catalytic site, inactivating the enzyme.

The A^2 allele has a single-base deletion immediately before the usual termination codon, creating a reading frameshift and abolition of this stop codon. This produces an A-transferase with 21 extraneous amino acids on its C-terminus, reducing its efficiency as a GalNAc-transferase.

H genes

At least two genes, *FUT1* and *FUT2*, on chromosome 19, are responsible for production of H antigen. Both encode α1,2-fucosyltransferases that catalyse the transfer of fucose to the terminal galactose of the H precursor chain (Figure 18.5). *FUT1* is active in mesodermally derived tissues, including haemopoietic tissues, and is responsible for H expression on red cells. Homozygosity for inactivating mutations in *FUT1* gives rise to O_h (Bombay) and related phenotypes. *FUT2* is responsible for the expression of H antigen in endodermally derived tissues, including secretions, and hence is the gene responsible for ABH secretion. Secretors are homozygous or heterozygous for an active *FUT2*; non-secretors are homozygous for an inactive allele usually containing a nonsense mutation.

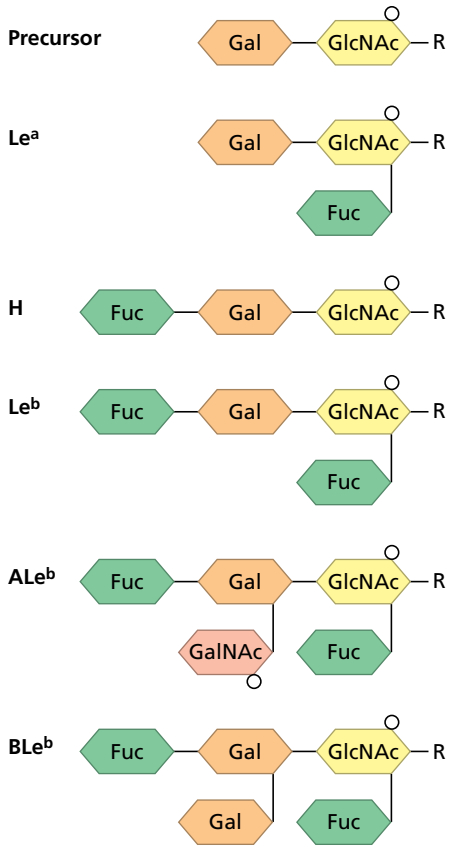

Figure 18.6 Diagrammatic representation of H and Lewis antigens in plasma and secretions. Le^a requires the action of the Lewis α1,4-fucosyltransferase (encoded by *FUT3*), H the action of the H α1,2-fucosyltransferase (encoded by *FUT2*), Le^b the action of both Lewis and H fucosyltransferases, and ALe^b and BLe^b the action of Lewis and H fucosyltransferases and the A or B glycosyltransferases.

The Lewis system

Lewis antigens and their biosynthesis

Lewis is primarily a system of soluble antigens present in secretions and in plasma: Lewis antigens on red cells are adsorbed passively from the plasma, and plasma is needed to maintain Lewis antigens on the red cells. There are two Lewis antigens: Le^a and Le^b. Expression of either requires the presence of an active Lewis gene, but Lewis phenotypes are also governed by the gene controlling H secretion (*FUT2*). Lewis antigens in saliva and plasma are glycoproteins and glycolipids, respectively.

The Lewis gene, *FUT3*, encodes an α1,4-fucosyltransferase that catalyses the addition of L-fucose in 1→4 linkage to the subterminal GlcNAc of type 1 chains (Figure 18.6). Since red cells have only type 2 chains, they cannot make Lewis antigens. If the type 1 chain has been unmodified, the Lewis-transferase makes Le^a antigen, whereas if the secretor α1,2-fucosyltransferase has converted the type 1 chains to type 1 H, Le^b is produced. In a white population, 75% have active Lewis and secretor genes and hence Le(a−b+) red cells; 20% have an active *Lewis* gene but are H non-secretors and have Le(a+b−) red cells; 5% are homozygous for *Lewis* genes with inactivating mutations and are Le(a−b−) (Table 18.4). Le(a+b−) and Le(a−b+) red cells incubated in Le(a−b−) plasma shed their Lewis antigens into the plasma. Similarly, if Le(a+b−) or Le(a−b+) red cells are transfused into an Le(a−b−) recipient, the transfused cells will gradually lose their Lewis antigens and will group as Le(a−b−) within 1 week of transfusion.

Development of Lewis antigens on red cells

The Lewis antigens are poorly developed at birth and red cells from cord blood are usually Le(a−b−). Thereafter, Le^a develops first, followed by Le^b if the relevant *Lewis* and secretor genes are present. Red cells of children between the ages of 6 months and

Table 18.4 The Lewis system and secretion of ABH.

Genotype		Antigens in saliva			Plasma/red cells*

* Le^a and Le^b on red cells are passively adsorbed from plasma.

4 years often type as Le(a+b+) if they are destined to become Le(a−b+). The definitive adult Lewis phenotype may not be reached until the age of 4–5 years.

Lewis antibodies

Lewis antibodies are generally made only by Le(a–b–) individuals. Anti-Le^a occurs fairly frequently. The incidence of Le(a−b−) is much higher in people of African and Southeast Asian origin than in Europeans, and Lewis antibodies may be found in up to 10% of random serum samples from black people.

Anti-Le^b commonly accompanies anti-Le^a. Pure anti-Le^b is uncommon.

Lewis antibodies are predominantly IgM. They usually agglutinate the appropriate cells at 20 °C. All Lewis antibodies that react at 37 °C will bind complement and may lyse antigen-positive cells. Lewis antibodies do not agglutinate red cells in saline at 37 °C, but can be detected with anti-complement in an indirect antiglobulin test (IAT).

Anti-Le^a active at 37 °C is usually more haemolytic than anti-Le^b, and some anti-Le^{a+b} can be very potent, leading to intravascular red cell destruction in the initial stages of transfusion. All Lewis antibodies active at 37 °C lead to two-component survival curves of transfused incompatible red cells, i.e. the first cells are destroyed at an accelerated rate and the remainder, which have lost their adsorbed Lewis antigens into the recipient's Le(a–b–) plasma, will have a normal survival.

For patients with Lewis antibodies reacting at 37 °C, ABO-identical red cells, compatible in an IAT cross-match at 37 °C, should be transfused. It is important to choose ABO-identical cells because group A, B and AB cells carry fewer Lewis antigens than group O cells, which are the cells routinely used in antibody screening. The provision of pre-typed Le(a−b−) blood for patients with Lewis antibodies is not necessary, as it is always easy to find ABO identical, cross-match-compatible red cells at 37 °C.

Lewis antibodies do not cause HDFN as they are IgM and, moreover, newborn infants have Le(a−b−) red cells.

P1, P^k and P blood group antigens and antibodies

P1 antigen is present on red cells of about 75% of Caucasians though P1 frequency varies in different populations. P1 is weakly expressed at birth and its strength varies considerably in adults. For this reason, identification of anti-P1 can be difficult, as panel cells will have varying expression of the antigen.

Anti-P1 is naturally occurring and commonly found in the serum of P1-negative individuals. Unlike anti-A and anti-B, anti-P1 rarely causes transfusion reactions because it is usually not reactive above 30 °C.

Anti-PP1P^k and anti-P invariably occur in the sera of the very rare individuals with p and P^k phenotypes, respectively. Anti-PP1P^k reacts with all red cells except those of the p phenotype; anti-P reacts with all red cells except those of the P^k and p phenotypes. They are usually strong IgM antibodies, often lytic at 37 °C, and can cause severe haemolytic transfusion reactions. If p or P^k patients need transfusion, rare allogeneic red cells will need to be sourced or pre-deposit autologous donation may need to be considered. Occasionally, IgG anti-P or anti-PP1P^k have been associated with spontaneous early abortion.

The biphasic Donath–Landsteiner autoantibody, found in the sera of patients suffering from paroxysmal cold haemoglobinuria, is always IgG and usually has anti-P specificity.

I and i antigens and antibodies

I and i antigens are carbohydrates and are on the interior structures of the complex oligosaccharides that carry ABO, H and Lewis antigens; i is the biosynthetic precursor of I. The i antigen represents linear structures that are converted to I-active branched structures by the transferase coded by the *I* gene. This enzyme is not active in neonates. Consequently, red cells of most adults are agglutinated strongly by anti-I and only weakly by anti-i, whereas red cells from cord blood give the opposite result. Adults who are homozygous for rare inactivating

mutations in the *I* gene have the adult i phenotype; their red cells react weakly or negative with anti-I and strongly with anti-i, and their serum contains anti-I.

Autoanti-I active at 20 °C, but not at 30 °C, occurs in a variety of disorders and after blood transfusions. These patients' red cells give a negative direct antiglobulin test. A transient increase in strength, titre and thermal range of anti-I regularly occurs after infections with *Mycoplasma pneumoniae* and occasionally leads to acute haemolysis; red cells of such patients give a positive DAT, as do those of patients suffering from chronic cold haemagglutinin disease (CHAD). In CHAD, the autoantibody is nearly always monoclonal and usually has anti-I specificity.

Autoanti-i is found transitorily in many patients suffering from infectious mononucleosis. Very occasionally, the titre and thermal range of this antibody may lead to acute haemolysis. Autoanti-i may occasionally be the antibody specificity in chronic CHAD. Such patients often have an underlying lymphoma.

The Rh system

Rh is the second most important blood group system in blood transfusion. Anti-D is formed readily when D-positive blood is transfused to a D-negative person. The Rh system contains a total of 56 antigens, but D is the most important, owing to its high immunogenicity and ability to cause severe HDFN and HTRs.

Rh antigens

Alloanti-D was initially considered to be identical to antibodies produced in rabbits and guinea pigs immunised with rhesus monkey red cells. Later animal anti-Rh was shown to detect a different determinant renamed LW. LW is now known to be intercellular adhesion molecule-4 (ICAM-4). A remnant of the original name, rhesus, remains in the name of the blood group system, Rh. For clinical purposes, individuals are often called Rh-positive if they have the D antigen and Rh-negative if they lack D. Approximately 85% of Caucasians, 95% of Africans and over 99% of eastern Asians are D-positive.

Two pairs of antithetical antigens, C (RH2) and c (RH4), and E (RH3) and e (RH5), are closely associated with D genetically. There is no antithetical antigen to D, so d represents the absence of D. From serological analyses, D, C/c and E/e behave like the products of three closely linked genes and the eight Rh haplotypes are often written as *DCe*, *DcE*, *dce*, etc (shorthand, R_1, R_2, *r*, respectively) (Table 18.5).

Molecular genetics has shown that there are only two *RH* genes, one encoding D, *RHD,* the other encoding the Cc and Ee antigens, *RHCE,* but as the Cc and Ee polymorphisms are determined by separate regions of a single gene, the DCE terminology is still suitable for understanding Rh at most levels. The approximate frequencies of the Rh gene complexes in three populations are shown in Table 12.5. Genotype frequencies vary considerably in different parts of the world: e.g. *dce/dce* (Rh-negative) varies from about 35% in Basques to 0.3% in Japanese and Chinese.

Table 18.5 Eight Rh haplotypes and their frequencies in English, Nigerian and Hong Kong Chinese populations.

Haplotype		Frequencies (%)

Results of testing, with anti-D, -C, -c, -E and –e, red cells from 2000 English donors, 274 Yoruba of Nigeria and 4648 Cantonese from Hong Kong.

Probable Rh genotype

When a person's Rh phenotype is known, the probable genotype can be discerned and its likelihood calculated from known genotype frequencies within the same population. When probable genotype determinations are carried out, it is very important that the ethnic origin of the person is known; figures for one population will not apply to people of other populations. For example, in white populations, *dce* is 15 times more common than *Dce*, whereas in African populations *Dce* has a slightly higher frequency than *dce*. Consequently, the phenotype D + C + c + E − e+ represents a probable genotype of *DCe*/*dce* in a white person, but of *DCe*/*Dce* in a black person.

Molecular genetics of Rh

Rh genes and proteins

Rh antigens are encoded by two closely linked genes with 92% sequence homology. *RHD* encodes the D antigen and *RHCE* the Cc and Ee antigens. Each consists of 10 exons and, unusually for homologous genes, the two genes are in opposite orientations on the chromosome (Figure 18.7). Each gene encodes a 416-amino-acid polypeptide of 30–32 kDa that is palmitoylated but not glycosylated. The polypeptides encoded by *RHD* and *RHCE* differ by 31–35 amino acids, depending on the *RHCE* genotype. The Rh polypeptides traverse the lipid bilayer 12 times, with both termini in the cytoplasm and six extracellular loops that provide the putative sites for antigenic activity (Figure 18.7). Rh antigen activity is very dependent on

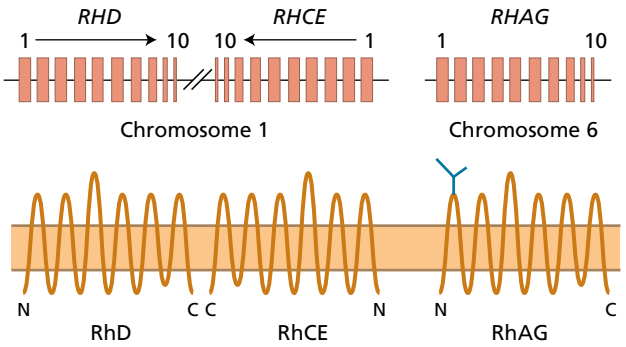

Figure 18.7 Rh and related genes (in pink) and the polypeptides they encode (in orange), showing the 10 exons of *RHD* and *RHCE* in reverse orientation on chromosome 1 and of *RHAG* on chromosome 6, and the RhD and RhCE polypeptides and RhAG glycoprotein crossing the membrane 12 times.

the conformation of the proteins within the membrane and may involve interactions between two or more of the extracellular loops.

D, C/c and E/e polymorphisms

In white people, the D-negative phenotype almost always results from homozygosity for a complete deletion of the *RHD* gene. D-negative represents the absence of the RhD protein from the membrane. D-positive people may be homozygous or hemizygous for *RHD*. However, most D-negative black Africans have an inactive *RHD*, called the *RHD* pseudogene (*RHDψ*).

The Cc polymorphism is associated with three or four amino acid substitutions encoded by exons 1 and 2 of *RHCE*, although the definitive change is Ser103 for C and Pro103 for c in the second extracellular loop of the RhCE protein. E and e are associated with Pro226 and Ala226, respectively, in the fourth extracellular loop.

The band 3/Rh molecular macrocomplexes

The two Rh proteins are closely associated in the red cell membrane with the Rh-associated glycoprotein (RhAG). RhAG has a similar conformation, spanning the membrane 12 times, but is glycosylated (Figure 18.7). The complex of Rh proteins and RhAG is part of a membrane macrocomplex, with band 3 (the anion exchanger and Diego blood group antigen) at its core, and also containing the LW glycoprotein (ICAM-4), CD47 and glycophorins (GP)A and B. This macrocomplex is attached to the cytoskeleton, primarily through ankyrin and protein 4.2 (Figure 18.1). Another macrocomplex containing band 3 and the Rh proteins also contains the Kell, Kx and Duffy proteins, plus GPC (Gerbich), which links the complex to the cytoskeleton.

The Rh proteins are only present on erythroid cells, but RhAG is more widely distributed.

Variants of D

Most D-negative individuals lack the whole RhD protein from their red cells and, when immunised by D-positive red cells, can make antibodies to an array of epitopes on the external loops of the RhD protein. About 30 D epitopes have been defined with monoclonal antibodies. There are numerous variants of D. These used to be divided into two types, weak D (formerly D^u) and partial D, though these terms are not adequately defined and of little value clinically. The usual understanding is weak D red cells express all epitopes of D at a low level and individuals with weak D phenotype cannot make anti-D, whereas partial D red cells lack some epitopes of D and so individuals with a partial D phenotype, if immunised by a normal complete D antigen, can make antibodies to the D epitopes they lack. These antibodies behave as anti-D in most circumstances. However, things are not that simple and some phenotypes named weak D have subsequently been found in individuals who have made anti-D, and in addition, some so-called partial D antigens are expressed very weakly. So, the terms weak D and partial D should be abolished and the abnormal D antigens all included in the term D variant.

The most important D variant, from a transfusion perspective, is DVI ('D six'). It is not the most common, but lacks most of the D epitopes and is, therefore, the D variant most commonly associated with the production of anti-D. In the UK, it is recommended that anti-D reagents for typing patients should not detect DVI. Consequently, DVI patients will be typed as D-negative and transfused with D-negative red cells and DVI pregnant women will be given anti-D prophylaxis. Ideally, one of the anti-D reagents used for typing donor red cells should detect DVI; hence DVI donors will be typed as D-positive. This strategy means that DVI individuals should be considered D-negative patients, but D-positive donors. Weak D types 1, 2, and 3 are three of the most common D variants and are almost never associated with anti-D production.

In view of the high quality of monoclonal anti-D in the UK, the recommended method for D typing of patients requires direct agglutination tests, in duplicate, with potent IgM monoclonal anti-D reagents. An antiglobulin test is no longer required. Patients whose red cells appear D-positive, but give weak or inconsistent reactions, suggestive of a D variant, are treated as D-positive and transfused with D-positive blood unless they are females of childbearing potential or transfusion dependent. In those cases, they are treated as D-negative and transfused with D-negative blood unless they are shown to have the weak D type 1, 2 or 3. This strategy is designed to conserve valuable stocks of D-negative red cells for patients who really need them.

Similarly, donors are not typed any longer for D by an antiglobulin test because it is unlikely that transfusion of very weak D red cells to a D-negative patient will result in immunisation of the patient. In some countries, however, the antiglobulin test for D typing of donors is still required and in some countries, a molecular test is mandatory for confirming D-negative status of donors.

Molecular basis of D variants

D variants result either from missense mutations in *RHD*, encoding single amino acid changes or from an *RHD* in which a segment has been replaced by the equivalent segment of an *RHCE* gene due to unequal crossing over or gene conversion. For example, the most common form of DVI is produced by an *RHD–CE–D* hybrid gene in which exons four to six have the nucleotide sequence of *RHCE*, and external loops 3 and 4 of the encoded hybrid protein have the amino acid sequence of an RhCe protein. Hence, a protein is produced with a sequence similar enough to RhD to be stable in the membrane, but different enough to lack many epitopes of D. A variety of names have been used to denote the different types of D variants, for example DIII, DVI, DFR, DAR and DBT, which can be distinguished by sophisticated serological techniques, and weak D types 1–145, which can only be distinguished by molecular techniques.

Antibodies of the Rh system

Naturally occurring antibodies

Generally, Rh antibodies are only produced following immunisation with red cells. However, anti-E is often naturally occurring; about half may occur without a history of pregnancy or transfusion. Rarely, naturally occurring anti-D and anti-C^W are found. All such naturally occurring Rh antibodies react optimally with enzyme-treated cells; if they react at 37 °C by IAT, they are clinically significant.

Immune antibodies

The clinical importance of the Rh system lies in the readiness with which anti-D arises in D-negative subjects after stimulation with D-positive red cells by pregnancy or transfusion. Prophylaxis against D immunisation with anti-D immunoglobulin in pregnancy (see below) has led to a significant decrease in the incidence of anti-D, but it still remains the most common immune antibody of clinical relevance detected in a routine blood transfusion laboratory. D is considerably more immunogenic than the other Rh antigens, which have the following order of immunogenicity: c > E > e > C.

About 20–30% of anti-D sera also appear to contain anti-C. Usually, this anti-C is not a separable antibody and is probably more correctly called anti-G. About 1–2% of anti-D sera also contain anti-E. Anti-C (and anti-G) in the absence of anti-D is very uncommon.

The incidence of other Rh antibodies is much lower, but together they are more common than anti-K (Kell system), which is the most immunogenic antigen after D. In routine screening, pure anti-E is the most common, followed by anti-c, although anti-c is a more common cause of HDFN, which can be severe. This is probably because many anti-E are weak, naturally occurring antibodies. Anti-e, like anti-C, is rare.

The vast majority of Rh antibodies are IgG and do not fix complement. Anti-D may occasionally be partly IgA. IgM anti-D is very rare.

D immunisation and immunoprophylaxis

The D antigen is very immunogenic; over 80% of D-negative recipients of a whole unit of D-positive red cells make anti-D and 17% of D-negative women will be immunised by one pregnancy with a D-positive offspring.

Prediction of fetal RhD type by molecular methods

Knowledge of the molecular basis for D-negative phenotypes has made it possible to devise tests for predicting fetal D type from fetal DNA. This is valuable in determining whether the fetus of a woman with anti-D is at risk from HDFN. Most methods involve PCR-based tests that detect the presence or absence of *RHD*, but it is important to test for more than one region of *RHD*, so that hybrid genes responsible for partial D antigens do not give a false result, and to test for the *RHD* pseudogene (*RHDψ*), so that this does not give rise to a false-positive result.

Although fetal DNA can be obtained by amniocentesis, this procedure is associated with a significant risk of fetal loss and fetal-maternal haemorrhage. The best source is the small quantities of free fetal DNA present in maternal plasma. This noninvasive form of fetal D typing is now provided for pregnant women with significant levels of anti-D as a routine service in the UK and other parts of Europe and should be considered the standard of care in these patients. This technology is now also applied to high-throughput non-invasive prenatal testing (NIPT) for fetal *RHD* genotype of D-negative pregnant women, to determine if anti-D prophylaxis is required. This approach means that only the D-negative women carrying a D-positive fetus will receive anti-D and those carrying a D-negative fetus will not have anti-D administered unnecessarily. Fetal D testing of all D-negative pregnant women is provided as a routine service in the UK and several European countries. When this testing is not available, it is common practice to offer antenatal anti-D prophylaxis to all D-negative pregnant women. In a predominantly white population, about 40% of these women will have a D-negative fetus and therefore receive the treatment unnecessarily.

The MNS system

Antigens of the MNS system

M and N are inherited as codominant Mendelian traits, giving rise to three common genotypes *M*/*M*, *M*/*N* and *N*/*N*. The *Ss* locus, which is closely linked to *MN*, also consists of two codominant alleles in Europeans and Asians, producing S or s antigens. In northern Europeans, haplotype frequencies are as follows: *MS*, 25%; *Ms*, 28%; *NS*, 8%; *Ns*, 39%. The system also contains

many variants. About 2% of black West Africans and 1.5% of African-Americans are S−s− and most of these lack the U antigen that is present when either S or s is expressed.

The MN antigens are carried on glycophorin A (GPA), which is encoded by the *GYPA* gene on chromosome 4. There are about 1 million molecules of GPA per cell, yet their absence in the rare En(a−) phenotype does not affect red cell function or survival. The negative charge of the red cells is mainly due to the ionised COOH groups of sialic acid (neuraminic acid), which is mostly carried on the oligosaccharides of GPA and can be removed with neuraminidase. En(a−) cells therefore have a reduced negative charge and behave serologically as if they have been treated with neuraminidase. GPB carries the S and s determinants. GPB is encoded by *GYPB*, which is closely linked and homologous to *GYPA*. S−s−U− red cells lack GPB. GPA and GPB are exploited as receptors by the malaria parasite *Plasmodium falciparum*.

Antibodies of the MNS system

Anti-M is uncommon and is usually naturally occurring, but can be immune and, very rarely, causes HDFN. Anti-N is also rare and is nearly always cold-reactive IgM. Useful anti-N lectin can be prepared from the seeds of *Vicia graminea*. Anti-S, the rarer anti-s and anti-U are usually immune, IgG and can cause HDFN. They have also been implicated in HTRs. Anti-U only occurs in S−s− black people and reacts with all cells that have the S or s antigens and up to 50% of cells that are S−s− and have a variant U antigen. Finding compatible blood for a patient with anti-U can prove difficult, especially in a predominantly White donor population.

The Kell blood group system

The Kell blood group system consists of 38 antigens, including one triplet and five pairs of allelic antigens – K and k; Kp^a, Kp^b and Kp^c; Js^a and Js^b; K11 and K17; K14 and K24; KHIZ and KHOZ – all of which represent amino acid substitutions in the Kell glycoprotein. Three sets of antigens are clinically important: K/k; $Kp^a/Kp^b/Kp^c$ and Js^a/Js^b.

In white Europeans, the incidence of the K/k phenotypes, the most important clinically, is as follows: K+k−, 0.2%; K+k+, 8.7%; K−k+, 91.1%. K is rare in non-white populations. Js^a is present in about 20% of black people, but is extremely rare in other ethnic groups. K_0, a very rare null phenotype of the Kell system in which no Kell antigens are expressed, results from homozygosity, or compound heterozygosity, for a variety of inactivating mutations in the *KEL* gene.

The Kell antigens are located on a glycoprotein that crosses the cell membrane once, with a large glycosylated C-terminal extracellular domain, maintained in folded conformation by multiple disulfide bonds. Reduction of these bonds by dithiothreitol (DTT) results in loss of expression of all Kell antigens, leading to artificial K_0 cells with elevated expression of Kx.

Anti-K is an important antibody in white populations; it is nearly always immune, IgG and complement-binding. It causes severe HTRs and HDFN. K stimulates the formation of anti-K in about 10% of K-negative people given one unit of K-positive blood. About 0.1% of all cases of HDFN are caused by anti-K; most of the mothers will have had previous blood transfusions. HDFN caused by anti-K differs from Rh HDFN in that anti-K causes fetal anaemia by suppression of erythropoiesis, rather than immune destruction of mature fetal erythrocytes. Kell antigens are expressed by erythroid cells at a very early stage of erythropoiesis and anti-K would facilitate destruction of K+ early erythroid progenitors, before they become haemoglobinised. Anti-k is very rare, reacting with 99.8% of random blood samples. It is always immune and has been implicated in HDFN. Most other Kell system antibodies are rare, best detected by the IAT and are usually clinically significant.

The Kell glycoprotein is linked by a single disulfide bond to the Kx protein, produced by an X-linked gene, *XK*. Absence of Kx, resulting from hemizygosity in males of a deletion of *XK* or of *XK* containing inactivating mutations, gives rise to the McLeod syndrome, in which there is no expression of Kx antigen, weak expression of all Kell system antigens and a neuroacanthocytosis that is usually characterised by late-onset muscular, neurological and psychiatric disorders, plus about 30% red cells with acanthocytosis and associated haemolytic anaemia. In some cases, an X chromosome deletion is large enough to encompass *XK* and *CYBB*, a gene for a subunit of flavocytochrome b_{558}, which leads to McLeod syndrome and chronic granulomatous disease (CGD). However, the majority of CGD patients have normal Kell antigens and Kx. If boys with McLeod syndrome and CGD are transfused, they are able to make anti-Kx, which can cause severe HTRs, most often needing to resort to the International Rare Donor Panel for compatible blood.

Other blood group systems

Fy^a and Fy^b antigens of the Duffy system represent a single amino acid substitution in the extracellular N-terminal domain of the Duffy glycoprotein. Their incidence in the UK is as follows: Fy(a+b−), 20%; Fy(a+b+), 46%; Fy(a−b+), 34%. About 70% of African–Americans and close to 100% of West Africans are Fy(a−b−). Anti-Fy^a is not infrequent. It is IgG, often complement-fixing and can cause HTRs, but seldom HDFN. It is best detected by IAT and does not react with red cells treated with the proteases papain and ficin. Anti-Fy^b is very rare and is always immune.

Kidd has two alleles, Jk^a and Jk^b, which represent a single amino acid change in the Kidd glycoprotein. Phenotype frequencies in the UK population are as follows: Jk(a+b−), 25%; Jk(a+b+), 50%; Jk(a−b+), 25%. The Kidd null phenotype, Jk(a−b−) is very rare in most populations but reaches an incidence of greater than 1% in Polynesians. Anti-Jk^a is uncommon and anti-Jk^b is even rarer, but they may both cause severe

transfusion reactions and, to a lesser extent, HDFN. Kidd antibodies have often been implicated in delayed HTRs; they are IgG and predominantly complement-fixing up to C3b, but may be difficult to detect because they tend to disappear and then reappear promptly in an anamnestic response. The antiglobulin test is the best method for detection; reactions are enhanced if the cells are protease-treated or if fresh serum is added as a source of complement.

Lutheran is a complex system and includes the antigens Lu^a and Lu^b, which represent a single amino acid substitution in the Lutheran glycoprotein. Phenotype incidence in the UK is as follows: Lu(a+b−), 0.1%; Lu(a+b+), 7.5%; Lu(a−b+), 92.4%. The extremely rare Lu_{null} phenotype, in which no Lutheran antigens are expressed, results from homozygosity for an inactive Lutheran gene; anti-Lu3 may be produced. Lutheran antibodies are uncommon and are not generally clinically significant, although anti-Lu^b may have caused mild delayed HTRs. Lu^a may be omitted from antibody screening cells.

The Diego system antigens represent single amino acid substitutions in band 3, the red cell anion exchanger. Di^a, is very rare in white and black people, but relatively common in certain populations, with frequencies varying between 1% in Japanese and 50% in some native South Americans. Anti-Di^a and anti-Di^b are immune and rare but can cause HDFN. Wr^a has a frequency of about 0.1%. Naturally occurring anti-Wr^a is present in approximately 1% of blood donors. Anti-Wr^a is often found in the serum of patients who have made other antibodies or who are suffering from autoimmune haemolytic anaemia. Very rarely, anti-Wr^a causes HDFN.

Do^a and Do^b of the Dombrock system represent a single amino acid substitution on the Dombrock glycoprotein. Approximately 67% of northern Europeans are Do(a+) and 82% Do(b+). Dombrock antibodies are extremely rare, immune and are best detected by IAT; they have been implicated in severe acute and delayed HTRs. Dombrock typing reagents are rare and unreliable, so typing is best achieved by molecular methods.

Co^a and Co^b of the Colton system represent a single amino acid substitution in the water channel aquaporin-1. Colton phenotype frequencies in white people are as follows: Co(a+b−), 90.5%; Co(a+b+), 9.0%; Co(a−b+), 0.5%. Colton antibodies are very uncommon. Anti-Co^a has caused severe HDFN and has been implicated in acute and delayed HTRs.

Yt^a and Yt^b of the Yt system represent a single amino acid change in red cell membrane acetylcholinesterase. Yt^a and Yt^b have frequencies of about 99.8 and 8% respectively. Anti-Yt^a and anti-Yt^b are exceptional and most are of no clinical significance.

There are other antigens, of either very high or very low prevalence, (classified by the International Society for Blood Transfusion, the ISBT, into the 901 series and 701 series respectively) and those with a serological or biochemical relationship but not yet assigned to blood group systems (collections, termed the 200 series). Some have caused HDFN and/or HTRs. Within other blood group systems, Jr^a, Lan, At^a, MAM and AnWj are clinically significant antigens of very high prevalence. Anti-Vel, an antibody to an antigen of high prevalence causes severe HTRs.

For those rare individuals who have formed antibodies to high-prevalence antigens, the provision of compatible blood can be a problem and it is often necessary to approach the national rare donor registries or, when rare units cannot be sourced nationally, the International Rare Donor Panel for compatible units. Antibodies to low-prevalence antigens are usually naturally occurring; they may occasionally give rise to unexpected incompatible cross-matches. Some antibodies to low-prevalence antigens have caused HDFN.

Polyagglutinable red cells

Erythrocyte polyagglutination is the agglutination of red cells irrespective of blood group by many sera from normal adults. Polyagglutinable red cells are not agglutinated by the patient's own serum. The abnormality is a property of the red cells, not of the sera, in contrast to panagglutination, which is the agglutination of most red cells by one serum.

There are two main categories of polyagglutination, acquired and inherited. The acquired forms can be subdivided into: (i) microbial polyagglutination, which results from the action of microbial enzymes on red cell surface oligosaccharides (T, Tk, acquired B); and (ii) non-microbial polyagglutination, which is caused by somatic mutation (Tn). There are four types of inherited polyagglutination: Cad (strong expression of Sd^a), congenital dyserythropoietic anaemia type II (CDAII or HEMPAS), NOR and Hyde Park. Lectins are required for the identification of the different types of polyagglutination.

The biological significance of blood group antigens

The functions of many red cell membrane proteins bearing blood group antigenic determinants are known, or can be deduced from their structure. Some are membrane transporters, facilitating the transport of biologically important molecules through the lipid bilayer: band 3 glycoprotein, the Diego antigen, provides an anion exchange channel for HCO_3^- and Cl^- ions; the Kidd glycoprotein is a urea transporter in red cells and renal endothelial cells; the Colton and GIL glycoproteins are aquaporin water and glycerol channels; JR and Lan are ATP-binding cassette transporters, which translocate various substrates across biological membranes. RhAG probably functions as a channel for rapid CO_2 transfer in and out of the cell. CO_2 in the red cell is converted to bicarbonate ions by carbonic anhydrase II and then transported rapidly out of the cell to the

plasma by band 3, part of the same macrocomplex as RhAG, where it is carried to the lungs.

The Lutheran, LW and Indian (CD44) glycoproteins are adhesion molecules, possibly serving their functions during erythropoiesis. The Duffy glycoprotein is a chemokine receptor and might function as a 'sink' or scavenger for unwanted chemokines. The Cromer and Knops antigens are markers for decay-accelerating factor and complement receptor 1, respectively, which protect the cells from destruction by autologous complement. Some blood group glycoproteins have enzyme activity: the Yt protein is acetylcholinesterase and the Kell protein is an endopeptidase that synthesises endothelin-3, a vasoconstrictor. The C-terminal domains of the Gerbich glycoproteins, GPC and GPD, and the N-terminal domain of the Diego glycoprotein, band 3, anchor the membrane to its skeleton. The carbohydrate moieties of the membrane glycoproteins and glycolipids, especially those of the most abundant glycoproteins, band 3 and GPA, constitute the glycocalyx, an extracellular coat that protects the cell from mechanical damage and microbial attack.

The difference between red cell antigens that represent the products of alleles (e.g. A and B, K and k, Fy^a and Fy^b) is small, often being just one monosaccharide or one amino acid. The biological importance of these differences is unknown and there is little evidence to suggest that one antigen confers any significant advantage over another. Most blood group systems have a null phenotype in which the whole blood group protein is absent from the red cells or any other cells. These usually result from homozygosity for gene deletions or inactivating mutations within the genes. In most cases, individuals with these null phenotypes are apparently healthy, suggesting that whatever the precise function of the missing structure may be, some other structure must be able to substitute in its absence. However, there are exceptions; rare Rh_{null} individuals, who lack RhD and RhCE proteins, as well as RhAG, have chronic haemolysis, which may be compensated by increased red cell production, but may require splenectomy for stabilisation. Absence of the Kx protein causes weakness of expression of all Kell antigens, as a result of linkage between the two proteins in the membrane, but is also associated with neuroacanthocytosis. Very rare patients lacking the RAPH glycoprotein, CD151, have disruption of basement membranes causing hereditary nephritis, epidermolysis bullosa and neurosensory deafness. A patient lacking all Diego blood group system antigens, which function as an anion transporter, only survived with extreme medical intervention. On the other hand, people with the rare Bombay phenotype lack ABH antigens from all cells and tissues, with no apparent ill effect or red cell abnormality.

Some blood group antigens are exploited by pathological microorganisms as receptors for attaching and entering cells. Consequently, in some cases absence of antigens can be beneficial. The Duffy glycoprotein is used by *Plasmodium vivax* to penetrate red cells. Hence, the Fy(a−b−) phenotype, common in Africans, confers resistance to *P. vivax* malaria. *Plasmodium falciparum* malaria appears to have played a part in the establishment of the ABO polymorphism. The geographic distribution of group O is consistent with selection pressure by *P. falciparum* in favour of group O individuals in malaria endemic regions.

Introduction

This chapter covers key aspects of blood donation and collection and the preparation and storage of blood components; it describes pretransfusion testing of donors' and recipients' blood, complications and adverse effects of blood transfusion, as well as the appropriate use of components and transfusion alternatives available in different clinical scenarios. The features of haemolytic disease of the foetus and newborn are also described. The regulatory and logistical descriptions mainly reflect a UK perspective, although some international considerations are made, and the principles for clinical practice are, to a great degree, universal.

Blood transfusion and regulatory aspects

Concerns about blood safety and in particular transfusion-transmitted infection have resulted in an increasingly stringent regulatory framework for transfusion medicine. The World Health Organisation (WHO) and the Council of Europe (CoE) have defined a code of ethical principles which serve as guidance for countries on blood donation and transfusion practice. The European Union (EU) Blood Directives set standards of quality and safety for the collection, testing, processing, storage and distribution of blood and components. The Good Practice Guidelines, prepared through co-operation between the European Directorate for the Quality of Medicines & HealthCare of the Council of Europe (EDQM) and the Commission of the European Union (EU), form an integral part of the 20th edition of the COE Guide to the preparation, use and quality assurance of blood components. In the UK these EU Directives have been transposed into law as the Blood Safety and Quality Regulations 2005. Aspects of the regulations apply to 'blood establishments' (the UK Blood Services) and hospital blood banks, and the Acting Competent Authority under these regulations is the Medicines and Healthcare products Regulatory Agency (MHRA) which regulates the Blood Services and hospital transfusion laboratories in the UK.

The blood donor

An adequate and reliable supply of safe blood can be assured by a stable base of regular, voluntary, unpaid blood donors who are also the safest group of donors with the lowest prevalence of blood-borne infections. World Health Assembly resolution WHA63.12 urges all Member States to develop national blood systems based on voluntary unpaid donations and to work towards the goal of self-sufficiency. However, whole blood donation and apheresis plasma donation are still remunerated in some countries.

Selection criteria and blood donation

Donor selection criteria are aimed at ensuring the safety of the donor and minimising risk to recipients, in particular the risk of the transmission of infection. Blood donors should be healthy adults within a permitted age range with minimum requirements for weight, haemoglobin, donation volume and donation frequency (see Table 19.1).

Table 19.1 Measures to protect the donor from adverse effects of large-volume blood withdrawal.

- Age 17–70 years (60 at first donation).
- Weight above 50 kg
- Haemoglobin >135 g/L for men, 125 g/L for women for whole blood and all component donors except those who only donate plasma by apheresis
- Minimum donation interval of 12 weeks (16 weeks for females)
- Pregnant and lactating women excluded because of high iron requirements
- Exclusion of those with:
  - Known cardiovascular disease e.g., ischaemic heart disease
  - Significant respiratory disorders
  - Epilepsy and other CNS disorders
  - Inflammatory bowel disease
  - Insulin-dependent diabetes
  - Chronic renal disease (CKD ≥ 3)
  - Ongoing medical investigation or clinical trials
- Exclusion of any donor returning to occupations such as driving bus, plane or train, heavy machine or crane operator, mining, scaffolding, etc. (delayed faint risks)

The minimum age for blood donation in many countries is 17 years, essentially aimed at avoiding donation in adolescence when iron requirements are high. Similarly, pregnant and lactating women are not permitted to donate. In the UK, the upper age limit for first-time donors is 65 years, with no upper age limit for regular donors in good health. Screening of blood donors should be carried out by a trained assessor, to ensure that the donation will not compromise the health of the donor, the health of the recipient or the quality of the blood collected. A full donor medical history will help identify those not suitable for donation (e.g. those with cancer, cardiovascular or renal disease). A full travel history including long stay/residency is essential together with any activities known to be associated with increased risk of acquiring infections with temporary or permanent deferral as needed (see below). Due to the risk of delayed faints, donors in hazardous occupations or hobbies (e.g. scaffolding, firemen, climbers) should not be allowed to return to work or their hobbies until the following day.

Donor haemoglobin screening is an important part of donor assessment. The haemoglobin level is assessed prior to each donation usually by a semi-quantitative, gravimetric method using a drop of capillary blood in a copper sulfate solution, but this may be supplemented by use of portable haemoglobinometers. The minimum acceptable haemoglobin level varies: it is 125 g/L for females and 135 g/L in males for most donations including whole blood and all component donors (except those who only donate plasma by apheresis, in whom a lower Hb may be tolerated). No more than 15% of the estimated blood volume should be taken during any one donation and, in general, 450 mL+/–10% of blood is collected with an interval of 12–16 weeks between whole blood donations. Individual components such as platelets and plasma can also be collected by apheresis using a cell separator with a maximum of 24 procedures in 12 months.

The appropriate frequency of blood donations has been investigated by the INTERVAL study which examined donation at 8-, 10- and 12-week intervals for men, and 12-, 14- or 16-week intervals for women. Although giving blood at the shorter intervals resulted in much more blood being collected without a major impact on the donors' quality of life, mental function or physical activity, some of those who gave blood more frequently did report minor symptoms including tiredness and restless legs. Haemoglobin estimation using the copper sulfate method failed to identify up to 10% of people with haemoglobin levels below the required limit, putting donors at risk of developing anaemia and iron deficiency. Portable haemoglobinometry (i.e. using capillary HemoCue) has been shown to have the highest accuracy across all haemoglobin thresholds examined for both men and women, as well as the smallest biases in comparison with the reference standard.

Donors with minor red cell abnormalities, such as thalassaemia trait and hereditary spherocytosis, are acceptable, providing the haemoglobin screening test excludes anaemia and donors have themselves not needed any transfusion support. Red cells from donors with sickle cell trait containing HbS may block leucodepletion filters and have limited survival under conditions of reduced oxygen tension and so should not be transfused to newborn infants and patients with sickle cell disease. Red cells from donors with glucose-6-phosphate dehydrogenase deficiency survive normally, unless the recipient is given oxidant drugs. Individuals with hereditary haemochromatosis are accepted for donation provided they meet other donor selection criteria and are under ongoing medical review.

Donor selection guidelines are reviewed regularly and, based on new evidence as well as estimated risks, these are updated regularly. In November 2017, the blood donor selection guidelines for men who have sex with men (MSM) were changed in England, Wales and Scotland from a 12-month deferral since last sex with a man to a 3-month deferral. Similar changes were made for other donor selection criteria related to higher-risk sexual behaviours. The For the Assessment of Individualised Risk (FAIR) steering group recommended a more individualised approach to donor selection in the UK. Under this new donor selection policy, donors who have had the same sexual partner (and no others) in the last 3 months and who do not have a sexually transmitted infection should be eligible to donate, allowing more gay, bisexual and men who have sex with men to donate blood.

Donated blood is not tested routinely for the SARS-CoV-2 virus that causes COVID-19 and, to date, there are no known cases of transfusion-transmitted SARS-CoV-2 infections reported and there is currently no evidence that SARS-CoV-2 is a transfusion-transmitted infection.

Transfusion-transmitted infection (TTI)

Several infections have the potential to be transmitted by transfusion of blood or its components (see Table 19.2). The epidemiology of infection in the population of a particular country can help guide the microbiological testing required. Careful donor selection criteria, with detailed questionnaires, aimed at excluding individuals at high risk of carrying infection, are supported by stringent microbiological testing (Table 19.3) with additional use of measures where appropriate to protect the recipient (see Table 19.4). Despite these measures, infection may still be transmitted, although rarely, due to the donor being in the incubation or 'window period' before testing becomes positive for infective markers or due to transmission of infections of unknown aetiology, or where no screening test is available to date (e.g. prion disease).

The viruses that pose the greatest potential risk for transmission by transfusion are those that have long incubation periods (often causing subclinical infection), and especially those that may be carried by asymptomatic individuals for many years, or even lifelong. Alternatively, some viruses that are transfusion-transmissible exhibit cell-associated latency. If the virus is latent in white blood cells, recrudescence of that virus, stimulated by allogeneic transfusion, can cause infection of the recipient. More rarely, a few viruses causing acute infection can be transmitted in the short presymptomatic-viraemic phase, if this coincides with the time of blood donation.

Some groups of people may be at particular risk of blood-borne infections, people who inject drugs and individuals paid to have sex, who are accordingly asked never to give blood. Temporary deferrals may also be applied in certain circumstances for example; in the UK, potential blood donors cannot donate for at least 3 months if they have taken part in chemsex activity, including the use of stimulant drugs.

The chance of not detecting and releasing an infectious donation made by a donor who has very recently acquired hepatitis B, hepatitis C or HIV is estimated over a rolling 3-year period each year. The current estimate of a window period donation being not detected on screening remains at less than one in a million, with the risk being highest for Hepatitis B. There is

Table 19.2 Transfusion-transmissible agents.

Agents		Characteristics related to transfusion
Viruses		
Hepatotropic	HAV	Very rarely transfusion transmitted (rare in the UK, generally imported cases) during incubation; no carrier state; faecal-oral transmission
	HEV	As above but person-to-person spread is rare
	HBV	2–6-month incubation period; carrier state; readily transmissible by blood
	HCV	Majority of cases asymptomatic; carrier state; readily transmissible by blood
Retroviruses	HIV-1 and HIV-2	Carrier state and latent in WBCs; readily transmissible by blood
	HTLV-I and HTLV-II	Latent in WBCs
Herpesviruses	CMV	50% of UK adults have been infected; latent in WBCs
	EBV	Most UK adults have been infected (therefore already exposed pretransfusion); latent in WBCs
Others	Parvovirus B19	Generally mild or asymptomatic, posing no transfusion risk except for non-immune aplastic anaemia patients, haemoglobinopathies and foetuses Approximately two-thirds of UK adults have been infected Seasonal variation (and epidemic years) in incidence rate
	West Nile virus	Recently exhibiting epidemic rates of transmission in summer months in North America
	Dengue virus	Transfusion transmission has been reported in Asia
Bacteria	*Treponema pallidum*	Inactivated by storage at 4 °C
Endogenous		
	Yersinia enterocolitica	Very occasional transmissions, usually contaminated red cells transfused late in the storage period
	E. coli	Very occasional transmissions, usually contaminated red cells transfused late in the storage period
Exogenous	e.g. *Staphylococcus epidermidis*, *Micrococcus*, *Sarcina*	Mainly skin commensals or contaminants Most common cause of platelet contamination
Parasites	Malaria	Frequently transmitted in endemic countries in Africa, Asia and the Caribbean.
	Chagas disease	No transmission of *Trypanosoma cruzi* by transfusion has been reported in UK; many cases in Latin America
Prions	Abnormal PrP	Transfusion risk from vCJD.

WBCs, white blood cells.

Table 19.3 Microbial testing in England.

HEV	RNA screening in pools
HIV	ELISA (combined HIV-1 antigen plus anti-HIV-1 and anti-HIV-2); NAT for RNA
HBV	HBsAg ELISA; NAT for DNA; anti-HBc on new donors
HCV	Anti-HCV ELISA plus NAT for RNA
HTLV	Anti-HTLV ELISA (on pools of samples)
CMV	Anti-CMV for selected immunosuppressed recipients only
Malaria	Antibody screening of potentially exposed donors
Chagas disease	Antibody screening of potentially exposed donors
Bacteria	All donations are tested for antibody to syphilis; all platelet preparations are tested by culture methods

Table 19.4 Measures to protect the recipient.

Measure	UK currently
Donor selection	Yes
Donor deferral/exclusion	Yes
Stringent arm cleansing	Yes
Diversion of the first 20–30 mL of blood collected	Yes
Microbiological testing of donations	Yes
Immunohaematological testing of donations	Yes
Leucodepletion of cellular blood components	Yes
Safest possible sources of donors for plasma-based products	For at-risk patients
Monitoring and testing for bacterial contamination	Yes
Pathogen inactivation of cellular components (e.g. psoralens)	No
Prion filtration	No

routine surveillance of all reported suspected TTIs to the blood services for full investigation.

Hepatitis viruses

Hepatitis viruses can be transmitted in cellular and plasma components, as well as plasma products, and currently across UK it's a permanent deferral post introduction of anti-HBc, other countries will allow donation with sufficient immunity. Since for hepatitis A, there is no carrier state and any transmission can be possible only during the incubation or acute phase, deferral is also required for a donor who has been in close contact with a case (e.g. household contact) as well as those who have developed hepatitis A within the last 12 months. HEV and HAV have a 6-month deferral post recovery now in the UK.

For hepatitis B, C and E which have carrier/chronic states, further testing is required. With hepatitis E, the chronic state is usually only in immunosuppressed individuals. For hepatitis B, all donations are tested for the presence of HBsAg by sensitive ELISAs that can detect at least 0.2 IU/mL of HBsAg. More sensitive screening tests, such as HBV nucleic acid testing (NAT), have been introduced in many countries: this shortens the 'window period' of infectivity. NAT testing is also used for hepatitis C, and the risk of transmission by blood transfusion has fallen dramatically since its introduction.

Hepatitis B, historically acute infections, most recently occult hepatitis B infections, are remains the most reported viral TTI in the UK because of window-period transmissions either during the incubation period or at the tail end of the carrier state. More recently, the specialist advisory committee on the safety of blood, tissues and organs (SaBTO) has recommended that all donors be tested at least once for anti-HBc, a marker of hepatitis B infection. Individuals who have recovered from hepatitis B will remain anti-HBc positive. There is a risk that reactivation of hepatitis B virus in such an individual could give rise to occult hepatitis B infection which is not detected by routine testing. For this reason, donors who are anti-HBc positive are deferred from donation. UK Blood Transfusion Services are currently implementing this.

For Hepatitis E: there have been several reported cases of transfusion-transmitted HEV following transfusion of red cells, platelet preparations, pooled granulocytes and fresh-frozen plasma. Because of the rising trend of HEV serological prevalence amongst the global population, and the fact that transfusion-transmitted-HEV infection can cause serious clinical consequences amongst those patients most in need of blood transfusion, universal hepatitis E screening was introduced in the UK in 2017. The screening approach, using pools of 24 donations, that is currently in operation to detect hepatitis E viraemia in donated blood is likely to detect the majority of viraemic donors. Those with viral loads below the level of detection remain a potential risk, though the likelihood of transmission from components containing very low levels of HEV RNA appears small. A total of 12 incidents (15 recipients) have been reported relating to HEV transmission through transfusions in the UK resulting in 2 deaths and 9 cases with major morbidity related to the viral infection. All except 2 HEV transmissions in the UK were reported before HEV RNA screening was introduced in April 2017 infections tend to be with genotype 3 in the UK.

Human immunodeficiency virus (HIV-l and HIV-2)

HIV can be transmitted in both cellular and plasma components, and blood services have robust processes to minimise this risk. Most patients infected by the transfusion of blood components were transfused before the introduction of screening of blood donations for HIV antibodies. Moreover, most recipients

of fractionated plasma products infected in the past were transfused before 1985 with unheated, non-Pasteurised pooled plasma products, mainly factor VIII and factor IX concentrates. Thus, HIV infection became an important sequel to transfusion of factor VIII concentrates to people with haemophilia in the early 1980s. HIV is more heat labile than HBV, especially when in solution and is also susceptible to other viral inactivation methods such as solvent-detergent treatment.

Every donation should be tested for antibodies to HIV-1 and HIV-2 and common subtypes, using a test system such as ELISA. Laboratory markers for HIV include anti-HIV, p24 antigen and viral RNA. To reduce the window period for HIV, many blood centres use combination tests for HIV antibody and p24 antigen, and/or perform NAT testing in addition to antibody testing.

Every donation in the UK is tested for antibodies to HIV (anti-HIV), and combined antigen–antibody for HIV (HIV Ag/Ab). Donated blood in the UK is tested in pools of 24 samples by multiplex HBV, HCV and HIV NAT as well. Routine screening, combined with well-established donor education and self-deferral schemes, can reduce the already small risk of HIV transmission by transfusion in those countries where blood donors are voluntary and mostly regular.

Human T-cell leukaemia viruses

Human T-cell leukaemia viruses (HTLV-I and HTLV-II) are related retroviruses. Infection with HTLV-I is associated with at least two distinct clinical conditions: it can occasionally lead to adult T-cell leukaemia, with an incubation period of approximately 20 years, and, on even rarer occasions, to tropical spastic paraparesis (also known as HTLV-I-associated myelopathy), with a shorter incubation period. Only about 1% of patients who are seropositive develop T-cell leukaemia.

Both HTLV-I and HTLV-II are cell-associated and not transmitted in plasma. In highly endemic areas, transmission of HTLV-I by transfusion was relatively common before mandatory screening was introduced. Both tropical spastic paraparesis and adult T-cell leukaemia have been associated with transfusion-transmitted HTLV-I. In England and Wales, an estimated 22,000 people are living with the virus, mainly those who have migrated from endemic countries, or their descendants. In the UK, screening using a sensitive ELISA for anti-HTLV-I/II on pooled plasma samples became mandatory in 2002. Additionally, universal pre-storage leucoreduction results in a significant reduction in the rate of transmission. If a donation tests positive for HTLV-I, -II it must be discarded, the donor notified and informed and referred to specialist care, and asked never to donate again.

Cytomegalovirus

Although most cases of post-transfusion cytomegalovirus (CMV) infection are subclinical, the syndrome of post-transfusion infectious mononucleosis-like illness is well recognised, especially after the transfusion of large amounts of blood. The infection is characterised by fever, splenomegaly and atypical lymphoid cells in the peripheral blood, with a negative Paul Bunnell test. The usually benign course of CMV infection in most recipients and the high prevalence of CMV antibodies in the general population have meant that there has been no necessity to screen all donors for evidence of past infection. Immunosuppressed individuals are at greatest risk from potentially fatal pneumonitis or disseminated CMV infection.

In 2011, following a review of available evidence, SaBTO recommended that leucodepletion of all blood components (other than granulocytes) provided adequate CMV risk reduction for most patients requiring transfusion (haemopoietic stem cell transplant recipients, organ transplant patients and immune deficient patients, including those with HIV) without the requirement to provide them, in addition, with CMV seronegative cellular blood components. CMV seronegative red cell and platelet components should continue to be provided for intrauterine transfusions and for neonates, as well as for pregnant women requiring repeat elective transfusions during pregnancy. Granulocyte components should be provided as CMV-negative for all CMV-negative allogeneic transplant patients (or potential patients) as these components cannot be leucodepleted. A medical decision may be made to transfuse units which are not CMV tested, or which are known to be CMV IgG positive, into a CMV-negative patient if the urgency to treat a non-responsive bacterial or fungal infection outweighs the risks of potentially developing CMV infection at a later stage.

CMV-negative blood components are those collected from donors who have been tested and found negative for CMV IgG antibodies.

Syphilis

According to WHO data, the global incidence of syphilis has increased in recent years. Each donation is tested by a serological test for syphilis. The syphilis spirochete (*Treponema pallidum*) is susceptible to time and temperature and will lose its ability to infect a recipient after several days of storage after donation, particularly if the storage is at 4 ± 2 °C. Serological tests for syphilis include a rapid plasma reagin test (RPR), treponema pallidum haemagglutination test (TPHA) and fluorescent treponemal antibody absorption test (FTA). Any donation from an individual giving a positive result is discarded, and subjects with positive tests are permanently withdrawn from donation, even after effective therapy.

Malaria

Plasmodia remain viable in red cells stored at 4 °C and are readily transmissible by blood transfusion. Red cells and whole blood are most likely to transmit infection but this is possible

with all cellular blood components. Transfusion-transmitted *Plasmodium falciparum* may cause severe malaria. Maintaining a malaria-free blood supply is an ongoing challenge for many blood services as malaria in asymptomatic carriers is difficult to detect due to the very low level of parasitaemia and blood donors from endemic areas often have circulating antibodies as a result of partial immunity to malaria.

In some endemic areas, all recipients are treated with antimalarial drugs. In non-endemic areas, there is a real risk of failure to recognise post-transfusion malaria owing to the rarity and unexpectedness of the infection. This fact, combined with increasing travel to tropical areas, necessitates the careful vetting of blood donors by direct questioning and, in some centres, by tests for malarial antibodies. In the UK, donors with a history of possible malaria exposure (provided it was more than 4 months previously and they are free of symptoms) can be accepted if a validated test for malarial antibody is negative. Donors who have had malaria diagnosed in the past can be accepted for blood donation if more than 3 years have passed since antimalarial therapy has been completed, symptoms caused by malaria have resolved and a validated test for malarial antibody is negative. Pathogen reduction methods that can be performed on whole blood or red cells are under development and show promise in reducing transmission.

Other infections

Acute viral infections, although associated with short phases of viraemia, can pose transmission risk by transfusion especially if their incidence is high. This has been demonstrated by West Nile virus (WNV) in North America. WNV is an arthropod-borne infection of birds, with humans and horses as incidental hosts. The annual outbreaks in recent years in the USA and Canada have resulted in several transmissions by transfusion, with severe morbidity and mortality in immunosuppressed and elderly patients. The EU Blood Safety Directive (and the Blood Safety and Quality Regulations) requires that travellers from an area with ongoing transmission of WNV in humans should be deferred for 28 days. Outbreaks of WNV infection in a number of areas within Europe in 2010/11 led to the introduction of WNV NAT testing of donations in affected areas.

Arboviruses, such as dengue, though rarely, can be transmitted by transfusion. Chikungunya virus might be transmissible.

Diseases such as Chagas disease cause significant problems for the blood transfusion services in Latin America and, due to immigration, in other areas. Potential exposure of UK donors necessitates stringent donor selection criteria and specific serological testing of those individuals to exclude the possibility of infection. *Babesia microti*, the agent of Nantucket fever, still poses a risk in certain areas of the USA. There are very few reports of possible transmission of *Leishmania donovani*, all outside Europe. Subjects giving a history of brucellosis are declined as donors in the UK due to the risk of transmission of this agent.

Bacteria

Bacteria from the donor arm can contaminate blood components. Rarely, low-grade or asymptomatic infections or translocated organisms from the gut in the donor, with *Salmonella* or *Yersinia*, may be an endogenous source of contamination of blood components. Coagulase-negative staphylococci from normal skin flora are rarely pathogenic, whereas *Staphylococcus aureus*, and Gram-negative organisms, such as *E. coli*, *Klebsiella* spp. and *Pseudomonas* spp., may result in life-threatening infections. Platelet components are at particular risk due to their storage at 20–24 °C, the risk increasing with length of storage. It is estimated that up to 1 in 2000 platelet packs contain detectable bacteria 5 days after donation and in the past, fatal reactions have been reported in 1 in 25,000–80,000 transfusions. Most pathogenic bacteria grow poorly in refrigerated temperatures needed for red cell storage, but some Gram-negative organisms, such as *Yersinia enterocolitica* and *Pseudomonas* spp., can grow under these conditions.

Bacterial contamination of blood has been significantly reduced in the UK by the introduction of improved donor arm cleansing using 70% isopropyl alcohol/2% chlorhexidine gluconate applied as a single-step procedure, and diversion of the first 20–30 mL of the blood donation. The risk of bacterial contamination has been further reduced, but not eliminated, by routine bacterial screening of platelet preparations with extension of shelf life from 5 to 7 days. The four UK Blood Services all use the BacT/ALERT system for bacterial screening which has been successful in reducing the risk of bacterial TTI (McDonald et al. 2017).

It is important to recognise that screening of platelet components cannot guarantee the absence of bacterial contamination. Packs are released for issue as 'negative-to-date', which may be before bacteria have multiplied sufficiently to trigger detection on screening. There have been ten bacterial near misses, all but one in platelet components, reported between 2011 and 2020 in the UK. Overall, out of a total of 44 bacterial transfusion transmissions to individual recipients, 37 (34 donations) have been caused by the transfusion of platelets, and 7 by red cells since reporting began in 1996.

Pathogen inactivation (PI) technologies for platelets and red cells, such as the use of light-activated psoralens that kill organisms by damaging their DNA or RNA have the potential to eliminate both bacterial and viral transfusion-transmitted infections. Whilst PI methods are now available, mostly for platelets, the cost-effectiveness of these techniques, together with the long-term risks, are uncertain, with the loss of viable platelets being a concern. Accordingly, although some parts of Europe have introduced PI, the potential for wide implementation in the UK is still under review.

Prions

Variant Creutzfeldt–Jakob disease (vCJD), the human form of bovine spongiform encephalopathy (BSE), was considered a potential threat to blood safety, particularly applicable to the UK.

To date, since 1996, when vCJD was first reported, there have been only four cases in the UK where blood transfusion of non-leucodepleted red cells may have been implicated in transmission of vCJD. All four cases occurred before 2007. A further possible transmission of vCJD prions was reported in February 2009 in a patient with haemophilia who had received batches of factor VIII to which a donor who subsequently developed vCJD had contributed plasma. The patient died of other causes but was found to have evidence of abnormal prion accumulation in his spleen.

There is no blood test at present for detecting prions in blood donations. The full risk of vCJD in the UK population is now thought to be low but the UK blood services have taken a number of precautionary measures to reduce the potential risk of transmission of prions by blood, plasma and blood products. These include: (i) barring various individuals from blood donation, such as those who have received a blood transfusion or tissue/organ transplant since 1980 or anyone who has received human pituitary-derived hormones or grafts of human dura or ocular tissue, and (ii) universal leucocyte depletion of all blood donations since 1999. Two other risk-reduction measures have now been withdrawn due to the re-assessed low risk of vCJD transmission: discarding UK plasma and importing plasma from countries other than the UK for fractionation into plasma products (withdrawn 2021), and importation of fresh-frozen plasma for use in patients born after January 1996 (withdrawn 2019).

Laboratory tests on blood donations

Samples for laboratory testing are taken at the time of donation in order to avoid later entry into the sterile blood pack. The routine tests are automated if large numbers of donor samples are tested daily, as is the case in the UK.

All blood donors in the UK are tested at each donation for syphilis, HBsAg, anti-HIV-1 and anti-HIV-2 and HIV antigen, anti-HCV, HCV and HIV RNA, HBV DNA and anti-HTLV. Anti-HTLV screening is only required for blood donations from previously untested donors and for blood donations destined for use to prepare non-leucodepleted products. Some donations are screened for CMV antibodies for patients in need of CMV-negative blood (as discussed previously). Additional testing may be needed of donors at particular risk based on travel history e.g. malaria antibodies, *T. cruzi* (Chagas) antibodies.

ABO and RhD grouping are determined routinely on each occasion. Typing for other Rh antigens (C, E, c and e) and K is now routinely performed on all blood donations in the UK. Phenotyping for other red cell antigens such as Duffy, Kidd and MNSs is performed on a restricted number of units in order to provide antigen-negative blood for alloimmunised patients and for transfusion-dependent patients likely to make multiple antibodies, such as those with sickle cell disease. Ideally, girls and women of childbearing age should be matched for c and K, as anti-c and anti-K are, after anti-D, the major causes of severe haemolytic disease of the newborn (HDN). In the UK, it is now recommended practice to give K-negative blood to females of childbearing potential to minimise the risk of forming anti-K.

All donations are also screened for the presence of atypical red cell alloantibodies. The incidence of clinically significant red cell alloantibodies in blood donors is very low (<0.3%) compared with the incidence in potential recipients (1–2%). Donations with potent clinically significant alloantibodies are not issued to hospitals. There are additional requirements for blood provision for neonatal and intrauterine use, including the use of repeat, rather than new, donors, HbS-negative and exclusion of high-titre anti-A and -B. Group O blood for emergency or 'flying squad' use, which may be given in an emergency to ungrouped recipients, should be given as red cells in additive solution such as saline-adenine-glucose-mannitol (SAGM) in order to avoid problems that might be caused by high-titre anti-A, B in donor plasma. As soon as the patient's group is known, group-specific blood should be given. If group O platelets have to be given to non-O recipients, donors with high-titre anti-A and B should be excluded as the providers of the plasma used to suspend the platelets; alternatively, platelet-additive solutions can be used to replace most of the plasma.

Molecular techniques are becoming increasingly available for blood group testing and extended red cell genotyping; they are likely to come into more routine use within blood services with the application of rapid automated technology.

Storage and processing of blood

Donor blood is collected into plastic packs containing anticoagulants and then transported without delay to the blood centre for processing. In the UK, all units undergo leucodepletion at different stages of processing, depending on the final components required (see below). Processing (see Figures 19.1 and 19.2) is undertaken to produce red cells, platelets and plasma or cryoprecipitate under stringent standards of quality control, as mandated by the Blood Safety and Quality Regulations 2005. Anticoagulants and preservatives prevent clotting and maintain cell viability and function during component storage. Storage conditions relate largely to the maintenance of temperature from the time of collection, through processing, testing and labelling and transportation, up to the point of issue for transfusion into a patient. This is known as 'cold chain management'.

Storage changes

Loss of red cell and platelet viability are the most important practical considerations. Progressive loss of viability varies according to the combination of anticoagulant used, how blood is stored prior to component separation, what storage medium the components are stored in, and the pack systems used. The time limit for storage of blood or its component parts is set,

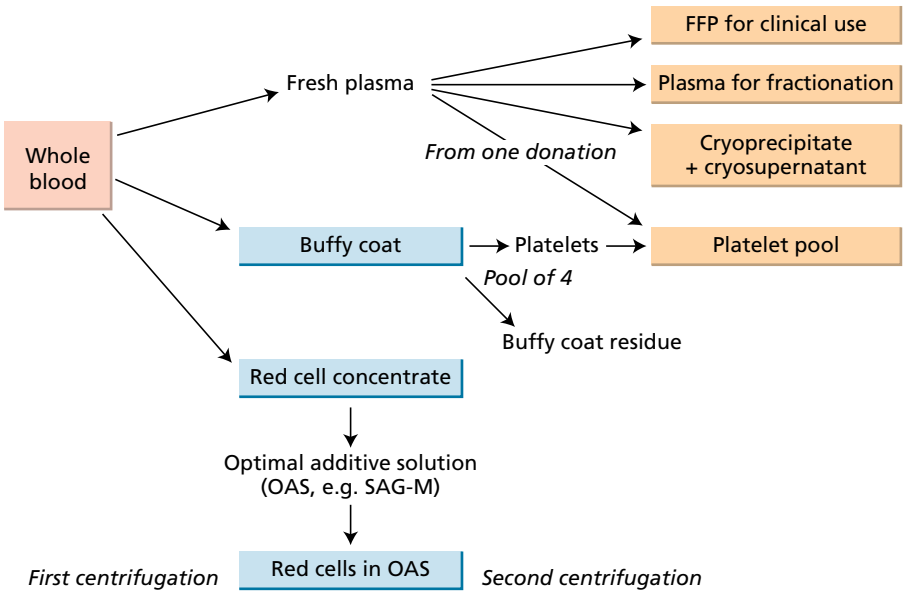

Figure 19.1 Diagrammatic representation of the preparation of components from whole blood by the 'top and bottom' or 'buffy coat' method. Items in boxes represent final components. One unit of plasma is no longer used for platelet pooling, instead a pack of Platelet Additive Solution (PAS) is used.

taking all these into consideration. After transfusion of stored red cells or platelets, a proportion is removed from the circulation within the first 24 hours. The remainder appear to survive normally. There are various changes in the *in vitro* characteristics of red cells during storage (the so-called storage lesion), including depletion of metabolic substrates such as adenosine triphosphate (ATP) and 2,3-diphosphoglyerate (2,3-DPG), leakage of potassium and changes in red cell morphology. Some of these changes can be partially reversed *ex vivo* by incubation with purine nucleosides, or *in vivo*, following transfusion. ATP seems to be an important determinant of red cell viability, although not the only one. 2,3-DPG is almost completely

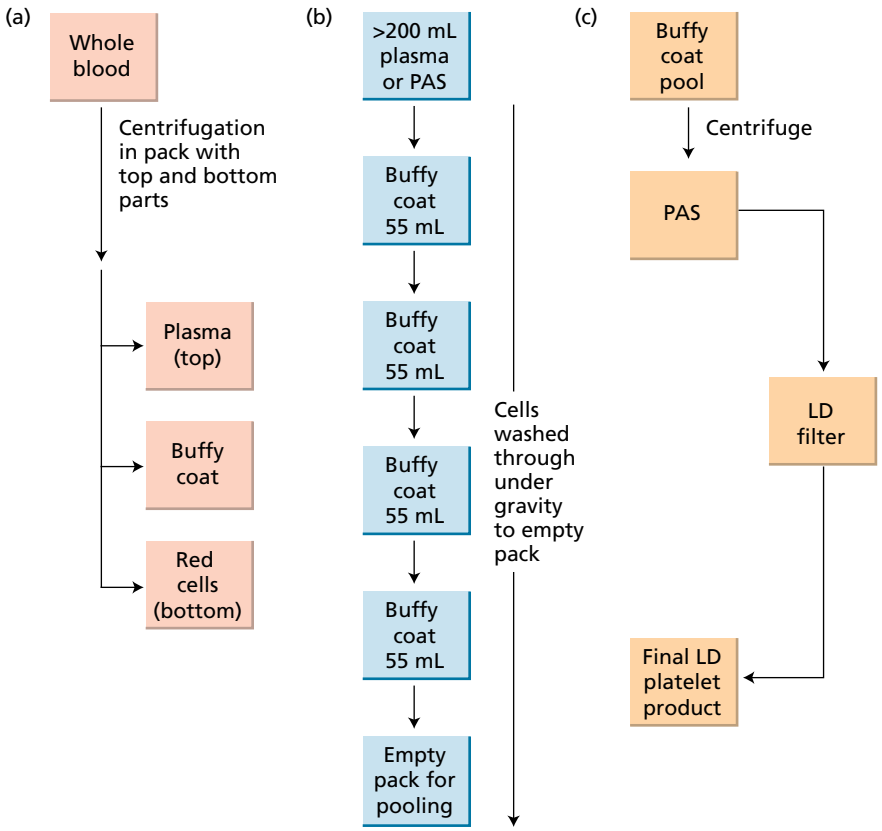

Figure 19.2 The 3 stages, a-c, involved in the manufacture of leucodepleted pooled, buffy-coat-derived platelet preparations. After gentle centrifugation of the buffy coat pool, the platelets remain in the plasma supernatant and the buffy coat residue is discarded. LD, leucodepletion; PAS, platelet-additive solution.

depleted in red cells after 14–21 days of storage. Red cell 2,3-DPG is restored to normal by approximately 24–48 hours after transfusion. The clinical significance of the low 2,3-DPG level of stored red cells is unknown, but only likely to be an important consideration in recipients with severe anaemia or coronary artery insufficiency.

During storage of red cells, potassium gradually leaks out through the cell membrane once active transport has been halted by the cooling of blood to 4 °C. There is rapid restoration of electrolyte levels after transfusion. The pH of blood decreases with storage, but most recipients can handle the acid load during transfusion without ill effect. Likewise, a number of changes in platelet function occur during platelet storage, including increased platelet activation and decreased responsiveness to agonists such as ADP. For both red cells and platelets, the relationship between these changes *in vitro* and the function of the cells following transfusion is complex, and it is notoriously difficult to predict post-transfusion viability from the results of laboratory testing.

Anticoagulants and optimal additive solutions

When blood is stored in a liquid state, there is a progressive loss of viability of the red cells, red cell ATP and depletion of 2,3-DPG. The purpose of modern anticoagulants used for the collection of blood, and additive solutions to store red cells and platelets, is to reduce these changes to a minimum.

Anticoagulant and preservative solutions vary depending on their composition. All anticoagulant preservative solutions contain sodium citrate, dextrose and citric acid, and some may, in addition, contain phosphate and adenine. The volume of anticoagulant required to prevent clotting and preserve red cells is dependent on the volume of blood collected from the donor. Most whole blood donations are collected into citrate-phosphate-dextrose (CPD) anticoagulant. Platelets from apheresis are collected into acid-citrate dextrose. Optimal additive solutions such as SAG-M containing saline, adenine, glucose and mannitol have been developed to improve the viability of plasma-depleted red cells on storage, and this is now the usual preservative solution for red cells in the UK. Due to theoretical concerns of adenine and mannitol toxicity, CPD continues to be used for the relatively large volume of red cells used for neonatal exchange transfusion and for intrauterine transfusion (no SAGM is added and the red cells remain suspended in plasma), with SAG-M red cells used for top-up neonatal transfusions.

Leucodepletion

Many developed countries have introduced universal leucocyte depletion of blood components. In the UK, leucodepletion of all allogeneic blood components, to a level below 5×10^6 white cells per unit, has been mandatory since 1999, as a measure which might decrease the risk of vCJD transmission by transfusion. Added benefits of leucodepletion include a significant decrease in the incidence of febrile non-haemolytic transfusion reactions (FNHTR), in the risk of human leucocyte antigen (HLA) alloimmunisation and in the risk of transmission of intracellular viruses such as CMV and HTLV. The UK specification for leucodepletion is that more than 90% of leucocyte-depleted components from relevant processes should have less than 1×10^6 leucocytes and more than 99% of components should contain less than 5×10^6 leucocytes, both with 95% confidence. Process performance should be assessed against the 1×10^6 limit when using statistical process control (statistical process monitoring) measurements.

Leucocyte depletion can be achieved by several methods, which must be validated before use. If filtration is used the recommended capacity of the filter must not be exceeded. Leucodepletion filters can be used at the initial stage on whole blood, leaving leucodepleted red cells and plasma, or later in the processing, for the preparation of platelet concentrates from pooled buffy coats, when the final components, red cells, platelets and plasma must be filtered individually (see Figures 19.1 and 19.2). These two alternative methods are necessary because whole blood filters remove a significant number of platelets, limiting production of platelet concentrates from filtered whole blood. Leucocyte depletion of components should take place before the end of day 2 (day 0 is the day of collection).

Blood components

Whole blood

At present, there is no whole blood (WB) product manufactured by the UK Blood Services, although there is increasing interest in the use of WB in a civilian pre-hospital setting, trail soon to be completed. Within international military settings, it has remained an option, and some civilian blood services across the world have introduced its use, particularly in health care settings with dispersed and remote populations.

Red cells

The vast majority of donor blood is separated into its components. A multiple 'bottom and top' blood collection pack is used (Figure 19.1) if the donation will be used to make platelets; otherwise, a simpler 'top and top' system is used to make red cells and plasma. In the bottom and top system, after centrifugation, whole blood collected in CPD is separated into plasma at the top, a buffy coat in the middle and red cells at the bottom (Figure 19.1). Fresh plasma is expressed from the top and red cells from the bottom of the pack, leaving the buffy coat in the original pack. The red cells are transferred to a pack containing an optimal additive solution to preserve red cell function during storage and are also filtered. The resulting red cells have a shelf

life of 35–42 days (35 days in the UK). Adult red cells in SAG-M in the UK have a volume of 220–340 mL with haematocrit of 0.5–0.7, minimum Hb of 40 g/unit and a residual plasma volume of 5–30 mL.

The specification for red cells for intrauterine (IUT), neonatal and infant transfusion is shown in Table 19.5.

Table 19.5 Specifications of red cells for foetal/neonatal/infant transfusion.

Red cell components for IUT
Plasma reduced (haematocrit 0.7–0.85)
In citrate phosphate dextrose (CPD) anticoagulant (theoretical risk of toxicity from additive solutions)
Leucocyte-depleted
Less than 5 days old (to avoid hyperkalaemia)
Cytomegalovirus (CMV)-antibody negative
Sickle screen negative
Irradiated to prevent TA-GvHD (shelf life 24 hours)
Usually group O with low-titre haemolysins
RhD- and K-negative and red cell antigen-negative for maternal alloantibodies
Compatible with the mother's plasma by an IAT cross-match
Red cells for neonatal exchange transfusion
Plasma reduced with haematocrit of 0.5–0.6 to reduce the risk of post-exchange polycythaemia
In CPD anticoagulant
Less than 5 days old
Irradiated (essential if previous IUT)
CMV-antibody negative
Sickle screen negative
Usually produced as group O (with low-titre haemolysins)
RhD negative (or RhD identical with neonate) and Kell negative
Red cell antigen-negative for maternal alloantibodies
Compatible with the maternal plasma by IAT cross-match
Red cells for small-volume transfusion of neonates and infants ('Paedipacks' – 6 splits from single unit)
Haematocrit 0.5–0.7
In SAG-M anticoagulant/additive solution (approximately 20 mL residual plasma)
Up to 35 days from donation
Group O (or ABO-compatible with baby and mother) and RhD negative (or RhD compatible with the neonate)
CMV-negative
If irradiated, 14-day shelf life
Red cells for large-volume transfusion of neonates and infants ('LVT') eg cardiac surgery
Less than 5 days old
If irradiated, shelf-life 24 hours to avoid hyperkalaemia
Rest of specification as for small-volume units

Source: Adapted from UK guidelines.

Washed red cells

Patients with recurrent or severe allergic or febrile reactions to red cells, and especially those with severe IgA deficiency with anti-IgA, may need washed red cells. These are produced in a closed, system in which the red cells are washed to remove most of the plasma and then resuspended in 100 mL SAG-M with a shelf life of 14 days after washing. Washed red cells can be irradiated at any time up to 14 days after collection. Irradiation should take place after washing. Following irradiation washed red cells that are suspended in a validated additive solution should be transfused as soon as possible and no later than 5 days after irradiation if irradiated on the day of washing, or 48 hours if irradiated after the day of washing.

Frozen red cells

Red cells can be stored for a prolonged period (up to 10 years) with minimal damage if glycerol is added before freezing. Thawed red cells must be washed free of glycerol before transfusion. This method of storage is expensive and time-consuming but is invaluable as a means of storing red cells with rare phenotypes (e.g. Bombay) and national banks of frozen rare cells have been established for this purpose.

Platelet preparations

Platelets are produced from whole blood (Figure 19.1) or by apheresis. Following the processing of whole blood, the buffy coat layer contains most of the platelets, over 80% of the white cells and 5–10% of the red cells. Four buffy coats are pooled together with platelet-additive solution (PAS). The plasma in the final component is made up of a small plasma content of each of the four buffy coats. The pool undergoes a second gentle centrifugation step and the supernatant is used to produce a platelet preparation, containing, on average, 3×10^{11} platelets. The residue from the buffy coat pool, containing mainly white cells and red cells, is then discarded. The systems that enable the separation of buffy coats in a semi-automated manner are called blood separators.

Unlike red cells, platelets must be stored at 20–22 °C, since storage at 4 °C results in poor survival following transfusion. Platelets have a shelf life of 5 days and are stored in gas permeable bags that allow the diffusion of oxygen into the pack, which, with constant gentle agitation, maintains aerobic metabolism and reduces the rate of fall of pH. The shelf life of platelet preparations can be extended to 7 days provided that systems are in place to monitor bacterial contamination (now used by the UK blood services) or to inactivate pathogens (not widely used at present).

The equivalent of two or even three adult doses of platelets (minimum 2.4×10^{11} each) may be obtained from one donor, with adequate platelet counts, by an apheresis procedure lasting approximately 90 minutes. A large HLA-typed donor panel is available in England to provide HLA-matched platelets for

immunologically refractory patients. Most apheresis platelet donors are also typed for human platelet antigens (HPA), in order to provide HPA-1a-negative platelets for newborns affected with neonatal alloimmune thrombocytopenia and also for a few HPA-1a-negative patients who have become immunologically refractory to platelet transfusions.

Platelets in additive solution (sometimes called 'washed platelets')

This component is indicated for patients with recurrent severe allergic or febrile reactions to standard platelet transfusions. After centrifugation and removal of most of the plasma, the platelets are resuspended in 200 mL of PAS but may still contain around 10 mL residual plasma.

Granulocyte concentrates

With the increase in intensive chemotherapy regimens, demand for granulocytes has risen in order to prevent or treat fungal or other serious, antimicrobial-resistant infections in severely neutropenic patients.

Granulocytes are extremely labile; they must be separated from whole blood immediately after collection and transfused within a maximum of 24 hours of preparation. Granulocytes prepared from routine blood donations (buffy coats) are heavily contaminated with red cells and platelets. Buffy coats from at least 10 donors are required to produce a therapeutic dose for an adult (at least 1×10^{10} granulocytes), or 10–20 mL/kg for children <50 kg. Ten buffy coats also contain the equivalent of two units of red cells and 2.5 pools of platelets, leading to reduction in transfusion requirements.

An optimised, pooled granulocyte component produced from whole blood donations is used in preference to buffy coats, when available. It has significantly less red cell contamination and provides double the number of granulocytes for a given volume (1×10^{10} per 250 mL pool; 2 pools for an adult therapeutic dose). Due to the overall high red cell content, granulocyte preparations should be ABO-compatible with the recipient and cross-match compatible by immediate spin against the recipient's plasma, if not eligible for electronic issue. Prospective recipients of granulocyte concentrates should be screened for HLA antibodies; if present, they can cause transfusion reactions, but more importantly, there is also increasing recognition that HLA-sensitisation impacts on engraftment and transplant success in mismatched allogeneic bone marrow transplant, particularly the increasingly used haplo-identical procedures.

All granulocyte concentrates must be irradiated prior to transfusion to reduce the Transfusion-associated Graft-versus-Host Disease (Ta-GvHD) risk. Other risks include febrile reactions and transfusion-related acute lung injury (TRALI).

Administration of granulocyte colony-stimulating factor (GCSF) or steroids can produce much higher yields of granulocytes collected by apheresis. This is not permitted for non-directed volunteer donors in the UK but is common in other blood services, particularly in the USA.

Importantly, the clinical effectiveness of granulocyte products remains a debated area, with published controlled trials producing conflicting results.

Fresh-frozen plasma (FFP)

Plasma that has been separated from whole blood (Figure 19.1) or obtained by apheresis is frozen within 24 hours to a temperature that will maintain the activity of the labile factors V and VIII. FFP contains all coagulation factors and FFP should be stored at a core temperature of –25 °C or below for a maximum of 36 months. Although a storage temperature below –25 °C improves the preservation of labile coagulation factors, lower temperatures increase the fragility of plastic. When needed, the plasma is thawed rapidly at 37 °C and then transfused without delay at a dose of 15 mL/kg in adults (see below).

Single units of FFP can be treated with photosensitising chemicals such as methylene blue (MB), riboflavin or amotosalen and exposed to visible or ultraviolet light to inactivate pathogens that may be present. If required, the residual chemicals can be removed before the plasma is rapidly frozen to −30 °C. Alternatively, FFP can be pooled with around 1500 other units and treated with solvent-detergent (SD) in order to inactivate pathogens. All methods of viral inactivation reduce the levels of labile clotting factors in FFP. This is considered to be a pharaceutical process with SD-FFP licensed as a medicinal product in the UK.

Following concerns about potential vCJD transmission in the UK, from 1998 until March 2019 FFP for use in patients born after 1996 was sourced from countries with a low risk of vCJD and pathogen-inactivated (MB or solvent detergent). Similarly, as a precautionary measure reversed in February 2021, UK plasma not used for FFP was discarded and not used for fractionation for the manufacture of immunoglobulins, albumin and coagulation factor concentrates. These decisions were reversed by the UK Advisory Committee on the Safety of Blood, Tissues and Organs (SaBTO) and the Commission on Human Medicines (CHM) respectively, following reviews of the safety of UK plasma and reduced concerns over the population risk of vCJD.

In recent years in the UK, every effort has been made to prepare FFP only from male donors in order to minimise the risk of passive transfer of donor white cell antibodies that can cause TRALI. PAS is used for suspension of pooled platelets.

Cryoprecipitate

Cryoprecipitate is prepared from FFP that is allowed to thaw slowly (classically at 4 °C overnight). After removal of the supernatant, factor VIII: C, von Willebrand factor (VWF), fibrinogen, fibronectin and factor XIII are left as a precipitate, which is then

refrozen in approximately 30 mL of plasma and stored at −30 °C or below for up to 24 months. Each unit should contain a minimum of 70 IU of factor VIII: C and 140 mg of fibrinogen. Cryoprecipitate is now used mainly as a source of fibrinogen in cases of major haemorrhage, disseminated intravascular coagulation (DIC), hepatic failure and hypofibrinogenaemia. A standard adult dose of cryoprecipitate is 10 units, which are thawed at 37 °C in about 10 minutes and should be used immediately. Pools of five single units are available in the UK. Fibrinogen concentrates are available in the UK with differing licences for use in congenital hypo-/a-fibrinogenaemia, and more recently in patients with acquired hypofibrinogenaemia and surgical haemorrhage.

Irradiated blood components

Patients at risk of transfusion-associated graft-versus-host disease (TA-GvHD, see further on) require irradiation of cellular blood components (red cells, platelets and granulocytes). For adults, red cells can be irradiated using gamma or X-rays within 14 days of donation, with a shelf life of 14 days from irradiation. Red cell components for exchange neonatal transfusion and intrauterine transfusion (IUT) should be irradiated within 5 days of donation with a post-irradiation shelf life of 24 hours. Platelets should also be irradiated to prevent TA-GvHD in susceptible patients and they retain their normal shelf-life post-irradiation. Frozen plasma components such as FFP and cryoprecipitate do not need irradiation.

Clinical and laboratory transfusion practice

In the UK, a series of three 'Better Blood Transfusion' Health Service circulars published in 1998, 2002 and 2007 promoted safe transfusion practices within hospitals, with emphasis on the appropriate use of blood and components in all clinical areas. Many of the principles of 'Better Blood Transfusion' are now encompassed in Patient Blood Management (PBM), an evidence-based, comprehensive multidisciplinary approach to the management of patients needing transfusion (see below).

All hospitals should have hospital transfusion committees (HTCs), with multidisciplinary representation from the clinical, laboratory and management areas. These committees are responsible for overseeing implementation of guidelines and for the audit and training of all staff involved in transfusion. The HTC is essential within the hospital clinical governance and must be accountable to the chief executive. The hospital transfusion team (HTT), composed of transfusion specialists with a nursing or biomedical background, the transfusion laboratory manager and the consultant haematologist specialising in transfusion, undertakes various activities on a day-to-day basis to achieve the objectives of the HTC.

EU blood directives (UK blood safety & quality regulations 2005): impact on hospital transfusion practice

The EU Blood Directives not only set standards for quality within the blood services, but also have had a far-reaching impact on hospital transfusion practice. In the UK, the chief executive of each hospital with a transfusion laboratory needs to submit a formal annual statement of compliance to the MHRA as the competent authority implementing the Blood Safety and Quality Regulations 2005. Hospital transfusion laboratories can be inspected by the MHRA and in the event of significant deficiencies be given the order to 'cease and desist from activities'. The key requirements for hospital transfusion laboratories include:

- a comprehensive quality management system based on the principles of good practice, including stringent requirements for storage and distribution of blood and components, with emphasis on 'cold chain' management;
- traceability, requiring all hospitals to trace the fate of each unit of blood/blood component (including name and patient ID) with records kept for 30 years;
- education and training of staff involved in blood transfusion, with maintenance of all training records;
- haemovigilance, with reporting of all adverse events of transfusion.

Hospital transfusion laboratories undertaking any processing activities, such as irradiation, must have a licence from the MHRA indicating they have a blood establishment status. NHSBT blood centres have such licences.

Laboratory tests in patients

Pretransfusion group and screen

The ABO and RhD groups of all potential recipients should be determined before transfusion, due to the universal presence of ABO antibodies in all subjects lacking the corresponding antigens and to the high immunogenicity of RhD (see Chapter 18).

The patient's red cells are grouped for ABO using monoclonal anti-A and anti-B. A 'reverse group' is carried out on the patient's plasma to demonstrate the presence of the corresponding antibody, using A and B reagent cells. RhD typing is undertaken using 2 IgM monoclonal anti-D reagents.

The patient's serum should also be screened for the presence of atypical red cell antibodies using the indirect antiglobulin test (IAT). If a positive result is obtained in this 2- or 3-cell screen, further investigation using a red cell panel of 8–10 cells is required to identify the antibody or antibodies and eventually provide antigen-negative cells for cross-matching. Depending on expertise in individual hospitals, antibody identification

may be carried out in-house or referred to red cell reference laboratories.

The majority of hospital laboratories in the UK carry out blood grouping and antibody screening using automated analysers with computer control of specimen identification and electronic transfer of results. This is safer than manual grouping techniques with manual transcription of results.

Since errors related to having the 'wrong blood in tube' (WBIT) are relatively common, with the potential risk of ABO-mismatched transfusions, the current British Society for Haematology (BSH) guideline recommends that a second sample should be requested for confirmation of the blood group of any new patient, provided this does not impede the delivery of urgent red cells or components, although there are numerous permutations by which other available historical blood group information might be acceptable. The exception to the 'two-sample rule' is the presence of a secure, electronic patient identification system; this significantly reduces the risk of WBIT although does not eradicate it completely. There is increasing adoption of this type of system within UK hospitals.

For most patients without clinically significant antibodies in their plasma, ABO- and RhD-compatible red cells are provided if transfusion is required. If the patient has clinically significant antibodies, the red cells provided must also be negative for the relevant red cell antigen(s), and serologically cross-matched before transfusion (see Chapter 18). Women of childbearing age should also receive K-negative units to avoid the risk of forming anti-K.

The BSH Compatibility Guidelines 2012 (updated 2017) provide pragmatic recommendations on the timing of pretransfusion samples; for the majority of patients this is up to 3 months, but testing should be performed using blood collected no more than 3 days in advance of the transfusion when the patient has been transfused or pregnant within the preceding 3 months. An extension to 7 days may be considered for regularly transfused patients and pregnant women with no significant alloantibodies who need blood on standby for a potential obstetric emergency such as placenta praevia.

Compatibility testing (cross-match)

Traditionally, a cross-match, by IAT at 37°C, between the patient's plasma and red cells from the donor unit has been the final step before blood is issued for transfusion. This still applies in specific cases (see below), but now there is no need for serological cross-match in many patients with no red cell alloantibodies, where the relevant laboratory requirements for safe electronic issue (EI) are in place.

Electronic cross-match/electronic issue (EI)

ABO- and RhD-compatible red cells can be provided using electronic issue (or 'computer cross-match') provided the patient does not have any alloantibodies and there are robust automated systems in place for blood grouping and antibody testing, interfaced with laboratory information systems to minimise risk of human error. If a patient has clinically significant red cell antibodies, EI should not be used and an IAT cross-match is required with antigen-negative red cell units. Electronic issue is also not suitable in certain patient groups, e.g. those with a history of an ABO-incompatible stem cell transplant or those who have had an ABO-incompatible solid organ transplant in the preceding 3 months.

In hospitals where electronic issue is not routinely used, a maximum (or standard) surgical blood ordering schedule (MSBOS, SBOS) can reduce the number of compatibility tests performed and avoid the reservation of red cell units unlikely to be transfused. The MSBOS is based on a retrospective comparison of the number of units of blood cross-matched and the number actually transfused, for each elective surgical procedure, at a given hospital. It should be agreed with the transfusion laboratory, surgeons and anaesthetists and ratified by the HTC. Procedures that are likely to require blood transfusion have a ratio of cross-matched:transfused below 2:1. Regardless of the MSBOS, if a typical antibodies are detected, antigen-negative blood should be cross-matched and reserved before surgery.

Special requirements for the selection of blood

Certain patient groups have special requirements regarding the selection of blood and components for transfusion. Clinical teams should be made aware of these requirements through the use of guidelines supported by education. Appropriate alerts for special requirements should be used within the transfusion laboratory. Serious Hazards of Transfusion (SHOT) haemovigilance reporting has highlighted the relative frequency of errors in this area of transfusion practice. The special requirements for intrauterine and neonatal transfusion are highlighted in Table 19.5.

Haemoglobinopathy

Patients with haemoglobinopathy, in particular those with sickle cell disease (SCD), are at a high risk of developing red cell alloantibodies, with reports of 20–30% in the literature (see also Chapters 14 and 15). Accordingly, from the start, patients with haemoglobinopathy should receive blood that has 'extended matching' for K and Rh antigens in addition to D, i.e. Cc Ee, in order to reduce the risk of alloimmunisation. Blood for transfusion to patients with SCD should also be HbS-negative. Blood for top-up transfusion in haemoglobinopathy patients should be

<2 weeks old, and <7 days old if used for exchange transfusion in patients with SCD.

In addition, the red cells of patients with SCD should be phenotyped extensively prior to transfusion for antigens apart from Rh and K such as for Kidd, Duffy and Ss antigens. Where patients have already been transfused, the genotype can be determined by molecular techniques. This information can assist with investigation of haemolytic transfusion reactions and expedite issue of blood in cases with complex serology. In addition, genotyping can identify variants, particularly in the Rh antigen group, which may have implications for red cell unit selection and complex antibody formation.

Haemato-oncology

Irradiation of cellular blood components (red cells, platelets, granulocytes) is required for certain groups of haematology patients, as highlighted in Table 19.6. Patients should be informed of the need for irradiated blood, supported by written information and cards flagging up their special requirements. Whilst CMV infection can be transmitted by cellular blood components and may produce fatal infection in immunocompromised patients, the risk can be reduced by leucodepletion (see previously). In haemato-oncology patients in the UK, there is no requirement to select for CMV-negative components apart from the rare circumstance of

Table 19.6 Indications for irradiated cellular blood components* in haemato-oncology patients.

Patient group	Irradiated blood components
Adults or children with acute leukaemia	Only for HLA-matched platelets, granulocytes or donations from first- or second-degree relatives, or if chemotherapy agent results in requirement.
Recipients of allogeneic (donor) HSC transplantation	From the start of conditioning chemo-radiotherapy, and continued until all the following criteria are met: >6 months have elapsed since the transplant date The lymphocyte count is >1·0 × 109/L The patient is free of active chronic GvHD The patient is off all immunosuppression If chronic GvHD or on immunosuppressive treatment, continue irradiated blood components
Bone marrow and peripheral blood stem cell donors	Provide irradiated cellular components during and for 7 days before the harvest
Bone marrow or peripheral blood stem cell harvesting for future autologous reinfusion	Provide irradiated cellular components during and for 7 days before the harvest
Autologous stem cell transplant patients	From start of conditioning chemo-radiotherapy until 3 months post-transplant (6 months if total body irradiation was used)
Adults and children with Hodgkin lymphoma at any stage of the disease	Irradiated cellular components indefinitely
Patients treated with purine analogues and related compounds (fludarabine, cladribine pentostatin, bendamustine)	Irradiated cellular components indefinitely
Patients treated with alemtuzumab (anti-CD52) or anti-thymocyte globulin (ATG) therapy**	Irradiated cellular components indefinitely
Chimeric antigen receptor T-cell (CAR-T) therapy	For 7 days prior to and during peripheral blood lymphocyte collections (in autologous CAR-T procedures) for future CAR-T cell reinfusion. Continue to be used until 3 months following CAR-T cell infusion unless conditioning, disease or previous treatment determines indefinite duration
Rituximab / anti-CD20	Not indicated as a sole reason

*Red cells, platelets and granulocytes.
**Irradiated components are now not recommended for solid organ transplant, vasculitis or multiple sclerosis patients receiving alemtuzumab or ATG at currently used dose schedules.
Source: Based on BSH guidelines 2020.

Table 19.7 Selection of ABO blood group of components transfused in the early* post-transplant period following allogeneic bone marrow transplant.

	Donor	Recipient	Red cells	Platelets	FFP
Major ABO incompatibility	A	O	O	A	A
	B	O	O	B	B
	AB	O	O	A	AB
	AB	A	A/O	A	AB
	AB	B	B/O	B	AB
Minor ABO incompatibility	O	A	O	A	A
	O	B	O	B	B
	O	AB	O	A	AB
	A	AB	A/O	A	AB
	B	AB	B/O	B	AB
Bidirectional ABO incompatibility	A	B	O	B	AB
	B	A	O	A	AB

* Once conversion to donor blood group is complete, components of the new ABO group can be given.
Source: Adapted with permission from Handbook of Transfusion Medicine 2014.

granulocytes given to CMV-negative allogeneic bone marrow transplant recipients.

Patients undergoing allogeneic stem cell transplantation may have a mismatch of ABO groups with their donor (perhaps up to 25% of HLA-identical sibling transplants) with a risk of haemolysis. There can be major ABO incompatibility whereby the recipient's plasma contains anti-A, anti-B or anti-A, B incompatible with donor red cells (e.g. group A donor and group O recipient), minor ABO incompatibility where the donor's plasma contains anti-A, anti-B or anti-A, B that can react with the recipient's red cells (e.g. donor group O and recipient group A) or bidirectional ABO incompatibility where both the donor and recipient's plasma contain anti-A, anti-B or anti-A, B reactive with recipient and donor red cells respectively (e.g. donor group A and recipient group B). Clear communication is essential between the clinical and laboratory teams, with an agreed post-transplant transfusion policy (see Table 19.7).

Antenatal testing

All women should have blood samples taken at antenatal booking for blood grouping and antibody screening. If no clinically significant antibody is detected, further samples should be tested at 28 weeks' gestation, before routine antenatal anti-D prophylaxis is given to RhD-negative women (see below).

Neonatal 'top-up' transfusion

Premature infants are amongst the most widely transfused patients, with 'top-up' transfusions being very frequent (Chapter 54). During the first 4 months of life, ABO antigens may be poorly expressed on red cells and the corresponding ABO antibodies may not have yet developed so that results of 'reverse grouping' will be unreliable. Passive transfer of maternal IgG ABO antibodies may result in the detection of these antibodies in neonatal plasma. Samples from both the mother and infant should be tested for ABO and RhD grouping wherever possible, with an antibody screen performed on the maternal sample. If there are no atypical maternal antibodies, top-up transfusions can be given without further testing during the first 4 months of life.

Ideally, the unit of red cells used for the first transfusion should be aliquoted into several (six to eight) satellite (or 'paedi') packs and used for the same infant until expiry in order to decrease exposure to multiple donors. Measures should be in place in all neonatal units and their supporting laboratories to minimise the quantities of blood required for testing, by use of micro-sampling techniques and near-patient testing, since frequent blood sampling significantly contributes to anaemia in these infants. Erythropoietin has been extensively studied as an alternative to transfusion in the anaemia of prematurity, but it does not consistently reduce the need for transfusion in these patients.

If a neonatal patient has received a prior IUT, any top-up transfusions must be irradiated.

Transfusion in autoimmune haemolytic anaemia

Patients with autoimmune haemolytic anaemia (AIHA) pose a significant challenge (see also Chapter 17). Whilst unnecessary transfusion should be avoided, this must not be withheld in the context of brisk haemolysis or where there is clinical concern such as risk of cardiac compromise. Close liaison between clinical teams, the transfusion laboratory and the specialist

immuno-haematology team within blood services is essential to assist with prompt investigation and issue of blood. These patients often have pan-reactive autoantibodies that can mask an underlying alloantibody, requiring investigation with serological techniques such as elution and absorption. Blood should then be selected that is ABO-compatible, matched with the patient's own full Rh and K type and negative for the antigens to which alloantibodies have been identified, if any. Avoidance of the specificity of the autoantibody (e.g. auto-anti-e in RhD-negative female patients) is not routinely recommended since this may expose the patients to antigens provoking the formation of clinically significant alloantibodies. Transfused red cells are likely to be destroyed by the autoantibody at the same rate as the patient's own blood. Hence, transfusion, if needed in AIHA, will serve only as a temporary 'holding measure' and should be accompanied by effective immunosuppressive therapy.

Safe administration of blood

The principles underpinning safe bedside transfusion practice should be encapsulated in a hospital transfusion policy covering aspects of requesting, collecting and administering blood components, as well as the monitoring of the patient during transfusion. It is imperative that staff involved in any part of the transfusion process maintain competence in the relevant skills, and responsibility for overseeing this competence assessment should lie with the HTT and the associated clinical governance procedures.

Patient identification

Positive patient identification (ID) is essential at all stages of the transfusion process, including blood sampling, collection of blood from storage, delivery to the clinical area and administration. Patients should have an identification band with the minimum identifiers, including their last name, first name, date of birth and unique identification number (e.g. hospital number). Many hospitals are investing in secure electronic patient identification systems which can replace the requirement for written/printed identification bands with digitally recognised wristbands. Electronic patient ID systems have been shown to reduce the number of 'wrong blood in tube' errors (WBITs) and wrong components transfused.

WBIT errors can result in death. These occur due to human error either when the blood in the tube is from the wrong patient and is labelled with the intended patient's details, or blood is taken from the intended patient, but the tube is labelled with the wrong details. It is estimated that this occurs in 1 in every 2000 samples taken. The SHOT UK haemovigilance scheme continues to report significant numbers of WBIT errors with 673 cases in 2020; these are mostly 'near-miss' events which could have resulted in the wrong blood being transfused. Nearly two-thirds of these events involve serial errors in the identification process rather than isolated ones, meaning there was more than one opportunity to identify the mistake. SHOT estimates that approximately 1 incorrect blood component is transfused for every 100 near-miss events.

Detection and approach to transfusion reactions

All patients should be transfused in clinical areas where they can be directly observed to allow prompt detection and immediate management of acute reactions. Baseline observations and regular monitoring of patients undergoing transfusion are essential so that reactions are detected and promptly managed. Patients with severe transfusion reactions can present suddenly with cardiovascular collapse, but the underlying cause may not be immediately apparent; these can include bacterial contamination, acute haemolytic transfusion reactions (AHTRs, usually due to ABO-incompatible transfusion), anaphylaxis, TRALI and transfusion-associated circulatory overload (TACO). If the presumed transfusion reaction is severe or life-threatening, the transfusion must be discontinued, with immediate assessment and the following steps taken:

1 stop and disconnect the blood pack and giving set immediately (but do not discard);
2 maintain venous access with physiological saline, commence resuscitation, if needed;
3 take samples for full blood count, renal and liver function tests, blood cultures, coagulation screen, repeat compatibility testing, DAT, LDH and assessment of urine for haemoglobin;
4 check identification details for the patient, their identity band and the blood component/s concerned;
5 consider key/additional features, e.g. fever and shock without anaphylaxis – consider ABO-mismatched transfusion or bacterial sepsis; dyspnoea – consider TRALI or TACO and check O_2 saturations or blood gases and chest x-ray; laryngeal oedema with dyspnoea/stridor – consider anaphylaxis or severe allergic reaction;
6 seek early support and advice from the critical care team.

Less severe acute transfusion reactions include haemolytic transfusion reactions due to other red cell antibodies in the recipient, FNHTR and allergic reactions. Whilst the latter two can often be managed with an antipyretic or antihistamine, respectively, ongoing close monitoring of the patient is essential, since these could be the early signs of a more severe transfusion reaction.

Complications of blood transfusion

The complications of blood transfusion can be conveniently divided into acute and delayed, immunological and non-immunological categories (Table 19.8).

Table 19.8 Hazards of transfusion.

Immediate (hours)
Non-immune complications
Bacterial: acute sepsis or endotoxic shock
Hypothermia
Hypocalcaemia in infants and in the context of massive transfusion
Transfusion-associated circulatory overload (TACO)
Immune complications
Febrile non-haemolytic transfusion reactions
Acute haemolytic transfusion reactions: intravascular (IgM), extravascular (IgG)
Allergic reactions
Anaphylactic reactions
Transfusion-related acute lung injury (TRALI)
Delayed (days to years)
Non-immune complications
HIV, HCV, HBV, CMV
Others: parvovirus B19, HAV, HEV, WNV, dengue, malaria, Chagas disease, brucellosis, syphilis, vCJD
Immune complications
Delayed haemolytic transfusion reactions (due to anamnestic immune responses with red cell alloantibodies)
Post-transfusion purpura
Transfusion-associated graft-versus-host disease

CMV, cytomegalovirus; HAV, hepatitis A virus; HEV, hepatitis E virus; WNV, West Nile virus.

Sensitisation to red cell antigens

As only the ABO and RhD antigens are routinely matched for the selection of blood, sensitisation can occur to other red cell antigens following transfusion. Although the D antigen is the most immunogenic, other antibodies can form with alloimmunisation being more likely in multi-transfused patients. Red cell antibodies can also develop during and following pregnancy. The consequences of sensitisation may be negligible but can lead to difficulty with compatibility testing, haemolytic disease of the foetus and newborn (HDFN) and haemolytic transfusion reactions (HTRs) in the future.

Haemolytic transfusion reactions

This is premature destruction of transfused red cells reacting with antibodies in the recipient. Naturally occurring antibodies, such as ABO antibodies, are mainly IgM and, if warm-reacting, can destroy red cells *in vivo* by complement fixation. Red cell alloantibodies in response to exposure through previous transfusions or pregnancies are usually IgG antibodies. HTRs may occur immediately after the transfusion or may be delayed for anything up to 2–3 weeks.

Immediate or acute haemolytic transfusion reactions

These may be intravascular or extravascular (Table 19.9).

Immediate intravascular red cell destruction is the most dangerous type of HTR; it is associated with activation of the full complement cascade by IgM antibodies and is practically always due to ABO-incompatible blood transfusions (haemolytic anti-A, B, anti-A or anti-B present mainly in the recipient or, rarely, in the donor plasma). Most of these ABO-incompatible transfusions are due to identification errors and occur with an approximate frequency of 1 in 220,000 patients transfused in the UK based on data from 2020. Major morbidity with patients needing intensive care or renal dialysis occurs in 20–25% of all cases with a mortality rate of 5–10%. In recipients (mostly group O) of ABO-incompatible blood with serious reactions, the symptoms are usually dramatic and severe; most are due to the anaphylatoxins C3a and C5a that are liberated during complement activation, releasing vasoactive amines and hydrolases from mast cells and granulocytes. The cytokines interleukin (IL)-1, IL-8 and tumour necrosis factor (TNF) also play an important role, causing inflammation, smooth muscle contraction, platelet aggregation, increased capillary permeability and hypotension. Typically, within less than 1 hour of the start of the transfusion, when the reaction is symptomatic, the patient complains of heat or pain in the cannulated vein, throbbing in the head, flushing of the face, chest tightness, nausea and lumbar

Table 19.9 Antibodies associated with haemolytic transfusion reactions.

Blood group system	Antibodies implicated in intravascular haemolysis	Antibodies implicated in extravascular haemolysis
ABO	-A,B; -A; -B	
Hh	-H (Bombay)	
Rh		All
Kell		K, k, Kp^a, Kp^b, Js^a, Js^b
Kidd		Jk^a, Jk^b, Jk^3
Duffy		Fy^a, Fy^b, Fy^3
MNS		M, S, s, U (some)
Lutheran		Lu^b (some)
Lewis	Le^a, Le^b, Le^{a+b}	
Cartwright		Yt^a (some)
Vel	Vel	Vel (some)
Colton		Co^a, Co^b
Dombrock		Do^a, Do^b

pain. These symptoms are usually accompanied by tachycardia and hypotension. In severe cases, there is profound hypotension, leading to shock and renal failure. Rigours and pyrexia usually follow.

Intravascular destruction of red cells also brings about liberation of thromboplastin-like substances that activate coagulation and lead to DIC. The bleeding diathesis and increased destruction of red cells (which may eventually involve the recipient's cells) further exacerbate the problem. Intravascular destruction of red cells liberates haemoglobin into the circulation. Once haptoglobins are saturated, haemoglobin will also appear in the urine. If haemoglobinuria is very severe, haemosiderinuria may be seen. Renal complications consist of acute kidney injury with oliguria and anuria, possibly the result of hypotension and/or the action of activated complement. The initial symptoms may of course be modified or abolished in anaesthetised or heavily sedated patients, in whom evidence of DIC, hypotension or the presence of haemoglobinuria may be the first signs.

The most severe reactions occur in major incompatibility, when a group O recipient with high-titre anti-A, B is transfused with group A, B or AB red cells. Less severe intravascular haemolysis occurs when group A red cells are transfused to a group B recipient, or vice versa, because group B and A subjects have less potent ABO antibodies than group O subjects. More rarely, intravascular red cell destruction may occur when group O plasma is transfused by mistake to A, B or AB recipients. For this reason, group O red cells, even in additive solution, should not routinely be used for non-O recipients; furthermore, this practice leads to unnecessary shortages of group O blood. If unavoidable, the group O blood must first be screened for the presence of high-titre haemolysins or should have very small volumes of plasma. ABO-compatible cryoprecipitate, FFP and platelet transfusions should be selected for all recipients, especially for children because of their smaller blood volume. Group A, B or AB plasma components are safe for group O recipients.

There is also the possibility of a laboratory error when tubes are transposed or there are transcription errors or mis-recording of results, or when there is insufficient time to complete an antibody screen or compatibility test.

In the UK haemovigilance (SHOT) system, approximately 55% of cases of incorrect blood component transfusion reported in 2020 ($n = 323$) have been primarily due to clerical or technical errors that originated in the hospital laboratory. Obviously, not all the errors led to ABO-incompatible transfusions; in fact, 5% of errors led to ABO incompatibilities. The remainder of reports (45%) relate to clerical or administrative errors in the ward, collection of the blood from the blood bank, failure to confirm the identity of the patient when taking samples, mislabelling of the sample of blood or failure to perform proper checks before removing the units from the refrigerator or transfusing the blood. The potentially serious consequences of failures resulting in ABO-incompatible transfusions emphasise the need for set protocols with meticulous checking at all stages. If an identification mistake has been made, it is important to check, as a matter of urgency, that the units intended for the patient under investigation have not also been misdirected to another recipient. Such events are results of errors that need further investigation with a root cause analysis so that corrective action can be taken to minimise recurrence.

Extravascular red cell destruction is mediated by IgG antibodies (Figure 19.3). Mononuclear phagocytic cells have receptors for the Fc fragment of IgG1 and IgG3; the binding of IgG-coated cells to these receptors is inhibited by free IgG in plasma. There are no receptors for IgM on macrophages. Red cells sensitised with IgG1 and/or IgG3 antibodies may or may not activate complement up to C3b only. If they do not, they are removed extravascularly (by phagocytosis or cytotoxicity) by mononuclear phagocytic cells, predominantly in the red pulp of the spleen, where the plasma is largely excluded and the IgG on the red cells can compete with free IgG in the plasma. However, cells coated with IgG antibodies, which activate complement up to C3b, adhere to the C3b

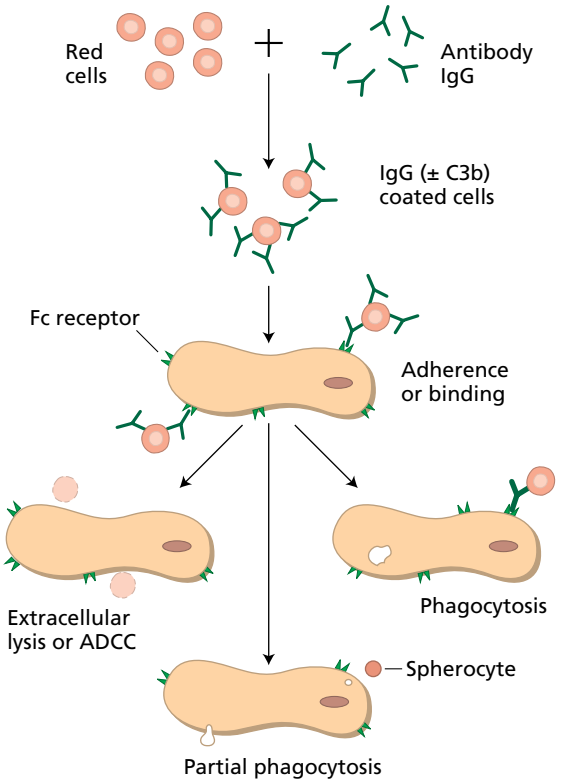

Figure 19.3 Mechanisms of extravascular destruction of red cells coated with IgG1 or IgG3 (± C3b). ADCC, antibody-dependent cell-mediated cytotoxicity.

receptor on macrophages and monocytes. The presence of C3b on red cells greatly enhances the extravascular destruction of IgG-coated cells. This is because the binding to C3b receptors is not inhibited as there is no native C3b in plasma and consequently IgG/C3b-coated cells are destroyed by phagocytosis or cytotoxicity, predominantly in the liver, where there are abundant macrophages (Kupffer cells) and a generous blood flow. As C3b is rapidly inactivated and converted into C3dg by the action of factors H and I and proteases, a proportion of the cells re-enter the circulation, coated with C3dg and are resistant to further lysis (Figure 19.3). Red cells coated with potent IgG antibodies, especially if they are C3b-binding, are destroyed mainly by cytotoxicity. Red cells coated with less potent antibodies are mostly destroyed by phagocytosis. Very rarely, red cell alloantibodies too weak to be detectable by routine pretransfusion testing may destroy donor red blood cells carrying the corresponding antigen.

The features of an immediate HTR vary according to a number of factors: whether the red cells are destroyed within the circulation or in the mononuclear phagocytic system, the strength, class and subclass of the antibody, the nature of the antigen, the number of incompatible red cells transfused and the clinical state of the patient. When antibodies are present in the circulation in low titres and a large volume of incompatible blood is given, all circulating antibodies will bind to the incompatible red cells, coating them weakly, without destroying them. There will then be no antibody detectable in the serum for a number of days until secondary antibody production is stimulated by the immune challenge. On the other hand, in the presence of an overloaded or poorly functioning mononuclear phagocytic system, large volumes of IgG-sensitised incompatible red cells can be present in the circulation with minimal or no premature removal, so the haemoglobin level may be stable with little evidence of haemolysis. The DAT will be positive, but as there is no free antibody, elution techniques will be necessary for antibody identification.

Immediate extravascular destruction of red cells may be accompanied by hyperbilirubinaemia, occasionally haemoglobinaemia due to antibody-dependent cytotoxicity (in severe cases), fever and failure to achieve the expected rise in haemoglobin level. The signs and symptoms are less severe and dramatic than in intravascular haemolysis and usually appear more than 1 hour after the start of transfusion. There may be no signs or symptoms at all. Acute kidney injury is very rare, even when the antibody binds the earlier components of the complement cascade. Symptoms are attributed in large degree to liberation of cytokines from mononuclear phagocytic cells after binding to IgG-coated red cells and to liberation of C3a when complement is bound up to C3b. The mortality is extremely low, but in an already sick patient the added complication of destruction of transfused red cells may contribute to death.

Table 19.10 Investigation of suspected acute haemolytic transfusion reaction.

Blood test	Rationale/findings
Full blood count	Baseline parameters, red cell agglutinates on film
Plasma/urinary Hb, haptoglobin, bilirubin	Evidence of intravascular or extravascular haemolysis
Blood group of patient and units transfused	Compare with retested pretransfusion sample, to detect ABO error Unexpected ABO antibodies may arise from transfusion of incompatible plasma. Re-checking labels is often sufficient
DAT	Positive in majority. Compare with retested pretransfusion sample. May be negative if all incompatible cells destroyed; eluate must still be checked in these cases.
Compatibility testing	Repeat antibody screen and compatibility testing on pre- and post-transfusion samples. Elution of antibody from post-transfusion cells may aid antibody identification or confirm specificities in plasma in cases of non-ABO incompatibility
Urea, electrolytes and creatinine	Baseline renal function
Coagulation screen	Detection and monitoring of DIC
Blood cultures of patient and units	In event of possible septic reaction caused by bacterial contamination of unit

The management of acute HTRs should be to terminate the transfusion as soon as the patient develops relevant signs or symptoms. The identity of the patient and the units transfused should be checked against the appropriate documentation. Blood samples must be taken for investigation (Table 19.10). The transfusion laboratory should be immediately informed and all packs of transfused units should be returned. Pretransfusion samples should be tested in parallel. All urine passed during the first 24 hours should be measured and examined for haemoglobin. The circulating blood volume should be restored and blood pressure and urinary flow maintained using fluid challenges and furosemide. Monitoring on a high-dependency unit may be required. The renal team should be involved early if urine output is poor (<1 mL/kg/hour) and haemofiltration may be necessary. Appropriate blood component therapy may be required if there is DIC.

Delayed haemolytic transfusion reactions (DHTRs)

Such reactions may not be predictable or preventable. They are always caused by IgG antibodies; hence, the haemolysis is always extravascular. In the majority of cases, an individual has been previously sensitised to one (or more) red cell antigen(s) by previous transfusion, pregnancy or transplant. Antibody is not detectable in routine pretransfusion testing, but the transfusion of blood containing the antigen/s to which the recipient has been sensitised previously, provokes a brisk anamnestic response that is characteristic of the secondary immune response. Within days, the antibody level rises and the transfused incompatible cells are removed from the circulation. The effects of the secondary immunisation are usually seen about 5–10 days after the transfusion, when the antibody level has been boosted and the recipient may already have left hospital. The clinical features are the same, though less severe than in immediate extravascular HTR.

The possibility of delayed HTRs underlines the importance of always taking fresh serum samples for antibody screening, direct antiglobulin test (DAT) and compatibility testing if a transfusion has been given more than 72 hours previously. Awareness of this complication may avoid unnecessary investigations to exclude infection when fever develops a few days after a transfusion. Most importantly, it will detect any alloantibody that has been boosted by the transfusion, thus enabling the provision of compatible blood. Similarly, it is important to have access to historical transfusion information since antibodies previously formed (e.g. Kidd antibodies) may become undetectable with time and may not be apparent in the current antibody screen. This is particularly important if patients are managed at more than one hospital, and highlights the continuing importance of improved inter-laboratory IT connectivity and data-sharing.

Laboratory investigations of suspected DHTRs include full blood count and reticulocytes, examination of the blood film, plasma bilirubin, renal function tests and lactate dehydrogenase test (LDH). Serological investigations should include repeat blood group and antibody screen (on pre- and post-transfusion patient samples), DAT and elution of antibodies from the post-transfusion red cells for identification.

Treatment of DHTRs is usually supportive, sometimes requiring further transfusion. The presence of any antibodies should be documented within the laboratory and clinical records, with patients issued with an 'Antibody Card'.

Febrile non-haemolytic transfusion reactions (FNHTRs)

Febrile reactions are most frequently due to the transfusion of blood components containing white cells to patients sensitised to white cell antigens. Antibodies are usually against HLA antigens, or sometimes against granulocyte and platelet-specific antigens; they are stimulated by previous transfusions or pregnancies. Cytokines released from white cells during storage may also be pyrogenic. These reactions are characterised by fever, sometimes accompanied by shivering, muscle pain and nausea, but are much less common since the introduction of leucodepletion of blood components. They can occur up to 2 hours after completion of the transfusion and are more common in multi-transfused patients receiving red cells.

Mild FNHTRs (pyrexia >38 °C, but <2 °C rise from baseline) can often be managed simply by slowing (or temporarily stopping) the transfusion and giving an antipyretic, such as paracetamol. However, the patient should be monitored closely, in case these are the early signs of a more severe transfusion reaction.

Transfusion-related acute lung injury (TRALI)

TRALI is non-cardiogenic pulmonary oedema, presenting during or within 6 hours of transfusion, with severe breathlessness accompanied by cough, fever and rigours. It is often associated with hypotension (due to loss of plasma volume) and there may be transient peripheral blood neutropenia or monocytopenia. Chest X-ray shows bilateral nodular shadowing in the lung fields with normal heart size, low oxygen saturation and low or normal central venous pressure. TRALI may be confused with acute respiratory distress syndrome (ARDS) of other causes, or with acute heart failure due to circulatory overload (see Table 19.11), but treatment with diuretics may worsen the outcome. Management is essentially supportive, requiring care in a high-dependency unit with ventilatory support, if needed. Steroid therapy is not effective. Managed appropriately, there is a high rate of survival and most patients recover within 1–3 days without long-term sequelae.

The reaction has been defined as due to passive transfer of leucoagglutinins (mostly anti-HLA class I or class II or, more rarely, granulocyte antibodies, i.e. anti-HNA) in donor plasma, reacting with granulocytes in the recipient's lungs, leading to complement activation, endothelial and epithelial injury, alveolar damage and inflammatory changes, mediated by anaphylatoxins, cytokines and other inflammatory mediators. This complication is more likely after infusion of a plasma-containing component and the implicated donors are usually multiparous women. In the UK, the incidence of classical antibody-mediated TRALI has declined to approximately 1 in one million units transfused, since the introduction of the policy to produce FFP and plasma to suspend platelet pools mainly from male donors.

In 2019 a true redefinition of the TRALI diagnosis was proposed by an international working group, requiring only a constellation of clinical features and no contributing immunological findings. This awaits further validation, but from the perspective of blood services, a definition that enables reduction of TRALI risk through amelioration of a well-documented immunological risk is advantageous.

Table 19.11 Comparison of transfusion-related acute lung injury (TRALI) and transfusion-associated circulatory overload (TACO).

	TRALI	TACO
Patient characteristics	More frequently reported in haematology and surgical patients. Any age	Most common in age >70, but can occur at any age
Implicated blood components	Usually plasma or platelets	Any
Onset	Up to 6 hours from transfusion (usually within 2 hours)	Within 6 hours of transfusion
Oxygen saturation	Reduced	Reduced
Blood pressure	Often low	Often high
Jugular venous pressure	Normal or low	Elevated
Temperature	Often raised	Normal
Chest X-ray	Bilateral peri-hilar and nodular shadowing or 'white out', heart size normal	Enlarged heart and characteristics of pulmonary oedema
Echocardiogram	Normal	Abnormal
Pulmonary artery wedge pressure	Normal	Elevated
Blood count	Fall in neutrophils and monocytes followed by neutrophil leucocytosis	No specific changes
Fluid challenge	Improves	Worsens
Response to diuretics	Worsens	Improves

Transfusion-associated graft-versus-host disease (TA-GvHD)

TA-GvHD is a very rare, but usually fatal, complication of blood transfusion. It is caused by transfusion of viable donor lymphocytes with engraftment and clonal expansion of HLA-compatible donor T-lymphocytes in the recipient. It is characterised by fever, skin rash, diarrhoea, impaired liver function and pancytopenia 7–14 days after transfusion. Patients at risk include foetuses receiving intrauterine transfusion, newborn infants who have received IUTs, some patients with inherited immunodeficiency disorders affecting T-cell function, and patients treated with allogeneic stem cell transplantation or specific chemotherapy drugs such as purine analogues. TA-GvHD has occasionally been reported in non-immunosuppressed patients receiving a blood transfusion from an HLA-matched donor or a close relative with HLA types in common; accordingly all directed donations must be irradiated. Patients receiving conventional combination chemotherapy for cancer are not at increased risk.

The diagnosis is made on the basis of typical features of acute GvHD in biopsies of affected organs, with detection of donor-derived cells or DNA in the patient's blood or tissues. The first SHOT reports in 1996 included 13 cases of Transfusion-associated Graft-versus-Host disease, all fatal, in patients for whom gamma-irradiated blood components were not indicated at the time. Only one case of TA-GvHD has been reported in the UK since 2000 (an IUT of non-irradiated maternal blood). Given the potential fatal outcome of this complication of transfusion, it is essential to ensure that all at-risk patients receive irradiated red cells or platelet components.

Post-transfusion purpura (PTP)

PTP is a rare complication of blood transfusion, characterised by sudden onset of severe thrombocytopenia 7–10 days following transfusion of, usually, red cells. The patients are mostly female, always with a history of previous blood transfusions or pregnancies. The most frequent cause is the presence in the recipient of an antibody (anti-HPA-1a) against the platelet-specific antigen HPA-1a (PI^{A1}); next in frequency is anti-HPA-5b. Women with foetal and neonatal alloimmune thrombocytopenia (FNAIT) pregnancies are therefore at risk. It appears that the antigen–antibody reaction causes both transfused and autologous platelets to be prematurely destroyed, either by the formation of immune complexes (in a manner similar to the 'innocent bystander' mechanism) or by cross-reaction of the causative antibody with the patient's own platelets.

The disease is serious and frequently associated with severe bleeding, meaning prompt therapy with high-dose intravenous immunoglobulin (e.g. 2 g/kg over 2–5 days) should be implemented as soon as a clinical diagnosis is made and without

waiting for the results of investigations. This is associated with a response in about 85% of patients. Platelet transfusion is not recommended and should only be considered in life-threatening bleeding. This severe, and potentially fatal, complication has become even rarer since the introduction of leucodepleted blood components.

Mild allergic reactions

Mild urticarial reactions without other symptoms are not uncommon during blood transfusion; they occur with an approximate incidence of 1% and are mediated by IgE antibodies, usually against plasma proteins or other allergens present in donor plasma. Symptoms include urticaria (hives) and pruritus but with no change in vital signs. They are most common in patients receiving plasma-rich components such as FFP or platelets.

Mild urticarial reactions may be treated effectively with antihistamines and do not always recur. Standard components can be given unless symptoms are recurrent and severe.

Severe anaphylactic reactions

Anaphylaxis is an acute, life-threatening emergency associated with shock or severe hypotension with associated features including bronchospasm, stridor from laryngeal oedema and swelling of face, limbs or mucous membranes (angioedema), although this may be absent in up to 20% of cases. Components with a high plasma component such as platelets or FFP are most likely to be implicated, but such reactions may occur with all blood components, as they all contain some plasma. Staff in clinical areas carrying out blood transfusions must be trained in the emergency management of anaphylaxis, and epinephrine must be available for emergency use. The UK Resuscitation Council Guidelines recommend the urgent administration of intramuscular (IM) adrenaline to treat anaphylaxis (see latest guidelines for dosing).

Although IgA deficiency is relatively common and may occur in up to 1 in 700 individuals tested, only a small minority of IgA-deficient patients are at risk of developing severe anaphylactic reactions to blood components. Those with severe IgA deficiency (<0.07 g/L), with anti-IgA are at greatest risk. Patients with less severe IgA deficiency, as part of a more generalised antibody deficiency disorder (e.g. common variable immunodeficiency or secondary to a lymphoproliferative disorder) and mild cases frequently detected when screening for IgA coeliac antibodies, are not at risk. Patients with no history of severe reactions to blood transfusion should be transfused with standard blood components. Accordingly, it is the small minority of patients with severe IgA deficiency and a clear history of serious anaphylactic reaction to blood components that require special precaution and, if possible, transfusion of blood components from IgA-deficient donors. However, this might be feasible only in the elective setting, in countries with well-established blood services. In an urgent situation, washed red cells and platelets resuspended in platelet-additive solution may be available, but in an extreme emergency, transfusion with standard blood components should not be withheld, but given with careful monitoring to allow timely detection and treatment of the anaphylactic reaction, as above.

Transfusion-transmitted infection

Bacterial contamination of blood components (see also section above under TTI)

This complication can rapidly be fatal and may occur particularly with platelet components, which are stored at 20–24 °C, rather than with red cells, which are refrigerated at 2–6 °C. These reactions can either be due to the septicaemia itself, to endotoxins or both. The patient can present dramatically with collapse, high fever, shock and DIC.

Various measures to reduce bacterial contamination from the donor arm as highlighted above have significantly reduced this risk, but awareness and prompt detection and management remain essential. It is important to note that only platelet donations are routinely screened for the presence of bacteria because they are stored at 22 °C – a temperature which may encourage the growth of bacteria. Following screening, platelets have a shelf life of up to 7 days and any platelet packs reactive on screening are removed from the supply and further tested. Most bacteria detected on screening are unlikely to cause harm, but sometimes more significant bacteria are detected such as those normally found in the gut. Donors are contacted if their platelet donation grows bacteria which may indicate an underlying illness, where appropriate donors will be referred to their physicians for further investigations.

Bacterial screening is one of several strategies introduced to reduce the risk of bacterial TTIs, though this cannot guarantee the absence of contamination: packs are released for issue as 'negative-to-date', which may be before bacteria have multiplied sufficiently to trigger detection on screening. Bacterial screening of platelets became universal in the UK in 2011; since then, there has been one confirmed bacterial TTI, due to Staphylococcus aureus, in 2015. There have been ten bacterial near misses, all but one in platelet components, reported in the UK between 2011 and 2020. Overall, out of a total of 44 bacterial transfusion transmissions to individual recipients, 37 (34 donations) have been caused by the transfusion of platelets, and 7 by red cells in the UK since reporting began in 1996.

The immediate management and investigation in any suspected case of a transfusion recipient follow the principles as outlined above. In particular, the pack should be inspected for abnormal discolouration or aggregates but may appear normal. Blood cultures should be taken from the patient and immediate treatment started for shock, as appropriate and with intravenous

broad-spectrum antibiotics, covering Gram-negative and Gram-positive bacteria. Any packs of implicated components must be returned to the transfusion laboratory for instigation of further testing including Giemsa staining for direct microscopic examination, as well as culture. The Blood Service should be informed without delay so that any associated components from the implicated donation can be identified and withdrawn before they can be transfused to other patients. In the UK, the implicated component packs should be returned to the Blood Service for investigation, where comprehensive bacterial testing is undertaken together with typing of strains to confirm the identity of contaminating bacteria.

Transfusion-associated circulatory overload (TACO)

TACO is defined as acute or worsening respiratory compromise and/or acute or worsening pulmonary oedema during or up to 12 hours (SHOT accepts cases up to 24 hours) of transfusion, with additional features including cardiovascular system changes not explained by the patient's underlying medical condition, evidence of fluid overload, and a relevant biomarker. A new surveillance definition for TACO was published in 2019 which facilitates more consistent reporting of TACO (Table 19.12).

TACO requires the presence of at least one 'required' criterion within 12 hours of transfusion, plus a total of three or more other criteria (either required or additional):

Serum brain natriuretic peptide (BNP) or NT-pro brain natriuretic peptide (NT-Pro BNP) are potentially useful investigations in supporting a diagnosis of TACO and can often be performed on the same sample type as that used for compatibility testing, allowing convenient retrospective testing of pre- and post-transfusion blood samples. Of note, the other 'additional' parameters shown for the diagnosis of TACO have their limitations, since changes in cardiovascular status may be non-specific and can occur in both TRALI and TACO; hypotension is more commonly seen in TRALI. Fever has been shown to be present in both TACO and TRALI in approximately 30% of TACO cases suggesting an inflammatory component in both and is therefore also a non-discriminatory clinical sign.

TACO continues to be the leading cause of transfusion-related deaths in the UK and the number of cases reported to SHOT, the UK haemovigilance scheme continues to increase year on year (see Figure 19.4). The 2020 reporting year recorded 149 TACO cases which is the highest ever reported to SHOT.

Table 19.12 TACO classification criteria.

Required criteria	Acute or worsening respiratory compromise
	Evidence of acute or worsening pulmonary oedema on physical examination or chest x-ray or other non-invasive assessment of cardiac function
Additional criteria	Cardiovascular system changes not explained by the patient's underlying medical condition, e.g. tachycardia, hypertension, raised jugular venous pressure, cardiomegaly on chest x-ray, peripheral oedema
	Evidence of fluid overload, e.g. positive fluid balance, clinical improvement with diuresis
	Supportive result of a relevant biomarker, e.g. raised B-natriuretic peptide or N-terminal pro-brain natriuretic peptide

Source: Original data from Osselton et al. Lancet Haematology, 2019.

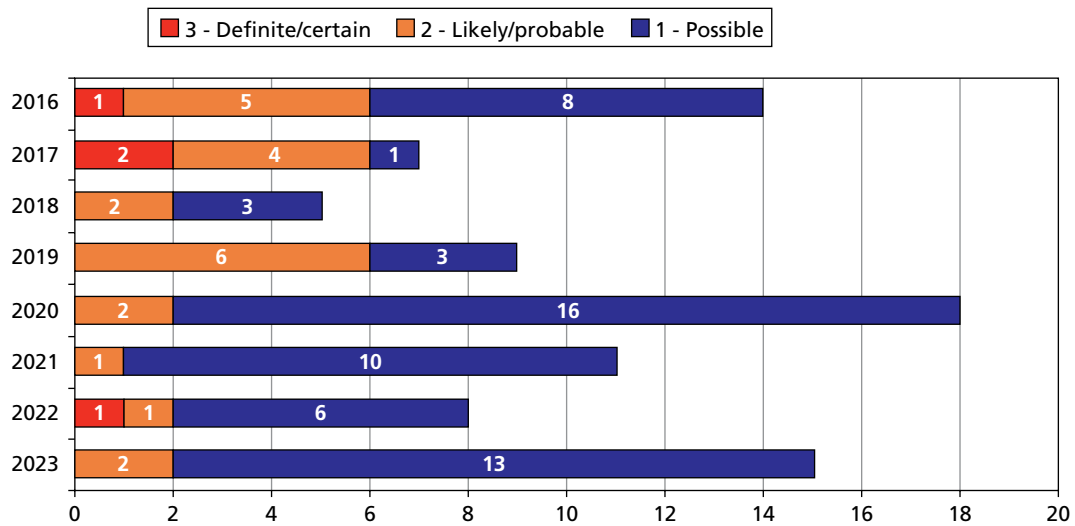

Figure 19.4 Deaths related to TACO reported to SHOT (with imputability) 2016–2023.

Furthermore, one-third of the TACO deaths reported to SHOT between 2016 and 2020 were deemed to be preventable, highlighting the importance of TACO risk assessment pretransfusion for all vulnerable patients.

The risk factors for TACO include age >70 years and comorbidities, including cardiac failure, renal impairment, severe anaemia and hypoalbuminaemia. Low-weight patients, such as the frail elderly and children, are at increased risk of receiving inappropriately high-volume and rapid blood transfusions, predisposing to TACO. Comprehensive pretransfusion assessment, with particular attention to the speed and volume of transfusion, fluid balance monitoring and use of diuretics, if indicated, may help identify at-risk patients and prompt mitigating measures to prevent this complication. SHOT data show that there is suboptimal use of pretransfusion TACO risk assessment and weight-adjusted red cell dosing is not sufficiently implemented.

Other adverse effects of transfusion

Haemosiderosis is a complication of repeated blood transfusions, seen more commonly as long-term blood transfusion therapy improves the survival of patients suffering from some chronic anaemias. It is most commonly seen in patients with thalassaemia, who commence transfusions in early childhood; increased iron absorption due to ineffective erythropoiesis compounds the iron overload in these patients. Transfusion-related iron overload can also be seen in people with other multi-transfused disorders such as sickle cell disease, other inherited anaemias, aplastic anaemia, myelodysplastic syndromes, other haematological malignancies and those who have undergone haemopoietic stem cell transplantation. Each unit of blood contains approximately 250 mg of iron, whereas the daily excretion rate is about 1 mg, and the body has no way of excreting the excess. Unless a patient is actively bleeding, hence losing iron, iron accumulation is inevitable.

For individuals without iron deficiency, it is generally accepted that transfusion of more than 15–20 units of RBCs (more than 10 units in smaller children) can cause clinically significant iron overload. However, some individuals with ineffective erythropoiesis who also have increased iron absorption may develop iron overload earlier. The correlation between the total volume of transfusions and clinical manifestations of iron overload is not exact, and clinical judgement is required in determining when to assess for iron overload. Optimal use of blood components and avoiding unnecessary transfusions are vital strategies to reduce the risk of iron overload. Chelation reduces morbidity in patients with transfusion dependency and iron overload, and it is routine practice in the management of patients with transfusion-dependent thalassaemia.

In addition to the more tangible adverse events of transfusion described above, there are increasing concerns about the impact of transfusion on overall patient outcome in relation to mortality and morbidity in critically ill patients, for example with potential impact on postoperative infection rates and length of hospital stay after surgery. This has led to more restrictive transfusion practices as described below. There is also an ongoing focus on the age of blood, with questions around the clinical impact of the age of blood on patient outcomes being tackled by randomised controlled studies.

Haemovigilance

Haemovigilance is defined by the International Haemovigilance Network as 'a set of surveillance procedures organised from the collection of blood and its components to the follow-up of its recipients, with the purpose of collecting and evaluating information on the undesirable and unexpected effects resulting from the therapeutic use of labile blood components and of preventing their occurrence or recurrence'.

The UK developed the first voluntary system in 1996, the SHOT – reporting is now professionally mandated and has ~100% participation from healthcare organisations across the UK. International haemovigilance data have resulted in changes in policy, products and practice, leading to improved blood donor safety, optimised product use and better clinical outcomes after transfusion.

SHOT is the UK's independent, professionally-led haemovigilance system, receiving reports of serious adverse transfusion reactions, errors and also near-miss events. There is a legal requirement to report serious adverse reactions and events to the MHRA under the Blood Safety and Quality Regulations 2005 in the UK. SHOT and MHRA now work closely together and have a joint reporting system.

Data collected show a reduction in the frequency of many of the most serious events, such as ABO-incompatible transfusions, transfusion-transmitted infections and TRALI. These trends follow changes in national policies on training and competency for staff involved in blood transfusion and a switch to male-only FFP. Overall mortality directly attributable to transfusion has decreased. However, errors related to transfusion remain the largest category of serious events, emphasising the significant potential for further improving safety. Fostering a strong and effective safety culture that is 'just and learning' is vital to ensure reductions in transfusion incidents and errors, thus directly improving patient safety.

SHOT also collects data on 'near-miss' events most of which are wrong blood-in-tube incidents highlighting the need for further improvements, particularly to ensure accurate patient identification. Whilst SHOT does not comprehensively collect data on fractionated plasma products, reports on events related to the inappropriate administration of anti-D Ig and prothrombin complex concentrates are collated with feedback on key learning points.

Appropriate use of blood and alternatives to allogeneic blood transfusion

In view of the inherent risks of blood transfusion and of the dependency of the blood supply on volunteer donors, blood and components should only be transfused when the benefits outweigh the risks. In addition to the clearly defined adverse events of transfusion, there are several reasons for aiming to reduce unnecessary allogeneic blood transfusions:

1 safety of the patient, by avoiding errors, as well as microbiological and immunological risks;
2 increasing difficulties in the recruitment of blood donors;
3 cost containment, with the ever-increasing demands by the regulatory agencies and technological advances;
4 high anxiety levels in patients, disproportionate to the real residual infectious risk of transfusion.

Patient blood management (PBM)

PBM is an evidence-based, multidisciplinary approach to optimising the care of patients who might need transfusion, considering alternatives, where feasible, and giving transfusion only when appropriate. PBM covers all aspects of decision-making in transfusion therapy, including initial patient evaluation with use of appropriate indications and transfusion triggers, minimising blood loss and optimisation of the patient's haemoglobin wherever possible. The application of the principles of PBM can reduce the need for transfusion and therefore health care costs whilst ensuring that limited donor blood supplies are available for the patients who need them most. In the surgical setting, the principles of PBM have been described as the 'three pillars', but it is important to note that the overall PBM strategy applies to all patients who might need transfusion, whether adults or children, elective or emergency, in any clinical setting, i.e. medical, surgical, obstetrics, intensive care, etc.

There should be clear guidelines for safe and appropriate use of blood components in all clinical specialities. These should be based on national and international data, with appropriately graded recommendations reflecting the quality of evidence available within the published literature. These should be complemented by regular multidisciplinary audits of transfusion practice, with feedback of results to all relevant staff and with re-audit where needed. The National Comparative Audit of Transfusion funded by NHS Blood and Transplant has active participation from hospitals across the country.

Although there has been a significant decrease in overall blood usage in the UK in the last couple of decades, several large regional and national audits of the use of red cells, platelets and plasma components continue to show ~15–20% inappropriate use, with ongoing variation in practice, highlighting the ongoing need to implement effective PBM.

Clinical decision to transfuse

The decision to transfuse requires a careful assessment of the patient's overall clinical status as well as their haematological laboratory data. Timely information should be made available to patients, ideally in written leaflets, about the indication for transfusion, the risks and benefits, and any alternatives available, in accordance with the principles of valid consent. The indication for transfusion and the patient's consent should be documented in the clinical records, along with the initial assessment including evaluation of the patient's TACO risk. Any special requirements, e.g. extended Rh- and K-matched blood for haemoglobinopathy patients or irradiated components for haemato-oncology patients should be considered when prescribing and requesting blood and components from the transfusion laboratory. Single-unit red cell transfusions are recommended where possible, especially in non-bleeding adult patients, and further units should not be prescribed without further clinical assessment and monitoring of the patient's haemoglobin. Computer-assisted clinical decision-making may help with appropriate transfusion therapy, but such systems need significant resources and are still not widely available.

Strategies to minimise transfusion of blood and components

Early preoperative identification of anaemia, as part of a general preoperative assessment, (see Table 19.13), may be followed by appropriate management with haematinics, and can reduce the

Table 19.13 Preoperative assessment of patients.

- Take a full history and examination, including previous surgical episodes and bleeding history, transfusion and obstetric history
- Arrange full blood count (FBC), group and antibody screen, routine chemistry, consider coagulation screen (not routinely needed unless specific clinical indication) and tube for haematinics assessment (ferritin level for iron stores, vitamin B_{12} and folate), which can be put on hold pending FBC results
- Consider use of tranexamic acid to prevent surgical blood loss
- Make cell salvage available if there is a likelihood of significant blood loss requiring transfusion and a 'clean' surgical procedure
- If iron deficiency give oral iron; use intravenous iron if intolerant or unresponsive to oral iron or if short timeframe prior to surgery (<2 weeks)
- Prescribe folic acid supplement or B12 if evidence of deficiency
- If patient on antiplatelet therapy or oral anticoagulant drugs then assess and implement appropriate management plan to minimise risk of bleeding in the perioperative period

need for transfusion. Appropriate management of anticoagulants and antiplatelets agents in this setting may also reduce the need for subsequent transfusion. Iron deficiency anaemia is also common in the obstetric setting, with often inadequate systems in place for timely intervention; oral or intravenous iron, as required, should be prescribed. Active management of anaemia is also indicated in the medical setting, with targeted management of true or functional iron deficiency, other haematinic deficiency (i.e. B12 and folate) or anaemia of chronic disease. The volume of blood samples taken at phlebotomy should be minimised since this can exacerbate anaemia, particularly in premature babies and the intensive care setting.

Surgical and anaesthetic techniques, and the use of fibrin glues and sealants, provide additional scope for the avoidance of donor transfusion in the context of surgery. Intraoperative cell salvage should be used where feasible but preoperative autologous blood deposit is no longer favoured, as evidence of efficacy is patchy and contradictory. High-quality evidence now supports the use of tranexamic acid in trauma and major obstetric haemorrhage but not in acute gastrointestinal bleeding. Patients with inherited bleeding disorders need careful planning and management plans discussed with appropriate expert input around options e.g. desmopressin (DDAVP) in patients with mild haemophilia. Erythropoietin can help reduce red cell requirements but is expensive and therefore of limited application. Point-of-care testing may aid decision-making around use of plasma components and platelets but validated protocols supported by training and appropriate quality control are essential where these techniques are used.

Red cell transfusion triggers

The seminal Transfusion Requirements in Critical Care (TRICC) study demonstrated no mortality benefit for patients with a higher transfusion threshold when compared to a restrictive haemoglobin trigger. The results of the TRICC study are strongly supported by further studies in high-risk patients needing hip surgery, cardiac surgery and acute upper gastrointestinal bleeding. This evidence from prospective, randomised, controlled studies and meta-analyses demonstrates that a restrictive transfusion strategy results in equivalent or possibly better clinical outcomes than more liberal transfusion and should inform clinical decision-making. Accordingly, a threshold for red cell transfusion of 70–80 g/L haemoglobin is appropriate in the majority of patients. A higher threshold of 80–90 g/L may be indicated in patients with acute coronary syndromes, pending further studies.

Platelet transfusions

Platelet transfusions are indicated for the prevention and treatment of haemorrhage in patients with thrombocytopenia or platelet function defects. The largest group of patients, receiving up to 67% of all platelet concentrates, are haematology patients. Most of these platelet transfusions are prophylactic. The decision to transfuse platelets should be based on clinical assessment, taking into account clinical risk factors for bleeding and the extent and site of bleeding, together with the platelet count.

There has been increasing research to try and support clinical practice in this area. Randomised, controlled studies have attempted to tackle key questions around decision-making on prophylactic platelet transfusions in haemato-oncology patients. In such patients, the platelet count threshold for prophylaxis is 10×10^9/L, but a higher threshold may be indicated, depending on additional patient risk factors e.g. sepsis. The dose of prophylactic platelets has been shown to have no effect on the incidence of bleeding – accordingly, only single doses ($2.4–3 \times 10^{11}$) of platelets should be administered prophylactically, with little justification for routine use of higher, or 'double', doses of platelets. More recent randomised controlled studies highlight the need for caution in certain clinical settings. Amongst preterm infants with severe thrombocytopenia, those randomly assigned to receive platelet transfusions at a platelet-count threshold of 50×10^9/L had a significantly higher rate of death or major bleeding than those treated at a platelet-count threshold of 25×10^9/L (PlaNeT 2 MATISSE study). Platelet transfusion seems inferior to standard care in patients with acute intracranial haemorrhage associated with antiplatelet therapy (PATCH study).

There is a lack of evidence for platelet thresholds, indicating the need for transfusion, in other clinical settings and, in particular, prior to procedures or surgery, with the use of empirical guidance to support practice e.g. 50×10^9/L for minor surgery and 80×10^9/L for major surgery.

Platelet transfusion response and refractoriness

The efficacy of platelet transfusions can be assessed by monitoring clinical response and by checking the platelet count increment. In patients requiring routine prophylactic platelet transfusions, a repeated failure to obtain a satisfactory response to two consecutive ABO-matched, relatively fresh platelet transfusions signifies refractoriness to platelet transfusions. Formulae to derive platelet recovery or corrected count increment are of limited value in the clinical setting and simpler, more pragmatic indicators include a failure of the post-transfusion (10 minutes to an hour) platelet increment to exceed the pretransfusion count or a rise of less than 10×10^9/L after 24 hours post-transfusion.

Refractoriness to platelet transfusions is commonly due to non-immunological causes associated with increased platelet consumption or losses such as infections, antimicrobials (amphotericin B and fluoroquinolones), splenomegaly/hypersplenism, DIC and major haemorrhage. Immunological refractoriness to platelet transfusions is due mainly to antibodies against antigens on platelets (HLA, HPA, ABO) and, more rarely, to platelet autoantibodies and drug-dependent antibodies or immune complexes. The most common cause of

immunological refractoriness is the presence of HLA antibodies in the recipient. Although HLA alloimmunisation is less common following universal leucodepletion of blood components, it is still a major problem in haemato-oncology patients needing prophylactic platelet transfusions.

The refractory patient should be assessed for the presence of non-immunological causes and if these have been excluded, and ABO-matched platelets have caused no increment, screening for HLA antibodies should be undertaken. If these are present, then platelet transfusions, collected by apheresis, from donors matched as closely as possible with the patient's HLA-A and HLA-B antigens should be given. The blood services in the UK have a large panel of HLA-typed donors, but this is not so in most countries, where the only alternative is to give cross-match-compatible platelets from the available stock. Immediate (10–60 minutes) and 24-hour post-transfusion platelet increments should be measured for evidence of effectiveness of therapy. If there is no response, then screening for HPA and other less common antibodies should be considered after advice from a transfusion medicine specialist. HLA-matched platelet preparations should be irradiated to prevent TA-GvHD. There has been some research in the use of epitope-matched platelets to support HLA-alloimmunised patients but these are not available for clinical use.

Use of fresh-frozen plasma (FFP) and cryoprecipitate

There is a relative lack of good evidence to support the clinical use of FFP and therefore transfusions are given empirically in many situations. FFP is indicated in patients with acute DIC in the presence of bleeding and abnormal coagulation results. The indication for FFP use in major haemorrhages is described below. FFP can also be used to treat inherited single coagulation factor deficiencies if the appropriate factor concentrates are not available. FFP should not be used for reversal of oral anticoagulation where the use of prothrombin complex concentrate is indicated. The coagulopathy of liver disease is also complex, with many studies showing the lack of evidence of clinical benefit of prophylactic FFP. Previous audits have shown that a large proportion of the FFP used in the UK and in many other countries is misused, exposing patients to unnecessary risks.

Cryoprecipitate is indicated for fibrinogen replacement largely in the major haemorrhage setting (see below). Cryoprecipitate must not be used for replacement of coagulation factors in inherited conditions such as haemophilia or von Willebrand disease, since specific factor concentrates are available.

Major haemorrhage

Major haemorrhage can occur in many settings, e.g. trauma, obstetric, GI bleeds, with significant challenges in management. Red cell transfusion is usually required when 30–40% of blood volume is lost (1500 mL in 70 kg male); more than 40% blood volume loss (1500–2000 mL) is life-threatening and requires immediate transfusion. Red cells are necessary for their oxygen-carrying capacity and also because they contribute to improved haemostasis through a rheological effect leading to axial flow and therefore margination of platelets.

Metabolic changes in stored blood include low pH, hypocalcaemia and hyperkalaemia. The reduced oxygen-carrying capacity of stored blood becomes significant only after 21 days' storage (for CPD-AI blood) and is due to low 2,3-DPG levels. Although, theoretically, excess citrate in transfused blood could cause toxicity, its metabolism in the liver is usually rapid. In practice, the only situations when citrate toxicity is a real problem is with extremely rapid transfusion (one unit every 5 minutes), or in infants, especially if premature, having exchange transfusion with blood stored in citrate for longer than 5 days. Hypocalcaemia and hyperkalaemia are usually transient and rapidly corrected once the transfused blood is circulating. Acidosis is not generally significant, as citrate metabolism leads to an alkalosis. However, if a patient is severely shocked and under-transfused, acidosis may be a clinical problem. All these changes due to stored blood are exacerbated by hypothermia. Cardiac irregularities, in particular ventricular fibrillation, may result from transfusion of large quantities of cold blood. The optimal functioning of coagulation factors and of platelets is also temperature dependent and effectiveness is reduced by hypothermia. Thus, the use of a blood warmer and keeping the patient warm are important measures in the management of patients with major haemorrhage.

Approximately one-quarter of patients bleeding with severe trauma present with clotting abnormalities, indicating that the coagulopathy is not merely dilutional related to infusion of fluids or red cells. Indeed, coagulopathy associated with massive haemorrhage is likely to be multifactorial with contributory factors, including activation of fibrinolysis and consumptive coagulopathy, exacerbated by hypothermia and hypocalcaemia. The use of anticoagulant/antiplatelet drugs prior to surgery may further contribute to bleeding post-surgery together with the heparin needed for bypass for cardiac surgery.

The practical management of major haemorrhage in any setting needs a coordinated, multidisciplinary approach. This should incorporate significant advances in techniques for resuscitation as well as surgical, radiological and endoscopy interventions to control bleeding.

Baseline blood samples should be taken for FBC, chemistry, coagulation screen and group and screen. In patients with severe haemorrhage, the initial use of group O red cells is indicated before the blood group is available; RhD-negative units should be given to females of childbearing age. A switch to group-specific blood should be made as soon as possible.

The CRASH-2 study has demonstrated the benefits of early use of antifibrinolytics in trauma and therefore tranexamic acid should be incorporated into trauma protocols. Tranexamic acid

is also of benefit in major obstetric haemorrhage as shown by the WOMAN trial. However the HALT- IT study showed that it should not be routinely used for patients with severe gastrointestinal bleeding.

There has been extensive interest in the effects of early and/or high-dose empirical plasma therapy on clinical outcomes in traumatic haemorrhage. Many observational studies concluded that higher ratios of FFP:RBC were associated with reduced mortality (confounding by survivor bias is a concern). Many UK centres use empiric FFP:RBC ratios of 1:1 for traumatic bleeding. Data are unclear regarding the role of early administration of platelets; an empirical approach of administration if the count falls below 75×10^9/L is often used in major haemorrhage.

Either cryoprecipitate or fibrinogen concentrate can be used for replacement depending on the product availability and licensing within the country. A target of a fibrinogen level of 1.5 g/L is used in traumatic haemorrhage or 2.0 g/L in obstetric haemorrhage.

There has been a resurgence of interest in the use of whole blood in the management of traumatic major haemorrhage as opposed to individual component therapy as a more balanced approach to replacement. In the UK, researchers are studying the pre-hospital clinical use of a 'Red Cell and Plasma' product whilst further exploring development of a suitable platelet-rich, leucodepleted 'whole blood' product.

Haemolytic disease of the foetus and newborn (HDFN)

HDFN is a condition in which the lifespan of the foetal/neonatal red cells is shortened due to maternal alloantibodies against red cell antigens inherited from the father. Maternal IgG can cross the placenta, and thus IgG1 and IgG3 red cell alloantibodies can gain access to the foetus. If the foetal red cells contain the corresponding antigen, then binding of antibody to red cells will occur. When the antibody is of clinical significance (e.g. anti-D, -c, -K), and of sufficient potency, the coated cells will be prematurely removed by the foetal mononuclear phagocytic system. The effects on the foetus/newborn infant may vary according to the characteristics of the maternal alloantibody. The blood film of a foetus affected by HDFN shows polychromasia and increased numbers of nucleated red cells (Figure 19.5). In most cases (except a few due to ABO antibodies), the DAT (Coombs' test) on the infant's cells is positive owing to IgG coating.

The antibodies giving rise to HDFN most commonly belong to the Rh or ABO blood group systems. The morbidity of Rh HDFN is explained by the great immunogenicity of the RhD antigen; HDFN due to anti-c is also important and its incidence comes second amongst the cases of severe HDFN, closely followed by anti-K. (The disease caused by anti-K is more properly called alloimmune anaemia of the foetus and newborn as it is due to direct inhibition of erythropoiesis by the antibody and haemolysis is not a feature.) Antibodies against antigens in almost all the blood group systems (e.g. Duffy, Kidd), and against the so-called 'public' and 'private' antigens, have also been occasionally responsible for HDFN. However, IgM cannot cross the placenta and Lewis and P_1 antibodies, which occur frequently during pregnancy, are usually IgM and do not lead to HDFN. Furthermore, the Lewis antigens are not red cell antigens per se and are not fully developed at birth.

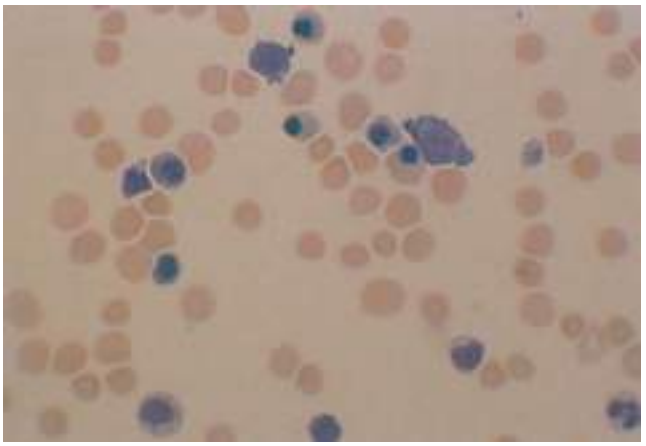

Figure 19.5 Blood film of a foetus affected by HDFN showing polychromasia and increased numbers of normoblasts.

Some antibodies (particularly anti-D, -K and -c) are associated with significant foetal and neonatal risks, such as anaemia requiring intrauterine or neonatal transfusion, jaundice or perinatal loss due to hydrops foetalis or kernicterus. There are many antibodies that are unlikely to significantly affect the foetus, but can cause neonatal anaemia and hyperbilirubinaemia), whilst others may cause problems for the screening and timely provision of appropriate blood for the mother or foetus/neonate. ABO antibodies can also cause mild to moderate anaemia and jaundice in the neonate and very occasionally in the foetus. In particular, IgG anti-A, B, anti-A and anti-B in group O mothers can cross the placenta and frequently cause HDFN in group A or B offspring.

The blood group and antibody status of the mother should be tested at booking and at 28 weeks of gestation to identify the ABO group and RhD status and to detect clinically significant red cell antibodies (see Figure 19.6). If red cell antibodies are detected in the booking sample, further testing of maternal blood should be undertaken to determine the specificity and level of antibody or antibodies, and to assess the likelihood of them causing HDFN (Figure 19.7). The levels of anti-D and anti-c are quantified using automated analysers, whereas the titre of all other antibodies is determined by doubling dilution. Once detected, anti-D, anti-c and anti-K levels should be measured every 4 weeks up to 28 weeks' gestation and then every 2 weeks, until delivery. All other antibodies should be retested at 28 weeks gestation. Referral to a foetal

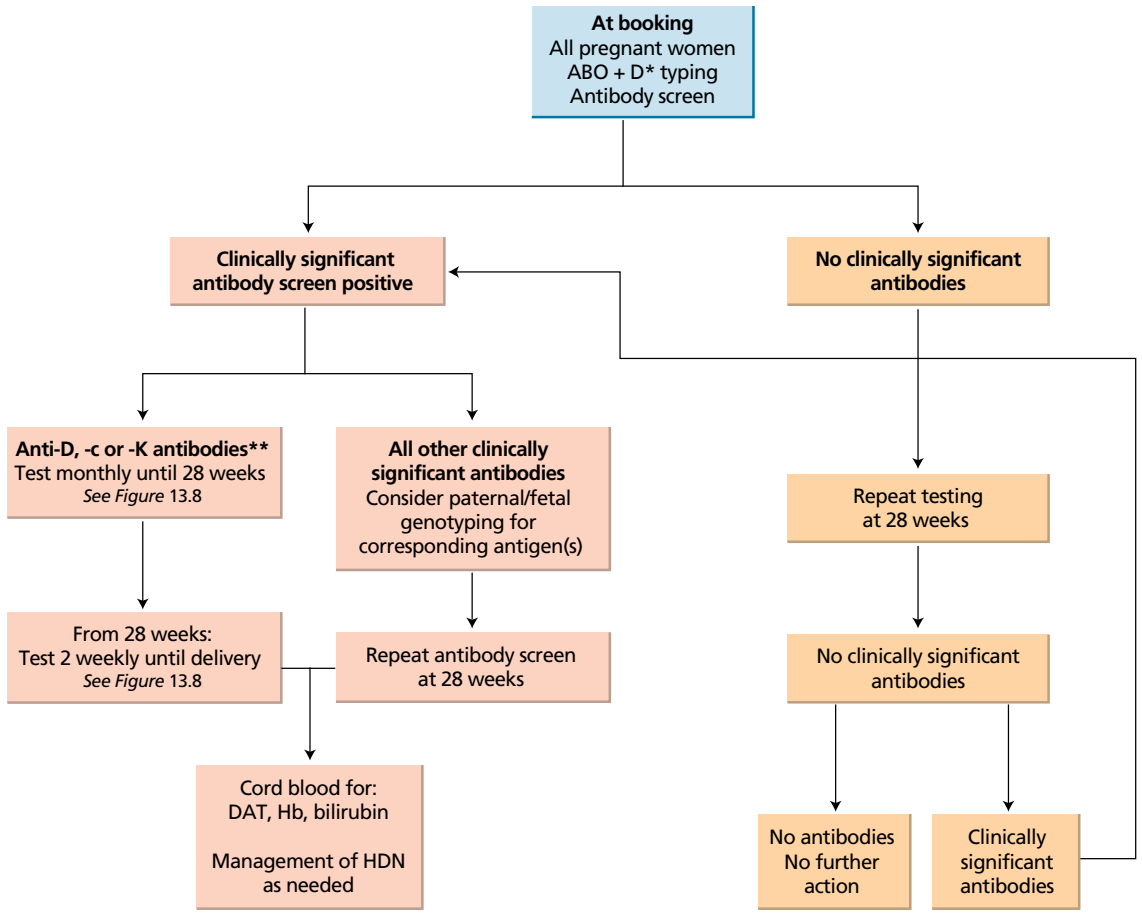

Figure 19.6 Blood group and antibody testing in pregnancy. If D-negative mother with no immune anti-D, advise anti-D Ig prophylaxis for any PSEs in pregnancy and give routine antenatal anti-D Ig prophylaxis (RAADP), either as a single dose or as two doses (see RCOG anti-D guidelines); after delivery check cord sample for D type and maternal sample for fetomaternal haemorrhage (e.g. Kleihauer) testing to check if further anti-D Ig needed, in addition to the standard dose, which should be given in the first instance after delivery. DAT, direct antiglobulin test; Hb, haemoglobin; RAADP, routine antenatal anti-D Ig prophylaxis. (Source: RCOG Greentop guidelines 65, 2014. Reproduced with permission of The Royal College of Obstetricians and Gynaecologists). **Pregnancies with immune anti-D, -K or -c are at particular risk of severe foetal HDFN, so further early assessment and referral to foetal medicine specialist is indicated.

medicine specialist should occur when there are rising antibody levels, but referral should also take place if there is a history of previous HDFN or of pregnancy with unexplained severe neonatal jaundice or anaemia requiring transfusion or exchange transfusion.

An anti-D level of >4 IU mL but <15 IU/mL correlates with a moderate risk of HDFN and an anti-D level of >15 IU/mL can cause severe HDFN. An anti-c level of >7.5 IU/mL but <20 IU/mL correlates with a moderate risk of HDFN, whereas a level of >20 IU/mL correlates with a high risk of HDFN. For anti-K, severe foetal anaemia can occur even with low titres, so early referral to a foetal medicine specialist is advisable.

Where clinically significant maternal red cell antibodies are detected, the father's sample should also be tested for paternal phenotype to determine the risk of the foetus carrying the relevant antigen. If the partner is a heterozygote or not available, free foetal DNA (ffDNA) extracted from maternal plasma can be tested for RhD and Rhc genotype from 16 weeks onward and for K from 20 weeks (see Chapter 18).

If the foetus is antigen-positive, then the pregnancy must be assessed and monitored for the development of HDFN by a foetal medicine specialist. Non-invasive techniques have largely replaced invasive testing, in particular with Doppler flow velocity; the use of middle cerebral artery (MCA) peak systolic velocity is a highly sensitive method for detecting foetal anaemia (see Figure 19.8). Ultrasound monitoring may help in detecting features suggesting severe foetal anaemia including polyhydramnios, skin oedema and cardiomegaly. The MCA peak systolic velocity related to gestation helps guide the need for further intervention including foetal blood sampling (see Figures 19.8 and 19.9) and IUTs. The specifications for blood used for IUT are shown in Table 19.7.

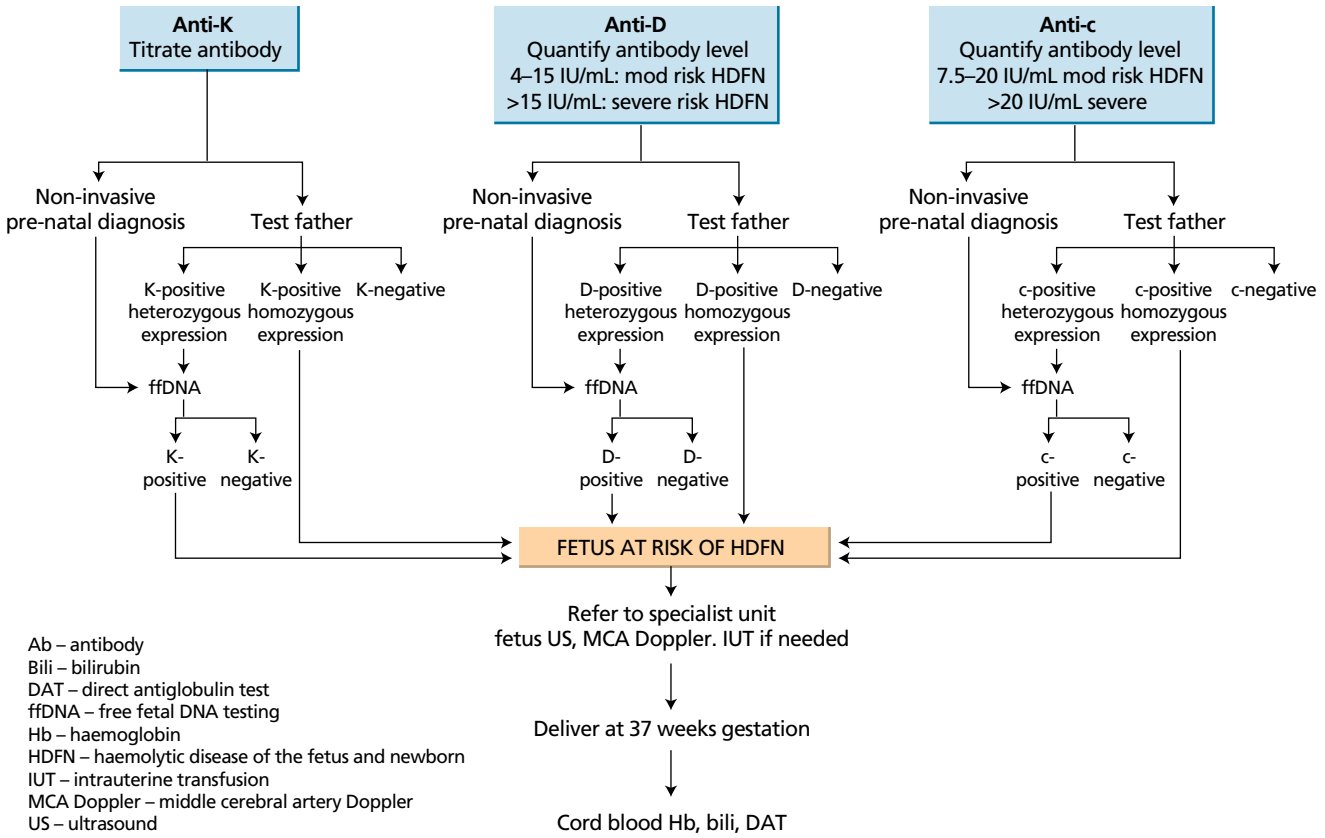

Figure 19.7 Management algorithm for pregnancies complicated with anti-D, anti-K or anti-c alloimmunisation from RCOG Greentop guideline 2014. (Source: RCOG Greentop guidelines 65, 2014. Reproduced with permission of The Royal College of Obstetricians and Gynaecologists)

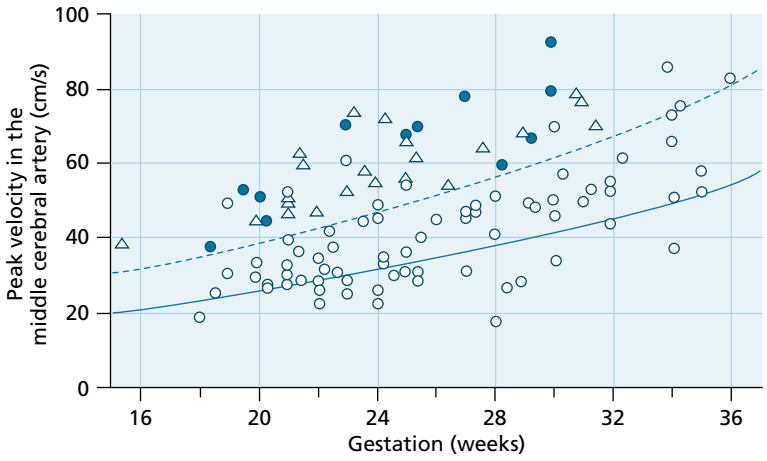

Figure 19.8 Middle cerebral artery Doppler. Peak velocity of systolic blood flow in the middle cerebral artery in 111 foetuses at risk for anaemia due to maternal red cell alloimmunisation. Open circles indicate foetuses with either no anaemia or mild anaemia (≥0.65 multiples of the median Hb concentration). Triangles indicate foetuses with moderate or severe anaemia (<0.65 multiples of the median Hb concentration). Solid circles indicate the foetuses with hydrops. Solid curve indicates the median peak systolic velocity in the middle cerebral artery and the dotted curve indicates 1.5 multiples of the median. (Source: Professor Charles Rodeck. Reproduced with permission)

Where the mother is known to have immune red cell antibodies, at delivery, cord blood should be taken for ABO and D typing and also for DAT, Hb and bilirubin levels. A positive DAT indicates that the infant's red cells are coated with antibodies, but in itself cannot predict the severity of haemolysis, if any. Notably, the DAT may be negative in ABO HDFN. It is therefore essential to also determine the Hb and bilirubin level to ascertain the degree of anaemia and haemolysis at birth, as this helps guide management, either with phototherapy or transfusion. The specifications for blood for exchange transfusion are shown in Table 19.5. Some infants may have anaemia persisting for a few weeks following birth. Whilst this may be due to passively acquired maternal antibodies causing continued haemolysis, it may also be due to suppression of erythropoiesis with extremely

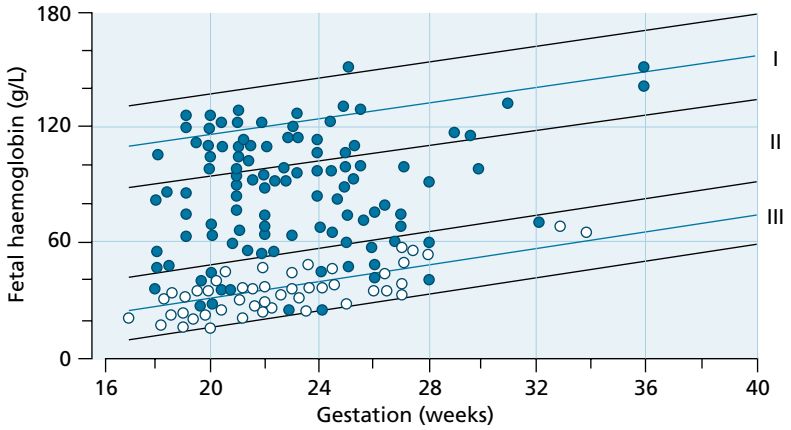

Figure 19.9 Foetal haemoglobin (Hb) concentration of 48 hydropic (open circles) and 106 non-hydropic (closed circles) foetuses from red cell isoimmunised pregnancies at the time of first blood sampling. Values are plotted on the reference range of foetal Hb for gestation. The individual 95% confidence intervals of the normal Hb for gestation define zone I and the individual 95% confidence intervals of the Hb for gestation of the hydropic foetuses define zone III. Zone II indicates moderate anaemia. (Source: Professor Charles Rodeck. Reproduced with permission)

low reticulocytes in the affected infants and further top-up transfusions may be needed.

Prevention of RhD HDFN

The introduction of prophylaxis with anti-D immunoglobulin (anti-D Ig) for D-negative mothers has greatly reduced the risk of HDFN, a previously significant cause of morbidity and mortality. Prior to the availability of anti-D prophylaxis, the first ABO-compatible, RhD-positive offspring resulted in the primary immunisation of about 17% of D-negative women. The rate of alloimmunisation fell considerably after administration of anti-D Ig postpartum and following other potentially sensitising events (PSEs) during pregnancy, as listed in Table 19.14. It was, however, recognised that 'silent' transplacental bleeds could still occur in the later stages of pregnancy and the introduction of routine antenatal anti-D prophylaxis (RAADP) further reduced the sensitisation rate to very low levels, ranging from 0.17 to 0.28%. Associated with this reduction in sensitisation is a reduction in mortality due to HDFN, from 46/100,000 births to 1.6/100,000 births.

Following sensitising events, anti-D Ig should be administered as soon as possible and ideally within 72 hours of the event. If, exceptionally, this deadline has not been met, some protection may be offered if anti-D Ig is given up to 10 days after the sensitising event. In pregnancies less than 12 weeks' gestation, anti-D prophylaxis is only indicated following ectopic pregnancy and therapeutic termination of pregnancy, but may also be indicated in some cases of uterine bleeding, where this is repeated, heavy or associated with abdominal pain. For events between 12 and 20 weeks' gestation, a minimum dose of 250 IU should be given. After 20 weeks' gestation, a minimum anti-D Ig dose of 500 IU is indicated and testing for fetomaternal haemorrhage (FMH) should be performed to determine if additional anti-D Ig is needed.

The National Institute for Health and Care Excellence (NICE) has recommended that D-negative pregnant women who do not have immune anti-D, should be offered RAADP during the third trimester of pregnancy. This can be with a single-dose regimen at 28 weeks, or two-dose regimen given at 28 and 34 weeks; practice has now shifted mainly towards a single-dose regimen due to ease of administration and availability of doses. It is important that the 28-week sample for blood group and antibody screen is taken prior to the first routine prophylactic anti-D Ig injection. RAADP should be regarded as a separate entity and administered regardless of, and in addition to, any anti-D Ig that may have been given for a sensitising event.

Following birth, the cord blood should be tested and if the baby is D-positive, all D-negative, previously non-sensitised, women should be offered at least 500 IU anti-D Ig within 72 hours following delivery. Maternal samples should be tested for FMH and additional dose(s) given as guided by FMH tests (see below). If there is an intrauterine death (IUD) and no sample can be obtained from the baby, an appropriate dose of prophylactic anti-D Ig should be administered. Anti-D prophylaxis is also indicated if intraoperative cell salvage is used during caesarean section in D-negative women, where the cord blood group is confirmed as D-positive (or unknown) with estimation of FMH on a maternal sample taken 30–45 minutes after reinfusion to check if additional doses of anti-D Ig are needed.

Table 19.14 Potentially sensitising events in pregnancy.

- Amniocentesis, chorionic villus biopsy and cordocentesis
- Antepartum haemorrhage/PV bleeding in pregnancy
- External cephalic version
- Fall or abdominal trauma (sharp/blunt, open/closed)
- Ectopic pregnancy
- Evacuation of molar pregnancy
- Intrauterine death and stillbirth
- *In-utero* therapeutic interventions (transfusion, surgery, insertion of shunts, laser)
- Miscarriage, threatened miscarriage
- Therapeutic termination of pregnancy
- Delivery – normal, instrumental or caesarean section
- Intraoperative cell salvage

Source: From BCSH guidelines 2014.

A dose of 500 IU intramuscularly (IM) is considered sufficient to treat an FMH of up to 4 mL foetal red cells. Where it is necessary to give additional doses of anti-D Ig, as guided by tests for FMH, the dose calculation is traditionally based on 125 IU anti-D Ig/mL foetal red cells for IM administration. However, the manufacturer's guidance should be referred to, depending on which product is used. In cases of large FMH, and particularly if FMH is in excess of 100 mL, a suitable preparation of intravenous anti-D Ig should be considered. Good communication between the antenatal teams and the transfusion laboratory is essential, with clear documentation of issues and administration of anti-D immunoglobulin. In the UK, the SHOT haemovigilance scheme continues to report on many errors with delayed or missed administration of anti-D prophylaxis.

Foetal RhD Screening

Several countries including the UK have now introduced a non-invasive pre-natal screening test using ffDNA in maternal plasma to determine foetal D blood group antigen status. This is able to predict the foetal D status from 11+2 weeks gestation with >99.9% negative predictive value, meaning the approximately 40% of D-negative women carrying a D-negative foetus would no longer require unnecessary anti-D injections as part of RAADP, antenatal sensitising event prophylaxis or post-partum prophylaxis.

A NICE review of the technology in 2016 recommended that it is cost-effective due to the cost-savings in reduced attendances to receive anti-D, reduced anti-D Ig usage and reduced lab testing for FMH estimation. Critically, it avoids unnecessary exposure of women to a blood product.

Testing for fetomaternal haemorrhage (FMH)

Commonly used techniques for quantification of FMH include the acid elution method, a modification of the Kleihauer–Betke test and flow cytometry.

The principle of the Kleihauer test relies on the different properties of foetal haemoglobin (HbF) and adult haemoglobin (HbA), whereby HbF is more resistant than HbA to both acid elution and alkaline denaturation. When a blood film from the maternal sample is fixed and immersed in an acid buffer solution, HbA is denatured and eluted, leaving red cell ghosts. Foetal red cells containing HbF that are resistant to elution stand out after staining in a background of maternal ghost cells. The relative percentages can then be counted using light microscopy to calculate an estimated volume of FMH. It is essential to have positive and negative controls. This is a manual test with a high coefficient of variation. Accordingly, current BSH guidelines recommend that more accurate testing with flow cytometry should be undertaken if the estimated FMH volume is >2 mL.

Flow cytometry is used to quantify the population of RhD-positive foetal cells in the RhD-negative maternal sample, using a fluorochrome-conjugated IgG monoclonal anti-D to label the D-positive cells.

A maternal sample should be taken for FMH testing after any sensitising event occurring after 20 weeks' gestation. When the sensitising event is before 20 weeks, the foetal blood volume is considered insufficient to exceed that covered by the minimum anti-D Ig dose, as recommended above. FMH testing should also then be undertaken after delivery, following which a standard dose of anti-D should be given after the baby is confirmed to be D-positive on cord blood testing. The result of the FMH testing is then used to decide if additional doses of anti-D Ig are needed. If additional doses of anti-D Ig are indeed needed, then follow-up FMH testing is indicated to confirm clearance of D-positive cells from the maternal circulation. Repeat FMH testing should be undertaken after 48 hours if anti-D is given intravenously or 72 hours after an intramuscular dose.

Rh D-positive platelet transfusions

Whenever possible, D-negative platelets should be transfused to D-negative girls or women of childbearing potential, but on occasions, depending on availability and clinical need, it may be necessary to transfuse D-positive platelets. In these circumstances, prophylaxis against possible Rh alloimmunisation by red cells contaminating the platelet product may be needed. In the UK, a dose of 250 IU anti-D Ig is considered sufficient to cover up to five adult therapeutic doses of D-positive platelets given within a 6-week period. In severely thrombocytopenic patients with platelet counts of $\leq 30 \times 10^9$/L, anti-D Ig should be given subcutaneously, or if an appropriate preparation is available, intravenously, to avoid the risk of intramuscular bleeding following IM injection.

Inadvertent transfusion of RhD-positive blood to RhD-negative women of childbearing potential

When less than one unit of red cells has been transfused, the appropriate dose of anti-D Ig may be given (see above). If more than 15 mL have been transfused, the larger anti-D immunoglobulin preparations (1500 or 2500 IU), if available, should be considered with intravenous anti-D immunoglobulin being preferable, achieving adequate plasma levels immediately. The quantitation of D-positive red cells should be performed by flow cytometry after 48 hours if an intravenous dose of anti-D has been given, or 72 hours if an intramuscular dose has been given and further anti-D Ig given until there are no detectable D-positive red cells in circulation.

When more than one unit of D-positive blood has been transfused, a red cell exchange transfusion should be considered to reduce the load of D-positive red cells in the circulation and the dose of anti-D Ig required to suppress immunisation. A single blood-volume red cell exchange transfusion will achieve a 65–70% reduction in D-positive red cells; a double-volume exchange will achieve an 85–90% reduction. Shortly after the exchange transfusion, the residual volume of D-positive red

cells should be estimated using flow cytometry to guide anti-D Ig dosage needed.

Advice should be sought from a transfusion medicine specialist. The patient should be counselled regarding the implications of both non-intervention (for future pregnancies) and of treatment, including any hazards from receiving donated blood, the exchange procedure itself and of larger doses of anti-D Ig, including intravenous anti-D. Passive anti-D Ig given in large doses may remain detectable and tests for immune anti-D may be inconclusive for several months.

Foetal and neonatal alloimmune thrombocytopenia (FNAIT)

This is a condition in which the platelets of the foetus and newborn are destroyed by maternal platelet-specific alloantibodies against platelet antigens inherited from the father (see also Chapter 54). It is analogous to HDFN, but for platelets. Although more than 15 HPA systems have been described, most cases are due to anti-HPA-1a in alloimmunised HPA-1b mothers. The difference with FNAIT is that the offspring of the first pregnancy can be affected and that the potency of the platelet antibodies is often not correlated with the severity of the foetal or neonatal thrombocytopenia. The most serious complication is intracranial haemorrhage, which may lead to death or severe neurological sequelae. Pending confirmatory testing, transfusion of HPA-1a/5b-negative platelets is usually indicated (depending on neonatal clinical situation and platelet count). Management in the foetus/pregnant woman requires specialist foetal medicine care and usually involves intravenous immunoglobulin. Specialist transfusion medicine advice should also be sought.

Infected blood inquiry

This was a public statutory inquiry examining the circumstances in which men, women and children treated by National Health Services in the United Kingdom were given infected blood and infected blood products, in particular since 1970. The report was released in 2024 with key lessons and recommendations for all health care professionals but critical for those involved in transfusion practice. The risk of acquiring infection from transfusion is now extremely low but that risk can never be removed completely. The Serious Hazards of Transfusion (SHOT) UK Haemovigilance scheme continues to highlight other adverse events related to transfusion. An important ongoing key message is that blood transfusion must only be given where essential and patients must be fully informed about the risks, benefits and alternatives available.

PART III

Lymphoid disorders

CHAPTER 20

The classification of lymphomas

20

Introduction

The classification of lymphoid neoplasms is based on two major principles: stratification of the neoplasms according to their cell lineage and the definition of non-overlapping distinct diseases that are clinically relevant. The identification of these diseases is based on a combination of morphology, immunophenotype, genetic and molecular features and clinical manifestations. The 2001 WHO classification of lymphoid neoplasms was based on the Revised European–American Classification of Lymphoid Neoplasms (REAL) published by the International Lymphoma Study Group (ILSG) in 1994. The validation of this proposal in a large series of tumours and the publication of the 2001 third edition of the WHO classification developed by the Society of Haematopathology (SH) and European Association for Haematopathology (EAHP) under the invitation of the International Agency for Cancer Research (IARC), the WHO agency in charge of the publication of the classification of tumours. This classification was based on a broad consensus of pathologists with clinicians and scientists in an ad hoc Clinical Advisory Committee (CAC). This ended a long history of controversy between different classification schemes that used different terminologies and concepts amongst pathologists and clinicians in different parts of the world. The subsequent 4th edition of the WHO classification in 2008 and its update in 2017 followed the same process of broad international effort promoted by the EAHP and SH, invited by the IARC, together with the CAC of pathologists, clinicians, geneticists and molecular scientists that integrated criteria developed by different working groups, refined definitions of well-established diseases, incorporated new entities and developed new concepts and ideas related to the biology of lymphomas. Unfortunately, in 2021 the IARC rejected the previous collaboration of the EAHP and SH. These societies decided to follow the same process of previous classifications with the nomination of different working groups of pathologists, clinicians and scientists who discussed the required changes in different groups and reached consensus for the update of the classification in a new CAC meeting establishing the International Consensus Classification (ICC) (Table 20.1a). The IARC nominated a group of experts to develop the 5th edition of the classification (WHO-HAEM5) (Table 20.1b). This chapter revises the most common lymphoid neoplasms with emphasis in the defining criteria, elements of the diagnosis and main clinical implications.

Mature B-cell neoplasms

This is a heterogeneous group of neoplasias that in most cases are related to different steps of the normal B-cell differentiation process. The combination of morphological, phenotypic and molecular features is essential for the diagnosis of the different entities (Table 20.2).

Chronic lymphocytic leukaemia/small lymphocytic lymphoma

Chronic lymphocytic leukaemia/small lymphocytic lymphoma (CLL/SLL) is a neoplasm of mature small B-cell lymphocytes that commonly express CD5 and CD23 and have dim expression of surface IgM/IgD, and CD20 (Table 20.2). The

Table 20.1a International consensus classification of mature lymphoid neoplasms.

Mature B-cell neoplasms
Chronic lymphocytic leukaemia/small lymphocytic lymphoma
Monoclonal B-cell lymphocytosis
  Chronic lymphocytic leukaemia type
  Non-chronic lymphocytic leukaemia type
B-cell prolymphocytic leukaemia
Splenic marginal zone lymphoma
Hairy cell leukaemia
Splenic B-cell lymphoma/leuakemia, unclassifiable
  Splenic diffuse red pulp small B-cell lymphoma
  Hairy cell leukaemia-variant
Lymphoplasmacytic lymphoma
Waldenström macroglobulinaemia
Immunoglobulin M (IgM) monoclonal gammopathy of undetermined significance (MGUS)
  IgM MGUS, plasma cell type*
  IgM MGUS, not otherwise specified (NOS)*
Primary cold agglutinin disease*
Heavy chain diseases
  Mu heavy chain disease
  Gamma heavy chain disease
  Alpha heavy chain disease
Plasma cell neoplasms
  Non-IgM MGUS
  Multiple myeloma (plasma cell myeloma)*
    Multiple myeloma, NOS
    Multiple myeloma with recurrent genetic abnormality
    Multiple myeloma with CCND family translocation
    Multiple myeloma with MAF family translocation
    Multiple myeloma with NSD2 translocation
    Multiple myeloma with hyperdiploidy
  Solitary plasmacytoma of bone
  Extraosseous plasmacytoma
Monoclonal Ig deposition diseases
  Ig light chain amyloidosis (AL)*
  Localised AL amyloidosis*
  Light chain and heavy chain deposition disease
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
Primary cutaneous marginal zone lymphoproliferative disorder*
Nodal marginal zone lymphoma
  Paediatric nodal marginal zone lymphoma
Follicular lymphoma
In situ follicular neoplasia
Duodenal-type follicular lymphoma
BCL2-R–negative, CD23-positive follicle centre lymphoma
Primary cutaneous follicle centre lymphoma
Paediatric-type follicular lymphoma
Testicular follicular lymphoma*
Large B-cell lymphoma with *IRF4* rearrangement*

Table 20.1a (*Continued*)

Mantle cell lymphoma
  In situ mantle cell neoplasia
  Leukaemic non-nodal mantle cell lymphoma
Diffuse large B-cell lymphoma, NOS
  Germinal centre B-cell subtype
  Activated B-cell subtype
*Large B-cell lymphoma with 11q aberration**
Nodular lymphocyte predominant B-cell lymphoma*
T cell/histiocyte-rich large B-cell lymphoma
Primary diffuse large B-cell lymphoma of the central nervous system
Primary diffuse large B-cell lymphoma of the testis*
Primary cutaneous diffuse large B-cell lymphoma, leg type
Intravascular large B-cell lymphoma
*HHV-8 and Epstein-Barr virus–negative primary effusion-based lymphoma**
Epstein-Barr virus–positive mucocutaneous ulcer*
Epstein-Barr virus–positive diffuse large B-cell lymphoma, NOS
Diffuse large B-cell lymphoma associated with chronic inflammation
  Fibrin-associated diffuse large B-cell lymphoma
Lymphomatoid granulomatosis
Epstein-Barr virus–positive polymorphic B-cell lymphoproliferative disorder, NOS*
ALK-positive large B-cell lymphoma
Plasmablastic lymphoma
HHV-8–associated lymphoproliferative disorders
  Multicentric Castleman disease
  HHV-8–positive germinotropic lymphoproliferative disorder
  HHV-8–positive diffuse large B-cell lymphoma, NOS
  Primary effusion lymphoma
Burkitt lymphoma
High-grade B-cell lymphoma, with *MYC* and *BCL2* rearrangements*
High-grade B-cell lymphoma with MYC *and* BCL6 *rearrangements**
High-grade B-cell lymphoma, NOS
Primary mediastinal large B-cell lymphoma
Mediastinal grey-zone lymphoma*

Classic Hodgkin lymphoma
  Nodular sclerosis classic Hodgkin lymphoma
  Lymphocyte-rich classic Hodgkin lymphoma
  Mixed cellularity classic Hodgkin lymphoma
  Lymphocyte-depleted classic Hodgkin lymphoma

Mature T-cell and NK-cell neoplasms
T-cell prolymphocytic leukaemia
T-cell large granular lymphocytic leukaemia
Chronic lymphoproliferative disorder of NK cells
Adult T-cell leukaemia/lymphoma

Table 20.1a (*Continued*)

Epstein-Barr virus–positive T-cell/NK-cell lymphoproliferative disorders of childhood*
- Hydroa vacciniforme lymphoproliferative disorder
  - Classic
  - Systemic
- Severe mosquito bite allergy
- Chronic active Epstein-Barr virus disease, systemic (T-cell and NK-cell phenotype)
- Systemic Epstein-Barr virus–positive T-cell lymphoma of childhood

Extranodal NK/T-cell lymphoma, nasal type
Aggressive NK-cell leukaemia
Primary nodal Epstein-Barr virus–positive T-cell/NK-cell lymphoma*
Enteropathy-associated T-cell lymphoma
- Type II refractory celiac disease*

Monomorphic epitheliotropic intestinal T-cell lymphoma
Intestinal T-cell lymphoma, NOS
Indolent clonal T-cell lymphoproliferative disorder of the gastrointestinal tract*
Indolent NK-cell lymphoproliferative disorder of the gastrointestinal tract*
Hepatosplenic T-cell lymphoma
Mycosis fungoides
Sezary syndrome
Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorders
Lymphomatoid papulosis
Primary cutaneous anaplastic large cell lymphoma
Primary cutaneous small/medium CD4 T-cell lymphoproliferative disorder
Subcutaneous panniculitis-like T-cell lymphoma
Primary cutaneous gamma-delta T-cell lymphoma
Primary cutaneous acral $CD8^+$ T-cell lymphoproliferative disorder*
Primary cutaneous $CD8^+$ aggressive epidermotropic cytotoxic T-cell lymphoma
Peripheral T-cell lymphoma, NOS
Follicular helper T-cell lymphoma*
- Follicular helper T-cell lymphoma, angioimmunoblastic type (angioimmunoblastic T-cell lymphoma)
- Follicular helper T-cell lymphoma, follicular type
- Follicular helper T-cell lymphoma, NOS

Anaplastic large cell lymphoma, ALK positive
Anaplastic large cell lymphoma, ALK negative
Breast implant–associated anaplastic large cell lymphoma

Immunodeficiency-associated lymphoproliferative disorders
Posttransplant lymphoproliferative disorders
- Nondestructive posttransplant lymphoproliferative disorders
  - Plasmacytic hyperplasia posttransplant lymphoproliferative disorder
  - Infectious mononucleosis posttransplant lymphoproliferative disorder
  - Florid follicular hyperplasia posttransplant lymphoproliferative disorder

Polymorphic posttransplant lymphoproliferative disorder
Monomorphic posttransplant lymphoproliferative disorder (B-cell and T-cell/NK-cell types)†
Classic Hodgkin lymphoma posttransplant lymphoproliferative disorder†
Other iatrogenic immunodeficiency-associated lymphoproliferative disorders

Intestinal T-cell lymphoma, NOS
Hepatosplenic T-cell lymphoma
Hepatosplenic T-cell lymphoma
Anaplastic large cell lymphoma
ALK-positive anaplastic large cell lymphoma
ALK-negative anaplastic large cell lymphoma
Breast implant-associated anaplastic large cell lymphoma
Nodal T-follicular helper (TFH) cell lymphoma
Nodal TFH cell lymphoma, angioimmunoblastic-type
Nodal TFH cell lymphoma, follicular-type
Nodal TFH cell lymphoma, NOS
Other peripheral T-cell lymphomas
Peripheral T-cell lymphoma, not otherwise specified
EBV-positive NK/T-cell lymphomas
EBV-positive nodal T- and NK-cell lymphoma
Extranodal NK/T-cell lymphoma
EBV-positive T- and NK-cell lymphoid proliferations and lymphomas of childhood
Severe mosquito bite allergy
Hydroa vacciniforme lymphoproliferative disorder
Systemic chronic active EBV disease
Systemic EBV-positive T-cell lymphoma of childhood

(*Source:* Alaggio *et al*. Leukemia 2022/Springer Nature/CC BY 4.0)

tumour usually involves the peripheral blood and bone marrow, but also lymph nodes, spleen, liver and other extranodal sites. The diagnosis of the disease requires, in the absence of extramedullary tissue involvement, $\geq 5 \times 10^9$/L monoclonal B lymphocytes with a CLL phenotype in the blood, sustained for at least 3 months. The diagnosis may be established with lower cell counts when the patient has disease-related cytopenias or symptoms. The term 'small lymphocytic lymphoma' refers to non-leukaemic neoplasms with the same morphology and phenotype. The presence in blood of a clonal population of B-cells with the CLL phenotype below this number of lymphocytes is called monoclonal B-cell lymphocytosis (MBL). MBL is considered a precursor of CLL, although not all MBL will progress to an overt CLL.

The bone marrow is infiltrated in virtually all cases with an interstitial, nodular or diffuse pattern. The lymph nodes show effacement of the architecture by a diffuse infiltration. Aggregates of prolymphocytes and paraimmunoblasts associated with some follicular dendritic cells and increased numbers of $CD4^+$ T cells, called proliferation centres, are an almost constant feature in the lymph nodes (Figure 20.1). In some cases, these areas are expanded and associated with more aggressive behaviour (accelerated CLL) but should not be diagnosed as transformation to DLBC. (see also Chapter 23).

The mutational status of the immunoglobulin genes (IG) distinguishes two major subtypes of CLL. Thus, 40–50% of cases have unmutated IG (>98% identity with the germline), whereas 50–60% have hypermutated genes. Patients with unmutated-IG CLL have a more aggressive disease. Analysis of immunoglobulin gene sequences has revealed a marked bias in use of the different VH families and the identification of subsets of cases with quasi-identical IGHV sequences called stereotypes, suggesting the influence of certain antigens in the selection of tumour cells. The relevance of the activation of the B-Cell Receptor (BCR) in CLL is highlighted by the identification of the activating mutations R110 in the V3–21 lambda light chain in approximately 7–15% of patients with either mutated or unmutated-IG and conferring an adverse prognosis. The most common chromosomal alterations are deletions of chromosome 13q (50%), trisomy 12 (20%), 11q deletions (15%) and 17p deletions (10%); 13q deletions are more common in mutated CLL, whereas 11q and 17p deletions are more frequent in unmutated CLL and are associated with a worse prognosis. Next-generation sequencing (NGS) studies have identified the complex mutational landscape of the disease that in addition to the frequent *TP53* (3–15%) and *ATM* (10–15%) alterations also include frequent mutations in *NOTCH1* (4–15%), *SF3B1* (5–17%) *BIRC3* (3%), *MYD88* (3%), amongst many others. The distribution of these mutations varies in different subgroups of patients and in the evolution of the disease.

Transformation into a more aggressive tumour occurs in 2–10% of patients (Richter transformation). The two most common forms of transformation are diffuse large B-cell lymphoma (DLBCL) and, less frequently, Hodgkin lymphoma (HL). DLBCL arising in unmutated-IG CLL usually corresponds to the clonal evolution of the preceding CLL, whereas in mutated CLL it frequently corresponds to a different lymphoid neoplasm. DLBCL transformation is frequently associated with *TP53* or *NOTCH1* mutations.

B-cell prolymphocytic leukaemia

B-cell prolymphocytic leukaemia (B-PLL) is a malignancy of B prolymphocytes that affects the blood, bone marrow and spleen and is characterised by more than 55% prolymphocytes

Table 20.2 Immunophenotypic features of common B-cell neoplasms.

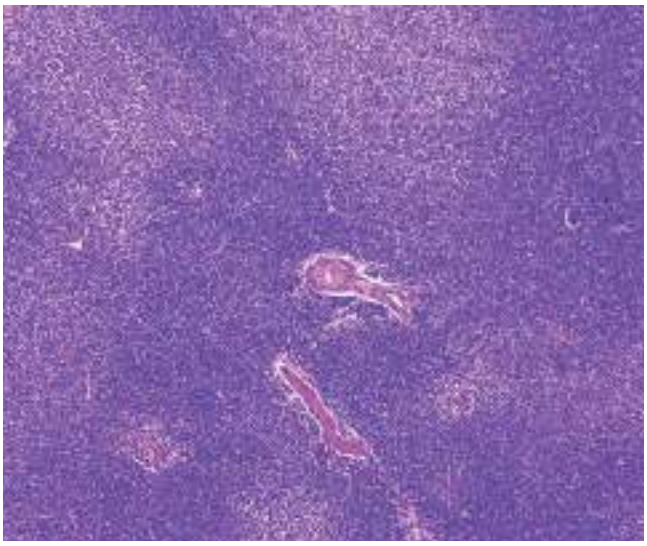
in the blood. B-PLL does not include transformed CLL, CLL with increased prolymphocytes, splenic marginal zone lymphomas or blastoid mantle cell lymphoma with t(11;14)(q13;q32), which should be excluded. B-PLL is an uncommon disease of old patients (median age 65–69 years) and similar male/female distribution (see also Chapter 23). Patients have 'B' symptoms, massive splenomegaly, absent or minimal lymphadenopathy and a rapidly rising lymphocyte count, usually over 100×10^9/L. Anaemia and thrombocytopenia are seen in 50%. The cells strongly express surface IgM with or without IgD and mature B-cell antigens. CD5 and CD23 are only positive in 20–30% and 10–20% of cases, respectively. Complex karyotypes are common and *MYC* translocation and 17p deletions associated with *TP53* gene mutations are detected in 40–60% of cases. Median survival is 30–50 months. IGHV somatic hypermutations are present in 50% of the cases but contrary to CLL are not of prognostic value. The ICC maintains the same criteria for this disease but the WHO-HAEM5 does not recognise this disease as a specific entity and assumes that some cases with these characteristics should be included in a new category called 'splenic B-cell lymphoma/leukaemia with prominent nucleoli' together with cases previously diagnosed as 'hairy cell leukaemia variant' – a disease which has also been eliminated in the new WHO-HAEM5 classification.

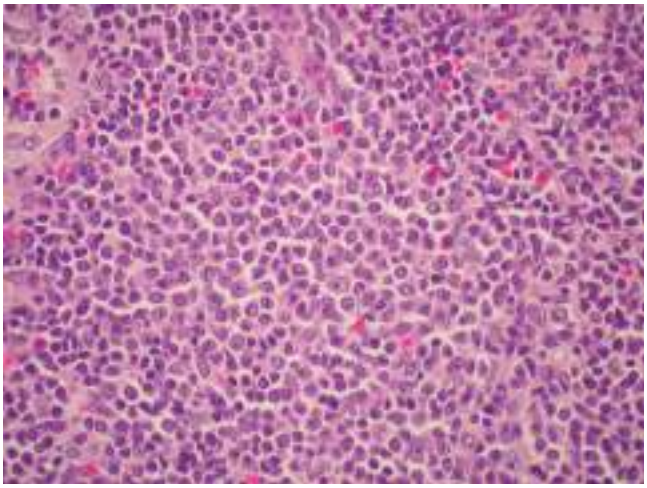
Splenic marginal zone lymphoma

Splenic marginal zone lymphoma (SMZL) is a B-cell neoplasm composed of small lymphocytes that surround and replace the germinal centres and mantle of the reactive follicles in the white pulp, and merge with a peripheral (marginal) zone of larger cells, including scattered transformed blasts. Both small and larger cells infiltrate the red pulp. The patients usually have a leukaemic and splenomegalic presentation with villous lymphocytes in the blood. The disease also involves the splenic hilar lymph nodes and bone marrow, but extension to peripheral lymph nodes is uncommon (Figure 20.2).

There are no distinctive phenotypic markers for SMZL, whose diagnosis requires the exclusion of other lymphoma types (Table 20.2). Most cases exhibit IgM/IgD and a mature B-cell phenotype, but other markers are usually negative (Figure 20.2). The immunoglobulin genes are unmutated in approximately half of the cases, which also tend to have deletions of chromosome 7q31–32 (45%) and a more unfavourable evolution. NGS studies have identified frequent mutations in *KLF2* (10–40%), *NOTCH2*



(a)



(b)

Figure 20.1 Lymph node with chronic lymphocytic leukaemia. (a) At low power the lymph node shows diffuse effacement of the architecture with vaguely nodular pale areas that correspond to the proliferation centres; (b) At higher magnification the proliferation centre contains larger cells with nuclei that have a central nucleolus (prolymphocytes and paraimmunoblasts).

(20–25%) and genes of the NF-κB pathway (*BIRC3*, *TNFAIP3*). A second group of tumours carry mutations in DNA damage, MAP kinase and TLR genes (*TP53*, *ATM, BRAF*). Some cases are positive for hepatitis C virus and may respond to antiviral treatment. The clinical course is usually indolent, but some patients may have progressive disease and transformation to a large-cell lymphoma may occur. In the ICC, the hairy cell leukaemia variant and lymphomas with a diffuse infiltrate of the red pulp are maintained as distinct provisional categories. In the WHO-HAEM5 tumours previously diagnosed as hairy cell leukaemia variant must be included in the new category of 'splenic B-cell lymphoma/leukaemia with prominent nucleoli' that also includes cases that fulfil the criteria of the former B-PLL.

Lymphoplasmacytic lymphoma/Waldenström macroglobulinaemia

Lymphoplasmacytic lymphoma (LPL) is a B-cell neoplasm composed of small lymphocytes, plasmacytoid lymphocytes and plasma cells, usually involving the bone marrow and sometimes lymph nodes and spleen that does not fulfil the criteria for any other B-cell neoplasm which may have plasmacytic differentiation. The ICC has adopted the diagnostic criteria proposed by the International Workshop on Waldenström's macroglobulinaemia. The diagnosis of LPL may be rendered in patients with abnormal lymphoplasmacytic aggregates in the bone marrow and evidence of clonal B cells and plasma cells, even when the aggregates represent <10% of cellularity of the trephine biopsy. Although the detection of a paraprotein is common, it is not required for the diagnosis. Waldenström macroglobulinaemia is an LPL with bone marrow involvement and an IgM monoclonal gammopathy of any concentration. Because these entities do not have specific markers (Table 20.2), it is essential to exclude the presence of any other B-cell neoplasm that may have a plasmacytic differentiation. NGS has identified activating mutations of *MYD88* in 90–100% of the cases and *CXCR4* in 28%. The latter has been associated with development of resistance to ibrutinib therapy. These findings may help in the differential diagnosis of the disease. Primary cold agglutinin disease is now considered a distinct entity from LPL and IgM MGUS in both ICC and WHO-HAEM5 classifications. The disease lacks the $MYD88^{L265P}$ mutation.

Plasma cell neoplasms

Plasma cell neoplasms encompass a spectrum of lesions characterised by the clonal expansion of terminally differentiated B cells that usually secrete a class-switched immunoglobulin (Table 20.3) (see also Chapter 28).

Monoclonal gammopathy of undetermined significance

Monoclonal gammopathy of undetermined significance (MGUS) is defined by less than 10% clonal plasma cells in the bone marrow and less than 30 g/L of an M-protein and absence of end-organ damage. This condition is considered a preneoplastic process since evolution to overt plasma cell malignancy does not always occur. The ICC distinguish two types of IgM MGUS: IgM MGUS of plasma cell type and IgM MGUS, not otherwise specified (NOS). The rare IgM MGUS of plasma cell type is considered a precursor of multiple myeloma (MM) and is defined by clonal plasma cells without a detectable B-cell component and with wild-type *MYD88*. This category also includes patients with t(11;14)(q13;q32) or

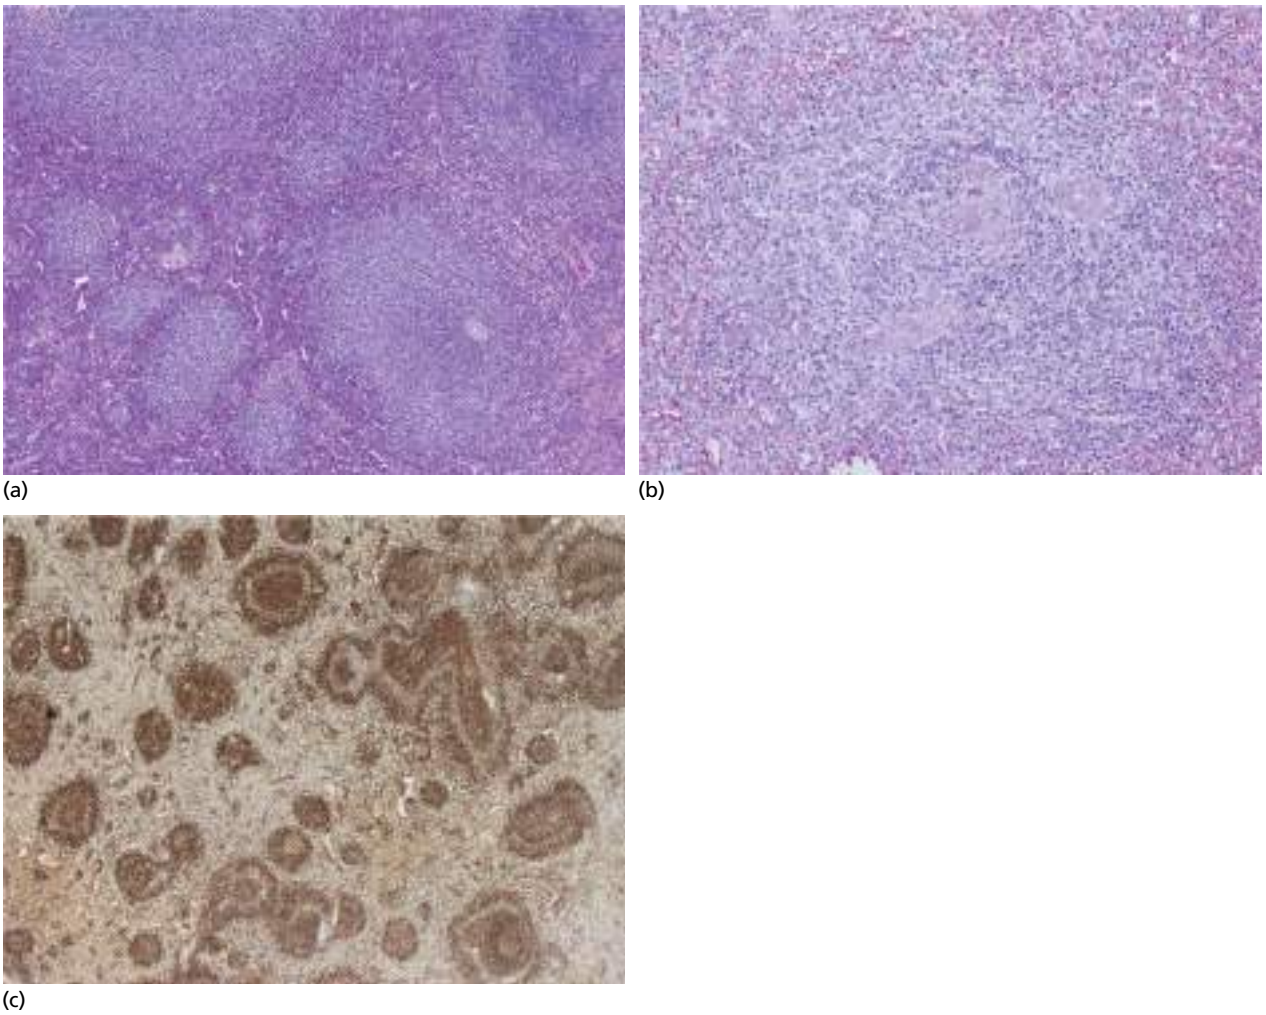


Figure 20.2 Splenic marginal zone lymphoma. (a) The spleen shows multiple nodular proliferations in the red pulp and expanding the white pulp areas; (b) At higher magnification, the nodules are composed of small lymphoid cells in the centre and larger cells at the periphery; (c) The tumour cells are IgD-positive.

TEMPI syndrome

other cytogenetic abnormalities typical of MM. The IgM MGUS, NOS includes all those with a *MYD88* mutation, those with detectable monotypic or monoclonal B cells by flow cytometry but without abnormal lymphoplasmacytic aggregates diagnostic of LPL, and those who lack evidence of other small B-cell neoplasms.

Multiple myeloma (Plasma cell myeloma)

The ICC preferred the term multiple myeloma over the previous WHO of plasma cell myeloma. It is a bone marrow neoplasm characterised by multifocal proliferation of plasma cells associated with a serum M-protein and symptomatic disease related to different organ dysfunction or lytic bone lesions. The plasma cells in the bone marrow expand in small or large clusters. Some cases may present asymptomatically, whereas in others, the

tumour cells spread to the peripheral blood in the form of a plasma-cell leukaemia. The phenotype of these cells is aberrant, with expression of CD19 and CD56 in 75% of cases and other markers such as CD117, CD20, CD52 and CD10. The ICC recommended the subclassification of this disease based on the presence of cytogenetic alterations including MM, NOS when no specific alterations are found and MM with recurrent genetic abnormalities including MM with CCND family translocations, MM with MAF family translocation, MM with NSD2 translocation and MM with hyperdiploidy. Detection of t(4;14), t(14;16) and secondary changes, including del(17p), amp1q and del(1p) identifies patients with high-risk disease. *MYC* translocations have been identified in around 20% of cases, also associated with plasmablastic features.

Plasmacytoma

Plasmacytoma is a solitary tumour lesion composed of clonal plasma cells that may occur in bones or extraosseous tissues (Figure 20.3). Bone plasmacytomas evolve to plasma cell myeloma in two-thirds of patients. In contrast, extraosseous localised lesions have a relatively indolent behaviour without bone marrow involvement, suggesting a closer relationship to MALT lymphomas than bone marrow plasma-cell neoplasms. Progression of solitary plasmacytomas to multiple myeloma is frequently associated with presence of clonal plasma cells in the bone marrow. The ICC recommends the study of bone marrow in all cases because minimal marrow involvement detected by flow cytometry (i.e. clonal plasma cells present but <10%) is associated with higher risk of progression, particularly with solitary plasmacytomas of bone.

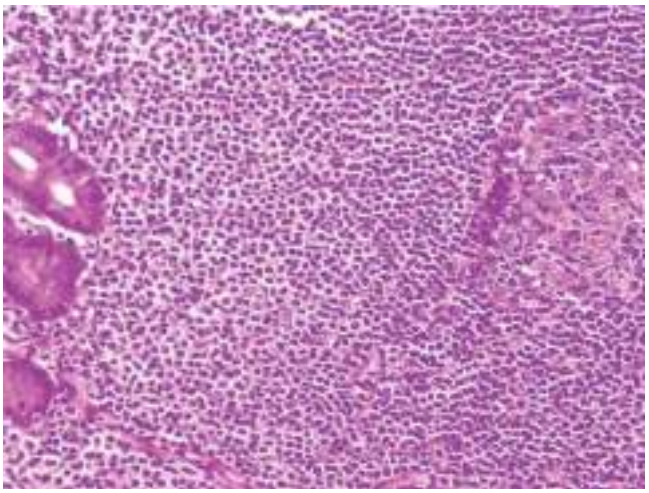
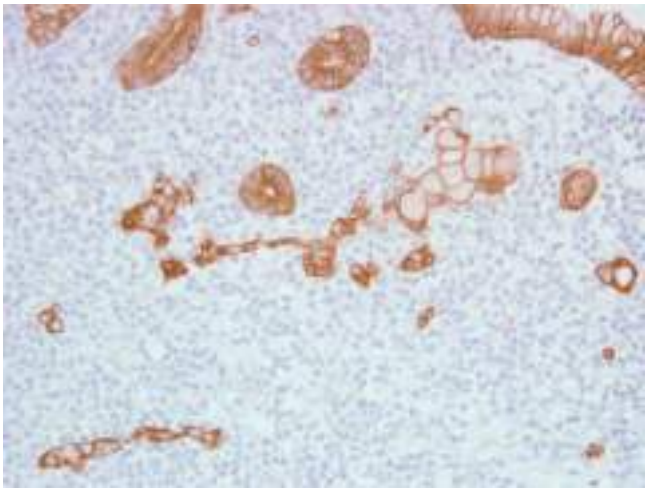
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)

MALT lymphomas are extranodal B-cell neoplasms composed of a heterogeneous population of small lymphocytes, marginal zone lymphocytes with cleaved nuclei (centrocyte-like), cells with clear cytoplasm resembling monocytoid B cells, cells with plasmacytic differentiation and occasional large, transformed cells. All these cells expand the marginal zone of reactive follicles and in some cases may colonise the germinal centres but preserve the mantle zone area. In epithelial tissues, the neoplastic cells infiltrate the epithelium forming lymphoepithelial lesions (Figure 20.4). These tumours occur most commonly in the gastrointestinal tract, salivary gland, lung, head and neck, ocular adnexa and, less frequently, thyroid and breast. Both ICC and WHO-HAEM5 consider that the primary cutaneous MZL is a different entity than MZL in other locations and the ICC proposed to name these cases as primary cutaneous lymphoproliferative disorder, instead of lymphoma, to highlight the very indolent behaviour of these cases. It recommends also to distinguish cases with IG class-switched from those expressing IgM, with the later requiring more caution for its possible associated with systemic disease.

The lymphoma cells express mature B-cell markers, IgM and less often IgG or IgA, but IgD is usually negative. CD5, CD10 and CD23 are negative, although some CD5-positive cases have been described (Table 20.2). Four major translocations have been associated with these lymphomas, t(11;18), t(1;14), t(14;18) and t(3;14), that generate the chimeric gene *BIRC3–MALT1* or activate *BCL10*, *MALT1* and *FOXP1*, respectively. The t(11;18) translocation tends to occur more frequently in gastric and lung lymphomas, whereas the t(14;18) translocation is more often seen in salivary gland and ocular adnexa tumours. Interestingly, *MALT1* and *BCL10* participate in activation of the same NF-κB pathway.



(a)



(b)

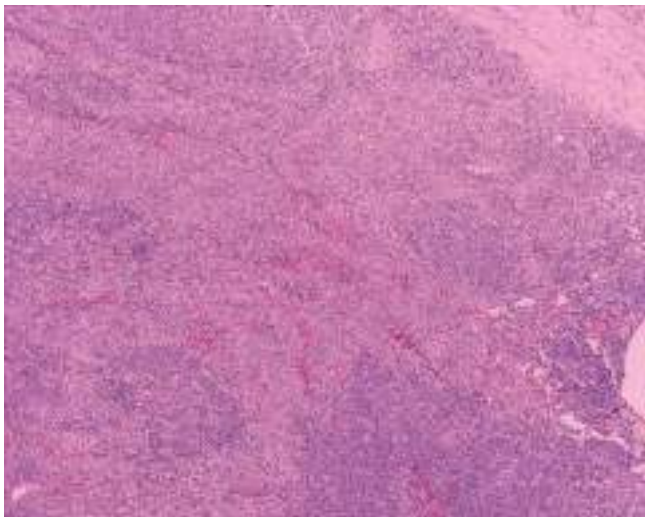
Figure 20.4 Gastric marginal zone lymphoma of the mucosa-associated lymphoid tissue (MALT lymphoma). The gastric mucosa is infiltrated by a monotonous population of lymphoid cells that surrounds a residual germinal centre (a) and destroys the glands, creating lymphoepithelial lesions clearly observed with cytokeratin staining (Cam 5.2 immunoperoxidase staining) (b).

These lymphomas arise in topographic sites with a pre-existing chronic inflammatory lesion induced by infectious, immunological or unknown stimuli. Thus gastric lesions are associated with *Helicobacter pylori*, *Campylobacter jejuni* is detected in the immunoproliferative small intestinal disease, *Chlamydia psittaci* in ocular adnexa tumours of certain geographic regions and *Borrelia burgdoferi* in some cutaneous MALT lymphomas. Autoimmune disorders of the salivary gland (Sjögren syndrome) and thyroid (Hashimoto disease) are the preceding lesions of MALT lymphomas in these locations.

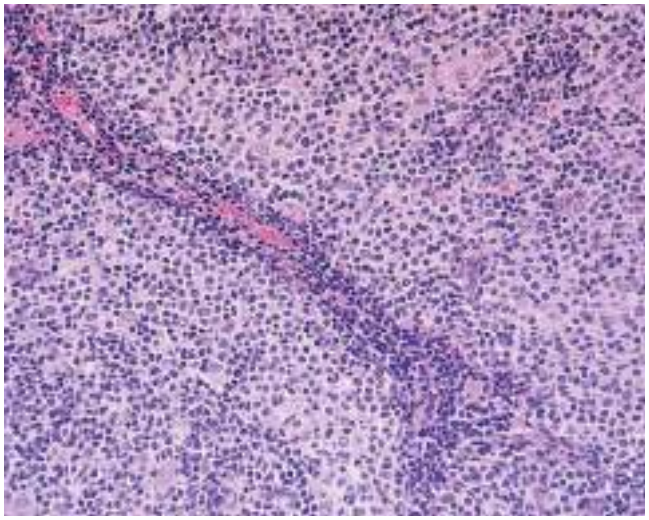
The lymphoma responds to control of the underlying infectious disease and local treatments but may relapse in extranodal territories after many years. Nodal dissemination may precede clinically the detection of extranodal involvement. Tumours with the translocations described appear to be resistant to antibiotic therapy. Transformation to large-cell lymphomas may occur.

Nodal marginal zone lymphoma

Nodal marginal zone lymphoma (NMZL) is a primary lymphoma of the lymph nodes that resembles extranodal MALT lymphomas (Figure 20.5). An extranodal or splenic lymphoma should be ruled out before this diagnosis is established. Although the morphology and phenotype are similar to MALT



(a)



(b)

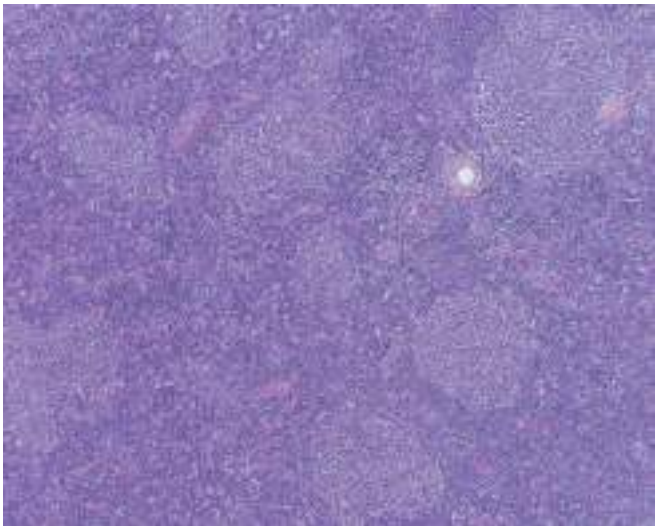
Figure 20.5 Nodal marginal zone lymphoma. (a) Tumour cells with a clear appearance infiltrate the node, with partial preservation of the architecture; (b) Higher magnification reveals the clear cytoplasm of the tumour cells.

lymphoma, primary NMZL does not exhibit the typical translocations of these tumours but have trisomy 3 and 18. The mutational profile is similar to that of SMZL, with frequent mutations in *KLF2, NOTCH2, TNFAIP3, KMT2D* and *TP53*. Disseminated disease may present in some patients and 60–80% survive more than 5 years. Some cases may evolve to large B-cell lymphomas.

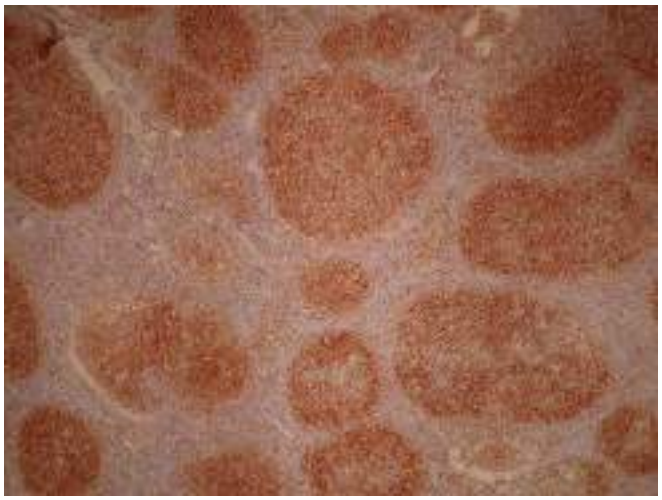
NMZLs in the paediatric age group seem to have distinctive clinical and morphological features. Thus, they present predominantly in males as asymptomatic localised tumours and morphologically the residual follicles may have features of progressive transformed germinal centres with eroded mantle zones by the tumour cell infiltration. These tumours may be a morphological variant of paediatric type follicular lymphoma. Molecular and genetic studies detect clonal rearrangements of the IG or chromosomal alterations in virtually all cases and mutations similar to paediatric type follicular lymphoma. These findings are useful in the differential diagnosis with reactive hyperplasias. The prognosis of these patients seems excellent with conservative therapy.

Follicular lymphoma

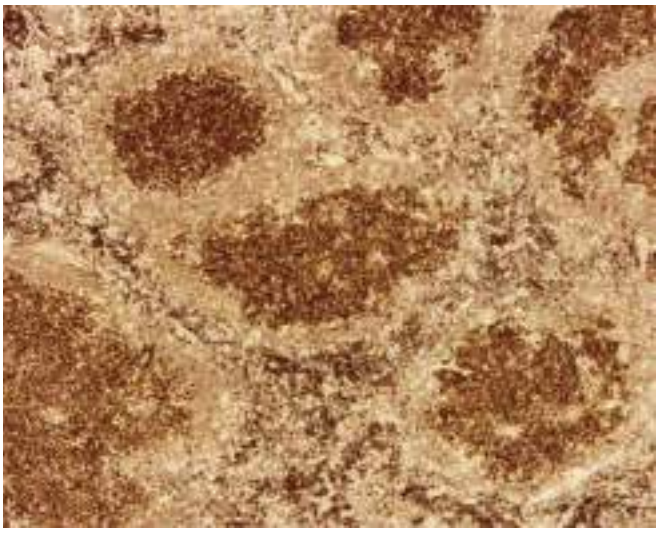
Follicular lymphoma (FL) is a neoplasm composed of cells of the germinal centres, with different proportions of small centrocytes and large centroblasts, that usually has a follicular growth pattern (Figure 20.6). These tumours are common in Western countries, accounting for around 20–30% of all lymphomas. These tumours have been graded histologically according to the



(a)



(b)



(c)

Figure 20.6 Follicular lymphoma. (a) The tumour grows in a follicular pattern with expanded germinal centres without macrophages. The tumour cells are positive for CD10 (b) and BCL2 (c).

number of large cells, as follows: grade 1 (0–5 large cells per high-power field), grade 2 (6–15 large cells) and grade 3 (>15 large cells). Grades 1 and 2 represent a morphological continuum that is not associated with relevant clinical or biological differences and therefore these cases are grouped together. However, grade 3 tumours are further distinguished into grades 3A and 3B according to the presence of intermingled small centrocytes in grade 3A, whereas grade 3B is composed entirely of large cells. FL grade 3A is genetically and phenotypically more related to FL grade 1–2, whereas FL grade 3B is closer to DLBCL. Any diffuse area composed of more than 15 large cells should be reported as DLBCL, and the percentage of the respective DLBCL and FL components indicated. The ICC maintains these criteria but the WHO-HAEM5 considers grading of FL as optional and denominates FL grade 3B as follicular large B-cell lymphoma. The WHO-HAEM5 also recognises a FL with unusual features characterised by blastoid cells or large centrocyte. The ICC recognises that some high-grade FL may be difficult to classify but recommends that cases with *BCL2* rearrangements and or CD10 expression be included in the group of grade 3A whereas the cases without these features may be closer to FL grade 3B.

FL has a mature B-cell phenotype with coexpression of the germinal-centre markers CD10, BCL6 and LMO2 (Figure 20.6) (Table 20.2). CD5, CD43 and CD23 are negative. BCL2 is positive in 85–90% of FL grade 1–2, but only in 50% of grade 3. BCL2 staining is very useful because reactive germinal centres are negative (Figure 20.6). This expression reflects the presence of the t(14;18) translocation that is the genetic hallmark of this lymphoma and which targets the *BCL2* gene. FL grade 3B is less frequently positive for CD10 and BCL2 protein and the t(14;18) translocation is only detected in 5–20% of cases. In contrast, these lymphomas express IRF4/MUM1 in 40% of the cases and carry 3q27 and *BCL6* rearrangements in 30–50% of cases, whereas these aberrations are rare in FL grades 1–3A. The strong expression of IRF4/MUM1 in grade 3 FL, particularly in young patients, should rise the possibility of large B-cell lymphoma with *IRF4* rearrangement. Some cases may progress to a DLBCL and this transformation may be associated with *TP53* mutations, *CDKN2A/B* homozygous deletions or t(8;14) translocations involving *MYC*.

The tumour cells in FL are associated with a rich microenvironment of different types of T cells and histiocytes that seem to play a major role in determining the biological behaviour of the lymphoma. NGS studies in FL have identified frequent mutations in genes involved in chromatin remodelling, particularly in *KMT2D* (90%), *CREBB* (40%) and *EZH2* (20%).

In situ follicular neoplasia

In situ follicular neoplasia is a variant in which the tumour cells are limited to the germinal centres of the follicles. Usually, only a number of the lymph node follicles are involved, whereas others are reactive. The tumour cells are recognised by their strong BCL2 and CD10 expression inside the germinal centres. These cells carry the t(14;18) translocation. Some of these cases may correspond to early involvement of a lymph node by a disseminated tumour. A second group of patients may develop overt FL during follow-up, but most patients (94%) remain free of lymphoma elsewhere after many years of follow-up.

BCL2-R negative, CD23-positive follicle centre lymphoma

The ICC recognises this category as a provisional entity as a lymphoma derived of follicle centre cells that may grow in a predominant diffuse pattern and lacks *BCL2* rearrangement. These cases usually present with large masses in inguinal or pelvic areas. The tumour expresses CD10, CD23 and carries del(1p36). The mutational profile is different from conventional FL since they have frequent mutations in *STAT6* and lack mutations of the conventional FL such as *EZH2*. These cases partially overlap with the diffuse variant of FL in the WHO-HAEM5. However, 30% of cases *BCL2*-R negative and CD23-positive with the same mutational profile are purely nodular.

Primary intestinal follicular lymphoma

Primary intestinal FL occurs frequently in the duodenum as an incidental finding (Figure 20.7). These cases have a conventional morphology, phenotype and genetic features, including the t(14;18). However, the tumours express IgA and remain localised, with an excellent prognosis, even without treatment.

Primary cutaneous follicle centre lymphoma

Primary cutaneous follicle centre lymphoma generally presents in the skin of the head and trunk. The tumour cells may grow with a follicular or more diffuse pattern. The cells express B-cell

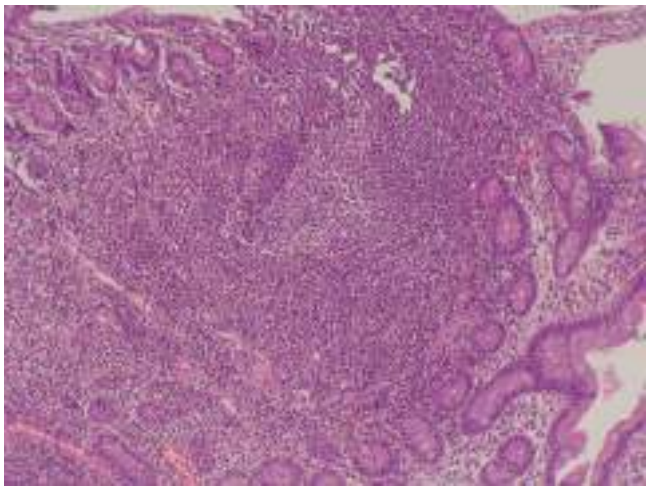


Figure 20.7 Follicular lymphoma of the duodenum.

markers and BCL6, whereas CD10 is positive in cases with a follicular pattern but tends to be lost in the diffuse component. BCL2 expression and the t(14;18) translocation are usually negative. The tumours may relapse, but have a good outcome without extracutaneous dissemination, even with only localised therapy.

Paediatric type follicular lymphoma

Paediatric type FL occurs in children and young adults, usually involving the head and neck region. The ICC recognises Testicular FL as a distinct category, usually in children with localised disease. The lymphomas are BCL2 negative, do not carry the t(14;18) translocation and are composed of large cells with blastoid nuclei. These cases have a good evolution with local therapy. These tumours have mutations in *MAP2K1*, *IRF8*, deletions and mutations of *TNFRS14* and lack mutations typical of adult FL.

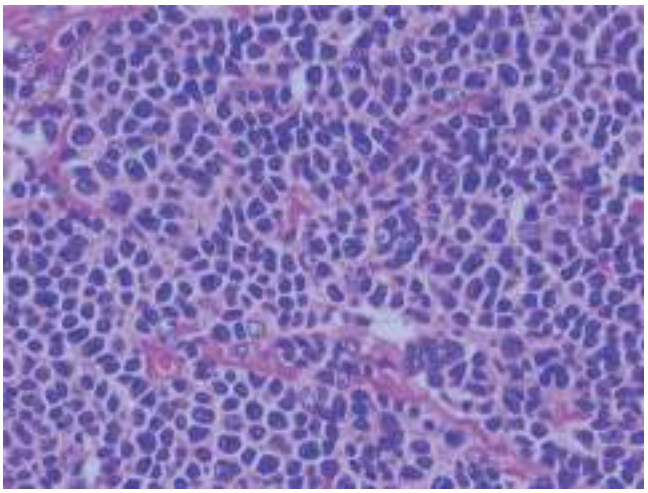
Large cell lymphoma with *IRF4* translocation

These tumours are derived from germinal centre cell and may have a follicular, follicular and diffuse or diffuse pattern. The tumour cells express germinal centre markers with strong IRF4/MUM1 due to and *IRF4* translocation with *IG* genes. The tumours present in the Waldeyer's ring, head and neck and abdominal nodes.

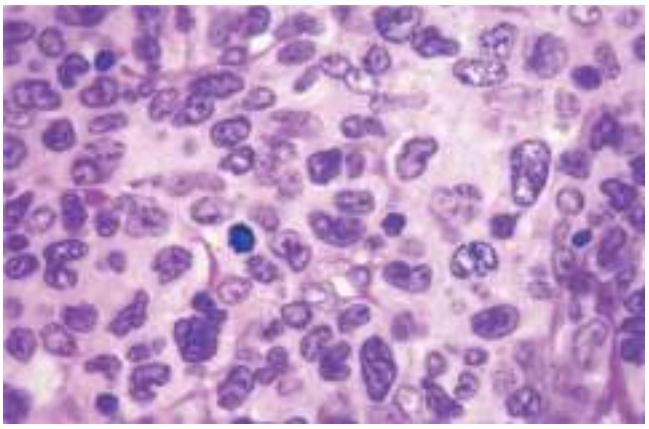
Mantle-cell lymphoma

Mantle-cell lymphoma (MCL) is a B-cell neoplasm composed of monomorphous small- to medium-sized lymphoid cells with irregular nuclear contours and cyclin D1 over-expression secondary to *CCND1* translocation (Figures 20.8 and 20.9). This tumour comprises 3–10% of non-Hodgkin lymphomas and occurs mainly in males, with a median age around 60 years. Most MCLs are diagnosed as disseminated nodal disease, but a number of patients are initially seen with leukaemic disease, bone marrow involvement and frequently splenomegaly, but without lymphadenopathy (leukemic non-nodal MCL). Extranodal involvement is very common. Some tumours may have a blastoid or pleomorphic cytology resembling lymphoblasts or DLBCL, respectively. These cytological variants are associated with higher proliferative activity, more complex karyotypes and worse prognosis. The tumour cells grow with a vaguely nodular, diffuse or mantle-zone pattern. Some cases may show restricted infiltration to the inner mantle zones of otherwise reactive follicles, a situation that has been named *in situ* mantle cell neoplasia. The tumour cells express mature B-cell markers, with intense CD20 and surface immunoglobulin, and coexpress CD5 and CD43. CD23 and germinal-centre markers are negative (Table 20.2).

MCL exhibits the t(11;14) translocation that targets *CCND1*. Some MCL cyclin D1 negative cases carry translocations and overexpression of CCND2 and CCND3. SOX11 is highly



(a)



(b)

Figure 20.8 Mantle-cell lymphoma with classical (a) and pleomorphic (b) morphology.

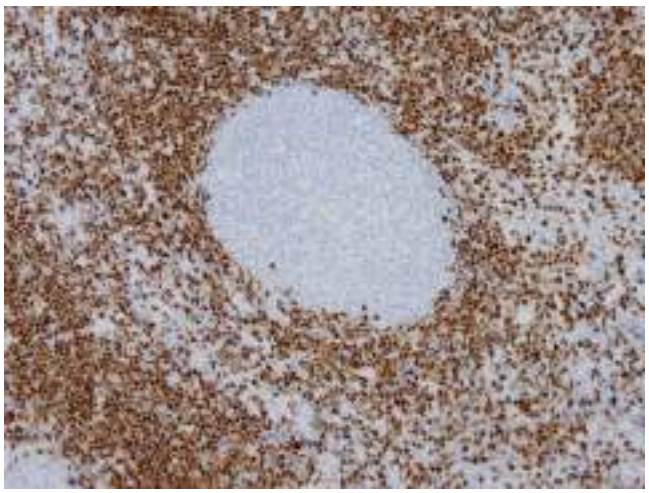


Figure 20.9 Mantle-cell lymphoma is positive for cyclin D1.

expressed in MCL but not in other mature B-cell lymphomas, with the exception of Burkitt lymphoma (30%). SOX11-positive tumours usually have unmutated IGHV and accumulate complex karyotypes. Leukaemic non-nodal MCL is a distinct molecular variant that does not express SOX11, has hypermutated IGHV and simple karyotypes. NGS has identified frequent mutated genes in conventional MCL including *ATM* (41%), *TP53* (28%), *NOTCH1/2* (10%), *KMT2D* (15%) *NSD2* (10%), *MEF2B* (3%) and activation of the NF-κB pathway (*BIRC3*, *TRAF2/3*) (6%). SOX11-negative tumours have *TP53* mutations associated with worse prognosis but usually do not have mutations in the other genes.

In general, MCL has an aggressive clinical course, with frequent relapses after responding to chemotherapy and a median survival of 3–5 years but it is improving with the new therapies. Proliferation is considered the best biological prognostic parameter. Leukaemic non-nodal MCL have an initial indolent disease and better prognosis although may progress to more aggressive behaviour usually associated with *TP53* mutations.

Diffuse large B-cell lymphoma, not otherwise specified

DLBCL is a neoplasm of large B lymphocytes with a diffuse growth pattern. These lymphomas are heterogeneous and several morphological variants, phenotypical and molecular subtypes and different entities have been recognised (Table 20.1b). DLBCL accounts for 25–30% of adult non-Hodgkin lymphomas. Usually, these cases present as primary tumours, but they can also represent the transformation of a less aggressive B-cell lymphoma. Morphologically, DLBCL not otherwise specified (NOS) may have centroblastic, immunoblastic or anaplastic cytology (Figures 20.10 and 20.11). Phenotypically, DLBCL, NOS expresses mature B-cell markers. CD5 is detected in a subset of these tumours. The expression of the germinal-centre markers CD10, BCL6 and LMO2 define a germinal-centre origin, whereas the expression of IRF4/MUM1 and FOXP1 has been associated with an origin in non-germinal-centre activated B cells (Figures 20.10 and 20.11). Although with some limitations, these two immunophenotypic subgroups of DLBCL correlate with the two molecular subtypes of germinal-centre (GCB) and activated B-cell (ABC) DLBCL, recognised by gene expression profiling. These two major molecular subtypes differ in genetic, molecular and clinical aspects, indicating that they correspond to different biological entities. ABC, but not GCB, DLBCL exhibits constitutive activation of the NF-κB pathway. The clinical outcome is also different, with 5-year survival rates of approximately 60 and 30% in GCB and ABC DLBCL, respectively, with current therapies. NGS has identified up to 7 genetic subtypes of DLBCL (Table 20.4) that are characterised by different mutated genes and/or chromosomal alterations. These subgroups are preferentially included in the GCB, ABC or unclassified gene expression-based molecular subtypes, but there are some overlaps. The prevalence of the different subgroups varies from 2 to 18% of the cases and the 5-year overall survival is also very variable from 27 to 84% of the patients. In addition to the prognostic interest of these subgroups, they may be of interest for future targeted therapies. A paradigmatic group is the so-called MCD/C5 group that carries frequent mutations in *MYD88*/*CD79B*. Cases in this group are mainly extranodal in location such as primary DLBCL of CNS and testis, primary cutaneous DLBCL, leg type and intravascular large B-cell lymphoma amongst others. Another interesting group is the EZB MYC$^+$ that has a germinal centre phenotype with *BCL2* and *MYC* rearrangement, that currently is pathologically classified as high-grade B-cell lymphoma with *BCL2* and *MYC* rearrangement. These cases have very aggressive behaviour.

(*Source:* Adapted from Wright GW, Huang DW, Phelan JD, *et al.* (2020) and Chapuy B, Stewart C, Dunford AJ, *et al.* (2018).

T-cell/histiocyte-rich large B-cell lymphoma

T-cell/histiocyte-rich large B-cell lymphoma is characterised by a limited number of scattered large B cells immersed in a rich background of T cells and frequently histiocytes. The tumour cells express mature B-cell markers and frequently BCL2 and EMA, although CD30, CD15 and CD138 are negative. The background is composed of CD3 and CD4 T cells and CD68-positive histiocytes. T-cell rosettes surrounding tumour B cells are not seen. Cases positive for Epstein–Barr virus (EBV) and a similar morphology must be classified as EBV-positive DLBCL, NOS. Recent studies suggest that this lymphoma may be closely related to nodular lymphocyte-predominant Hodgkin lymphoma. Patients present with disseminated disease involving lymph nodes but also spleen, liver and bone marrow. Failure of therapy and International Prognostic Index (IPI) score are predictors of survival.

Primary mediastinal large B-cell lymphoma

Primary mediastinal (thymic) large B-cell lymphoma (PMBL) originates in a thymic B cell and predominates in young women presenting with a large mediastinal mass that frequently invades adjacent structures. Progression outside the mediastinum frequently involves extranodal sites such as kidney, liver, adrenal or central nervous system (CNS). The tumour is mainly composed of large cells with abundant pale cytoplasm, which express mature

B-cell markers, but usually lack surface immunoglobulin. CD30 is positive in 80% of cases, although not as uniformly as in HL. CD23 is also frequently positive. CD15 is negative. (Table 20.2) Genetically, PMBL has frequent gains and amplifications of 9p24 including *PDL1*, *PDL2* and *JAK2*. Frequent mutations involving genes and pathways similar to those in Hodgkin lymphoma and mediastinal grey zone lymphomas including JAK-STAT, NF-κB and immune escape pathways (e.g. *SOCS1*, *STAT6*, *NFKBIE* and *CIITA*) are observed. These tumours also carry translocations of the MHC class II transactivator *CIITA* and the immunoresponse modulator *PDL1* and activating mutations of the phosphatase *PTPN1*. Intriguingly, all these alterations may also be seen in a proportion of Hodgkin lymphomas highlighting the genetic relationship between these entities that is also seen in the gene expression profile. Some patients may present with combined HL and PMBL at diagnosis or relapse or have tumours with intermediate features of both (see below). The outcome of these tumours is more favourable than other DLBCL, with a 5-year survival of 65%.

DLBCL with a predominant extranodal location

Several DLBCL subtypes are characterised by extranodal presentation. Intriguingly, although the particular topographic site of these entities configure a unique clinical presentation all of them share a similar *ABC* gene expression profile and landscape of somatic mutations defined in the MCD/C5 genetic subgroups with mutations in *MYD88* and *CD79B*, that suggest they may correspond to the same entity with particular differences related to the site of origin.

Primary DLBCL of the central nervous system (CNS)

This lymphoma originates in the brain, spinal cord, leptomeninges or eye and may appear in patients with a broad range of age. The tumour cells are large with a non-GCB phenotype (*IRF4*/*MUM1* and *BCL6*) and frequently have molecular alterations that favour immune escape (e.g. deletion of HLA). EBV is negative. Sequencing studies have shown frequent mutations in *MYD88, CD79B* and *PIM*.

Primary diffuse large B-cell lymphoma of the testis

Both the ICC and WHO-HAEM5 recognise these tumours as a distinct entity biologically related to primary DLBCL of the CNS. These tumours are mainly of the ABC subtype with frequent mutations in *MYD88/ CD79b* similar to the MCD/C5 genomic subtypes.

Intravascular large B-cell lymphoma

This lymphoma is a distinctive entity characterised by the growth of large B cells within the lumina of small- to medium-sized vessels and capillaries (Figure 20.12). It is relatively rare in Western countries, but more common in Eastern populations.

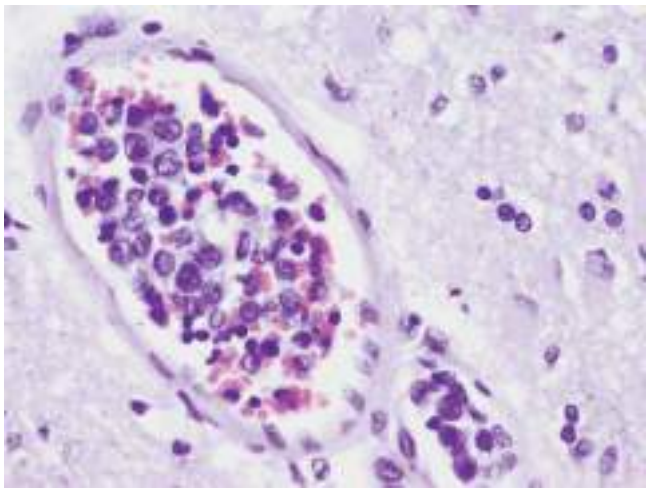

Figure 20.12 Intravascular lymphoma in the brain.

This lymphoma is very aggressive and frequently diagnosed only at postmortem. An isolated cutaneous variant with better prognosis has been identified, mainly in women.

Primary cutaneous DLBCL, leg type

Primary cutaneous DLBCL, leg type, is composed almost exclusively of atypical large B cells that commonly, but not exclusively, present in the lower extremities. These tumours express an activated B-cell phenotype with positivity for IRF4/MUM1 and CD10 negativity. BCL6 is frequently positive, and BCL2 is strongly expressed. The prognosis is poor and the tumour tends to disseminate to extracutaneous sites.

Large-cell lymphomas of terminally differentiated B cells

A group of large B-cell lymphomas that have in common the proliferation of large lymphoid cells with a terminally differentiated B-cell phenotype characterised by variable or total lack of CD20 expression, and less frequently CD79a, but which express plasma-cell-associated antigens such as CD38 and CD138 (Table 20.2). Most of these tumours are infected with EBV or human herpesvirus (HHV)-8 and occur in patients with a certain immunodeficiency status.

ALK-positive large B-cell lymphoma

ALK-positive large B-cell lymphoma is characterised by proliferation of large B cells with plasmablastic differentiation, CD30 negative, that express ALK and are EBV negative. These tumours present in young immunocompetent patients, usually with nodal involvement and aggressive behaviour. ALK expression is due to *ALK* rearrangements, particularly with clathrin [t(2;17)] or less frequently nucleophosmin [t(2;5)]. Contrary to other lymphomas in this group, viral infection and immunodeficiency are absent.

Plasmablastic lymphoma

Plasmablastic lymphoma is a large B-cell lymphoma with frequent immunoblastic morphology and plasma-cell immunophenotype (Table 20.2) that presents mainly in extranodal sites such as oral mucosa and gastrointestinal tract of immunosuppressed patients. HIV infection is the main cause, but post-transplant or immunosuppressive treatments are also common causes. Most of the tumours are EBV positive and latent membrane protein (LMP)-1 negative. The clinical behaviour is aggressive, with poor response to therapy. *MYC* is rearranged in around 50% of the cases. NGS studies have demonstrated a specific profile with frequent mutations in *TP53*, JAK/STAT3 and MAPK (*NRAS*, *KRAS*) pathway genes.

Primary effusion lymphoma

Primary effusion lymphoma occurs mainly in immunosuppressed patients associated with HHV-8 and, frequently, EBV infection. It is characterised by proliferation of large pleomorphic B cells that lack expression of B-cell markers and immunoglobulin, but express plasma-cell-associated antigens and CD30 (Figure 20.13). These tumours usually present as effusion lymphomas, with no involvement of tissues. However, some patients may present with, or later develop, a solid tumour in extranodal sites.

Burkitt lymphoma

Burkitt lymphoma (BL) is mainly a tumour of children and young adults characterised by monotonous proliferation of medium-sized B cells with a mature B and germinal-centre phenotype, negative or very weak BCL2 expression, high proliferation (Ki-67 >95%) and the t(8;14) translocation with *MYC* rearrangement. These tumours occur endemically in equatorial Africa and other geographic areas and sporadically throughout the world. BL is also seen associated with immunodeficiency, particularly HIV infection. The tumour mainly involves extranodal sites, particularly the abdominal cavity, and, in endemic areas, jaws and facial bones. The tumour may infiltrate the CNS. A leukaemic phase may be seen in patients with bulky disease. Occasional patients may present with a pure leukaemic disease (Burkitt leukaemia variant) but in these cases the *MYC* rearrangement seems to be acquired in precursor cells and should be considered a form of acute lymphoblastic leukaemia. The tumour is clinically aggressive but potentially curable with current protocols.

Morphologically, the tumour cells are very monomorphic, highly proliferative, associated with a 'starry sky' pattern of histiocyte phagocytosing apoptotic bodies (Figure 20.14). Genetically, the t(8;14) translocation is found in most tumours with very few if any additional genetic alterations. NGS studies

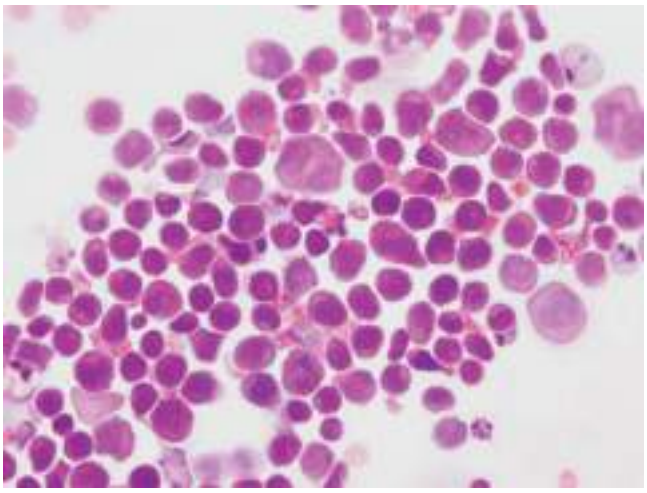

Figure 20.13 Primary effusion lymphoma. The tumour cells are present in the pleura and have a large plasmablastic morphology.

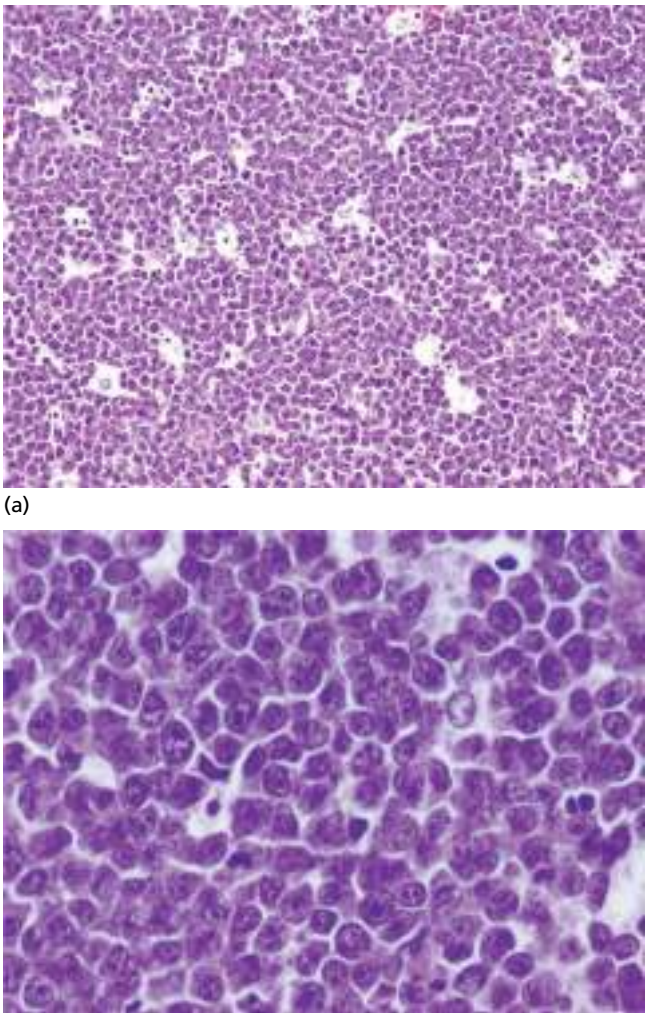

(a) (b)

have identified a distinctive profile of somatic mutations targeting the *ID3* (11%)/*TCF3* (40–70%) pathway, not detected in DLBCL, *DDX3X* (30–50%) and *CCND3* (38%).

High grade B-cell lymphomas (HGBL) with *MYC* and *BCL2* rearrangements

This category is recognised in both the ICC and WHO-HAEM5 and includes tumours with these two rearrangements. The ICC includes all tumours carrying these translocations independently of the morphology that may be DLBCL, intermediate between BL and DLBCL or blastoid. The WHO-HAEM5 splits tumours carrying the two translocations as DLBCL or HGBL depending on the morphology of the tumours cells. These tumours seem to derive from the dark zone of the germinal centre and express a mature B-cell phenotype with CD10 and BCL6 and have a very high proliferative index. Strong expression of BCL2 and MYC in a GCB large cell lymphoma should suggest the presence of the rearrangements of these genes that must be confirmed by genetic studies. Clinically, the patients are older than those with conventional BL, the disease is usually disseminated, and the bone marrow and peripheral blood may be involved. The clinical evolution is very aggressive, with poor response to conventional therapy. Some cases may represent transformed FL. However, independent of the possible biological significance, these patients should be recognised and studied separately from conventional DLBCL and BL. Cases with blastoid or intermediate morphology between BL and DLBCL but without this combination of rearrangements are diagnosed as high-grade B-cell lymphoma, NOS and probably is a more heterogeneous category. The ICC recommends to identify cases with similar morphologies carrying *MYC* and *BCL6* rearrangements as a separate category to allow further studies to better define these tumours whereas the WHO-HAEM5 recommends to include these cases as DLBCL, NOS.

Mediastinal grey zone lymphoma

These tumours are B-cell lymphomas that have clinical, morphological and/or immunophenotypic features that overlap those of PMBL and HL. The term mediastinal grey zone lymphomas (MGZL) is preferred for these tumours over the previous one of B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma. These cases are diagnosed frequently in young men presenting with a large mediastinal mass that is sometimes associated with surpraclavicular lymph nodes. Most of these cases are composed of sheets of large cells with a pleomorphic aspect, associated with some inflammatory infiltrate. The phenotype combines strong expression of a complete B-cell programme (CD20, CD79a, BOB-1, OCT2, PAX5) with CD30 and CD15 positivity. Mediastinal grey zone lymphomas have a similar mutational profile than PMBL and HL (*B2M*, *TNFAIP3*, *GNA13*). Tumours with overlapping features between Hodgkin and DLBCL outside the mediastinum have a mutational profile similar to DLBCL (Rearrangements of *BCL6* or *BCL2*, *TP53* mutations), and should be considered as DLBCL rather than included in this category. Composite lymphomas with clear areas of PMBL and HL are not included in this group and both components should be mentioned in the diagnosis. Microarray expression profiling has demonstrated the similarities between PMBL and HL and the intermediate profile of MGZL that probably represent evidence of plasticity of B cells.

Mature NK-cell/T-cell neoplasms

These tumours derive from natural killer (NK) cells and T cells of peripheral lymphoid organs and can be roughly subdivided into three groups: leukaemic, extranodal and nodal. The combination of morphological, phenotypic and molecular features is essential for the diagnosis of the different entities (Table 20.5). These are discussed in the following sections, with the exception of T-cell prolymphocytic leukaemia, T-cell large granular lymphocyte leukaemia and chronic lymphoproliferative disorders of NK cells, which are considered in Chapter 24.

Aggressive NK-cell leukaemia

This is a rare neoplasm, mainly observed amongst Asians, and exhibits systemic proliferation of NK cells almost always associated with EBV and an aggressive clinical course. Patients are usually middle-aged of either sex. The most commonly involved sites are the peripheral blood, bone marrow, liver and spleen (Figure 20.15). Fever and constitutional symptoms are common. Frequent complications are coagulopathy, haemophagocytic syndrome (HPS) or multiorgan failure. A specific overlap with extranodal NK/T-cell lymphoma may exist. Circulating

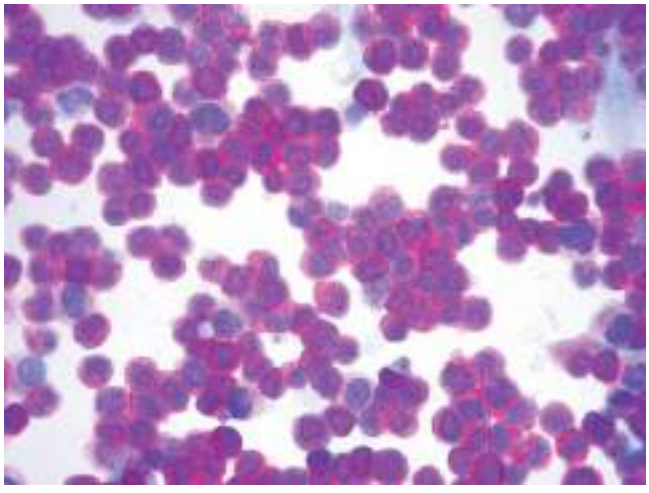

Figure 20.15 Cytospin from the peripheral blood of a patient with aggressive NK-cell leukaemia, stained for CD56 (alkaline phosphatase anti-alkaline phosphatase technique).

leukaemic cells exhibit a morphological spectrum, from 'normal LGL' to elements with atypical unfolded nuclei, open chromatin and distinct nucleoli. They express CD2, CD3ε, CD56, cytotoxic molecules and FASL. Surface CD3 is absent. T-cell receptor (*TCR*) genes are in germline configuration. Most cases pursue a fulminant clinical course.

EBV-positive T-cell and NK-cell lymphoproliferative disorders (LPDs) of childhood

They include: chronic active EBV (CAEBV) disease (T-cell and NK-cell phenotype) hydroa vacciniform LPD, classic, with cutaneous involvement and systemic mosquito bite allergy, and systemic EBV-positive T-cell lymphoma. They are prevalent in Far East Asia and people with native-American ancestry, with no sex predilection, and can develop shortly after primary EBV infection or in the setting of chronic active EBV infection. EBV-positive T-cell lymphoma of childhood has a fulminant course, usually associated with haemophagocytic syndrome. The other forms of T/NK LPDs show a broad range of clinical manifestations, from indolent, localised forms (such as hydroa vacciniform LPD and mosquito bite allergy) to systemic disease with fever, hepatosplenomegaly and lymphadenopathy, associated or not with cutaneous manifestations. Since an overlap of morphologic features is not infrequently observed amongst these EBV-positive LPDs of childhood, the knowledge of clinical data is of paramount importance for the correct diagnosis. On pathogenetic grounds, there is strong suggestion of a genetic defect in the host immune response to EBV. The infiltrating cells are usually small and lack significant cytological atypia, but at times are pleomorphic, medium/large with irregular nuclei and frequent mitoses (Figure 20.16). T-cell LPDs are positive for CD2, CD3, TIA and EBV, but negative for CD56, and have monoclonally rearranged TCR genes. NK-cell cases express CD2, CD3ε, CD56 and cytotoxic molecules, while lack surface CD3 and clonal rearrangement of *TCR* genes. Occasional cases with γδ-*TCR* and expression of *CCR4* have been reported.

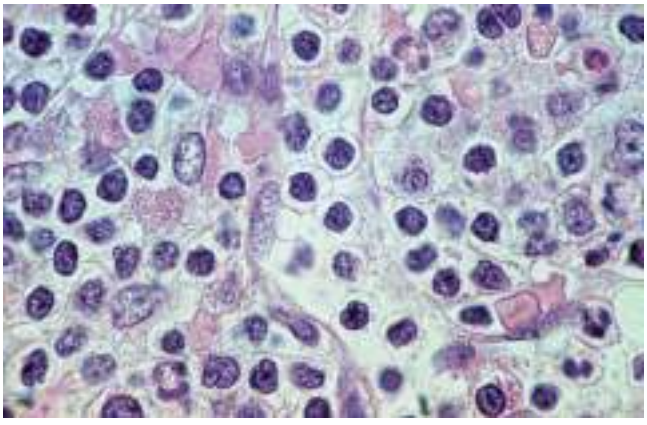

Figure 20.16 Bone-marrow involvement by EBV-positive lymphoproliferative disorder in a 16-year-old boy.

Adult T-cell leukaemia/lymphoma

Adult T-cell leukaemia/lymphoma (ATLL) is endemic in south-western Japan, the Caribbean basin and parts of Central Africa, its distribution resembling that of human T-cell leukaemia/lymphoma virus (HTLV)-I (see also Chapter 24). The disease has a long latency with exposure of affected individuals to the virus very early in life. Although causally linked to ATLL, HTLV-I itself is insufficient to cause neoplastic transformation, additional genetic events being required, such as mutations affecting *PLCG1*, *PRKCB*, *VAV1*, *IRF4*, *FYN*, *CARD11*, *STAT3* and *CCR4*, and intragenic deletions of *TP73*. Most patients present with widespread lymph node and peripheral blood involvement, the skin being affected in more than 50%. ATLL is characterised by variable clinical and histological features. In particular, the behaviour varies from acute (with usual hypercalcaemia and possible lytic bone lesions) to lymphomatous, chronic or smouldering, while the growth may consist of small- to large-sized pleomorphic cells or display anaplastic or even angioimmunoblastic-like morphology (Figure 20.17). Tumour elements are usually $CD2^+CD3^+CD5^+CD25^+CD7^-$. Most cases are $CD4^+CD8^-$, a few $CD4^-CD8^+$ or $CD4^+CD8^+$. CCR4 and FoxP3 are frequently expressed, while cytotoxic molecules are absent. CD30 positivity is at times detected, especially in cases lacking FoxP3, by heralding a more aggressive clinical course. CCR4 and CD30 can represent the targets for *ad hoc* therapy with monoclonal antibodies. *TCR* genes are clonally rearranged. Clinical subtypes, age, performance status, serum calcium and lactate dehydrogenase levels are major prognostic indicators. The acute and lymphomatous variants have a short survival (2 weeks to more than 1 year), while the chronic and smouldering

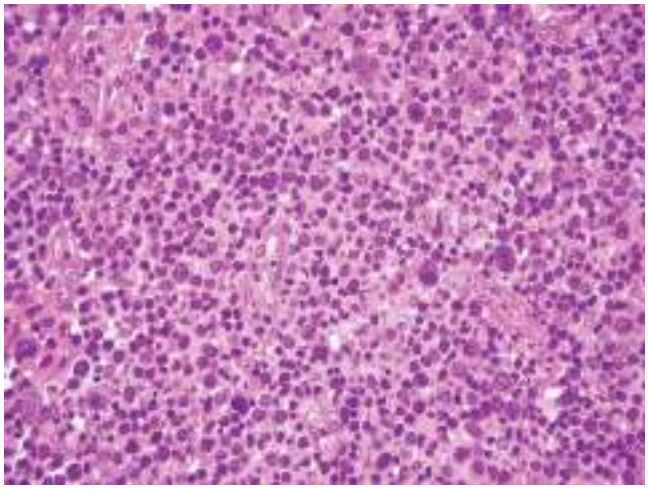

Figure 20.17 Lymph node infiltration in a patient with adult T-cell leukaemia/lymphoma.

forms behave more indolently, but can progress to an acute phase (see also Chapter 24).

Extranodal NK/T-cell lymphoma, nasal type

Extranodal NK/T-cell lymphoma, nasal type, more often occurs in adult males from Far East Asia, and from native-American ancestry (see also Chapter 24). The tumour is EBV positive with type II latency, although LMP-1 expression is variable. Usually, these lymphomas affect the nasal cavity, nasopharynx, paranasal sinuses and palate. Extranasal locations include the skin, soft tissue, gastrointestinal tract and testis. Patients with nasal disease suffer from nasal obstruction or epistaxis, or extensive mid-facial destruction (so-called lethal midline granuloma). Irrespective of the site of presentation, the lymphomatous infiltrate is diffuse with angiocentric and angiodestructive features and frequent necrosis. Neoplastic cells may be small, medium-sized, large or anaplastic with numerous mitotic figures and azurophilic granules in Giemsa-stained touch preparations (Figure 20.18). Phenotypically, they are positive for CD2, CD56, CD3ε and cytotoxic markers, but negative for surface CD3. About one-third of cases expresses CD30. *TCR* and *IGHV* genes are usually in germline configuration, the former being clonally rearranged in a few instances. The prognosis is variable, being always poor for cases occurring outside the nasal cavity. Survival has been improved with more intensive regimens, including up-front radiotherapy and L-asparaginase. The WHO-HAEM5 recognises these tumours but has eliminated the term nasal type.

Intestinal T-cell lymphomas

Intestinal T-cell lymphomas include enteropathy-associated T-cell lymphoma (EATL), monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL, intestinal T-cell lymphoma, NOS and indolent clonal T-cell lymphoproliferative disorder of the gastrointestinal tract, and Indolent NK-cell lymphoproliferative disorder of the gastrointestinal tract (see also Chapter 24).

Enteropathy-associated T-cell lymphoma

EATL is an intestinal tumour of intraepithelial T lymphocytes that occurs in individuals with coeliac disease. It consists of medium-sized to large lymphoid cells admixed with numerous histiocytes and eosinophils and associated with necrosis. The adjacent small intestinal mucosa shows villous atrophy, crypt hyperplasia, increased lamina propria lymphocytes and plasma cells and intraepithelial lymphocytosis (Figure 20.19). The disease occurs more often in areas with a high prevalence of coeliac disease (i.e. northern Europe) and has a strong association with *HLA-DQA1*0501* and *HLA-DQB1*0201* genotypes. EATL may be preceded by type II refractory coeliac disease that is now included in the ICC classification. In particular, 30–52% of patients with type II refractory coeliac disease (RCD2), characterised by an aberrant clonal intraepithelial population, evolve to frank EATL within 4–6 years. Patients (usually adults) present with abdominal pain, frequently associated with intestinal perforation. The tumour forms one or more ulcerating mucosal masses that invade the wall of the intestine (frequently jejunum or ileum). Neoplastic cells are positive for CD3, CD7, CD103, TCR-β and cytotoxic molecules, negative for CD4, CD5 and MATK, with variable expression of CD8 and CD30. TCRβ and γ genes are always clonally rearranged. Cytogenetics reveals that most EATLs (~80%) either display gains of the 9q34 region, which harbours known proto-oncogenes (e.g. *NOTCH1*, *ABL1* and *VAV2*) or, alternatively, deletions of 16q12.1. Similar changes are also observed in MEITL. However, EATL frequently shows gains of chromosomes 1q and 5q, which are less common in MEITL. Loss at 9p21 (*CDKN2A/B*) and 17p12-13.2 (*TP53*) are common (25–50%) Sequencing studies have shown recurrent mutations in constituents of the JAK-STAT signalling pathway. The prognosis is poor, with death frequently resulting from abdominal complications.

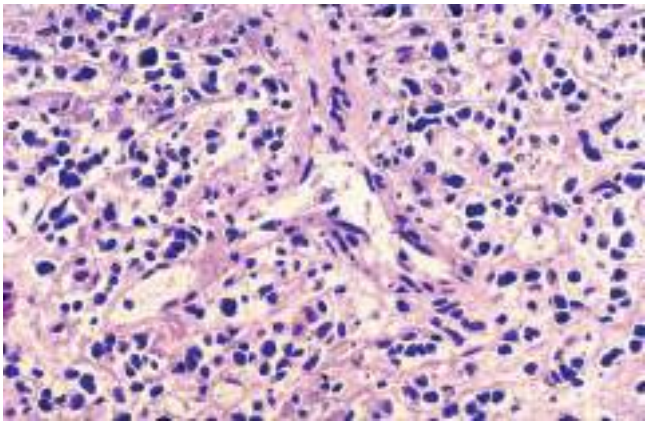

Figure 20.18 Destructive lesion of the nasal cavities in the course of extranodal NK/T-cell lymphoma, nasal type.

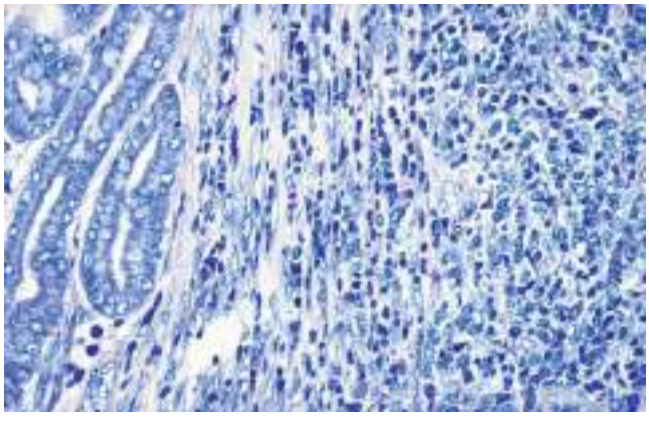

Figure 20.19 Enteropathy-associated T-cell lymphoma. Remnants of the mucosa are seen on the left-hand side.

Monomoprphic intestinal T-cell lymphoma

MEITL is a primary intestinal T-cell lymphoma derived from intraepithelial lymphocytes. It has no clear association with coeliac disease. MEITL has a worldwide distribution, with a higher prevalence amongst Asians, Hispanics and American indigenous populations. It is composed of monomorphic medium-sized cells with no inflammatory background and rare necrosis. Enteropathic changes in the surrounding or adjacent mucosa consists of focal or extensive epitheliotropism in the absence of villous atrophy and crypt hyperplasia. 'MEITL has a distinctive immunophenotype ($CD3^+CD4^-CD5^-CD8^+CD56^+$, $MATK^+$). In a significant proportion of cases, neoplastic cells carry γδ-TCR. Gain of 9.34.3 and 8q24 (*MYC*) are detected in most instances. Activating mutations of *STAT5B* are frequently observed, along with *SETD2* mutations. EBV is negative.

Intestinal T-cell lymphoma, NOS

Intestinal T-cell lymphoma, NOS corresponds to tumours more often localised in the colon, which cannot be assigned to any of the above categories. This can often be due to an inadequate biopsy and/or incomplete clinical information.

Indolent clonal T-cell and NK lymphoproliferative disorders of the gastrointestinal tract

Indolent clonal T-cell lymphoproliferative disorder of the gastrointestinal tract is a clonal T-cell disorder that can affect the mucosa of the gastrointestinal tract, most commonly of the small intestine and colon. The lymphoid proliferation appears monotonous, consists of small cells and involves the lamina propria, usually sparing the mucosal glands. It expresses CD3, mainly CD4 and less frequently CD8 or double negative. The Ki-67 marking is below 10%. The clinical course is indolent and most patients do not respond to conventional chemotherapy. Occasional cases progress to a higher-grade T-cell lymphoma with spread beyond the gastrointestinal tract. The NK lymphoproliferative disorder of the gastrointestinal tract is now recognised as a neoplasm with very indolent behaviour.

Hepatosplenic T-cell lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) is a rare neoplasm derived from cytotoxic T cells, mostly of the γδ type. It mainly affects young adults, with male predominance. Up to 20% of these lymphomas arise in the setting of chronic immunosuppression, usually for solid organ transplantation or prolonged antigenic stimulation. It may also occur in patients, especially children, treated with azathioprine and infliximab for Crohn's disease. Clinically, it is characterised by hepatosplenomegaly, systemic symptoms and marked thrombocytopenia. Morphologically, neoplastic cells are monotonous, with medium-sized nuclei, loosely condensed nuclear chromatin, inconspicuous nucleoli and a rim of pale cytoplasm. In the spleen, they infiltrate the red pulp cords and sinuses with atrophy of the white pulp, while in the liver and bone marrow, they show intrasinusoidal diffusion (Figure 20.20). Phenotypically, most cases are positive for CD3 and TCR-δ1, partly positive for CD56 and CD8, and negative for TCR-αβ, CD4 and CD5 (Table 20.5). A minority carries the α/β dimer. The cells express TIA1 and granzyme-M but not granzyme-B and perforin. They have rearranged *TCR*-γ genes. Cases of γδ origin show biallelic rearrangement of *TCR*-δ genes. Isochromosome 7q is present in most instances. Trisomy 8 and loss of a sex chromosome may also be present. In more than 60% of cases, chromatin-modifying genes, including *SETD2*, *INO80* and *ARID1B,* are mutated. Furthermore, in 40% of HSTCLs, missense mutations in *STAT5B* and more rarely *STAT3* have been found, in keeping with the enrichment in genes of the JAK/STAT pathway of gene expression profile. The course is aggressive, with initial response to chemotherapy, but rapid relapse. The median survival is less than 2 years.

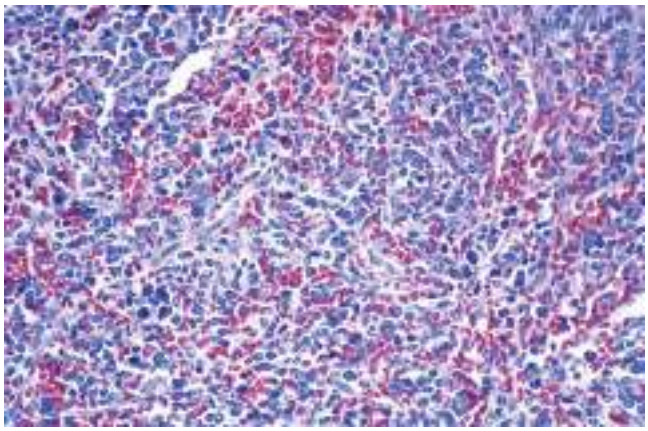

Figure 20.20 Splenic red pulp involvement by hepatosplenic T-cell lymphoma.

Subcutaneous panniculitis-like T-cell lymphoma

Subcutaneous panniculitis-like T-cell lymphoma is a rare cytotoxic T-cell lymphoma that preferentially infiltrates subcutaneous tissue, is slightly commoner in females and has a broad age spectrum. Cases expressing *TCR*-γδ are excluded and instead classified as primary cutaneous γδ T-cell lymphoma. About 20% of patients have an associated autoimmune disease, mostly systemic lupus erythematosus. Patients present with multiple subcutaneous nodules, usually in the absence of other involved sites. Systemic symptoms are recorded in more than 50% of patients. Cytopenias and elevated liver function tests are common, and frank HPS is seen in 15–20%. The infiltrate consists of cells homogeneously sized in the single case, although the cell size can vary form case to case. It involves the fat lobules with riming around individual fat cells and usually

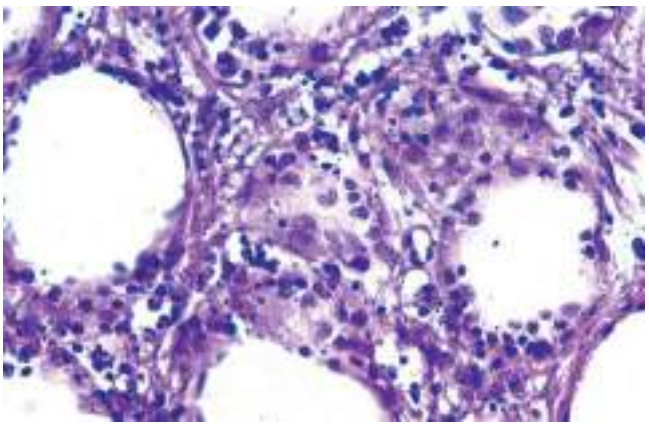

Figure 20.21 Example of subcutaneous panniculitis-like T-cell lymphoma. Features of 'rimming' are easily seen.

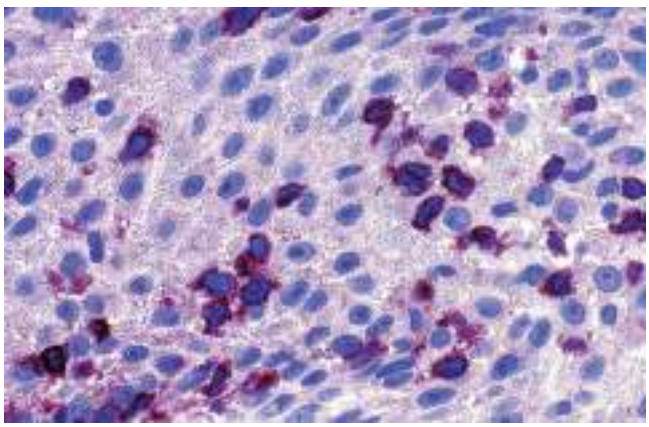

Figure 20.22 Mycosis fungoides. The epidermis is infiltrated by neoplastic T cells with cerebriform nuclei and strong CD3 expression.

spares septa as well as the overlying dermis and epidermis (Figure 20.21). Vascular invasion is seen occasionally, while necrosis and karyorrhexis are common. The cells have a mature αβ T-cell phenotype (βF1$^+$), usually CD8$^+$ with expression of cytotoxic molecules and negative for CD56. The neoplastic cells show rearrangement of TCR genes and are negative for EBV. Dissemination to lymph nodes and other organs is rare. The 5-year overall survival (OS) is 80%; however, if HPS occurs, the prognosis is poor.

Mycosis fungoides

Mycosis fungoides is the commonest primary cutaneous T-cell lymphoma (CTCL) and is characterised by epidermotropic infiltrates of small to medium-sized T lymphocytes with cerebriform nuclei (Figure 20.22) (see also Chapter 24). It usually affects adults or the elderly with a male predominance, but can also occur in children and adolescents. The disease is limited to the skin, often confined to sun-protected areas, with classical evolution of

patches, plaques and tumours. Extracutaneous dissemination occurs in advanced stages. Erythrodermic manifestations at presentation or during the course of the disease are rare. They lack the haematological criteria of Sézary syndrome. Mycosis fungoides slowly progresses over years or sometimes decades. Histological transformation (i.e. >25% blasts in the dermal infiltrates) occurs mainly in the tumour stages. The typical phenotype is $CD2^+CD3^+TCR\text{-}\beta^+CD5^+CD4^+CD8^-CD7^-$. Recently, some reports have highlighted occasional cases expressing follicular T-helper (FTH) markers or γδ T-cell phenotype. Partial expression of CD30 may be found in all stages but is more frequent in plaques and tumours. *TCR* genes are clonally rearranged in most patients, when sensitive techniques are applied. By whole-genome sequencing, it has been observed that *PD1* mutations drive aggressive behaviour. The single most important prognostic factor is the clinical stage. In the more advanced stages, the prognosis is poor, as it is in the case of histological transformation. Rare clinical–morphological variants include folliculotropic mycosis fungoides, pagetoid reticulosis and granulomatous slack skin.

Sézary syndrome

Sézary syndrome (SS) is a distinct entity, which is defined by the triad of erythroderma, generalised lymphadenopathy and presence of neoplastic T cells with cerebriform nuclei (so-called Sézary cells) in skin, lymph nodes and blood (see also Chapter 24). In addition, one or more of the following criteria are required: an absolute Sézary cell count ≥1000/μl, a CD4/CD8 ratio over than 10/1 and loss of one or more T-cell antigens. SS is a rare disease accounting for less than 5% of CTCLs. It occurs in adults, with a male predominance. The histological and phenotypic features in Sézary syndrome may be similar to those of mycosis fungoides. *TCR* genes are clonally rearranged. NGS studies have revealed mutations predicted to affect chromatin, immune surveillance, MAPK signalling, NF-kB signalling, PI-3-kinase signalling, RHOA/cytoskeleton remodelling, RNA splicing), T-cell receptor signalling and T-cell differentiation. Mutations or deletions of *TP53* and deletions of *CDKN2A* are frequently encountered. The 5-year OS is 10–30%.

Primary cutaneous CD30-positive T-cell lymphoproliferative disorders

These lesions include primary cutaneous anaplastic large-cell lymphoma (C-ALCL) and lymphomatoid papulosis, which form a spectrum with overlapping histopathological and phenotypic features. Their clinical appearance and course are therefore critical for the diagnosis.

Primary cutaneous anaplastic large-cell lymphoma

C-ALCL is composed of large cells with an anaplastic, pleomorphic or immunoblastic morphology, the vast majority of which express CD30. By definition, C-ALCL should not be preceded by or coincide with mycosis fungoides. It must also be distinguished from systemic ALCL, which is a different entity. Most patients present with solitary or localised nodules or tumours, and sometimes papules located on the trunk, face, extremities or buttocks that often undergo ulceration and sometimes show partial or complete spontaneous regression, as in lymphomatoid papulosis. Besides CD30 positivity, the neoplastic cells display an activated $CD4^+$ T-cell phenotype, with variable loss of CD2, CD5 and/or CD3. Unlike systemic ALCL, C-ALCL expresses CLA, but not EMA or ALK. The latter molecule has been reported in some exceptional cases, which run the same course as the negative ones. Of course, under these circumstances, it is pivotal to exclude a systemic ALCL ALK^+. Unlike Hodgkin and Reed–Sternberg cells, staining for CD15 is generally negative. Most cases show clonal *TCR* gene rearrangement. In a proportion of cases, it has recently found the occurrence of *DUSP22* rearrangement, which requires the exclusion of an underlying systemic ALCL, ALK^- (see below). The prognosis is favourable, with a 10-year OS of approximately 90%, although local relapses are frequent.

Lymphomatoid papulosis

Lymphomatoid papulosis (LyP) is a chronic, recurrent, self-healing skin disease that most often occurs in adults, with male preponderance, affects trunk and extremities and is characterised by paradoxical eruptions of papular, papulonecrotic and/or nodular lesions that tend to disappear within 3–12 weeks, possibly leaving a scar. The duration of the disease may vary from several months to over 40 years. The prognosis is excellent. Morphologically, the large CD30-positive cells may be intermingled with a variable number of inflammatory cells or predominate as a monotonous population. The phenotype is similar to that of C-ALCL. Depending on the amount and distribution of atypical cells, five variants of LyP (A–E) are recognised, which can mimic other conditions, including mycosis fungoides and primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma. More recently, a further variant has been reported, characterised by *DUSP22* rearrangement, as observed in ALCL ALK^- (see below). Clonally rearranged *TCR* genes are detected in about 60% of lesions.

Primary cutaneous peripheral T-cell lymphoma, rare types

Primary cutaneous γδ T-cell lymphoma

This tumour consists of a clonal proliferation of activated γδ T cells with a cytotoxic phenotype. This lymphoma is rare (1% of CTCLs) and more often observed in the extremities of adults with no sex predilection. It may be predominantly epidermotropic with patches/plaques or may give rise to deep dermal or subcutaneous tumours, with or without epidermal necrosis and ulceration. Dissemination to mucosal and other extranodal sites

is frequent. HPS may occur. 'B' symptoms are seen in most patients. The tumour cells characteristically exhibit a βF1−CD3$^+$CD2$^+$CD5$^-$CD7$^{+/-}$CD56$^+$ phenotype with strong expression of cytotoxic proteins. The cells are strongly positive for *TCR*-δ and γ with appropriate detection methods. The cells show clonal rearrangement of the *TCR*-γ and *TCR*-δ genes. *TCR*-β may be rearranged or deleted but is not expressed. Primary cutaneous γδ T-cell lymphoma is resistant to multiagent chemotherapy and/or radiation and has a poor prognosis, with a median survival of approximately 30 months.

Primary cutaneous CD8$^+$ aggressive epidermotropic cytotoxic T-cell lymphoma

Primary cutaneous CD8$^+$ aggressive epidermotropic cytotoxic T-cell lymphoma is characterised by proliferation of epidermotropic CD8$^+$ cytotoxic T cells, aggressive clinical behaviour and a short survival. It should be differentiated from LyP variant E and CD8$^+$ mycosis fungoides. Clinical information is essential. Conversely to the latter forms, primary cutaneous CD8$^+$ aggressive epidermotropic cytotoxic T-cell lymphoma shows rapid dissemination of ulcerated nodules, tumours or plaques, with possible spread to lungs, testes, CNS and oral mucosa.

Primary cutaneous acral CD8$^+$ T-cell lymphoproliferative disorder

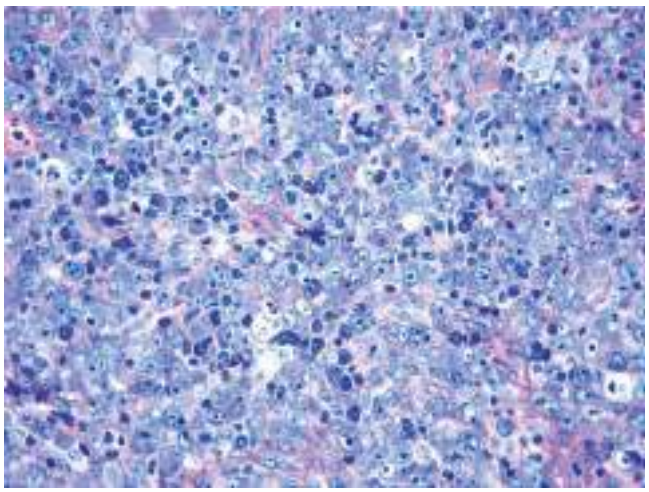
This is a rare cutaneous tumour characterised by skin infiltration of clonal atypical medium-sized to large cytotoxic lymphocytes CD3$^+$, CD8$^+$, βF1$^+$ and TIA1$^+$, but granzyme$^-$ and perforin$^-$. The Ki-67 index is below 10%. The tumour is clinically characterised by preferential involvement of acral sites (in particular the ears) and by a good prognosis. Both the ICC and WHO-HAEM5 have proposed to substitute the previous term of lymphoma by lymphoproliferative disorder to emphasise the very indolent nature of these tumours.

Primary cutaneous CD4$^+$ small/medium T-cell lymphoproliferative disorder

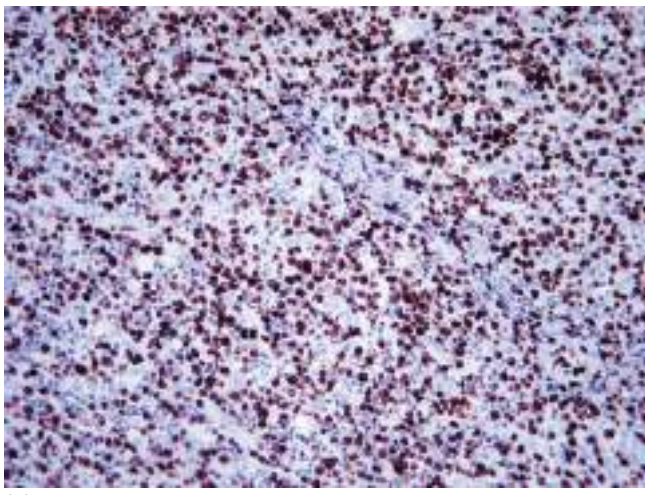
Primary cutaneous CD4$^+$ small/medium T-cell lymphoproliferative presents with a solitary skin lesion in face, neck or upper trunk. The atypical CD4$^+$ T cells are admixed with variable amounts of small reactive CD8$^+$ T-cells, B-cells, plasma cells and histiocytes (including multinucleated giant cells). Patients have an excellent prognosis, being treated with intralesional steroids, surgical excision or radiotherapy. Local recurrences are rare.

Peripheral T-cell lymphoma, not otherwise specified

Peripheral T-cell lymphoma not otherwise specified (PTCL, NOS) is a heterogeneous group of tumours whereby the diagnosis is established by exclusion of other T-cell lymphoma entities (see also Chapter 24). It accounts for approximately 30% of PTCLs in Western countries. Most patients are adults, with a slight male predominance, and show peripheral lymphadenopathy and 'B' symptoms. Generalised disease is often encountered, with bone marrow, liver, spleen and extranodal tissue involvement. Leukaemic spread is uncommon. The cytological spectrum is extremely broad, from highly polymorphous to monotonous. Clear cells and Reed–Sternberg-like elements can be seen. An inflammatory background is often present (Figure 20.23). The differential diagnosis with ALCL ALK$^-$ may at times be difficult. In fact, some PTCL, NOS tumours almost exclusively consist of CD30$^+$ elements, although they lack hallmark cells and cytotoxic profile. PTCL/NOS usually displays an aberrant T-cell phenotype, with frequent loss of CD5 and CD7. A CD4$^+$CD8$^-$ profile predominates



(a)



(b)

Figure 20.23 Peripheral T-cell lymphoma not otherwise specified. (a) The tumour consists of large cells with immunoblastic-like appearance. (b) The proliferative rate as shown by Ki-67 marking is very high.

in nodal cases. $CD4^+CD8^+$ or $CD4^-CD8^-$ is sometimes seen, as is CD8, CD56 and/or cytotoxic granule expression (Table 20.5). Aberrant CD20 and/or CD79a expression is occasionally encountered. In half of cases, 25–100% of lymphomatous elements carry CD30, which can represent a therapeutic target. Proliferation is high and Ki-67 rates over 80% are associated with poor outcome. *TCR* genes are clonally rearranged. EBV integration is found in some cases. Gene and miRNA expression profiling studies have revealed signatures distinct from those of other PTCLs. In addition, they have allowed the identification of morphologically unrecognisable subtypes, respectively related to T_H1, T_H2 and cytotoxic T-cells. In particular, three main subgroups have been reported, respectively provided with a *TBX21*, *GATA3* or null gene signature. This signature has recently become applicable to formalin-fixed, paraffin-embedded tissue sections, by an immunohistochemical algorithm. The *TBX21*, *GATA3* and null cases are characterised by a more favourable, aggressive and intermediate clinical course, respectively. The behaviour of *TBX21* cases becomes even better, if cytotoxic cases are excluded from their context, which are provided with the worst prognosis amongst PTCLs/NOS. NGS studies have revealed mutations of *TET2, DNMT3A, KMT2D, KMT2C, SETD2*, *LATS1, STK3, ATM, TP53* and *TP63*. PTCL/NOS is highly aggressive with poor response to chemotherapy, frequent relapses and 5-year OS of 20–30%, unless autologous bone-marrow transplantation is used in the first line.

Follicular helper T-cell lymphoma

Both classifications have proposed a unifying view of peripheral T-cell lymphomas with a T follicular helper (TFH) phenotype. Angioimmunoblastic T-cell lymphoma (AITL) type represents the commonest form of TFH lymphomas. Collectively, these neoplasms – which account for at least 25% of PTCLs – express at least two, preferably three of the markers carried by normal FTH cells, i.e. CD10, BCL6, CXCL13, PD1, SAP, ICOS and CCR5 (Figure 20.24). AITL is characterised by a polymorphous infiltrate constantly involving lymph nodes with prominent proliferation of high endothelial venules and follicular dendritic cells (Figure 20.24). Spleen, liver, skin and bone marrow are also frequently affected. It occurs in middle-aged/elderly individuals of both sexes. Virtually all patients present with advanced-stage disease, systemic symptoms, polyclonal hypergammaglobulinaemia, circulating immune complexes, cold agglutinins with haemolytic anaemia, positive rheumatoid factor and anti-smooth-muscle antibodies. Skin rash is frequently observed. Other common findings are pleural effusion, arthritis and ascites. AITL is characterised by partial effacement of the lymph node architecture with sparing of the peripheral cortical sinuses and some follicles. The neoplastic infiltrate is composed of small- to medium-sized lymphocytes, with clear to pale cytoplasm and mild cytological atypia. They often represent a minority of the examined population, being admixed with small reactive lymphocytes, eosinophils, plasma cells and histiocytes. An expansion of EBV-positive B immunoblasts is usually present. TCR genes are clonally rearranged in most cases. Clonal IGHV gene rearrangements are found in about 25–30% of cases and correlate with expanded EBV-positive B cells that may form a large B-cell lymphoma. NGS has identified mutations in *RHOA*, *TET2*, *IDH2*, *DNM3TA*, *FYN* and *ITK/SYK* genes. The search for *RHOA* and *IDH2* mutations may assist in proving the neoplastic nature of the process in cases with a small number of neoplastic cells, in which the detection of *TCR* rearrangement may be hampered. Notably the same clinical and cytological features as well as GEP and WES findings have also been encountered in tumours that in the past were classified as PTCL/NOS and now are named TFH lymphoma, NOS both in the ICC and WHO-HAEM5. These have a diffuse growth pattern without overt hyperplasia of FDCs and HEVs. A third type of TFH lymphomas is recognised with a predominantly follicular growth pattern named TFH lymphoma, follicular type. The clinical course of AILD and other nodal PTCLs of TFH derivation is aggressive with a median survival of less than 3 years. Patients often succumb to infectious complications. Supervening large B-cell lymphoma (often but not invariably EBV positive) can occur.

Anaplastic large-cell lymphoma, ALK^+

ALCL ALK^+ is characterised by large neoplastic cells with abundant cytoplasm and kidney/horseshoe-shaped nuclei (so-called hallmark cells), with a translocation involving the *ALK* gene and expression of both ALK protein and CD30. ALCL with similar morphology and phenotype, but lacking *ALK* rearrangement and ALK protein, is considered as a separate category (ALCL ALK^-). ALCL ALK^+ shows a higher prevalence in the first three decades of life and a male predominance, and frequently involves both lymph nodes and extranodal sites. Most patients present with stage III–IV disease and 'B' symptoms. The morphology may be variable. The 'common' appearance (60% of cases) consists of large tumour cells, frequently with hallmark appearance, that tend to grow within the sinuses, resembling a metastatic tumour (Figure 20.25). Some cases may have a lymphohistiocytic pattern (10%) characterised by few tumour cells overwhelmed by reactive histiocytes. A small-cell variant (5–10%) has been recognised that seems to have a worse prognosis. Some cases (3%) may mimic HL, but the cells are ALK-positive and CD15-negative. Relapses may reveal morphological features different from those seen initially. The tumour cells are CD30 positive. In cases with t(2;5)/*NPM–ALK* translocation, ALK staining is both cytoplasmic and nuclear. In cases with variant translocations, ALK staining may be membranous or cytoplasmic. Most ALCL ALK^+ are positive for EMA, express cytotoxic markers and bear one or more T-cell antigens, although some may have

null phenotype. EBV is negative and the *TCR* gene is rearranged. The most frequent genetic alteration is t(2;5)(p23;q35) involving the *ALK* and nucleophosmin (*NPM*) genes. Variant translocations lead to fusion of the *ALK* gene with other partners on chromosomes 1, 2, 3, 17, 19, 22 and X. All these aberrations result in upregulation and different subcellular distribution of ALK protein, but do not have clinical relevance. ALCL ALK⁺, ALCL ALK⁻ and PTCL/NOS have different chromosomal and gene expression profiles. The IPI predicts the clinical outcome and the 5-year OS is about 80%.

Anaplastic large-cell lymphoma, ALK⁻

ALCL ALK⁻ is morphologically and phenotypically indistinguishable from 'common' ALCL ALK⁺ (Figure 20.26). The tumour affects adults, with a slight male predominance, involves lymph nodes and, less frequently, extranodal sites. Most patients are stage III–IV, often with 'B' symptoms. Usually, the organ architecture is effaced by solid cohesive sheets of neoplastic cells. In the lymph node, the latter tends to diffuse through sinuses, mimicking metastatic carcinoma. Most cases show clonal *TCR* gene rearrangement and EBV is negative. The main differential diagnosis is with PTCL, NOS and classical HL. In this regard, PAX5 staining is useful: classical HL shows weak positivity in most cases, a finding not observed in ALCL ALK⁻. In contrast, the distinction between ALCL ALK⁻ and CD30⁺ PTCL/NOS is not always easy on conventional grounds, especially when no careful search for hallmark cells and cytotoxic markers is performed. Molecular tools based on gene expression and miRNA profiling can assist in this differential diagnosis, even when applied to formalin-fixed, paraffin-embedded (FFPE) material. Such distinction may be relevant. In fact, on average ALCL ALK⁻, although more aggressive than ALCL ALK⁺ (5-year OS 49% versus 80%) has a more favourable course than CD30⁺ PTCL/NOS (5-year OS 32 versus 49%). Recent molecular studies have shed new light on the pathobiology of ALCL ALK⁻. First, a proportion of cases carry *JAK1* and *STAT3* mutations that cause downstream the same effects as the t(2;5)

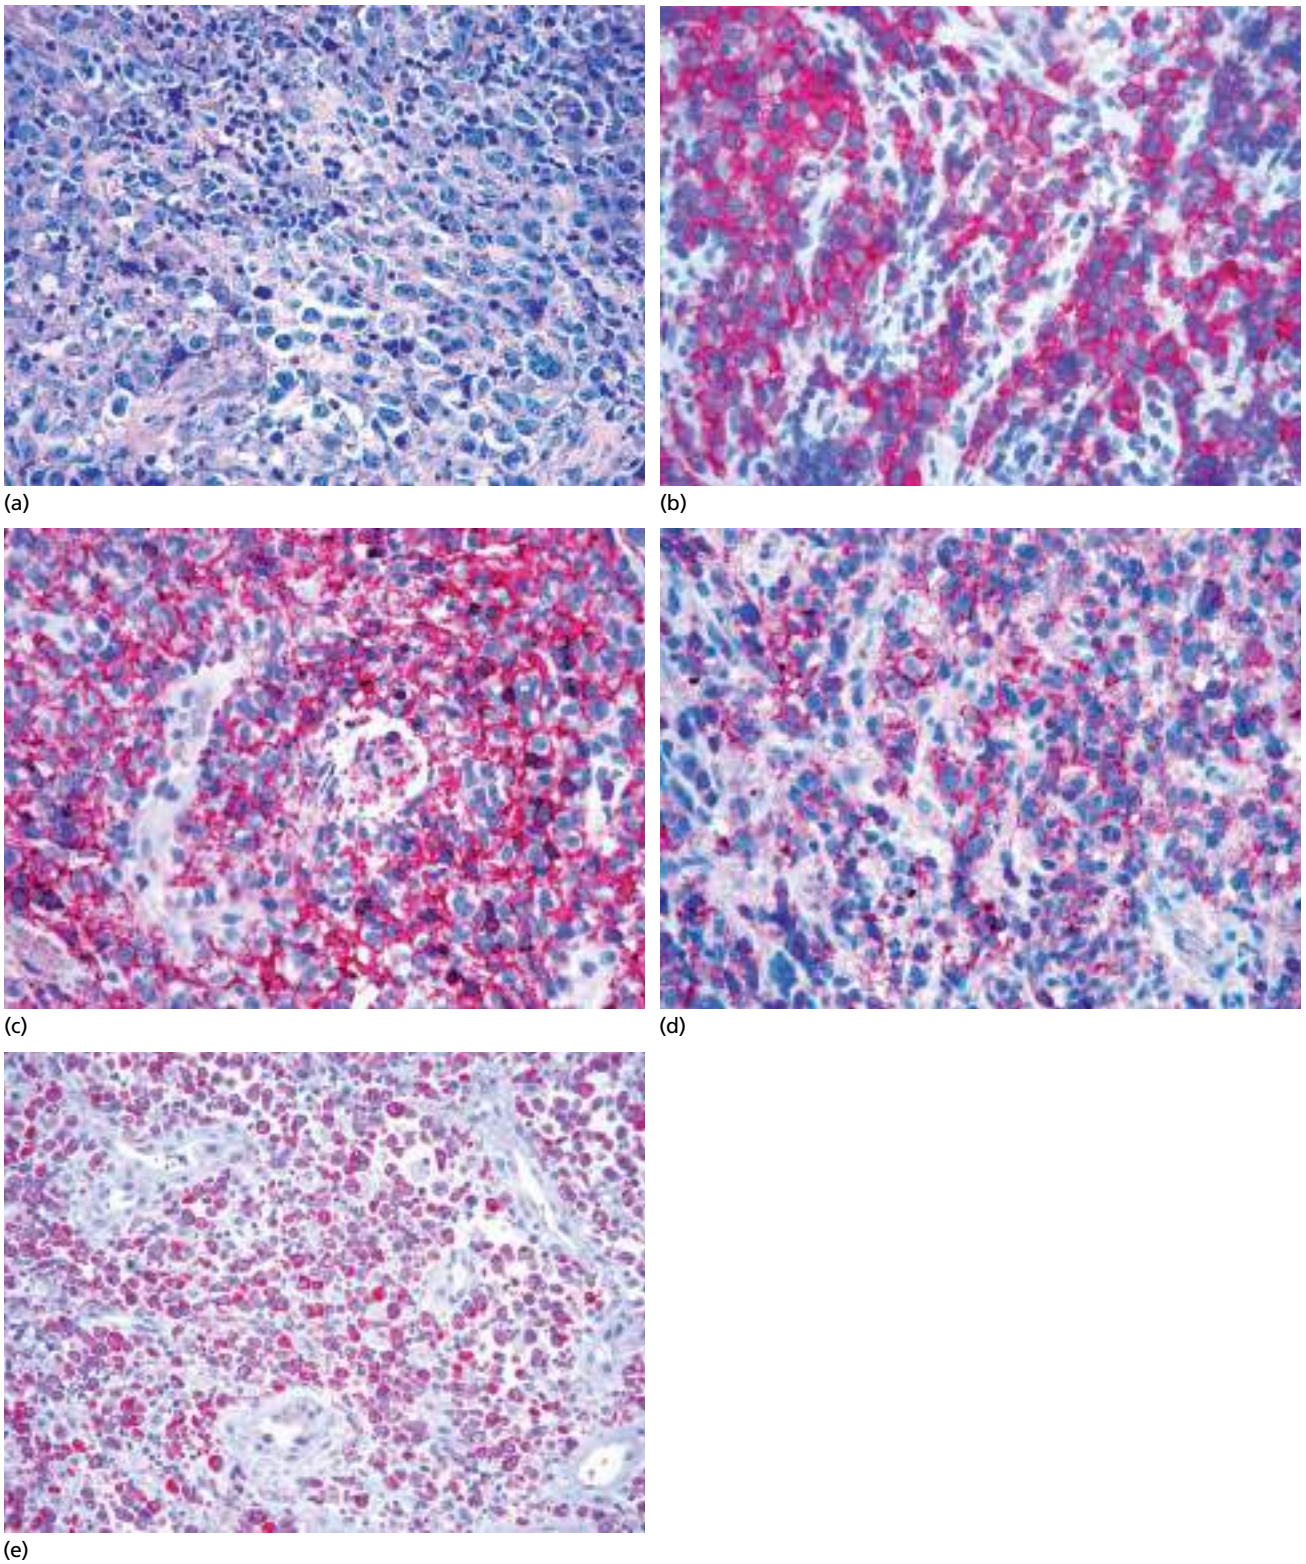

Figure 20.26 Anaplastic large-cell lymphoma, ALK$^-$. (a) The tumour consists of large cells partly showing hallmark appearance, and strong positivity for CD30 (b), CD45 (c), CD3 (d) and granzyme B (e).

and variants. Second, *ERBB4*- truncated transcripts have been detected in about one-quarter of cases, which show oncogenic potential. Third, the search for *DUSP22* and *TP63* rearrangements has allowed the identification of three subcategories amongst ALCLs ALK$^-$. The cases with *TP63* rearrangement (8%) are associated with an aggressive clinical course and poor response to therapy. The ones with *DUSP22* rearrangement (30%) are characterised by a quite monotonous centroblastic-like morphology, strong positivity for IRF4, and negativity for EMA and cytotoxic markers. They have a very good response to therapy with OS rates comparable to ALCL ALK$^+$, a fact that might be due to an active immunological response of the host against the tumour. Finally, the cases triple-negative (i.e. lacking *ALK*, *DUSP22* and *TP63* rearrangements) have an intermediate prognosis.

Breast implant-associated anaplastic large-cell lymphoma

Breast implant-associated anaplastic large cell lymphoma (BIA-ALCL) occurs in individuals, who usually received a textured breast prosthesis because of reconstructive or cosmetic reasons. The prevalence is low (2.03 per 1 million persons-years). The predisposing conditions have not been established yet. BIA-ALCL shows the same features as ALCL ALK$^-$. No *DUSP22* rearrangement has so far been recorded. Importantly, the TNM criteria have been applied to the staging of BIA-ALCL. The cases confined within the periprostatic capsule and/or infiltrating the mammary gland are cured by the removal *en block* of the prosthesis and peri-prosthetic capsule. Those infiltrating the thoracic wall or with systemic diffusion of the disease have a worse prognosis and may require systemic therapy.

Hodgkin lymphoma

HL accounts for about 10% of lymphoid tumours. Irrespective of the histotype, HL is characterised by the following features: (i) usual onset in the lymph nodes, preferentially cervical ones, (ii) predilection for young adults and (iii) small number of mononucleated and multinucleated tumour cells (Hodgkin and Reed–Sternberg cells) within an exuberant inflammatory milieu and often ringed by rosettes of T lymphocytes (see also Chapter 25). Biological and clinical studies have shown that HL comprises two disease entities: nodular lymphocyte-predominant HL (NLPHL) and classical HL. The ICC has proposed to substitute the term Hodgkin by B-cell (nodular lymphocyte predominant B-cell lymphoma) to emphasise the different cells of origin and nature compared to classical HL. The ICC also recognises the close relationship of this entity with TCRLBCL.

Nodular lymphocyte-predominant B- cell lymphoma/ Nodular lymphocyte-predominant Hodgkin lymphoma

This entity is well characterised with a monoclonal proliferation of germinal centre-derived large multilobulated B-cell cells known as 'popcorn' or LP cells (Figure 20.27). These cells reside in a follicular background with large FDC networks filled with non-neoplastic lymphocytes and histiocytes. One-third of the cases diagnosed in the past as NLPHL were lymphocyte-rich classical HL. These cases represent approximately 5% of HL cases. Patients are predominantly males in the fourth decade of life. LP cells are regularly positive for CD20, CD79a, EMA, BCL6 and CD45. In contrast to Hodgkin and Reed–Sternberg cells of classical HL, tumour cells are positive for Oct-2, BOB.1 and immunoglobulin light and/or heavy chains but – with a few exceptions – lack CD15, CD30 and EBV infection. The tumour cells are ringed by TFH cells that are positive for CD3, CD4, PD-1 and (to a lesser extent) CD57. Histologically most NLPBL have a nodular pattern with the large tumour cells mixed in a background of B cells. In some cases the background of small B cells is substituted by increasing number of T-cells and the nodular pattern may become a more diffuse pattern. These cases have a worse outcome. Tumour cells show clonal *IGHV* gene rearrangement, with a high load of somatic mutations that may be ongoing. Aberrant somatic hypermutations of *PAX5*, *PIM1*, *RHOH* and *MYC* genes are recorded in 80% of cases. This entity is indolent with frequent relapses that usually remain responsive to therapy. Advanced stages have an unfavourable prognosis. Progression to large B-cell lymphoma is seen in 1–14% of cases.

Classical Hodgkin lymphoma

Classical Hodgkin lymphoma is a monoclonal B-cell neoplasm composed of Hodgkin and Reed–Sternberg cells (HRSCs) within a variable mixture of reactive lymphocytes, eosinophils, neutrophils, histiocytes, plasma cells, fibroblasts and collagen fibres (Figure 20.28). Based on the microenvironmental composition, four histological subtypes are distinguished: lymphocyte-rich, mixed cellularity, lymphocyte-depleted and nodular sclerosis (characterised by HRSC variants, known as 'lacunar cells'). The immunophenotype and genetic features of HRSCs are identical in these histological subtypes, whereas clinical features and EBV association vary. Classical HL accounts for 95% of HLs, with a bimodal age curve in resource-rich countries, showing a peak at 15–35 years and a second peak in later life. Classical HL most often involves cervical lymph nodes and in approximately 60% of patients (usually with the nodular sclerosis subtype) causes a mediastinal mass. HRSCs typically represent 0.1–10% of the cellular infiltrate

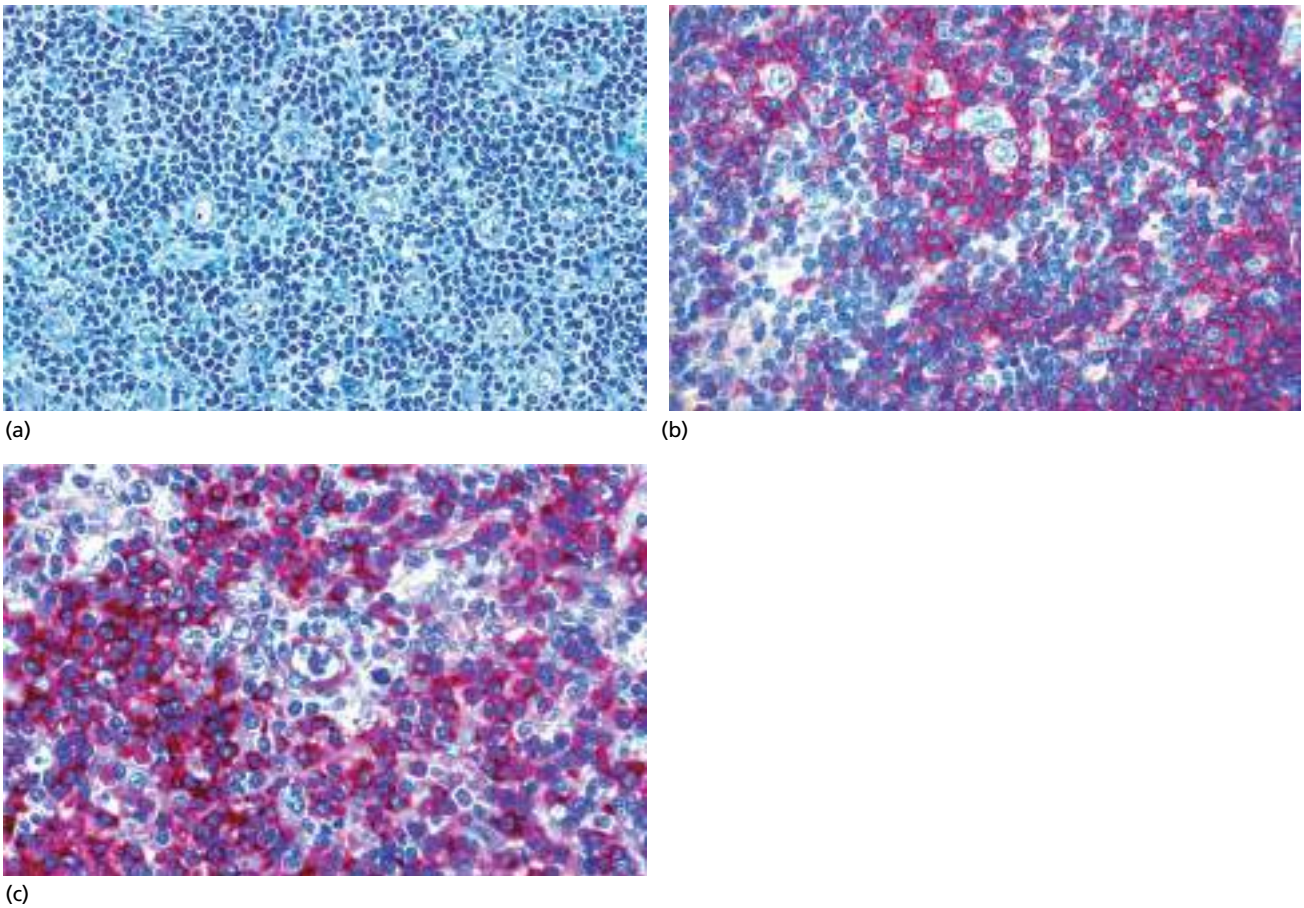

Figure 20.27 Nodular lymphocyte predominant (LP) B-cell lymphoma. (a) Typical LP cells within a milieu of small lymphocytes; (b) The LP tumour cells are surrounded by rosettes of $CD3^+$ T lymphocytes; (c) LP cells and most small lymphocytes express CD79a.

and are CD30 and CD15 positive in nearly all and most cases, respectively. The constitutive expression of CD30 represents the rationale for targeted immunotherapy, extensively applied in the treatment of patients with relapsing/resistant disease. In 30–40% of cases, CD20 may be detected, usually of varied intensity and in a minority of HRSCs. The B-cell nature of neoplastic cells is sustained in about 95% of cases by their expression of PAX5, though weaker than that of reactive B cells. EBV-positive HRSCs show a latency II pattern ($LMP1^+$, $EBNA\text{-}2^-$). Characteristically, the transcription factors Oct-2 and BOB.1 are absent in about 90% of cases, while PU.1 is consistently absent. HRSCs contain clonal IGHV gene rearrangements in more than 98% of cases. The significance of is debatable. Clonal *TCR* gene rearrangements in rare instances. The rearranged *IGHV* genes harbour a high load of somatic hypermutations, usually not ongoing. By analysing microdissected HRSCs, GEP has provided the molecular demonstration of their loss of the B-cell identity, while NGS has shown frequent mutations affecting *STAT6*, *GNA13*, *XPO1* and *ITPKB*. Overall, most cases reveal dysregulation of the JAK-STAT pathway by genetic alterations in multiple genes (also including *STAT3*, *STAT5B*, *JAK1*, *JAK2* and *PTPN1*). The determination of microenvironmental components expressing CD68, CD163 and FoxP3 may assist in better defining the prognosis of patients with classical HL. During the last few years, special attention has been deserved to the expression of

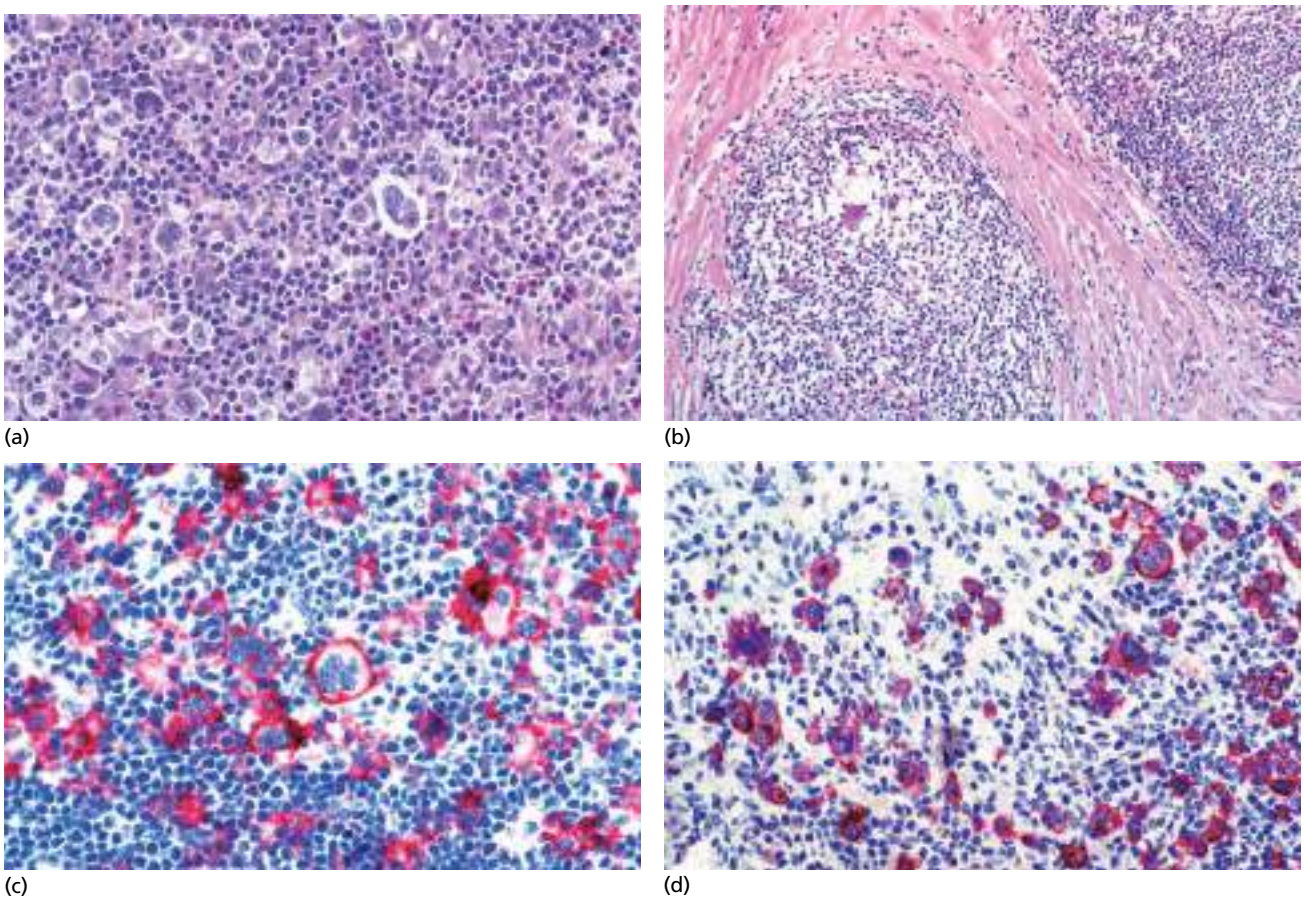

Figure 20.28 Classical Hodgkin lymphoma. (a) Mixed cellularity type; (b) Nodular sclerosing type (H&E, ×100); (c, d) Neoplastic cells positive for CD30 (c) and CD15 (d).

PD-L1 by neoplastic cells (due to copy number alterations of 9p24.1) and tissue macrophages, which contribute to the tumour immune escape along with PD-1$^+$ T-lymphocytes. This has led to the therapeutic usage of immune checkpoint inhibitors in relapsing/resistant cases. More recently, the combination of immune checkpoint inhibitors and anti-CD30 immunotherapy has produced impressive results in patients with relapsing/resistant disease.

CHAPTER 21

Adult acute lymphoblastic leukaemia

21

Clare J Rowntree[1] and Adele K Fielding[2]

[1] Department of Haematology, University Hospital of Wales, Cardiff, UK
[2] Centre for Blood Research, Hull York Medical School, University of York, UK

Introduction

Acute lymphoblastic leukaemia (ALL) is an aggressive malignancy of T or B lymphocytes. The onset of ALL is usually rapid, with patients presenting with signs and symptoms of bone marrow failure. Occasionally patients will present with primary involvement of nodal or extranodal sites, with minimal evidence of bone marrow involvement. In these cases the diagnosis is one of lymphoblastic lymphoma (LL). The distinction between ALL and LL is arbitrary. If a patient presents with a mass lesion and less than 25% blasts in the marrow then the diagnosis is one of LL. Where marrow blasts total more than 25% the diagnosis is of leukaemia.

ALL is primarily a disease of childhood, with 75% of cases occurring in children under the age of 10 years at diagnosis. However, although ALL is rare in adults, there is an increasing incidence with age after the age of 40 years. The aetiology of ALL is currently unknown.

A new presentation of ALL is a clinical emergency and should be diagnosed and treated without delay. Most patients present with a combination of symptoms resulting from bone marrow failure, including fatigue and weakness due to anaemia, haemorrhagic complications of thrombocytopenia and/or signs and symptoms of recurrent infection due to neutropenia. Approximately 10% of patients will have obvious signs of organ involvement at diagnosis with splenomegaly, liver impairment, lymphadenopathy, testicular swelling or meningeal syndrome with neurological symptoms. Patients with T-cell disease may have large mediastinal masses and can present with features of superior vena cava obstruction.

Diagnosis of adult ALL

Morphology

In adults, the blood count will usually be very abnormal, with features of bone marrow infiltration. There is frequently a normochromic normocytic anaemia. The white cell count may be increased (59% of cases), normal (14%) or decreased (27%), and there is usually a thrombocytopenia, with one-third of patients having a platelet count of less than 25×10^9/L at diagnosis. Examination of a blood film reveals circulating lymphoblasts in over 90% of cases. Approximately 15% of patients will have a very elevated white cell count above 100×10^9/L and very occasionally the white cell count can be over 500×10^9/L. It is more common to see very high white cell counts in T-cell disease rather than B-cell disease. Most adults will be anaemic at diagnosis, although severe anaemia <80 g/L is unusual.

A bone marrow aspiration is mandatory for the diagnosis of ALL. The bone marrow will be hypercellular with a marked infiltration of leukaemic blasts, which amount to over 25% of total nucleated cells. The majority of cases will have more than 50% infiltration by leukaemic blasts. In some cases, the marrow may be difficult to aspirate due to increased reticulin and a trephine biopsy should be performed. Blastic transformation of chronic myeloid leukaemia should be ruled out by morphologic examination where possible (presence of basophilia, prominent granulocyte component and dwarf megakaryocytes in the bone marrow). However, the distinction between de novo Ph+ ALL and CML in lymphoid blast phase by morphology can be very challenging. Molecular studies may be helpful, i.e. the presence

Hoffbrand's Postgraduate Haematology, Eighth Edition. Edited by Adam J Mead, Michael A Laffan, Graham P Collins, Deborah Hay, and A Victor Hoffbrand (Consulting Editor).

of the p190 *BCR::ABL1* transcript strongly suggests de novo ALL, although the finding of the p210 *BCR::ABL1* transcript is less helpful as it can occur in both scenarios.

Lymphoblasts in both B-cell and T-cell ALL vary from small blasts with scant cytoplasm, condensed nuclear chromatin and indistinct nucleoli to larger cells with moderate amounts of light blue to blue-grey cytoplasm, occasionally vacuolated, dispersed nuclear chromatin and multiple variably prominent nucleoli. Historically, the FAB classification was used to classify ALL blasts based on morphological appearances and size of blasts. This classification was of no relevance prognostically and included mature B-cell disease (Burkitt lymphoma), which has now been removed from classifications of ALL. Burkitt lymphoma in leukaemic phase can clearly be defined by its different immunophenotype (see below) and is now treated on different protocols to ALL.

The current World Health Organization (WHO) classification, shown in Table 21.1, defines ALL and acute lymphoblastic lymphoma together, grouped by their cell of origin, i.e. B cell or T cell. B-cell disease is then further subclassified, based on the presence of recurrent cytogenetic abnormalities that are known to have prognostic value clinically (Table 21.1).

Table 21.1 WHO classification of ALL.

B-lymphoblastic leukaemia/lymphoma
- B-lymphoblastic leukaemia/lymphoma NOS (not otherwise specified)

Cell-surface marker analysis

In diagnosing ALL, the bone marrow – or peripheral blood if the count is high – should be examined using a panel of monoclonal antibodies to T-cell-associated and B-cell-associated antigens, which will identify most cases of ALL. Aberrant expression of myeloid antigens is not uncommon and should not detract from the correct diagnosis. Both B-cell and T-cell ALL are divided into subtypes based on the pattern of cell-surface markers present on the leukaemic blast cells. These subtypes are defined according to their stage of differentiation, although aberrant or asynchronous antigen expression is common. The European Group for the Immunological characterisation of Acute Leukaemia (EGIL) has defined a unified classification for ALL based only on phenotypes. The World Health Organization (WHO) also classifies ALL according to genetic entity – see Cytogenetics below.

B-lineage ALL

The vast majority of cases of B-ALL express HLA-DR, terminal deoxynucleotidyltransferase (TdT) and CD19. CD79a, CD22 and CD34 are frequently – but not always – expressed and levels can vary. B-ALL accounts for approximately 75% of adult cases of ALL and is subdivided into the following groups:

- *Pro-B-ALL* represents approximately 10% of adult ALL; CD10 is negative, as is cytoplasmic immunoglobulin.
- *Common ALL* (c-ALL) is the major immunological subtype in adult ALL, comprising more than 50% of all cases; c-ALL is characterised by the presence of CD10 and absence of cytoplasmic immunoglobulin.
- *Pre-B-ALL* is characterised by the expression of cytoplasmic immunoglobulin, which is absent in c-ALL, but is identical to c-ALL with respect to the expression of all other cell markers.
- *Mature B-cell ALL* is found in approximately 4% of adult ALL patients and is now classified as Burkitt lymphoma rather than ALL. The blast cells are negative for TdT and express surface antigens of mature B cells, including surface membrane immunoglobulin.

T-lineage ALL

T-cell ALL accounts for approximately 25% of adult ALL. Cells are TdT+, in addition to cytoplasmic CD3+ and CD34+. All cases express the T-cell antigen gp40 (CD7) and they may, according to their degree of T-cell differentiation, express other T-cell antigens, for example the E rosette receptor (CD2) or the cortical thymocyte antigen T6 (CD1). A minority of T-cell ALL blast cells express CD10 together with T-cell antigens. In most cases of T-cell ALL, one or more of the T-cell receptor (*TCR*) genes are rearranged. These properties make it possible to

classify T-cell ALL according to their stage of intrathymic differentiation:

- *Early T-precursor ALL* accounts for 6% of adult ALL and is associated with inferior outcomes compared to other types of T-cell ALL; it shows characteristic T-cell markers (cyCD3 and CD7), but no further differentiation markers.
- *Thymic (cortical) T-ALL* is the most frequent subtype of TALL (10% of ALL). It is characterised by the expression of CD1a; surface CD3 may be present. Since this subtype is associated with a better prognosis, its identification is of particular importance.
- *Mature T-ALL* has a frequency of 6%; the blast cells do not express CD1a, but they are positive for surface CD3.

Genetics

Techniques for diagnosis

ALL is characterised by somatic genetic alterations which initiate and drive leukaemogenesis and have prognostic relevance. These lesions consist of recurring chromosome abnormalities, kinase-activating gene fusions, or so-called 'Ph-like' ALL. Cytogenetic and/or other relevant genetic screening to identify these lesions is mandatory at diagnosis. Whilst examination of metaphases is now less commonly carried out, fluorescence *in situ* hybridisation (FISH) with specific probes e.g. for *BCR::ABL1*, *MLL::AF4, ETV6::RUNX1* is a common, rapid and effective way to screen for known translocations. Screening by reverse transcriptase polymerase chain reaction (RT-PCR) for the potential *BCR::ABL1* transcripts, p190 and p210, should also be performed at diagnosis. Using standard techniques, about 20–30% of B-ALL cases cannot be classified into current WHO genetic subgroups shown in the table. Whole genome sequencing, RNA sequencing and other genomic studies such as SNP (single nucleotide polymorphism) arrays and array CGH (comparative genomic hybridisation) have revealed several recurring genetic abnormalities amongst those without the 'typical' driver lesions. Examples include fusions involving *MEF2D*, *DUX-4* or *ZNF384*.

Summary of most common genetic lesions

Up to 70% of children between 1 and 10 years presenting with ALL will have so-called 'good-risk' cytogenetics with the presence of either hyperdiploidy (between 51 and 65 chromosomes) or the translocation t(12;21)(p12;q22), resulting in the fusion product *ETV6::RUNX1* (see Chapter 22). By contrast, 'good-risk' cytogenetic abnormalities are rare in adult ALL and decrease with increasing age. However, when good-risk aberrations are detected at diagnosis in adults they carry the same prognostic value as they do in children. Conversely, the incidence of poor-risk cytogenetics, such as hypodiploidy and *BCR::ABL1* (Philadelphia chromosome)-positive ALL generally rises with age, although there appears to be a plateau in incidence above the age of 50 years.

The poor prognostic impact of the finding of a t(9;22) leading to the *BCR::ABL1* fusion – approximately 25% of adults ALL – has long been recognised. The so-called Philadelphia chromosome t(9;22)(q34;q11), results from a translocation involving the *BCR* gene on chromosome 22 and the *ABL1* gene on chromosome 9. One-third of adult patients with *BCR::ABL1+ ALL* will have the 'Major'-*BCR* rearrangement (resulting in a 210-kDa protein), as seen in chronic myeloid leukaemia, detectable by PCR. The remaining two-thirds will have the 'minor'-*BCR* rearrangement (resulting in a 190-kDa protein). Patients with *BCR::ABL1+* ALL were – in the past – less likely to enter complete remission (CR) with CR rates of 70–80%. Such patients had an overall survival of 15–20%.

ALL treatment protocols have typically assigned patients with *BCR::ABL1+* to 'very high-risk' protocols and a myeloablative transplant has typically been offered, even when sibling donors have not been available. The advent of tyrosine kinase inhibitors has completely changed the outcome for this subset of patients, as discussed below.

The translocation t(4;11)(q21;q23), involving the *KMT2A* gene on chromosome 11q23, has also been recognised as carrying a poor prognosis in adult ALL. In an analysis of data from 1522 adult patients participating in the UKALLXII/ECOG2993 study, the following four groups of patients with distinct karyotypes were shown to have markedly inferior rates of event free survival and overall survival when compared to the whole cohort: t(9;22), t(4;11), complex karyotype (defined as five or more chromosomal abnormalities) and low hypodiploidy/near triploidy. Amongst patients with *BCR::ABL1*-negative ALL, the prognostic relevance of these abnormalities was independent of other previously known poor prognostic factors, such as age and presenting white cell count. This was the first demonstration that cytogenetic subgroups other than *BCR::ABL1* can be used for risk stratification of adults with ALL. It is highly likely that additional risk stratifications based on genetic abnormalities at diagnosis will be part of routine clinical practice within the next 5–10 years.

Minimal residual disease

Morphological detection of remission post treatment has very limited sensitivity of 1–5% and a patient in a morphological complete remission may still bear a considerable disease burden. It is now possible to quantitate treatment response very accurately and reproducibly, to the level of 1 leukaemic cell in 10,000 using various methods, as shown in Table 21.2. The most standardised method identifies patient-specific immunoglobulin heavy chain and *T-cell* receptor gene rearrangements, which can then be quantified by real-time polymerase chain reaction (PCR) in a patient-specific assay with a sensitivity of 10^{-5} (1 in 100,000 cells). Flow cytometry can also be used to determine a

Table 21.2 Comparison of MRD assays in ALL.

Method	Applicability	Sensitivity of leukaemia cell detection	Specimens needed
Flow cytometry	Approx. 95%	1 in 10^4	Fresh cells
RQ-PCR for Ig/*TCR* rearrangements	Approx. 90%	1 in 10^5	DNA
RQ-PCR for fusion gene transcripts such as *BCR::ABL1*	Depends on frequency of abnormality; *BCR::ABL1* is 20–25%	1 in 10^5	RNA
High throughput sequencing to quantify Ig/*TCR* rearrangements	Approx. 90%	1 in $10^{5–6}$	DNA

disease-associated immunophenotype at diagnosis, which can also form the basis of an minimal residual disease (MRD) assay. A diagnostic sample is required in both cases. Where there is a known molecular abnormality such as *BCR::ABL1*, this can also be quantified, using a housekeeping gene as a reference standard for PCR, to determine the level of residual ALL with similar sensitivity. Both molecular and flow cytometry techniques for quantification of MRD are labour intensive when performed properly and should be carried out in reference laboratories, according to standardised protocols. Studies in both childhood and adult ALL have shown a significant correlation between MRD levels and subsequent relapse risk (see Chapter 22). However, it should be noted that interpretation of MRD results is always protocol-dependent. It is not yet known whether high-risk interventions such as stem cell transplant can overcome the poor prognostic significance of residual MRD, and this question is the current focus of several ongoing large Phase III clinical trials.

It is also possible to use MRD analysis to monitor the progress of patients in remission in order to detect impending relapse – the time window between molecular and haematological relapse is on the order of a few months, possibly yielding an opportunity for early intervention. However, the clinical potential of treatment prior to haematological relapse is not yet clear. Table 21.2 shows a comparison of different methods for detection of MRD with advantages and disadvantages.

Prognostic and predictive factors in ALL

A prognostic factor is a clinical or genetic characteristic that is objectively measurable and that provides information on the likely outcome of the ALL in an untreated person. A predictive factor is a clinical or genetic characteristic that provides information on the likely benefit from treatment. Prognostic and predictive factors are summarised in Table 21.3. A number of clinical and genetic factors have been clearly identified as poor prognostic factors in ALL; advancing age, higher presenting white cell count at diagnosis, presence of CNS disease, certain cytogenetic abnormalities, specific immunophenotypes and specific genetic abnormalities such as *IKZF1* (Ikaros gene) deletions. Response to initial therapy, early steroid response and quantification of minimal residual disease at protocol-defined time points are validated predictive factors.

Most current treatment strategies and trials take some or all of these factors into account in defining a risk status in ALL. There is no universally accepted algorithm by which risk status is measured in all cases. Additionally, whilst there is sometimes a relationship between these poor risk factors (for example, patients with T-ALL often have very high presenting white cell counts and CNS disease), the poor outcome portended by initial presence of poor prognostic factors can be superseded by a good treatment response, as documented by having a negative MRD status after induction. Hence, how we vary our therapeutic strategy in response to prognostic and predictive factors will change as studies identify new markers and define their inter-relationships. Figure 21.1 (kindly provided by Anthony Moorman and Christine Harrison, Leukaemia Research Cytogenetics Group, Northern Institute for Cancer Research, Newcastle University, UK) is based on an analysis of adults entered into UK trials of ALL. It shows the genetic heterogeneity of adult ALL, detailing some of the relationships between risk groups and further, their relationships with outcome. Table 21.3 highlights some of the factors that are currently taken into account internationally when making decisions about prognosis and approach to treatment.

Initial approach to a patient with ALL

Clinical presentation

The majority of adult patients with ALL will present with clinical symptoms of bone marrow failure. The history is often very short, i.e. a few weeks and patients frequently report a very rapid progression of their symptoms. The commonest symptoms

Table 21.3 Factors commonly used to predict outcome or stratify therapy.

Factor	Poor risk	Neutral or good risk
Presenting WCC	$>30 \times 10^9$/L B ALL $>100 \times 10^9$/L T-ALL	Low presenting WCC
Age	Worse outcome with advancing age	Younger age
Immunophenotype	T-cell phenotype better outcome than B-cell phenotype Early T precursor ALL (ETP) Expression of CD20 (some studies)	Expression of myeloid antigens
Cytogenetics	t(9;22) (*BCR::ABL1*) t(4;11) (*MLL::AF4*) Complex karyotype (five or more chromosomal abnormalities) Low hypodiploidy/near triploidy	t(12;21) (*ETV6::RUNX1*) Hyperdiploidy
Specific genetic abnormalities	*IKZF1* deletions, particularly in Ph+ ALL	*NOTCH1* and *FBXW7* mutations in T-ALL
Early response to steroid	Poor initial response to steroid therapy	
MRD	Positive signal at protocol-relevant time point predicts less good outcome	Negative signal at protocol-relevant time point

that cause the patient to seek medical advice are recurrent infection or petechiae or other haemorrhagic problems. Weakness and fatigue due to anaemia are also common presenting features. Approximately half of all patients will have findings of lymphadenopathy, splenomegaly and/or hepatomegaly at presentation. According to data from two large German trials, 14% of patients will have a mediastinal mass at presentation and the majority of these (85%) will subsequently be shown to have T-cell disease. Examination of the cerebral spinal fluid (CSF) at diagnosis reveals leukaemic blasts in 7% of patients, although only 4% have central nervous system (CNS) symptoms such as headache, vomiting, lethargy and cranial or peripheral nerve dysfunction.

Almost any organ can be infiltrated by leukaemic blasts at diagnosis and approximately 10% of patients will have demonstrable involvement clinically. Pleural effusions are most common and tend to occur in association with mediastinal masses in T-cell disease. Bone pain at presentation is rare in adults compared to children, with bone lesions being demonstrated in 1% of adult patients. Involvement of the testes is very rare (<1%) in adult male patients. Leukaemic infiltration of other organs such as lung, kidney and skin is rarely observed and tends to be associated with poorer outcomes.

Diagnostic approach

A new diagnosis of ALL is a medical emergency and should be investigated and treated without delay. All patients require a detailed history to be taken alongside a thorough medical examination. The admitting clinician needs to pay particular attention to signs and symptoms of pre-existing infection, including fungal infection. Patients should be asked specifically about the presence of symptoms of sinusitis and haemoptysis. A careful neurological examination is also mandatory.

Investigations at diagnosis must include a full blood count, blood film examination and bone marrow. Urgent biochemical testing, including analysis of urate levels, calcium, renal function, liver function and lactate dehydrogenase (LDH) are required. A coagulation screen should also be performed.

Many modern protocols include the use of monoclonal antibodies such as rituximab in induction. Testing of hepatitis B and C serology prior to the start of therapy is mandatory if rituximab is to be used. It is also good practice to check the HIV status of a patient before starting induction chemotherapy.

A lumbar puncture should be performed in patients at diagnosis, if there is clinical evidence of CNS involvement with leukaemia, to assess whether or not there is leukaemic infiltration of the CSF. Ideally the CSF should be examined by flow cytometry. If there is no clinical suspicion of CNS involvement then many protocols start systemic chemotherapy to lower the disease burden before the first lumbar puncture is performed to reduce the risk of introducing disease into the CSF. Intrathecal methotrexate should always be given at the first lumbar puncture.

A chest X-ray (CXR) is mandatory for all newly diagnosed patients with ALL, but computerised tomography (CT) scans are not routinely required. However, where there is clinical evidence of lymphadenopathy, mediastinal widening or organ infiltration, a CT scan should be performed.

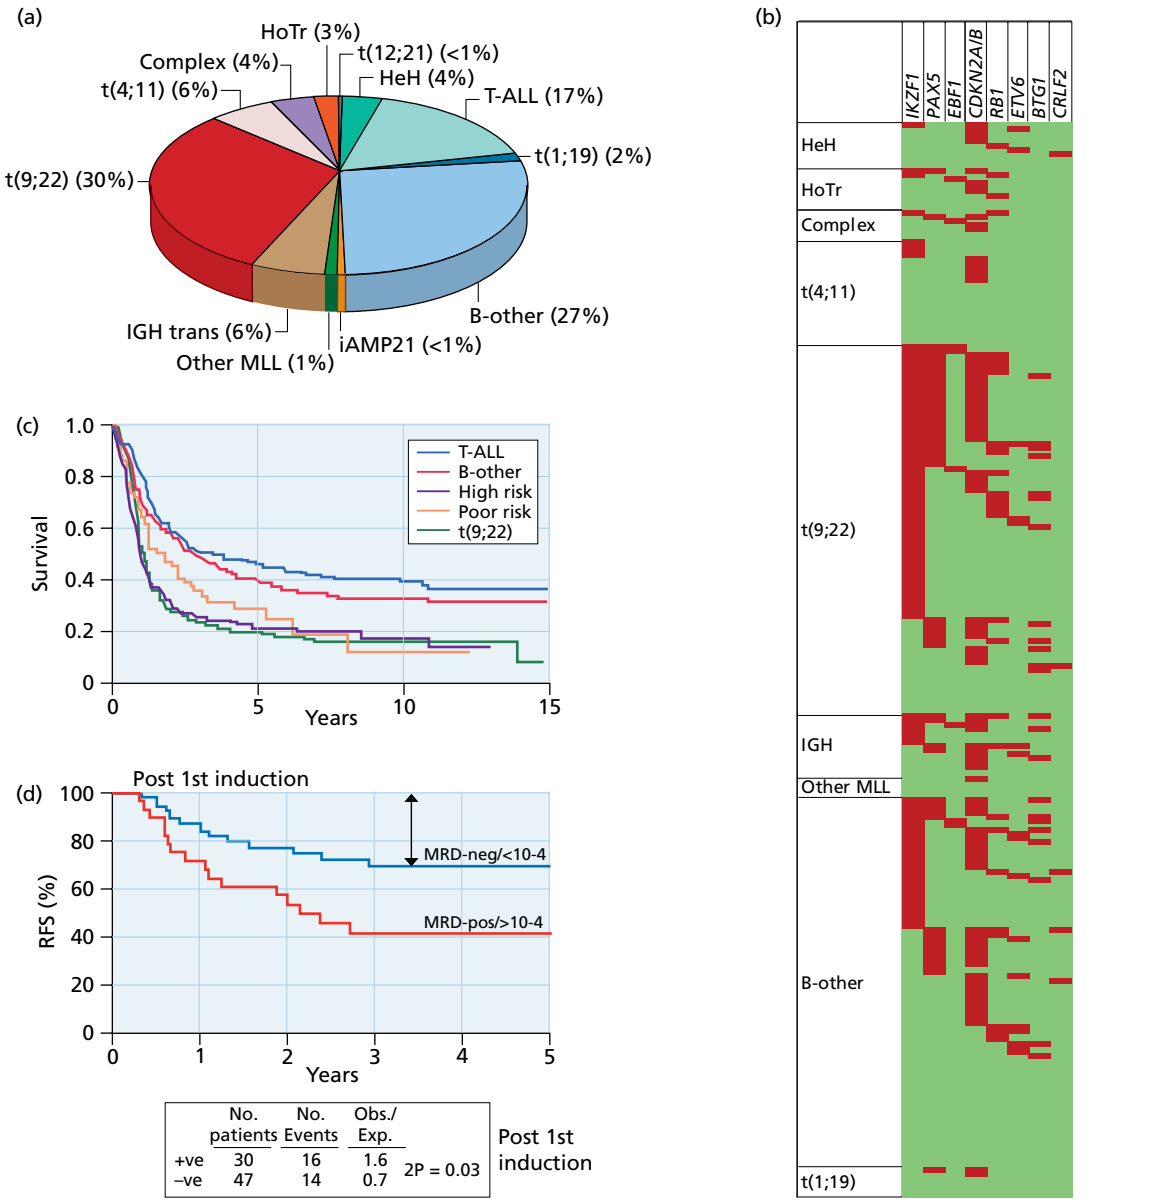

Figure 21.1 *Genetic and outcome heterogeneity within adult ALL.* (a) Distribution of 1014 UKALLXII/UKALL14 patients (25–60 years) according to primary genetic subtype. (b) Correlation of eight key secondary copy number alterations with the main primary genetic subtype in 257 adults (25–60 years). (c) Outcome of 1065 UKALLXII/ECOG2993 adults (25–60 years) by genetic subgroup. The high-risk group comprises those abnormalities which are now used to direct high-risk treatment on UKALL14: t(4;11), HoTr, complex. The poor-risk group comprises those aberrations which have recently been identified as being associated with a poor outcome, but are not currently used to direct treatment: *IKZF1* deletions, *CRLF2* rearrangements and *IGH* translocations. The B-other group comprises all cases with successful cytogenetics but that do not harbour an established abnormality. NB: Patients with rarer subtypes e.g. t(12;21), HeH, t(1;19) have been excluded for clarity. (d) Disease-free survival of t(9;22)-negative B-cell precursor UKALLXII patients according to Ig/TCR-based MRD levels post first induction. HeH, High hyperdiploidy (51–65 chromosomes), t(12;21), t(12;21)(p13;q21)/*ETV6::RUNX1*; HoTr, Low hypodiploidy/near-triploidy (30–39/60–78 chromosomes; complex karyotype (five or more unrelated aberrations in the absence of another primary abnormality), t(4;11), t(4;11)(q21;q23)/*MLL::AF4*; t(9;22), t(9;22)(q34;q11)/*BCR::ABL1*; *IGH* trans, translocations involving the *IGH*/14q32 locus; Other *MLL*, translocations involving *MLL* except t(4;11); iAMP21, intrachromosomal amplification of chromosome 21, t(1;19), t(1;19)(q23;p13)/*TCF3::PBX1*. Supportive care

Before starting treatment, patients should be well hydrated and receive appropriate medication to prevent urate nephropathy (see also Chapter 55). ALL can be exquisitely sensitive to small amounts of treatment, even in the steroid prephase, and tumour lysis syndrome is not uncommon. Allopurinol should be started 24 hours before induction therapy with steroids or chemotherapy and should be continued for a minimum of 5 days. Rasburicase should be considered as an alternative to allopurinol if the white cell count is high ($>100 \times 10^9$/L), if there is bulky nodal or extranodal disease or if the patient already has impaired renal function. It should be noted that rasburicase can cause haemolytic anaemia in patients with glucose-6-phosphate dehydrogenase deficiency (G6PD). Consideration should be given to G6PD testing in patients prior to commencing rasburicase.

Due to the combination of myelosuppressive chemotherapy drugs and steroids that patients with ALL receive, they are at high risk of infectious complications from treatment, particularly during the induction phase of therapy. Adherence to strict anti-infective strategies is important. All patients should receive prophylaxis against herpes simplex virus and varicella zoster reactivation with aciclovir or an equivalent treatment. Patients also require prophylaxis against *Pneumocystis jirovecii* from the start of therapy. The recommended prophylaxis is cotrimoxazole. It should be noted that allergy to cotrimoxazole is not uncommon and alternative agents such as pentamidine or dapsone should be used for these patients.

Antifungal prophylaxis is strongly recommended for all patients on ALL therapy from induction until the start of maintenance. Azoles should be avoided when a patient is concurrently receiving vincristine due to the high risk of potentiation of the toxicity of vincristine, particularly neurotoxicity. There is no clear evidence currently about which antifungal prophylaxis regimen should be followed and local policies should apply.

The use of granulocyte-colony stimulating factor (G-CSF), given in parallel with induction chemotherapy, has been shown to reduce the incidence and severity of infections during the first 4 weeks of therapy. Its use has been associated with reduced induction mortality due to infection in several studies. Consequently, the addition of G-CSF in induction (and all subsequent cycles of therapy except maintenance therapy) is also strongly recommended for all adult patients on ALL therapy.

Patients with newly diagnosed ALL have a high risk of venous thromboembolism (VTE), particularly during induction therapy, even if they do not receive an L-asparaginase-containing regimen. This prothrombotic state can exist despite a coexisting bleeding tendency due to thrombocytopenia. It is strongly recommended that all hospitalised patients receive low molecular weight heparin (LMWH) as prophylaxis against VTE unless there are contraindications e.g. a platelet count below 50×10^9/L or clinical evidence of active bleeding.

A checklist of procedures required prior to commencing anti leukaemia therapy in a patient with newly diagnosed ALL is given in Table 21.4. General aspects of supportive care in haematology are also discussed in Chapter 55.

Specific treatment of ALL

The standard treatment for adult ALL has so far not been defined. It is strongly recommended that, where available, all patients with newly diagnosed ALL are offered treatment within the context of a large Phase III clinical trial. Many countries have well-organised study groups, which focus on developing, running and analysing data from clinical trials. Increasingly, there is stronger, regular communication with practical collaborations between clinicians and scientists to use patient specimens coupled to clinical outcome data to ask questions about the genetics of ALL, using, for example, next-generation sequencing approaches. Treatments have been developed on regimens that have evolved over time, with the gradual introduction of novel agents and new approaches, such that current interventions are now based on a strong literature with clinical and scientific contributions from numerous large international clinical trials.

The aim of initial treatment is to achieve complete remission (CR), which is currently defined on a morphological basis of less than 5% blasts in the bone marrow in the presence of overall haematological recovery (neutrophils $>1.0 \times 10^9$/L, platelets $>100 \times 10^9$/L).

Corticosteroids are amongst the most important drugs in the initial treatment of ALL. Paediatric trials have shown improved outcomes when dexamethasone is used as opposed to prednisolone. Dexamethasone does have better anti leukaemic activity than prednisolone *in vitro*; it has better penetration of the CNS and causes fewer thromboembolic events. Although there are less data in adult ALL showing a survival advantage with dexamethasone compared to prednisolone, many adult regimens now have dexamethasone as the preferred corticosteroid of choice in induction. A generalised schema for treatment is shown in Figure 21.2.

Prephase

A steroid prephase for 5–7 days prior to commencing chemotherapy can be very beneficial in the treatment of ALL. Patients will often have a good partial response to steroids. Early steroids can reduce disease burden and improve performance status allowing the patient to be in a better position to receive induction chemotherapy. Steroids are also very useful when there is liver infiltration with ALL and vincristine and anthracyclines cannot be administered as planned due to high levels of serum bilirubin. There are rare situations where a steroid prephase is not recommended, due to the need for emergency anthracycline-based chemotherapy, such as superior vena cava obstruction due to a large mediastinal mass. The risk of tumour lysis is always high in these situations and rasburicase should be given prior to chemotherapy.

Table 21.4 Suggested checklist for the initial assessment of an adult patient with ALL.

Procedure	Mandatory (M)/ Recommended (R)
Clinical assessment:	
• Full history	M
• Clinical examination including examination of the CNS	M
• Height, weight and body surface area	M
• Assessment of performance status	R
Investigations	
• Full blood count and film	M
• Coagulation screen	M
• Biochemical profile, LDH and urate levels	M
• Blood cultures if patient is febrile	M
• Check G-6-PD status if rasburicase to be used	R
• Pregnancy test for women of childbearing age	M
• HIV testing	R
• Hepatitis B and C serology if monoclonal antibody therapy, e.g. rituximab, is part of the planned therapeutic regimen	M
• Bone marrow aspirate:	M
◦ Morphology	M
◦ Flow cytometry	M
• Cytogenetics (G-banding and FISH analysis)	M
• Molecular diagnostics	M
• Evaluation for MRD marker	M
• Lumbar puncture if evidence of CNS involvement	M
◦ Examination of CSF for blasts by cytospin	M
◦ Flow cytometry of CSF	R
• CXR	M
• CT of neck, thorax, abdomen and pelvis if evidence of nodal/extramedullary disease	R
• CT head if clinical evidence of CNS/ophthalmic disease	M
• Tissue typing of patient and siblings (unless a young adult being treated on a paediatric protocol)	R
Pretreatment	
• Gain IV access. Avoid central line in induction if possible due to increased risk of VTE	R
• Adequate hydration. Use IV fluids if WCC is high or significant extramedullary disease	M
• IV antibiotics if patient is febrile	M
• Prevention of urate nephropathy with allopurinol or rasburicase	M
• Infection prophylaxis against:	
◦ Pneumocystis jrovecii	M
◦ *Varicella* zoster	M
◦ Fungi	R
• Growth factor support during induction	R
• Thromboprophylaxis for in-patients if platelets $>50 \times 10^9$/L	R
Treatment	
• Steroid prephase for 5–7 days	R
• Consider entry into clinical trial if available	R

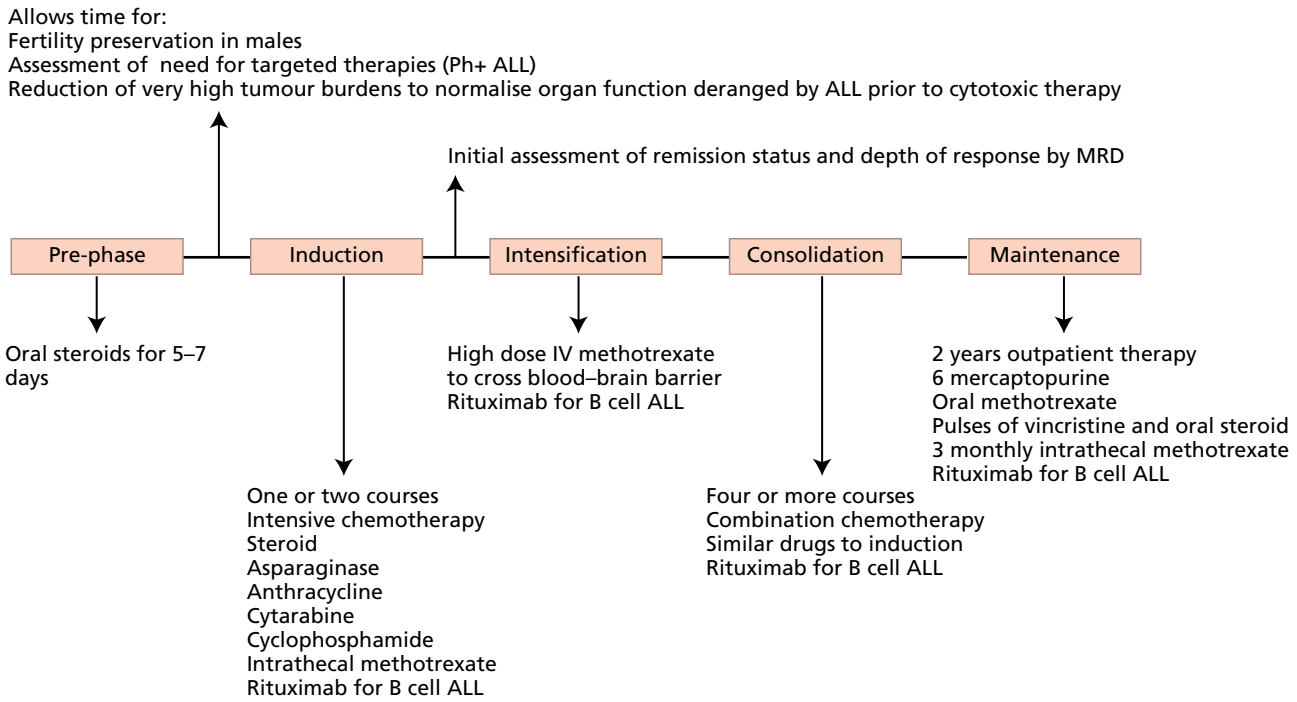

Figure 21.2 A generalised schema for treatment of adult acute lymphoblastic leukaemia.

Induction therapy

The primary goal of induction therapy is complete eradication of ALL cells from the blood, bone marrow, CNS and other extramedullary sites when initially involved. Ideally, CR should be achieved as early as possible with minimal toxicity. Nonetheless, toxicity is often high, especially by contrast to that seen when treating children and many adult patients are hospitalised for weeks to months. There is no universally agreed induction protocol, but most adult treatment regimens are broadly similar in the drug dosing and scheduling. Many protocols use two phases of induction, with the second part being applied regardless of the initial response. Induction regimens in adult ALL are composed of steroid, vincristine, anthracycline (usually daunorubicin or doxorubicin) and L-asparaginase. Cyclophosphamide and cytarabine may also be included. It is also now standard practice to include the anti CD20 monoclonal antibody, rituximab in induction for patients with CD20-positive B-cell ALL, following the demonstration of benefit in a randomised trial conducted by the French GRAALL group. With modern protocols, CR rates following induction therapy are high with over 90% of unselected adults with ALL achieving an initial good response to treatment.

Toxicity during induction

Induction is generally the most risky time during a patient's treatment and they should be monitored closely and seen regularly for clinical assessment. Induction death rates range from 2 to 20%, depending on the protocol used and the patient's age. Most induction deaths are due to severe bacterial sepsis, with fungal infection also posing a significant risk. Steroids often mask signs and symptoms of infection, so astute clinical judgement is required. All patients should have access to a specialist haematology unit 24 hours a day, and they must be treated promptly with intravenous antibiotics for signs of neutropenic sepsis. Any patient with a persisting fever should be investigated for invasive fungal infection.

In addition to the risk of infection, patients are also at risk of problems relating to specific drugs used in induction. L-asparaginase is one of the most effective and important drugs in the treatment of ALL, but it is also one of the most difficult drugs to dose and manage. A major problem with L-asparaginase is the occurrence of coagulation abnormalities during treatment.

L-asparaginase therapy results in reduced levels of fibrinogen and antithrombin levels, but there is little or no evidence that infusions of fresh frozen plasma or fibrinogen can correct the coagulation abnormalities and prevent thrombosis or bleeding. Conversely, there is also some evidence that giving fresh frozen plasma replenishes the asparaginase pool that the drug is being used to deplete, negating its effectiveness. Consequently, the use of plasma-derived products to correct coagulation abnormalities is not recommended unless the patient is actively bleeding.

Despite deranged coagulation being the abnormality measured in the laboratory, an increased risk of VTE is the main clinical problem with L-asparaginase. Data indicate that 10–20% of adults receiving L-asparaginase will develop a VTE. As a

consequence, strategies to reduce the risk of VTE are important. It should be noted that with modern adult ALL protocols, patients might not be thrombocytopenic throughout the whole of induction. Hospitalised patients should be given LMWH thromboprophylaxis if there are no contraindications as discussed above. The presence of a central venous catheter increases the risk of VTE and many centres avoid placing a central venous catheter in induction until the patient has achieved a remission. There are little data available on how to manage post L-asparaginase VTE. When a catheter-related thrombosis occurs then the treatment of choice is LMWH. Treatment of a central venous thrombosis is less clear. Patients should be treated with either LMWH or unfractionated heparin. Adequate monitoring of the heparin dosing using the anti-Xa assay should be performed as patients may be resistant to heparin due to depletion of antithrombin. In this situation, replacement of antithrombin is likely to be valuable, and specialist coagulation advice should be sought.

There are data showing inferior outcomes for patients who develop VTE during induction therapy for ALL despite the fact that the thromboses that occur with L-asparaginase therapy are not usually fatal. It is assumed that the occurrence of a thrombosis results in treatment delays, which are then detrimental to the patient in the longer term.

Patients with previous L-asparaginase-related VTE can be given further L-asparaginase with anticoagulation cover during consolidation therapy.

It is common for patients on L-asparaginase to develop transaminitis and hyperbilirubinaemia during induction therapy. If the patient develops acute sepsis then this will exacerbate the problem. All non-essential drugs that are liver metabolised should be withheld. With supportive care, the liver abnormalities usually fully resolve, but severe treatment delays often result.

Pancreatitis is a rare, but life-threatening, complication of L-asparaginase, which is more common in children than in adults. Serum amylase levels should always be checked in a patient post L-asparaginase therapy who is complaining of abdominal pain. The development of pancreatitis is a contraindication to further use of the drug.

Consolidation therapy

Consolidation therapy is given to patients in CR with the aim of eliminating residual leukaemia cells and to prevent the re-emergence of drug-resistant disease. Consolidation therapy has typically consisted of several cycles of treatment with multiagent chemotherapy, including CNS-directed therapy and further doses of L-asparaginase. Modern adult protocols frequently contain at least one delayed intensification block of therapy, which constitutes a modified re-induction schedule mirroring phases 1 and 2 of induction therapy. Rituximab should also be incorporated into consolidation for patients with CD20-positive B-cell ALL. Smooth progression between courses of therapy to minimise delays is likely to be important, although there are usually specific requirements for peripheral blood count recovery between courses. Slow recovery between courses should be taken seriously as it may indicate actual or impending relapse. Consolidation is generally better tolerated than induction, partly because the patient will have achieved CR and will begin therapy with adequate bone marrow function. Many patients can receive at least some elements of their consolidation therapy as outpatients.

With the approval of the CD19-CD3-directed bispecific antibody, blinatumomab, for use in patients with MRD persisting after induction at the level of 0.01% or greater, it is possible and desirable to deliver this agent as a non-chemotherapy consolidation to patients with higher levels of residual disease after induction.

Maintenance therapy

Maintenance therapy remains obligatory for all adult patients who have not undergone an allogeneic stem cell transplant as part of their treatment for ALL. Studies evaluating the omission of maintenance therapy have concluded that this results in inferior outcomes. The standard approach to maintenance includes daily 6-mercaptopurine and weekly methotrexate with pulses of vincristine and steroids for a period of approximately 2 years post consolidation. However, individual protocols vary. Rituximab should also be incorporated into maintenance therapy for patients with CD20 positive B-cell ALL, to a total of 14–16 cycles across the entire ALL treatment protocol. The aim of maintenance is to eliminate minimal residual disease and dosing of the chemotherapeutic agents needs to be strictly adjusted to induce moderate myelosuppression, whilst not putting the patient at risk of neutropenic sepsis or haemorrhage. CNS-directed prophylaxis with intrathecal chemotherapy should continue during maintenance. Pneumocystis prophylaxis and herpes zoster prophylaxis should also continue throughout the maintenance period (and for at least 6 weeks post completion of chemotherapy), although antifungal prophylaxis is no longer required.

CNS-directed therapy

Without CNS-directed treatment, approximately one-third of patients with ALL will experience a CNS relapse. Risk factors include T-cell disease, high white cell count at diagnosis, CNS disease at diagnosis, other extramedullary sites of disease and high-risk cytogenetics such as Ph+ ALL. Traditionally intracranial radiotherapy was used to prevent CNS relapse. Whilst effective, this resulted in long-term complications including neurocognitive sequelae, second cancers and endocrinopathies. In adults, several trials have reported CNS recurrence rates of 5–7% when a combination of high-dose methotrexate ($\geq 3\ g/m^2$) and intrathecal chemotherapy is used

without additional cranial radiotherapy. The use of dexamethasone in induction has also been shown to reduce CNS relapse rates in children and young adults. In most adult and paediatric protocols, CNS irradiation is no longer used in the prophylactic setting.

Intravenous (IV) and intrathecal (IT) methotrexate is the mainstay of therapy targeted at preventing CNS relapse in patients with ALL. It is commonly given via the lumbar puncture route throughout all phases of treatment, including maintenance therapy. Cytarabine and steroid can also be given intrathecally and are sometimes given with methotrexate as 'triple therapy', although there are no data suggesting the superiority of adding the additional drugs.

The precise number of lumbar punctures needed during therapy is not defined. In adult ALL, between 10 and 20 doses of IT therapy are given, dependent upon treatment protocol. In addition, many adult protocols include an intensification block of high-dose methotrexate given at doses $\geq 3\,g/m^2$.

It is important that only non-cutting lumbar puncture needles are used to administer IT chemotherapy during ALL therapy. The commonly available cutting needles that are often used for diagnostic procedures are more likely to cause a dural tear and subsequent CSF leak which can result in post lumbar puncture headache. The potentially serious complication of bilateral hygromas developing as a consequence of delivering repeated IT chemotherapy via a cutting needle has also been reported in adult patients receiving ALL therapy. The incidence of both post lumbar puncture headache and development of hygromas can be significantly reduced with the use of non-cutting needles.

One of the most dramatic complications of ALL therapy is methotrexate (MTX)-induced encephalopathy. Although this side effect is rare, it is very frightening for patients and their relatives when it does occur. MTX-induced encephalopathy is more frequently seen in young adults than older adults and usually occurs when IT methotrexate is being given during a phase of intravenous cytarabine. It may present with fits, focal neurological signs or stroke-like syndrome with or without impaired consciousness. It occurs within 1 day to 3 weeks after exposure to IT methotrexate and hence it is not always the most evident explanation for the signs and symptoms. Fortunately, patients usually make a full recovery, although there have been case reports where a degree of neurological damage has persisted. It is important to differentiate MTX-induced encephalopathy from cerebral sinus thrombosis with the appropriate imaging. The presence of ALL within the CNS also needs to be ruled out in any patient presenting with a sudden onset of neurological symptoms. In the case of MTX-induced encephalopathy, IT methotrexate should not be given whilst the patient is receiving systemic cytarabine. It can often safely be reintroduced later in the protocol, but this should be approached on a case-by-case basis. Alternatively, the patient can be given cytarabine intrathecally, in association with IT steroids.

Treatment of CNS disease at diagnosis

For those patients where there is evidence of CNS disease at diagnosis, the current advice is to give twice-weekly IT chemotherapy (methotrexate with or without cytarabine and steroids) alongside induction therapy until the CSF is clear of lymphoblasts on two consecutive samples. Cranial radiotherapy post induction remains the standard treatment of CNS disease for this small group of patients. However, if the patient is due to receive allogeneic stem cell transplant with total body irradiation conditioning, CNS irradiation can be withheld. Further IT methotrexate should be given in consolidation and maintenance post radiotherapy as per protocol

Stem cell transplantation

Myeloablative allogeneic haemopoietic stem cell transplantation (alloHSCT) is undoubtedly one of the most effective anti-ALL therapies available and there is a clear graft-versus-ALL effect. One of the biggest ever studies of adult ALL (UKALL12/E2993) demonstrated a survival advantage for myeloablative sibling alloHSCT over chemotherapy in a 'donor versus no donor', intention-to-treat analysis. Unfortunately, it is also the most toxic approach within our therapeutic scope. It has played a significant role in the treatment of ALL over many years, in some country's approaches, being reserved for those thought to be at high risk of poor outcome by dint of having poor prognostic factors and in others, being more widely applied wherever a matched sibling donor is available. As alloHSCT practice changes, with unrelated donor stem cells being widely available and the use of haploidentical donor cells, or umbilical cord blood becoming more routine, and with the widespread introduction of reduced-intensity conditioning regimens, so its role, which has never been clearly defined by clinical trial, will also change. Its role will also be affected by changes in ALL therapy, for example the use of immunotherapies such as blinatumomab or chimeric antigen receptor (CAR) T cells. As we learn more about predictive factors, develop new predictive biomarkers and have a larger set of therapeutic tools at our disposal, so we will need to alter our focus on who should receive alloHSCT. The application of alloHSCT is one of the most controversial areas of clinical practice in ALL.

Specific approaches to defined clinical populations in the treatment of ALL

Targeted therapies for ALL: Philadelphia chromosome-positive (Ph+) disease

BCR::ABL1+ ALL is identified by the presence of the fusion between the Abelson (*ABL1*) tyrosine kinase gene on chromosome 9 and the breakpoint cluster region (*BCR*) gene on chromosome 22, resulting in a *BCR::ABL1* fusion protein that

is a constitutively active tyrosine kinase. This acquired genetic abnormality is necessary and sufficient for the development of CML (see Chapter 33), but in *BCR::ABL1*+ ALL, other abnormalities, such as deletions within the Ikaros gene, are common and an acute leukaemia occurs *de novo*. In the past, this genetic abnormality conferred the poorest prognosis in ALL. However, the treatment of *BCR::ABL1*+ ALL has been revolutionised by the addition of selective inhibitors of the action of this fusion protein – tyrosine kinase inhibitors, (TKI) – to treatment. These non-chemotherapy agents bind to the kinase domain of *ABL1* and disrupt the ATP binding site. They block the catalytic activity of the kinase and subsequent downstream phosphorylation, essentially 'switching off' a growth signal that is otherwise permanently and erroneously switched on. Although there have been no randomised controlled trials of TKI in *BCR::ABL1*+ ALL, there is no doubt that the overall outcome of therapy is superior with the inclusion of TKIs. Agents that have been evaluated and are licenced for use in ALL include imatinib, nilotinib, dasatinib and ponatinib. Furthermore, many of the more toxic elements of chemotherapy e.g. anthracyclines and L-asparaginase can be omitted without compromising outcome. A higher rate of alloHSCT is typically seen when TKIs are used which may also contribute to the improvement in outcome, although there is now a move to define subsets of patients who may not require alloSCT. There is some evidence that *BCR::ABL1*+ ALL in children can be treated successfully with chemotherapy and TKI combinations alone; in adults, there is no completely compelling evidence to date in the adult setting that *BCR::ABL1*+ ALL can be optimally managed without alloHSCT. ALL generally becomes resistant to TKIs, most often by acquisition of mutations in the kinase domain. Mutational analysis should be obtained in any patient with *BCR::ABL1*+ALL whose disease relapses or becomes resistant to TKI therapy. Many mutations have been mapped and the implications for therapy with various TKI are known. As an example, the occurrence of the T315I mutation confers resistance to most TKIs leaving only ponatinib of clinical utility in this scenario. Recent single-arm studies have shown good outcomes from chemotherapy-free protocols – TKI combined with blinatumomab – in *de novo BCR::ABL1*+ ALL. Longer-term follow-up is needed, but this is likely to represent an important advance.

Ph-like ALL

'Ph-like' or '*BCR::ABL1*-like' ALL is a recently defined entity that encompasses a diverse group of genetic alterations which activate cytokine receptor or kinase signalling. The name derives from the fact that these abnormalities result in a gene expression profile resembling that of *BCR::ABL1*+ALL. This range of genetic lesions typically confers an unsatisfactory response to standard chemotherapy. Although the entity was first identified independently by US and European Groups in 2009, there is still no single diagnostic test or universally agreed approach to uncovering this entity in clinical practice. However, as a practical summary, the majority of patients with this entity will have either (i) JAK-STAT pathway abnormalities, most of which involve cytokine receptor-like factor-2 (*CRLF2)* signalling, through which the JAK-STAT pathway is activated (e.g. *IGH::CRLF2, P2RY8::CRLF2* translocations), or other fusions activating that same pathway including but not limited to those affecting JAK2 and EPOR, the erythropoietin receptor or (ii) ABL-class fusions, including *ABL1*, *ABL2*, *CSF1R*, *LYN* and *PDGF*α::β gene fusions. *BCR::ABL1*-like ALL is not sufficiently common in adults that all patients need to be screened at diagnosis but a suitable screening method should be carried out in any patient with no known primary genetic lesion and a less than optimal response to induction therapy including refractory disease or high-level MRD. This is a very important practical aspect of clinical management as patients with ABL-class fusions often benefit from the addition of TKI to their therapy. At present, there is no evidence for the benefit of JAK-inhibitors in JAK-STAT pathway abnormalities.

Teenagers and young adults

Age is known to be a prognostic factor in ALL. Even in paediatric ALL it is well known that children under the age of 10 years have better outcomes than children over the age of 10 years. These differences are at least partly due to the reduced incidence of good-risk cytogenetics in children over 10 years of age (see Chapter 22). However, it was noticed in the late 1990s that there was a further sharp drop in outcomes for adolescents over 16 years of age. Whilst changing disease biology and patient biology play a role, many national ALL study groups demonstrated a significant impact of the protocol used on long-term outcomes for teenagers and young adults (TYAs) on retrospective data analysis. Traditionally adult protocols have been very transplant-focused, whereas paediatric trials only use first remission transplantation in very high-risk disease. In addition, paediatric protocols historically contained significantly more doses of vincristine and L-asparaginase in induction and consolidation, compared to adult protocols.

In the UK, patients up to the age of 25 years at diagnosis have been treated on national paediatric trials since 2007 (UKALL 2003 and more recently UKALL 2011). With this approach outcomes for TYAs have significantly improved with patients aged 16–25 years now having a predicted long-term survival of 75%, with fewer patients requiring allogeneic stem cell transplantation in first response. However, analysis of outcomes from the UKALL 2003 trial has continued to show an impact of age on outcomes, with adolescents having inferior long-term survival compared to younger children. MRD status post induction and consolidation is the most important predictor of long-term

outcomes in TYAs with ALL. As with older adults, new approaches with the use of novel agents and the selected application of first remission allogeneic transplantation within the context of clinical trials, are required for TYA patients with persistence of high levels of MRD post consolidation therapy.

ALL in older adults

The mean age of adults diagnosed with ALL is 60 years, with an age-specific annual incidence in the UK rising from 0.45/100,000 for adults aged 35–39 to 0.78/100,000 for adults aged 60–64 and 1.2/100,000 for those over 85 years. Despite these figures, patients over the age of 65 years have typically not been included in most large Phase III national trials. The lack of well-designed trials for the older patient with ALL may be one of the reasons why survival in this group has not improved over time.

Importantly, studies have shown that when the effect of cytogenetics on overall survival was accounted for, age was not a significant prognostic factor. This suggests that the worsening prognosis with advancing age in adult ALL could at least in part be a manifestation of the age-related increase in unfavourable cytogenetics.

There is no standard regimen for the older patient worldwide. Data from intensive transplant-based trials show that older patients fared poorly, with 15% long-term survival. Where patients have been deemed ineligible for national trial protocols, local practices have varied widely and treatment is often given with palliative rather than curative intent. Data from the UK National UKALL12 trial reported significantly more infections during induction for patients over the age of 55 years, with chemotherapy doses having to be reduced more commonly in this age group in order to manage toxicity. Infection during induction in this trial was related to poorer outcomes overall. Published data indicate a 3–10 times higher rate of induction deaths in older individuals after treatment for ALL.

Ironically, there has been some progress in improving short-term outcomes for older patients with *BCR::ABL1*+ disease. It is possible to achieve CR with minimal toxicity with the use of a tyrosine kinase inhibitor alone. CR rates of over 90% are reported with imatinib in patients over 55 years of age. When combined with steroid therapy, median survival rates of 20 months from diagnosis are reported, with most patients not requiring any admissions to hospital. The long-term follow-up of these patients suggests ongoing relapses and long-term cures are unlikely with this approach. Balancing toxicity of treatment against potential long-term disease control in older patients is an enormous challenge. Emerging novel agents such as monoclonal antibodies have the potential of adding an independent anti leukaemic effect without the addition of substantial toxicity. The challenge will be how to integrate these novel agents into ALL protocols for older individuals, where a current standard of care is not defined.

Treatment of relapsed/refractory disease

If ALL fails to respond to therapy or relapses in adults, survival has generally been very poor and alloHSCT in second complete remission is the only known curative therapy. Several large studies of patients who relapsed following initial therapy have recently been published. Once relapse has occurred, it is generally the features of the relapsed disease, rather than the disease at original diagnosis which determine outcome. Factors predicting poor outcome from relapse include older age, a short duration of first remission and relapse in the CNS. Salvage therapy in older adults with conventional chemotherapy agents in B-ALL has largely been supplanted by the CD19-targeted bispecific antibody, blinatumomab (CR2 rate approximately 45%) or the CD22-directed antibody-drug conjugate, Inotuzumab ozogamicin (CR2 rate approximately 80%). Both agents are much better tolerated than conventional chemotherapy. Additionally, CD-19 directed chimeric antigen receptor T-cells (CAR-T) are now licenced for treatment of children and adults with relapsed/refractory B-cell ALL.

For relapsed T-ALL, there are fewer directed options: nelarabine is available although is generally used in combination with traditional chemotherapy agents. CAR-T approaches are a more technically difficult option than B-ALL but are under very active pursuit. Other agents under active clinical study include venetoclax combined with navitoclax and the antiCD38 antibody daratumumab Despite the increasing availability of novel agents in this clinical space, the optimal outcome for adult ALL can only be achieved by avoiding relapse. It is highly likely that including novel, non-chemotherapy approaches in de novo disease will facilitate better outcomes and trials are ongoing to determine how best to achieve this.

Introduction

Acute Lymphoblastic Leukaemia is the most common form of cancer (25–30%) and predominant subtype of leukaemia (75–80%) in children. However, childhood ALL is not a single disease and has considerable phenotypic and genotypic heterogeneity which is of diagnostic and prognostic importance. Modern protocols take account of this heterogeneity by incorporating complex risk stratification models to determine content and intensity of therapy received by an individual patient. Despite no new drugs being available during that period, treatment outcome has improved substantially in the last four decades such that over 90% of patients can expect to survive without disease in the long term. Translation of recent advances in understanding of the molecular biology of ALL and its influence on phenotype and clinical outcome are identifying specific subgroups that might benefit from targeted therapy.

Epidemiology

The median age at diagnosis for ALL is 13 years and nearly 60% of cases are diagnosed under the age of 25.

There is a sharp peak in ALL incidence amongst 2–3 year olds (>80 per million) which decreases to a rate of 20 per million for 8–10 year olds. The incidence of ALL amongst 2–3 year olds is approximately fourfold greater than that for infants and is nearly tenfold greater than that for 19 year olds. The incidence is higher in boys than in girls (four times for T-cell ALL), except that girls have a slightly higher (1.5 times) incidence of leukaemia in the first year of life. The reported incidence of ALL is higher in Northern and Western Europe, North America and Oceania, and lower in Asia, South America and Africa. In industrialised countries, the incidence is higher amongst children of European descent than amongst those of African descent. For example, the annual rate (per million population) of childhood ALL from birth to 19 years of age is 29.7 in the UK and 11.0 in India; in the USA, it is 32.9 for white people and 14.8 for African–Americans. T-cell ALL and pre-B leukaemia with *TCF3::PBX1* fusion are more prevalent amongst African–American children, who are less likely to have ALL with high hyperdiploidy. The incidence of ALL amongst children younger than 15 years of age has shown a moderate increase in the past 20 years

Aetiology

Genetic factors

Only a small proportion (<5%) of patients with childhood ALL have underlying hereditary genetic abnormalities. Children with Down syndrome have a 10- to 30-fold increased risk of developing ALL. Other genetic disorders associated with an increased incidence of ALL include ataxia telangiectasia, Shwachman-Diamond syndrome and Bloom syndrome. There is no definite evidence of an association between leukaemia and congenital immunodeficiencies such as X-linked agammaglobulinaemia. Patients with Li-Fraumeni syndrome (germline *TP53* mutation)

have an increased riks of developing low hypodiploid (30–39 chromosomes) ALL. Recent genomic sequencing of families with an increased frequency of haematological malignancies have identified rare high-penetrance mutations in several genes including *ETV6, PAX5* and *IKZF1* which have been linked to an increased risk of developing childhood ALL. In addition, patients who carry a Robertsonian der(15;21)(q10;q10) translocation have a very high likely of developing ALL with an iAMP21.

Fraternal twins and siblings of affected children are at a twofold to fourfold greater risk of leukaemia during the first decade of life than are unrelated children. In the case of identical twins, when leukaemia occurs in one twin, there is a 20% probability that it will also occur in the other twin, owing to ALL transfer *in utero* via the shared placental circulation. When leukaemia is diagnosed before 1 year of age it almost invariably develops in the other twin, generally within a few months. In identical twins with *KMT2A::AFF1*, the concordance rate is nearly 100%, with a short latency period (weeks to a few months). In contrast, the concordance rate in twins with the *ETV6::RUNX1* fusion or T-cell phenotype is lower and the postnatal latency period longer, in keeping with the requirement for additional genetic events for leukaemic transformation in these subtypes of ALL. High hyperdiploid ALL also appears to arise before birth but requires postnatal events for full malignant transformation. In contrast, *TCF3::PBX1* ALL appears to have a postnatal origin in most cases.

Genome wide association studies (GWAS) have discovered polymorphisms at numerous genomic loci associated with a moderate increased genetic susceptibility to childhood ALL in general or a specific genetic subtype. Germline variants in *ARID5B* have the strongest association with ALL susceptibility across the genome, especially high hyperdiploid ALL, and the loss of Arid5b in mouse leads to significant defects in lymphoid cell development. The lower incidence of B-ALLwith high hyperdiploidy in African–American children in the US may at least partially reflect lower prevalence of the *ARID5B* risk allele. Other polymorphisms in *GATA3* and TP63 have been linked with Philadelphia/*BCR::ABL1*-like and *ETV6::RUNX1* respectively. Polygenic risk analysis indicates that ALL susceptibility increases cumulatively with the number of risk alleles the child carries. Several of the genes implicated in GWAS studies as conferring increased risk of ALL are known to be involved the pathogenesis of ALL; e.g. *IKZF1*, *CDKN2A, CDKN2B*, *CEPEBE*, *ETV6* and *PAX5*. *IKZF1*, an important transcription factor in all lymphoid lineages, is frequently targeted by copy number alterations in ALL blast cells, and *IKZF1* deletion is associated with a poor prognosis. Loss of *CDKN2A/CDKN2B* occurs in up to 40% of B-precursor ALL and is likely to contribute to cell cycle deregulation in leukaemia. *CEBPE* is related specifically to myeloid cell maturation and terminal differentiation, but interchromosomal translocations involving the immunoglobulin heavy locus (*IGH*) and *CEBPE* genes also have been described in childhood ALL. The convergence of germline ALL susceptibility loci and somatic aberrations on genes involved in lymphoid cell development, cell cycle control and tumour suppression reinforces the contribution of these key pathways to leukaemogenesis and also points to the possibility that inherited and acquired genetic variations act synergistically in the development of childhood ALL.

Environmental factors

Ionising radiation and chemical mutagens have been implicated in the induction of leukaemia but clear aetiological factors for ALL cannot be identified in a majority of cases. *In utero* exposure to diagnostic X-rays is associated with a slightly increased risk of ALL, proportional to the number of exposures. The association between leukaemia and maternal exposure to potential mutagens, neonatal administration of vitamin K, parental use of medications and drugs, proximity to electromagnetic fields and exposure to other potential mutagens have been proposed but not proven. In the UK, it has been demonstrated that the geographical incidence of childhood leukaemia shows more clustering than would be expected if it were due to chance variations, which could be due to the geographical distribution of environmental risk factors, including infectious agents.

Some childhood ALL initiating mutations such as *ETV6::RUNX1* fusion originate in utero and are regarded as a first hit. However, these first hits occur at a higher frequency than the incidence of childhood ALL, suggesting the need for additional second hits. The drivers for these second hits are unclear, though infection remains the strongest candidate. Although a time/space cluster of common ALL was reported in Milan with a possible association to Influenza H1N1 infections, rather than being in response to a specific virus, it is more likely that the leukaemic transformation is as a result of an abnormal or dysregulated immune response to one or more common infections (viral or bacterial) in a genetically susceptible individual at a young age when the immune system is less mature.

Further support for a dysregulated immune response to an infection has come from animal studies. Mice with germ line *PAX5* mutations or *ETV6::RUNX1* fusion only develop common ALL when housed in conventional facilities where they are exposed to infectious agents and don't do so if kept in a pathogen-free environment. These genetically predisposed mice also have a distinct gut microbiome compared to wild-type mice. Disrupting the microbiota with antibiotics in these genetically susceptible mice also triggered the development of common ALL even in the absence of infection. These studies suggest that there is a complex interaction between genetic and environmental factors in the development of childhood ALL.

Pathogenesis

As described above, ALL develops through the acquisition of driver mutations that define the characteristics of the disease (Figure 22.1). Typically, an initiating events such as *ETV6::RUNX1* will give rise to a pre-leukaemic clone that expands and, with

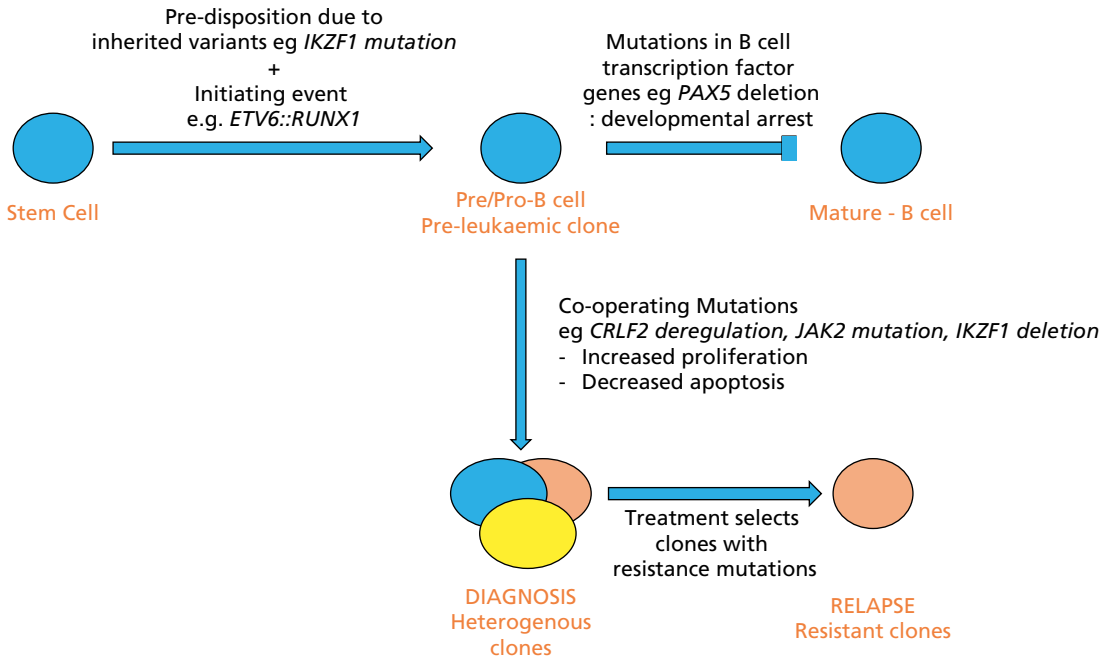

Figure 22.1 Pathogenesis of ALL.

time, acquires secondary co-operating mutations resulting in developmental arrest, increase proliferation and decreased apoptosis. Occasionally, a single genetic event is sufficient to drive the development of the disease as observed in *KMT2A* rearranged infant ALL. The average number of mutations acquired during the pathogenesis is thought to be around six or seven; far fewer than that observed in adult solid tumours. The spectrum of primary or initiating genetic abnormalities ranges from gene fusions to ploidy shifts and complex chromosomal rearrangements (see cytogenetics). Secondary or cooperating mutations are typical micro-deletions or point mutations affecting lymphoid differentiation, cell cycle regulation, cell survival, proliferation and transcriptional cofactors. The majority of patients will harbour a single primary clonal genetic abnormality along with a series of subclonal mutations that give rise to genetic heterogeneity. The spectrum of secondary events is linked, sometimes strongly, to specific primary abnormalities indicating epistatic interactions. Examples include *BCR::ABL1* and *IKZF1* deletion, *ETV6::RUNX1* and loss of the second untranslocated *ETV6* allele and *IGH::DUX4* with *ERG* deletions. The primary abnormality observed at initial diagnosis is always retained at first and subsequent relapses. In contrast, the pattern of secondary abnormalities evolves between each time point often driven by the expansion of treatment-resistant minor subclones. The acquisition of *CDKN2A/B* deletions and RAS pathway mutations are frequent findings. Relapse-specific mutations linked to resistance to certain therapies are increasingly being reported. For example, *NR3C1* mutations linked with glucocorticoid resistance, *NT5C2* mutations and thiopurine resistance, *ABL1* mutations and resistance to tyrosine kinase inhibitors.

Clinical features

Children with ALL frequently present with symptoms and signs of pancytopenia due to marrow failure. Fever, often due to leukaemia rather than infection, is present in 60% of patients. A meta-analysis of more than 3000 children with childhood leukaemia found that more than half presented with at least one of the following five features: palpable liver, palpable spleen, pallor, fever or bruising. Lymphadenopathy was noted in nearly a half of children and musculoskeletal pain was a presenting feature in 43% of cases. Young children with bone pain may present with a limp or refusal to bear weight. Bulky extramedullary disease, especially overt CNS disease, mediastinal mass and renal infiltrates are more common in T-lineage ALL. Mediastinal masses can cause superior vena cava (SVC) syndrome which can present with swelling of the face and upper limbs due to compression of the SVC. CNS involvement is usually lepto-meningeal rather than parenchymal and may present with symptoms of meningism or cranial nerve palsies. Ocular involvement is more common at relapse than first presentation and can affect the retina, ocular nerve, orbit, cornea or anterior chamber with hypopyon. Painless enlargement of the scrotum may be due to a testicular infiltrate or hydrocele resulting from lymphatic obstruction. Rarely, the diagnosis is made in a child who has a blood count for minor, non-specific, symptoms.

Differential diagnosis

Immune thrombocytopenic purpura (ITP) is the most common benign condition to be associated with symptoms that raise concern about leukaemia. Severe skin haemorrhage in an otherwise well child with isolated severe thrombocytopenia and normal blood film without circulating blasts makes it possible to distinguish the condition from leukaemia in a vast majority of cases. The presence of mild anaemia due to nose or gum bleeding and activated lymphocytes on blood film due to a recent viral illness may create diagnostic uncertainty in some cases but it should be possible for an experienced morphologist to exclude the presence of blasts on a blood film without resorting to a bone marrow aspirate.

Pancytopenia due to aplastic anaemia is difficult to distinguish from 'aleukaemic leukaemia' without marrow examination. Rare cases of ALL present with an aplastic marrow without blasts, often accompanying severe sepsis, with spontaneous reconstitution of normal haemopoiesis on recovery from the infection. They represent several weeks to months later with low counts and circulating lymphoblasts. Clonal rearrangements are invariably detected on retrospective examination of the initial marrow using sensitive genetic techniques and it's likely that the 'aplastic' presentation of ALL in such cases is due to severe sepsis causing marrow aplasia followed by spontaneous remission due to a cytokine release phenomenon.

Bone pain, arthralgia and occasionally arthritis may mimic juvenile arthritis in a minority of patients.

Paediatric small round cell tumours that involve the bone marrow, including neuroblastoma, rhabdomyosarcoma and retinoblastoma, may be confused with ALL on marrow morphology but can be easily distinguished on flow cytometry or immune-histochemistry.

Laboratory features

A blood count at diagnosis shows varying degrees of pancytopenia which is more severe in B-lineage than T-lineage ALL. Initial leucocyte counts (Table 22.1) range from 0.5 – $>1000 \times 10^9$/L (median 12 × 10^9/L); they are greater than 10 × 10^9/L in slightly over half of patients and greater than 100×10^9/L in 10–15% of patients. Most patients have circulating blasts, but they may be difficult to detect in those with leucopenia without careful scrutiny of a blood film ('aleukaemic leukaemia'). Reactive hypereosinophilia with pulmonary infiltration and cardiomyopathy is a feature of a rare subtype of B-lineage ALL with t(5;14)(q31;q32)/*IGH::IL3*. Coagulopathy is less common than in acute myeloid leukaemia, usually mild, and not associated with severe haemorrhage except in patients with very high white cell counts who are at risk of CNS haemorrhage due to leukostasis and tumour lysis. Elevated uric acid and phosphorus levels may be seen due to rapid tumour proliferation in patients with high tumour burden. An enlarged kidney can be detected in 30–50% of patients but has no prognostic or therapeutic implications. Raised liver enzymes due to leukaemic infiltration are present in 10–20% of patients, are usually mild and have no important clinical or prognostic consequences. A minority of patients may have cholestatic jaundice due to nodes at the porta hepatis or portal tract infiltration. Abnormalities of the bone, such as metaphyseal banding, periosteal reactions, osteolysis, osteosclerosis or osteopenia, are present in half of the patients. As these changes do not affect treatment and outcome, routine diagnostic imaging studies (except for chest radiography to rule out mediastinal mass) is not necessary.

Leukaemic blast cells are identified morphologically at diagnosis in a cytospin of cerebrospinal fluid (CSF) in approximately one-third of cases, most of whom have no neurological symptoms. Only a minority of such cases (2–3%) fulfil the criteria for CNS leukaemia (CNS3) which is defined by the presence of at least five leucocytes per microlitre of CSF and the detection of leukaemic blast cells, or by the presence of cranial nerve palsy. A recent Scandinavian group (NOPHO) study detected CSF blasts in newly diagnosed ALL patients by cytospin in 13.8% and by flow cytometry in 25.4%. Patients with T-ALL, high count ALL and traumatic lumbar punctures (defined as >10 RBC/μL) were more likely to have blasts detected by flow cytometry. CSF positivity, either detected by a cytospin or by flow cytometry was associated with a higher risk of relapse. Further studies are planned to determine the prognostic value of CSF leukaemia detection by flow cytometry.

A dense infiltrate of lymphoblasts is usually detected in a marrow aspirate. Occasionally, the aspirate may be difficult to obtain and appear hypocellular with sparse blasts due to haemodilution. In such cases, a trephine invariably shows a dense infiltrate but in rare cases with 'aplastic' presentation (see differential diagnosis) may also be severely hypocellular. Morphological analysis of leukaemic cells distinguishes three subtypes of ALL (L1, L2 and L3) according to the French–American–British (FAB) classification. Unlike in AML, the FAB classification has no prognostic or therapeutic relevance in ALL and, along with cytochemical staining, has been replaced by immunophenotypic and genotypic diagnostic investigation and classification.

Immunophenotypic classification

Early pre-B ALL

Leukaemic blast cells of early pre-B ALL resemble normal marrow B-cell precursors. The leukaemic cells always express CD19 and almost all cases have cytoplasmic CD22 and CD79α; surface CD22 expression is also evident in most cases. CD10 and terminal deoxynucleotidyltransferase (TdT) are expressed in 90% of

Table 22.1 Characteristics and 10-year survival rates for 3113 patients in UKALL 2003 (10/2003–06/2011).

			Relapse rate (RR)			Event free survival (EFS)			Overall survival (OS)

cases, and CD34 in more than 75% of cases. The CD20 antigen is present on a minor proportion of blast cells in half of cases but its intensity might increase during treatment. Early pre-B ALL cells lack expression of surface and cytoplasmic immunoglobulins.

ALL with *KMT2A* fusions typically have an early pre-B (pro) ALL phenotype with distinctive features such as expression of CD15, CD65 and chondroitin protoglycan sulfate and absence of CD10. High hyperdiploidy is typically associated with weak or undetectable CD45 expression and *ETV6::RUNX1* with aberrant CD13/33 expression.

Pre-B ALL

The pre-B immunophenotype is defined by the accumulation of cytoplasmic immunoglobulin μ heavy chains with no detectable surface immunoglobulins and is found in approximately 20–25% of cases. Leukaemic cells that express both cytoplasmic and surface immunoglobulin μ heavy chains without κ or λ light chains, a rare finding, have been designated transitional pre-B ALL. Pre-B ALL expresses CD19, CD22 and CD79α and, usually, CD10 and TdT but only two-thirds express CD34. In many cases of pre-B ALL, surface CD20 is absent or is weakly expressed. ZAP-70 expression is more prevalent in cases with a pre-B phenotype. Between 20 and 25% of pre-B ALL cases have *TCF3::PBX1* fusion.

(Mature) B-cell ALL

In 2–4% of childhood ALL cases, cells express surface immunoglobulin μ heavy chains plus either κ or λ light chains. Commonly, cells have L3 morphology according to the FAB classification and express CD19, CD22, CD20 and frequently CD10; CD34 is negative. The less common subtype of B-cell ALL is characterised by blast cells with L1 or L2 morphology, and expression of TdT and/or CD34. These patients should be treated for stage IV B non-Hodgkin's Lymphoma (Burkitt's lymphoma) if they have re-arrangement of the *MYC* gene.

T-lineage ALL

Around 15% of children and young people have T-lineage ALL, but the incidence is lower in younger children and increases with age. T-lineage ALL cells express CD7 and CD3, the latter most commonly only in the cytoplasm. Other markers commonly expressed include CD2, CD5 and TdT; CD1a, surface CD3, CD4 and CD8 are detected in fewer than 45% of cases. HLA-DR expression is uncommon, and 40–45% of cases are positive for CD10 and/or CD21. CD79α is also weakly expressed in approximately one-third of cases.

T-lineage ALL has been divided into three stages of immunophenotypic differentiation: early ($CD7^+$, $cCD3^+$, surface CD3−, CD4− and CD8−), mid or common ($cCD3^+$, surface CD3−, $CD4^+$, $CD8^+$ and $CD1a^+$) and late (surface $CD3^+$, CD1a− and either $CD4^+$ or $CD8^+$). However, many cases have immunophenotypic patterns that do not fit these thymic maturation stages. T-cell receptor (TCR) proteins are heterogeneously expressed in T-lineage ALL. In approximately two-thirds of cases, membrane CD3 and TCR proteins are absent. In half of these cases, however, TCR proteins (TCR-β, TCR-α, or both) are present in the cell cytoplasm. Most cases with membrane CD3 and TCR chains express the αβ form of the TCR, whereas a minority express TCR γδ proteins.

A subtype of T-ALL, named early thymic precursor (ETP) ALL has been recently identified, which exhibits the gene expression profile of normal ETP cells, a population of recent immigrants from the bone marrow to the thymus that retains multilineage differentiation potential. The phenotype is characterised by positive CD7 and cCD3, negative CD1a and CD8 expression, weak or absent CD5 expression and expression of at least one stem cell or myeloid-associated antigen (e.g. CD34, CD117, CD13, CD33 and CD11b). ETP ALL was reported as having a dismal outcome in initial reports but a more recent UK report shows that it's outcome is only slightly worse than for non-ETP ALL

Cytogenetic and molecular classification

High Hyperdiploidy (51–65 chromosomes)

High hyperdiploidy (HeH) is the most common primary genetic abnormality observed in 35% children with ALL. The frequency decreases with age and HeH is observed in less than 20% of adolescents and young adults. It is defined by the non-random gain of whole chromosomes typically trisomies of 4, 6, 10, 14, 17 and 18, tetrasomy of 21 and additional copies of chromosome X. Numerous studies have shown that patients with HeH have a better outcome than their age-matched counterparts, which is possibly due to methotrexate sensitivity. Several studies have reported differential outcome according to the pattern of trisomies and some study groups use specific combinations to define patients with the lowest risk of relapse (e.g. triple trisomy (+4, +10 and +17), UKALL HeH good profile based on the trisomic status of chromosomes 5, 17, 18 and 20)

Near-haploidy (<30 chromosomes)

Near-haploidy is a rare finding in paediatric ALL accounting for <1% cases but is associated with a very high rate of relapse. The pattern of chromosome loss is non-random. Chromosome 21 is never lost, monosomy of chromosome 14 is rare and the sex chromosomes are usually retained. Near-haploid leukaemia clones often evolve by chromosome doubling which can cause a diagnostic dilemma because the modal chromosome number of the doubled component overlaps with high hyperdiploidy. SNP array analysis is the ideal technique for resolving this dilemma.

Low hypodiploidy (30–39 chromosomes)

Low hypodioloidy is another rare (1%) ploidy subgroup associated with a very high risk of relapse. The frequency increases with age and it occurs in 10% of older adults with ALL. It is distinct from near-haploidy because 90% cases harbour a *TP53* mutation that is germline in ~50% cases. Hence genetic testing and counselling for Li-Fraumeni Syndrome is advised when this subtype is detected. As with near-haploidy, the pattern of chromosome loss is non-random and chromosome doubling is a common feature that can cause diagnostic issues.

ETV6::RUNX1 fusion

The chromosomal translocation, t(12;21)(p13;q22), results in the chimeric fusion product *ETV6::RUNX1* (formerly *TEL::AML1*) and is the most prevalent translocation in paediatric ALL (~25% BCP-ALL) but it is rare amongst adults. Unlike many chromosomal translocations, it is cytogenetically cryptic, and hence detection requires FISH or molecular testing. Virtually all major clinical trial groups around the world have reported that children with *ETV6::RUNX1* fusion enjoy excellent overall survival with very low rates of relapses. There is some evidence to suggest that the favourable outcome of *ETV6::RUNX1* ALL is related to optimal asparaginase therapy.

TCF3::PBX1 fusion

Approximately 20–25% of pre-B ALL cases (5% B-ALL cases) have *TCF3::PBX1* fusion resulting from t(1;19)(q23;p13) or the unbalanced form [der(19)t(1;19)]. The translocation juxtaposes the *TCF3* (formerly *E2A*) gene on chromosome 19 and the *PBX1* gene on chromosome 1. The resulting *E2A::PBX1* fusion protein contains the transcriptional activation domains of E2A linked to the DNA-binding domain of PBX1 and the encoded protein inappropriately activates the transcription of genes normally regulated by *PBX1*. With contemporary treatment protocols, patients with this leukaemia subtype have excellent response to initial therapy and a favourable overall outcome. Importantly, ~5% of cytogenetically visible t(1;19)(q23;p13) translocations involved other genes, hence FISH or molecular confirmation of *TCF3::PBX1* fusion is important.

TCF3::HLF fusion

Another *E2A* fusion gene is created by t(17;19)(q22;p13), in which *E2A* is fused to the gene that encodes the transcription factor hepatic leukaemia factor (*HLF*). Patients with ALL and this gene fusion frequently present with hypercalcaemia and coagulopathy. This gene fusion is extremely rare (<0.1%) but is almost universally fatal with very few known survivors.

Fusions involving *KMT2A* (formerly *MLL*)

Structural alterations involving band q23 on chromosome 11 are the most frequent cytogenetic abnormality in infant ALL and occurs in 1–2% of older children in both B-cell and T-cell disease. The target is the *KMT2A* gene formerly called *MLL* (for mixed-lineage leukaemia). The most common *KMT2A* fusion results from the t(4;11)(q21;q23) and produces a chimeric protein that contains the N-terminal portion of *KMT2A* linked to the C-terminal portion of *AFF1*. Numerous other *KMT2A* fusions (>50) have been reported with the C-terminal portion of different partner genes. The *KMT2A* gene encodes a DNA-binding protein that regulates the expression of many genes including multiple *HOX* genes. *KMT2A* is crucial for embryonic development and haemopoiesis, and *KMT2A* fusion proteins can transform haemopoietic cells into leukaemia-initiating cells. Treatment outcome of patients with *KMT2A* fusions differs by age group, with infants having the worst outcome, but they are always considered high risk. Infant ALL with the *KMT2A::AFF1* gene fusion also has a high prevalence of immature, non-productive and/or oligoclonal antigen-receptor gene rearrangements.

BCR::ABL1 fusion

The t(9;22)(q34;q11) translocation encodes a chimeric gene consisting of the 5′ portion of *BCR* fused to the 3′ portion of *ABL1*, whereby N-terminal sequences of *ABL1* are replaced by *BCR* sequences. In ALL, breaks tend to occur in the minor breakpoint cluster regions, forming a 190-kDa *BCR::ABL*. This alteration results in a constitutively active ABL tyrosine kinase that induces aberrant signalling and activates multiple cellular pathways. Genome-wide analysis of *BCR::ABL1* ALL samples revealed deletions of *IKZF1* in >60% of cases whereas deletions were not found in chronic-phase CML samples. Moreover, deletion of *IKZF1* appeared to be a lesion acquired at the time of transformation from CML to lymphoid blast crisis. *BCR::ABL1* ALL is refractory to standard chemotherapy but outcomes have improved significantly in recent studies in which a tyrosine kinase inhibitor (TKI) such as Imatinib was given in combination with chemotherapy throughout a 2-year treatment programme. Thus, first remission allogeneic stem cell transplant is no longer indicated for the vast majority of patients (nearly 90%) who obtain a good MRD response after 12 weeks of chemotherapy plus TKI. Patients with resistance to first-generation TKI agents may respond to second and third-generation TKIs such as nilotinib, dasatinib and bosutinib.

Intrachromosomal amplification of chromosome 21q (iAMP21)

This recurrent chromosomal abnormality defines a distinct genetic subgroup of childhood ALL. They have a common/pre-B immunophenotype, are significantly older (median 9 years) and

have a lower white cell count (median 3.9) compared to children without this abnormality. When treated with standard-risk chemotherapy iAMP21 patients had a very relapse risk (>80% at 10 years) However, when treated with high-risk chemotherapy (as per UKALL2003) the risk of relapse reduces to <20% at 10 years.

BCR::ABL1-like ALL

Around 15% of B-ALL cases exhibit a gene expression profile similar to that of *BCR::ABL1* ALL but do not have the fusion. They commonly harbour *IKZF1* deletions and have a poor outcome. Next-generation sequencing, including transcriptome and whole-genome sequencing, has shown that these cases harbour a diverse range of rearrangements, deletions and sequence mutations often activating cytokine receptor and kinase signalling. The majority, but not all, *BCR::ABL1*-like cases can be classified as ABL-class fusions or JAK-STAT abnormalities.

JAK-STAT abnormalities

This genetic subgroup comprises genomic rearrangements whose downstream consequence is the constitutive activation of the JAK-STAT pathway. The rearrangements *P2RY8::CRLF2*, *IGH::CRLF2*, *JAK2* fusions and *EPOR* deregulation. *EPOR* deregulation occurs via point mutations or more rarely *IGH::EPOR* fusion. *JAK2* fusions comprise the 3′ end of *JAK2* fusing with variable 5′ partner genes (e.g. *PAX5* and *BCR*). *IKZF1* deletions are common in this subgroup and *JAK2* mutations frequently accompany *CRLF2* rearrangements. The frequency of this subtype is 5–10% B-ALL cases but >50% Down syndrome patients with ALL will harbour a *CRLF2* rearrangement, often *P2RY8::CRLF2*. The outcome of patients with a JAK-STAT abnormality is not well established. While some study groups have reported a poor outcome the relapse risk is not as high as observed for patients with classical high-risk genetics (e.g. *KMT2A* fusions, iAMP21 and *BCR::ABL1*).

ABL-class fusions

This subgroup of gene fusions include fusions involving the 3′ end of *ABL1 (*except *BCR::ABL1)*, *ABL2*, *PDGFRB*, *CSF1R* and, more rarely, *PDGFRA*. The resulting fusion has similar functional consequences to the canonical *BCR::ABL1* fusion, i.e. deregulation of tyrosine kinase activity. The 5′ partner genes are highly variable but include *EBF1, ETV6, NUP214* and *SSBP2*. The most prevalent fusion is *EBF1::PDGFRB* accounting for up to 50% cases. Studies have found that patients with an ABL-class fusion have very high levels of MRD post induction and a significantly higher relapse risk when treated with standard chemotherapy. Although predominantly found in BCP-ALL, studies have identified cases with T-ALL especially *NUP214::ABL1*. There is good *in vitro*, *in vivo*, *ex vivo* and clinical evidence that patients harbouring an ABL-class fusion are sensitive to tyrosine kinase inhibitors (TKI), e.g. imatinib and dasatinib. This evidence includes reports of patients with refractory disease at EOI achieving complete remission after treatment with a TKI. Several clinical study groups now give patients with an ABL-class fusion adjuvant TKI therapy.

IGH::DUX4 fusions

Overexpression of *DUX4* results from *IGH::DUX4* fusion or more rarely *ERG::DUX4* fusion and occurs in ~5% B-ALL cases. *DUX4* over-expression is accompanied by transcriptional deregulation of *ERG*, usually via deletion, resulting in loss of function of ERG, a transcriptional regulator, required for normal haematopoietic stem cell function. Patients with a *DUX4* fusions have a very good outcome with several study groups reported relapse rates as low of 2–3%. *DUX4* is located on the long arm of chromosome 4 in the highly repetitive subtelomeric region. This location and presence of multiple copies make the detection of *IGH::DUX4* extremely challenging. Accurate detection requires careful analysis of whole genome or RNA sequencing.

Other genetic abnormalities in B-ALL

Genomic analysis including whole genome sequencing and RNA sequencing have identified and continue to identify novel genetic abnormalities. The frequency and prognosis of these abnormalities have not been established and will require large comprehensive prospective studies. These abnormalities are invariably novel gene fusions or clusters of abnormality driving distinct expression profiles. *ZNF384* gene fusions occur in ~3% B-ALL cases but up to 40% patients diagnosed with mixed phenotype acute leukaemia (MPAL). They are associated with low CD10 expression and aberrant CD13/33 expression. The most common partner genes are *EP300, TCF3* and *TAF15*. *MEF2D* fusions (usually with *BCL9* or *HNRNPUL1*) account for a similar proportion of B-ALL cases and also have low CD10 expression. These cases frequently have high expression of CD38 and results in increased *MEF2D* expression and in turn activation of the histone deacetylase, *HDAC9*. Genes from the CEPB family (e.g. *CEPBA*, *CEPBE*, *CEPBG*, etc.) and *ID4* are over-expressed via juxtaposition to the IGH enhancer. These cases are rare overall but tend to be older children or young adults. The *ETV6* and *PAX5* genes are well-known to be involved in ALL development via specific gene fusions (e.g. *ETV6::RUNX1* and *PAX5::JAK2*) and deletions (see below). Transcriptomic and genomic studies have identified distinct subgroups termed *ETV6::RUNX1*-like and PAX5alt which encompasses a range of abnormalities centred on these two genes and include variants fusions and mutations.

Copy number alterations

Microdeletions of key B-cell development and cell cycle genes are the most prevalent secondary abnormalities in ALL. One or more deletions affecting *EBF1, IKZF1, CDKN2A/B, PAX5,*

ETV6, BTG1, RB1 or the pseudo-autosomal region (PAR1) occurs in 60% of children with B-ALL. Extensive risk profiling by the UKALL study group revealed that patients without any deletion affecting these genes/regions or isolated deletions of *ETV6, PAX5, BTG1* or *ETV6* deletions with a single additional deletion of *BTG1*, *PAX5*, *CDKN2A/B* comprised a good risk group. This UKALL-CNA good risk group was enriched for cases with *ETV6::RUNX1* and high hyperdiploidy but also defined as a good risk amongst other B-ALL cases. In contrast, *IKZF1* deletions are associated with a poor outcome overall but their effect is context-dependent. Patients with an IKZF1plus profile (*IKZF1* deletion plus concomitant deletion of *CDKN2A/B*, *PAX5* or PAR1 in the absence of *ERG* deletion) and high MRD at the end of induction have a very poor outcome.

Genetic abnormalities in T-cell ALL

The genetic and genomic landscape of T-ALL is largely distinct from that observed B-ALL. The exceptions include *KMT2A* fusion, ABL-class fusions and *CDKN2A/B* deletions. There are at least six distinct genetic subgroups of T-ALL defined by type A abnormalities that block T-cell differentiation. The subgroups are driven by deregulation of *TAL1*, *TLX1*, *TLX3*, *NKX2-1*, *HOXA* or *LMO2/LYL1*. In addition, to type A abnormalities all patients will harbour one or more type B abnormality which are mostly deletion and mutations affecting proliferation and cell cycle control. The most frequently affected genes include *CDKN2A/B*, *NOTCH1*, *FBXW7*, *PTEN*, *KRAS*, *NRAS* and *PHF6*. None of the T-ALL genetic abnormalities predict outcome to the extent that treatment should be stratified on the basis of specific abnormalities.

Prognostic factors

Presenting features

Age, presenting white cell count and immunophenotype are independent predictors of relapse risk in childhood ALL. Although the association of outcome with age and presenting white cell count is linear, current risk stratification models use a threshold for both variables to define standard and high-risk groups. For example, the National Cancer Institute (NCI) criteria employed by the UKALL and US Children's Oncology groups categorises patients below 10 years with white cell count less than 50×10^9/L as standard risk (60% of patients) and older patients or those with a higher white cell count as high risk.

Historically, the outcome for boys was worse compared with girls but the difference is not evident in some contemporary studies. In some, but not all, US studies, patients of African–American and Hispanic origin had a significantly worse outcome.

Primary chromosomal and genomic abnormalities are strong independent prognostic factors that are frequently used to risk-stratify patients. Patients with *ETV6::RUNX1*, high hyperdiploidy, *IGH::DUX4* and *TCF3::PBX1* have all been associated with good response to standard chemotherapy and multiple studies have reported 5-year EFS rates exceeding 90%. Patients with *ETV6::RUNX1* and high hyperdiploidy who have other good risk features such as low WCC, young age or low MRD post induction are frequently eligible for treatment with reduced or lower intensity chemotherapy. In contrast, patients with *BCR::ABL1*, *KMT2A* fusions, near-haploidy, low hypodiploidy, iAMP21, *TCF3::HLF* and ABL-class fusions are deemed high-risk abnormalities and have invariably been linked with poor survival in multiple studies. Patients with iAMP21 have improved outcome when treated with high-risk chemotherapy but survival is still <85%. Patients with *BCR::ABL1* or ABL-class fusion have improved outcome when treated with a TKI. Whilst many of the other primary genetic subtypes listed above have been associated with linked outcome, the evidence to date is insufficient to justify altering therapy. Several secondary abnormalities, usually CNA profiles, are emerging as robust prognostic factors. However, there is less consistency in approach than for primary genetic abnormalities. Several studies have focussed on *IKZF1* deletions as a high-risk biomarker but use different definitions (deletion versus IKZF1plus profile) and have chosen different interventions. One study has opted to incorporate the UKALL-CNA good risk profile to identify patients who have intermediate-risk MRD and a low risk of relapse.

Early response

Risk stratification based on clinical criteria, though, is relatively non-specific. For example, a high-risk group with a 5-year EFS of around 50% defined by age, gender and presenting WCC identifies only 20% of patients destined for relapse, with the majority of relapses still arising out of the remaining, apparently, low-risk patients. Speed of response in the first few weeks of treatment is a powerful determinant of outcome. Morphological slow early response, measured as slow clearance of blood or marrow blasts after a week or two of induction therapy, is associated with a relatively high risk of relapse and around 1% of patients who are not in complete remission at the end of induction (induction failures) have a poor outcome. However, over 60% of relapses arise from the group with a rapid morphological response in the first 2 weeks of therapy. Measurement of Minimal Residual Disease (MRD) offers a much more sensitive and specific means of distinguishing between patients who will and will not relapse.

Minimal residual disease

The bone marrow of patients in morphological complete remission may contain up to 10^{10} residual leukaemic cells. This submicroscopic level of leukaemia (Minimal Residual Disease, MRD) can be detected using sensitive molecular or flow cytometric methods. Molecular quantitation of MRD using

Real-Time Quantitative PCR of antigen receptor gene rearrangement (Immunoglobulin and T-cell receptor) is the method of choice in the UK and Europe. Each leukaemic clone carries a unique molecular signature of rearranged antigen receptor genes which can be detected at diagnosis using appropriate PCR primers and sequenced. A patient-specific probe designed against the junctional region of the rearranged gene is then used to track the leukaemic clone in remission samples. Flow cytometric methods utilise combinations of cell surface antigens uniquely expressed on leukaemic cells (Leukaemia Associated Immunophenotype, LAIP) to detect MRD.

Several large studies have revealed that the positive and negative predictive value of a particular MRD result depends on the sensitivity of the technique used to measure it, the time point at which it is measured, and the treatment received by the patient before and after the point of assessment. Despite differences in these variables amongst published studies, there is sufficient consensus in the results relating to certain clinical endpoints. Around 50% of patients become MRD negative for two clonal markers by the end of induction (EOI) and have a <5% risk of relapse. Patients with detectable MRD at the end of induction subdivide into two groups on follow-up. In around 95% of these patients (45% of all patients) the MRD level falls below 0.5% by the end of consolidation therapy. This group has a 20% relapse risk and benefits from further intensification of therapy as demonstrated in UKALL 2003. The remaining 5% (1% of all patients) have persistent MRD ≥0.5% at post induction follow-up and an associated >80% risk of relapse. The optimal therapy for this MRD very high-risk group is uncertain and many groups consider them eligible for experimental therapy followed by first remission allogeneic stem cell transplant. The kinetics of MRD clearance is slower in T-lineage compared with B-lineage ALL and the prognostic outlook for a given detectable MRD level is worse at earlier time points for B-lineage and later time points for T lineage.

Integrated risk factor analysis

Historically, risk factors in ALL were usually binary and applied sequentially without integration. Analysis of UKALL2003 data revealed that end of induction (EOI) MRD was log-normally distributed and MRD distributions of patients with distinct genetic subtypes were different (Figure 22.2). Patients with good-risk cytogenetics demonstrated the fastest disease clearance, whereas patients with high-risk genetics and T-cell disease responded more slowly. The risk of relapse was correlated with MRD kinetics, and each log reduction in disease level reduced the risk of relapse by 20%. Although the risk of relapse was directly proportional to the MRD level within each genetic risk group, the absolute relapse rate associated with a specific MRD value or category varied significantly by genetic subtype. Hence adopting genetic-specific MRD thresholds improves relapse prediction. This concept has been integrated in the ALLTogether1 trial risk stratification algorithm where three separate MRD thresholds are used for different genetic subtypes to selected good-risk patients for the intermediate-low-risk treatment group (Figure 22.3) intermediate-risk MRD patients. Future risk algorithms are likely to build upon these findings to develop and implement fully integrated models. The UKALL study group has developed and validated a prognostic index that integrates genetics, white cell count and end of induction MRD to assign patient-specific risk scores on a continuous scale (Figure 22.4). One of the major advantages of such an approach is the ability to tailor the number, size and outcome of risk groups to the treatment options or randomisation under investigation.

Pharmacogenetic variables

Mutations and polymorphisms of genes encoding several drug-metabolising enzymes have been associated with response to therapy. The best-known are thiopurine *S*-methyltransferase (TPMT) gene, which encodes the enzyme that catalyses mercaptopurine to non-cytotoxic methyl mercaptopurine metabolites and Nudix Hydrolase 15 (*NUDT15*) gene which degrades oxidised purine nucleoside triphosphates (e.g. 8-oxo-dGTP) by dephosphorylation to prevent incorporation into DNA. Approximately 1 in 300 patients have an inherited homozygous deficiency of TPMT which results in all the administered dose of mercaptopurine (a pro-drug) being converted to cytotoxic thioguanine nucleotides (TGNs).

Patients heterozygous for *TPMT* and/or *NUDT15* risk variants in general tolerate a dose of 6MP of 50–60 mg/m^2, and some even 75 mg/m^2. Thus, pre-emptive dose reductions are not recommended for these patients. Patients who are homozygous for *TPMT* low activity alleles or homozygous for *NUDT15* low activity alleles should as a starting dose receive 6 MP 5 mg/m^2/day (i.e. 5–10% of standard dose) to avoid marrow aplasia. If tolerated the dose can then carefully be increased. Recently, low activity polymorphisms have been described in the *NUDT15* gene that encodes the Nudix hydrolase 15 protein which hydrolyses the thiopurine active metabolites 6-Thio-GTP and 6- thio-DGTP. Low-activity genotype variants of *NUDT15* are inherited as monogenic autosomal codominant traits associated with increased risk of myelosuppression, especially in the homozygous state. Inherited *TPMT* deficiency is primarily seen in Europeans and Africans, whereas risk alleles in *NUDT15* explain most of thiopurine-related myelosuppression in Asians and Hispanics with native American ancestry. *NUDT15* variants are rare amongst Europeans (<1.0%) and even rarer in Africans. However, a recent study in a London population has indicated a higher frequency of *NUDT15* variants in self-identified British Caucasian and mixed-race individuals in addition to those of Asian ancestry. Hence all UK patients are genotyped for the common *NUDT15* and *TPMT* variants in an accredited laboratory.

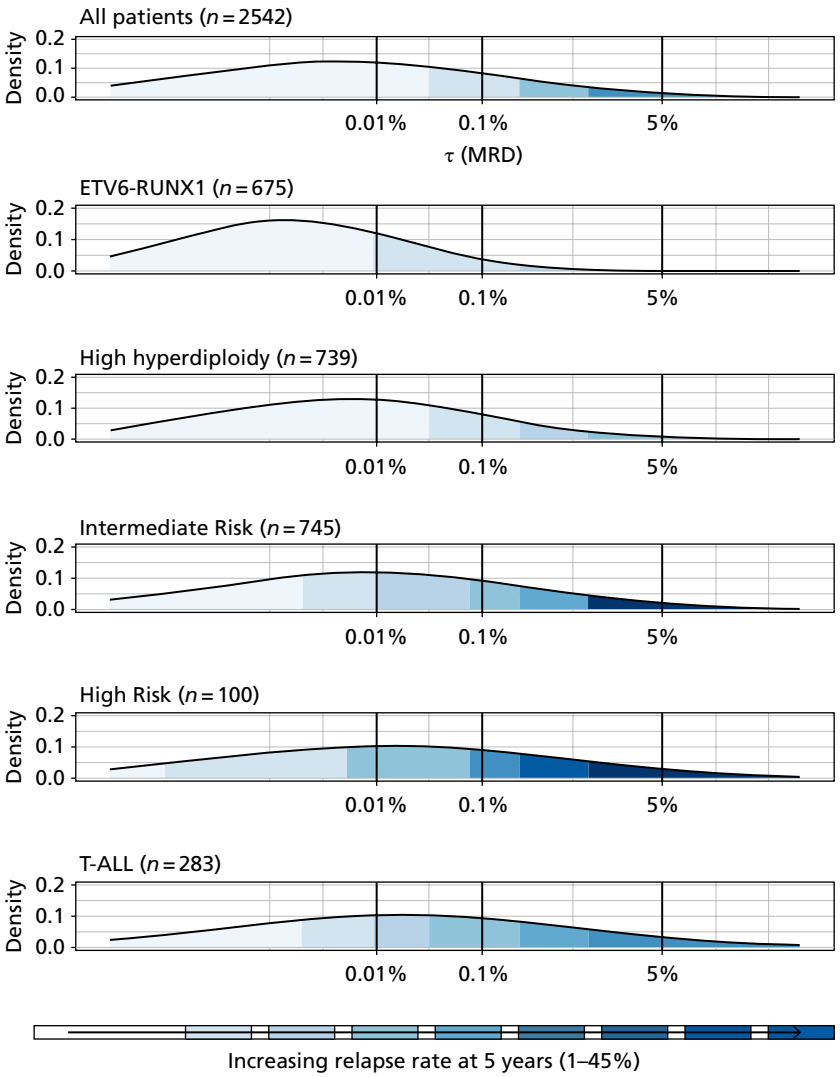

Figure 22.2 Relationship between minimal residual disease (MRD) and relapse risk by different genetic subtypes. Absolute MRD values were log-transformed [τ(MRD)] and each panel shows a smoothed density distribution for cases in a particular genetic subtype. The darker shading indicates high risk of relapse.

Treatment

Drugs and protocols

Eleven categories of chemotherapeutic drugs form the mainstay of childhood ALL therapy (Table 22.2). Current front-line treatment protocols contain varying combinations of these eight drugs given over a 2–3-year period. A typical treatment regimen consists of induction, pre-emptive CNS-directed, intensification and maintenance (also called Continuing) therapy courses. Induction and intensification therapy are designed for rapid debulking of tumour load during the first few months of therapy, while maintenance therapy, administered over the remaining 2–3 years, is aimed at clearing MRD. Systemic therapy has variable penetration across the blood–brain barrier and, therefore, is insufficient to prevent isolated CNS relapse, the risk of which is substantially reduced by pre-emptive CNS-directed therapy.

Historical background

Studies conducted by collaborative groups in many different countries have contributed to the current generally gratifying outcome of treatment of childhood ALL. The first attempt at a cure was pioneered in the mid-sixties by the St. Jude's group in Memphis, USA, who showed that durable remissions could be achieved in roughly 30–40% of patients with a combination chemotherapy protocol, which they called total therapy, containing remission induction, pre-emptive Central Nervous System (CNS) therapy and prolonged continuation therapy. While other groups tried to optimise this basic template by doing randomised studies of various components within it, the Berlin-Frankfurt-Munster (BFM) group took the second major step forward in the late 1970s, documenting that long-term remission rates could be improved to 60–70% by intensified induction and consolidation therapy. Others, including the MRC in the UK, subsequently confirmed the benefits of intensified therapy even using different combinations and schedules of intensification from the original BFM model. Subsequent UK studies have investigated alternatives to cranial radiotherapy for CNS-directed treatment (UKALLXI) and compared the efficacy and toxicity of dexamethasone with prednisolone and thioguanine with mercaptopurine (ALL97). Cranial radiotherapy and HD MTX reduce the risk of CNS relapse compared with prolonged IT MTX but are associated with equivalent overall EFS due to an increase in non-CNS relapses. Hence, presently in the UK, cranial radiotherapy is restricted to patients with overt CNS disease

Table 22.2 Drugs used in the treatment of childhood ALL.

Drug Class	Mechanism of Cytotoxicity	Route(s) of administration	Part in treatment protocol	Significant Toxicities	
				Acute	Late
Vinca Alkaloids	Disruption of mitotic spindle	Intravenous bolus	Throughout	Neurotoxicity Constipation Vesicant	Neurotoxicity
Glucocorticoids	Apoptosis by binding to intracellular Steroid Receptors	Oral and intravenous	Throughout	Hyperglycaemia Weight gain Mood alteration Hypertension	Osteoporosis Obesity Avascular Necrosis of Bone
L-Asparaginase	Depletion of L-Asparagine	Sub-cutaneous or Intra-muscular	Induction and Intensification	Hypersensitivity Thrombosis Pancreatitis Hyperlipidaemia Neurotoxicity	None?
Anthracyclines	DNA intercalation Inhibition of Topo-isomerase II function	Intravenous infusion	Induction and Intensification	Vesicant Myelosuppression	Cardiotoxicity
Alkylating agents (Cyclophosphamide)	Interstrand DNA cross-links	Intravenous bolus or infusion	Intensification	Myelosuppression Haemorrhagic cystitis	Secondary leukaemia Infertility
Methotrexate	Anti-folate	Oral, intravenous and intra-thecal	Maintenance CNS-directed therapy	Mucositis Nephrotoxicity (High Dose) Hepatotoxicity	Osteopenia Neurotoxicity
Thiopurines (Mercaptopurine and Thioguanine)	Incorporation of thioguanine nucleotides into newly synthesised DNA	Oral.	Maintenance	Hepatotoxicity Myelosuppression	Hepatic?
Epipodophyllotoxins (Etoposide and Teniposide)	Interferes with topo II religation of double-stranded DNA breaks	Intravenous infusion	Intensification	Myelosuppression	Secondary leukaemia
Cytarabine	Inhibits DNA polymerase	Intravenous, Sub-cutaneous or intra-thecal	Intensification	Hypersensitivity Myelosuppression Central neurotoxicity	Neurotoxicity
Blinatumomab	Bispecific antibody. Cytotoxicity through T-cell engagement with CD19 positive cells	Continuous intravenous infusion	Relapse, MRD positivity	Cytokine release syndrome Neurotoxicity Myelosuppression	B cell aplasia
Inotuzumab	Antibody targeted calicheamin mediated cytotoxicity of CD22 positive cells	Intravenous	Relapse	Hepatoxicity Myelosuppression	Veno-occlusive disease post SCT
Tisagenlecleucel (CD 19 directed CART)	Cytoxicity of CD19 cells by re-engineered chimaeric antigen T cells expressing CD19 directed antibody	Intravenous	Relapse, Primary refractory	Cytokine release syndrome Neurotoxicity Myelosuppression	B cell Aplasia

(CNS3) at presentation who have persistent CSF blasts after two intrathecal methotrexate injections. Dexamethasone is more effective than prednisolone in reducing the risk of systemic and CNS relapses in several studies. Thioguanine is more effective than mercaptopurine at preventing CNS relapses, especially in younger boys, but is associated with an increased risk of death in remission and sinusoidal occlusion syndrome or veno-occlusive disease (SOS/VOD) of the liver. A proportion of patients with the latter toxicity have chronic portal hypertension due to periportal liver fibrosis.

Current UK strategy

UKALL 2019 guidelines

When no clinical trial is available for childhood ALL, the usual approach is to follow the standard treatment arms of the most recent randomised trial which in the UK was UKALL 2011. This treatment regimen designated UKALL 2019 guidelines is described below. The guidelines are designed for all patients from age 1 (first birthday) to 24 years 364 days (at time of diagnosis) with a first diagnosis of acute lymphoblastic leukaemia or lymphoblastic lymphoma (T-NHL or SmIg negative precursor B-NHL) diagnosed using standard criteria.

Treatment

Patients receive 1 of 3 escalating intensity treatment regimens depending on their clinical and MRD risk group. Initial treatment allocation is on the basis of clinical risk criteria with treatment post induction being determined by MRD response.

Induction and consolidation

NCI standard risk precursor B cell precursor ALL standard risk patients receive a three drug induction containing vincristine, steroids and asparaginase for 4 weeks (Regimen A) and NCI high-risk patients receive in addition Daunorubicin (Regimen B). All patients receive three doses of intrathecal methotrexate (IT MTX) in induction with patients who have blasts in their cerebrospinal fluid at diagnosis receiving an additional two doses. All patients with T cell ALL (independent of NCI risk) will receive a Regimen B induction. A small number of NCI Standard Risk BCP ALL patients initially treated according to Regimen A induction will subsequently be found to have high-risk cytogenetics (*KMT2A* fusions, near haploidy, low hypodiploidy, iAMP21 and *TCF3::HLF*) and should transfer to Regimen C induction (four drug induction) on day 15 of induction.

For consolidation, Regimen A patients who are MRD low-risk receive daily oral mercaptopurine and three doses of weekly intrathecal methotrexate. Regimen B patients who are MRD low-risk receive in addition 4 weeks of cyclophosphamide and cytarabine (Berlin Frankfurt Munster (BFM) consolidation). Patients with high-risk cytogenetics or who are MRD positive at end of induction transfer to Regimen C. Regimen C patients receive an additional four doses of vincristine and two doses of pegylated asparaginase during the BFM consolidation course (called Augmented BFM Consolidation).

Primary refractory ALL

B-lineage patients with induction failure (defined at end of induction MRD>5%) receive a Regimen C consolidation. Depending on age, phenotype and response patients may receive licensed autologous CART (if mid-consolidation MRD>1%) or be recruited to a CART trial (if NCI high risk and end of consolidation MRD>0.01%). Patients not eligible for CART are recommended Blinatumomab (bispecific CD19/3 targeting antibody) as a bridge to transplant. Patients not responding to Blinatumomab receive intensive chemotherapy such as FLA-Ida as bridge to transplant. Younger children (<16 years) with good response to consolidation continue on Regimen C.

Based on the results of COGAALL0434 study, T-ALL patients with induction failure receive Regimen C consolidation + Nelarabine as bridge to transplant. Those refractory to this combination either receive intensive chemotherapy such as FLA-Ida or experimental treatment including Daratumumab or Venetoclax/Navitoclax.

Interim maintenance and delayed Intensification

Following consolidation, patients receive 2 months of interim maintenance prior to a single delayed intensification course. MRD low-risk (Regimen A/B) patients receive oral mercaptopurine and methotrexate with monthly vincristine and steroid pulses during interim maintenance. Interim maintenance for MRD intermediate-risk patients (Regimen C) consists of escalating doses of intravenous methotrexate without folinic acid rescue, vincristine and pegylated asparaginase.

All patients receive a single delayed intensification. For MRD low-risk (Regimen A/B) patients, this consists of a single dose of pegylated asparaginase at day 4 and vincristine, dexamethasone, doxorubicin for 3 weeks followed by cyclophosphamide and cytarabine as given during the BFM consolidation course. MRD intermediate (Regimen C) patients receive in addition two doses of vincristine and one dose of pegylated asparaginase.

Continuation therapy

Regardless of clinical and MRD risk group, all patients receive oral mercaptopurine and methotrexate, monthly vincristine and steroid pulses and 3 monthly intrathecal methotrexate. Boys receive treatment for 3 years and girls for 2 years from the start of interim maintenance.

Steroid and asparaginase formulations, doses and schedules

All patients received dexamethasone 6 mg/m^2 with a 10 mg ceiling dose during induction and maintenance courses. In delayed intensification courses, all patients receive dexamethasone at 10 mg/m^2

(without a cap) for 14 days in a week on, week off schedule. All patients receive pegylated asparaginase 1000 units/m^2/dose given intramuscularly throughout treatment. Regimen A/B patients receive three doses (two in induction and one in delayed intensification course) and Regimen C patients eight doses (additional two in interim maintenance and delayed intensification courses).

Central nervous system (CNS) directed therapy

Patients with ≥5 leucocytes/microlitre and blasts in a diagnostic cerebrospinal fluid (CSF) sample with <10/microl red cells (CNS-3) receive an extra two IT MTXs in induction. Patients with traumatic lumbar puncture and blasts in the CSF as well as those with <5 leukocytes/microlitre which were blasts (CNS-2) also receive an extra two IT MTXs during induction. All other patients received intrathecal methotrexate as described above. Regimen C patients receive Capizzi intravenous methotrexate at doses <500 mg/m^2 without folinic acid rescue. Thus no patients receive cranial radiotherapy or high-dose methotrexate during first-line treatment

Allogeneic haemopoietic stem cell transplantation

Less than 5% of patients are eligible first remission transplant, primarily for primary refractory disease once they have achieved an optimal MRD response (<0.01%).

ALLTogether1 protocol

In 2014, an international consortium of study groups came together to develop a common protocol for newly diagnosed children and young adults with acute lymphoblastic leukaemia (ALL). The consortium includes study groups from the UK (UKALL), The Nordic countries plus Lithuania and Estonia (NOPHO), Germany (CoALL), Belgium (BSPHO), Portugal (SHOP), France (SFCE), Ireland (PHOAI) and the Netherlands (DCOG). The new trials that commenced in summer 2020 will recruit approximately 1400 patients annually and employ a new risk stratification (see above). The trial will address randomised questions about de-escalation of treatment for low-risk groups and use of novel agents (Inotuzumab, TKIs and CART) for higher-risk patients.

Current outcomes

Given the above treatment, the 5-year event-free survival (EFS) of over 3000 children and young people (ages 1–25 years) recruited to UKALL 2003 (2003–2011) was 87.2%, which compares favourably with outcomes reported from contemporary trials by other groups (Tables 22.1 and 22.3). A low incidence of isolated CNS relapse (1.9%) was observed, equivalent to that observed in studies in which a significantly higher proportion of patients received cranial irradiation. Randomised interventions within the trial demonstrated that treatment can be de-escalated without compromising survival in MRD low-risk patients, and augmentation of post-remission therapy reduces relapse risk for patients with detectable MRD at the end of induction. Thus, in the current UK trial, post-remission treatment intensity is stratified by MRD response at the end of induction and recovery from consolidation.

The improved outcomes reported in UKALL 2003 and other recent trials have been obtained in the absence of new drugs for the treatment of ALL for over 40 years. The use of dexamethasone and pegylated asparaginase throughout treatment is likely to be an important contributor to the improvement seen in UKALL 2003. Several large randomised clinical trials have demonstrated the improved efficacy of dexamethasone in preventing systemic and CNS relapse compared with prednisolone. Pegylated asparaginase has better pharmacokinetic and pharmacodynamic properties than the native formulation and a lower risk of hypersensitivity reactions on re-exposure. The successor study to UKALL 2003, UKALL 2011 study recruited patients between 2011 and 2018 and a preliminary analysis has shown similar outcomes to UKALL 2003.

Treatment of distinct subgroups

ABL-class fusions

A subset of patients with *BCR::ABL1*-like ALL harbour an ABL-class fusion. Patients with refractory disease on the UKALL2003 trial harboured a high frequency of ABL-class fusions (10%) Specifically *EBF1::PDFGRB* patients had high levels of end of induction MRD and a high rate of relapse An analysis of 13 patients with an ABL-class fusion on UKALL2011 treated with imatinib in first remission demonstrated a superior event free survival compared to contemporary controls ($n = 8$) not treated with a tyrosine kinase inhibitor. As such, all patients ABL class fusion are treated with imatinib (340 mg/m^2/day) on day 15 of induction which is then given continuously. They are also transferred to Regimen C with further treatment allocation dependent on end consolidation MRD.

Young people (age 16–25 years)

A decade ago, retrospective comparisons demonstrated a consistent and large EFS or OS advantage for young people with ALL treated according to paediatric protocols compared with adult protocols. The reasons for this were unclear but possibly included physician experience and compliance, patient compliance, supportive care and specific aspects of protocol design. In particular, early dose intensification of chemotherapy, higher cumulative doses of steroids, vincristine and L-asparaginase and less frequent use of alkylating agents, anthracyclines, high dose cytarabine and allogeneic stem cell transplant (with the associated higher treatment-related mortality) in paediatric protocols.

Table 22.3 Outcomes with contemporary childhood ALL protocols.

Trial	Group	Region	Years	Subgroup (n)	EFS (yrs)	OS (yrs)
Several	COG	US, Canada, Australia, New Zealand	2006–10	All patients (8090)	N/A	91.5% (5-yr)

* infants <1 year old excluded where possible.

The results of these retrospective comparisons have been validated in prospective trials that recruited 16–25 year old patients to a paediatric protocol, such as UKALL 2003, in which that age group had a 5-year EFS of 75%.

Infants

Acute lymphoblastic leukaemia (ALL) in infants under 1 year of age is rare and biologically different from ALL in childhood. Infant ALL is characterised by a high frequency of *KMT2A* gene rearrangements, a very immature B-cell phenotype (proB ALL), expression of myeloid markers, lack of CD10 expression, presentation with a high tumour load and a poor outcome. *KMT2A* rearrangement status, presenting white blood cell count (WBC), age at diagnosis and prednisone response are independent prognostic factors and a model comprising age, *KMT2A* status and WBC stratifies patients into three risk groups with distinct 4-year EFS (Low: *KMT2A* germ line, EFS 74%; Intermediate: *KMT2A* fusion, WBC < 300 or age < 6 months, EFS 43% and High: *KMT2A* fusion and age < 6 months and WBC > 300, EFS 18%) in the Interfant99 international trial. Its successor, Interfant 06, combined this risk stratification algorithm and MRD response to select patients for first remission allogeneic transplant. The trial also tested 'myeloid' versus lymphoid consolidation but the former was not found to be of benefit except in a subgroup with expression of myeloid markers and MRD > 0.05% at the end of induction. Unfortunately, the overall outcome for *KMT2A* fusion patients was poor even with myeloid consolidation. A recent small Japanese study has reported better outcomes using a chemotherapy dose-intensive approach combined with CR1 HSCT in a higher proportion of patients than Interfant06. Molecular investigations, pre-clinical studies and early phase clinical studies indicate that epigenetic modifiers and immune-based approaches might be effective in *KMT2A* fusion cases. The UK is piloting an approach of replacing toxic consolidation therapy with Blinatumomab which will form the basis for a non-randomised question in Interfant21. Recent studies have found that *KMT2A* germ line infant ALL patients have genetic abnormalities similar to those seen in older patients, including *NUTM1* and *PAX5* fusions. The former is associated with an excellent prognosis and, in the UK, *KMT2A* germ line patients have been treated the same as older children since Interfant06 closed.

Down syndrome

Children and young people with DS have a 10–20-fold increased risk of developing ALL compared to those without DS. This increased risk is limited to the first three decades of life but with a notable absence of ALL in those under a year of age. T cell ALL is rare in DS, as is the presence of CNS disease at diagnosis. ALL associated with DS (DS-ALL) has a distinct frequency of genetic changes from ALL seen in the non-DS population. Recurring cytogenetic abnormalities conferring either a favourable or poor prognosis are less common and *CRLF2* rearrangements (especially *P2RY8::CRLF2*) are present in nearly 50%. Secondary events including *IKZF1* deletions and *JAK2* mutations are also common. DS-ALL historically had an inferior survival due to a combination of increased relapse risk and high treatment-related mortality (TRM) (21 versus 3% for non-DS-ALL on UKALL2003). TRM occurred in all treatment phases in the DS-ALL cohort unlike the non-DS cohort where TRM occurred predominantly in induction. As a result, several modifications were made from July 2009 in UKALL2003 and for the successor trial UKALL 2011 trial including better supportive care and de-escalation of treatment. As a result, TRM has reduced to 2% (similar to non-DS) without an increase in relapse risk. In the forthcoming ALLTogether1 Study (see below), DS-ALL patients with detectable end of induction MRD Blinatumomab will be replacing 2 consolidation chemotherapy blocks to further reduce toxicity while maintaining efficacy.

Relapse

Relapse may occur during or after treatment, the latter usually within 2 years after cessation of therapy but occasionally later (relapses occurring as late as 10 years after diagnosis have been reported but rarely). The bone marrow remains the most common site of relapse, but the proportion of patients with relapse involving an extra-medullary site, particularly the CNS, has steadily increased as systemic first-line therapy has become more effective. Even when extra-medullary relapse appears to be an isolated event, it is often associated with submicroscopic residual disease in the bone marrow. Although the clonal populations at relapse may not genetically identical to the dominant population at diagnosis, sensitive PCR techniques reveal that they are present as minor subclones that have been selected due to their relative resistance to chemotherapy or through acquisition of epigenetic changes.

The chances of cure after relapse are related primarily to timing of relapse in relation to first diagnosis, immunophenotype, genetic risk group and site. Adverse risk factors include short initial remission, high-risk genetics (see above), T-cell immunophenotype and poor response to relapse therapy. The outcome for relapse patients has not significantly improved in the last 20 years, particularly for high-risk relapses who had dismal outcomes with 5-year EFS and OS of 24 and 26% respectively in the UKALLR3 trial and subsequent UK audit of relapse outcomes. Furthermore, intensive chemotherapy with or without CR2 HSCT exposes patients to a high risk of treatment-related mortality (10–15%) and morbidity including late neuro-cognitive side effects of cranial radiotherapy and TBI. Hence the approach in the UK since 2018 has been to replace the toxic elements of treatment with immune therapy to reduce toxicity whilst maintaining efficacy. Preliminary analysis of this approach is showing promise and is supported by results of randomised studies showing improved disease-free survival and reduced toxicity with Blinatumomab consolidation compared with intensive chemotherapy in high-risk relapses. Other options are the anti-CD22/calicheamycin conjugate antibody Inotuzumab which has been shown to induce MRD-negative remissions in 80% of relapse patients. CD19-directed CAR-T cell therapy (Kymriah) is licensed for primary refractory and post-transplant or refractory relapse and offers a chance of cure to patients who have failed all other treatment including HSCT. Real-world experience using a stringent definition of events to include B cell recovery and use of further therapy shows a 1-year EFS of 34%. Ongoing studies of autologous and allogeneic CART cells are addressing their role in first-line and first-relapse settings including those with isolated CNS relapse. There are also studies of CART cell therapy for relapse T-cell ALL which are showing promise as are those targeting multiple antigens.

Early and late toxicity

Modern intensive therapy is associated with a small risk of mortality (1% in induction, 2% in CR) and significant acute and late morbidity (Table 22.4). A majority of the latter are attributable to cranial radiotherapy and there has been a gratifying reduction in the number of patients with endocrine, growth and neuropsychological problems since it was replaced by alternative approaches to prevention of CNS relapse. Dexamethasone is more toxic than prednisolone and likely to be a significant contributor to the risk of serious bacterial and fungal infection. In a recently concluded European study, AIEOP-BFM 2000, there were twice as many induction deaths amongst patients in the dexamethasone arm compared with the prednisolone arm and other studies have reported a similar experience. Infection remains the biggest cause of TRM. An analysis of infection-related mortality (IRM) on UKALL 2003 demonstrated that the incidence of IRM was 2.4% accounting for 30% of trial deaths and 64% of TRM deaths. The risk for IRM as a proportion of TRM was greater in induction than other phases (77 versus 56%; $P = 0.02$). Sixty-eight percent of cases were associated with bacterial infection (64% Gram-negative) and 20% with fungal infection. Down syndrome was the most significant risk factor for IRM (odds ratio 12.08). The excessive IRM in Down syndrome has now reduced substantially following the amendments made in the subsequent study UKALL2011 (see section on Down syndrome for further details).

Table 22.4 UKALL 2003 serious adverse events.

Risk group	All patients (%)	Reg A (%)	Reg B (%)	Reg C (%)	*p*-value (Reg C vs A/B)
Any infection	307 (13.3)	134 (11.1)	98 (17.5)	75 (14.0)	0.63
Fungal infection	81 (3.5)	25 (2.1)	35 (6.2)	21 (3.9)	0.58
Encephalopathy (excluding seizure)	164 (7.1)	43 (3.6)	58 (10.4)	63 (11.7)	**<0.0001**
Asparaginase Hypersensitivity	47 (2.0)	4 (0.3)	3 (0.5)	40 (7.4)	**<0.0001**
Pancreatitis	33 (1.4)	9 (0.7)	8 (1.4)	16 (3.0)	**0.0006**
Osteonecrosis	88 (3.8)	9 (0.7)	52 (9.3)	27 (5.0)	**0.097**
Thrombosis	51 (2.2)	20 (1.7)	15 (2.7)	16 (3.0)	0.17
CNS Thrombosis	31 (1.3)	12 (1.0)	10 (1.8)	9 (1.67)	0.45
Number in risk groups	2300	1203	560	537	

There is also concern that dexamethasone is associated with a higher risk of osteonecrosis than prednisolone, but that has not been a universal experience. Toxicity attributable to asparaginase occurs in a significant proportion and is dependent on the cumulative exposure to Asparaginase. In the NOPHO 2008 study, a randomised intensification of PEG-asparaginase did not improve EFS but was associated with almost a doubling of serious adverse events such as hypersensitivity, pancreatitis, thrombosis and osteonecrosis) compared with the control arm.

Treatment in a resource poor setting

The drugs, staffing and infrastructure required to deliver the treatment described above are very expensive with an estimated UK cost of £50,000/case for first-line therapy and over £1million for CART therapy using number needed to treat cost analysis. Over 80% of new cases of ALL will arise in countries that cannot afford this cost. Thus, there is an urgent need for studies to test more affordable treatment protocols that can be delivered within a resource-poor setting. The challenge of delivering optimal care to such a large number of patients in a resource-poor setting has been met by clinicians in those countries through a combination of adaptation and innovation, including use of generic alternatives for expensive drugs, although the latter bring with them issues of quality control particularly of biological agents. For a number of reasons, apart from lack of resources, outcomes are worse compared with the West, even within a tertiary care setting. A lower incidence of good-risk karyotypes (*ETV6::RUNX1*, high hyperdiploidy), malnutrition, partial compliance and poor general hygiene conspire to increase the risk of relapse and infection-related deaths. There are no easy solutions to these problems. Simple flow cytometric algorithms for measurement of MRD may be applicable in this setting and could provide a relatively cheap method to identify low-risk patients who can be cured without post-remission intensification therapy, thus avoiding infection-related deaths in this group. Learning from the experience of tuberculosis, pilot programmes should test the feasibility of directly observed treatment to improve compliance with maintenance chemotherapy. Universal access to treatment though remains the single most difficult challenge in this setting. As these nations' overall wealth increases, only a massive investment in public health infrastructure will address this challenge.

Future strategies and conclusions

Given the good results of current protocols, future studies of childhood ALL therapy are faced with the law of diminishing returns. However, there remains a substantial minority of patients with primary refractory disease (around 2%) or early relapse (10%) who cannot be cured with current treatment, including Haemopoietic Stem Cell Transplant. These patients can be identified in first CR as having persistent high-level MRD during the first 20 weeks of treatment. Intervention with novel agents (monoclonal antibodies, tyrosine kinase inhibitors, Nelarabine, Clofarabine and CART cells) with or without HSCT early in first CR might offer some of these patients a cure.

More importantly, attention is being focussed on reducing treatment-related deaths which make up an increasing proportion of treatment failures. Identification of groups at high risk of toxicity (e.g. Down syndrome) and pharmacogenomic expression profiling will guide targeted supportive care and individualised drug dosing to reduce toxic deaths. There is evidence that gene expression profiling of leukaemic blasts can predict *in vitro* and *in vivo* chemosensitivity and treatment in future could be customised to a patient's pharmacogenomic and leukaemia gene expression profiles. A recent study testing Blinatumomab to replace toxic chemotherapy and HSCT has shown that such a 'de-escalation' strategies can maintain and improve EFS by reducing both relapse rates and treatment-related mortality and morbidity. Translation of recent advances in understanding the molecular biology of ALL and its influence on phenotype and clinical outcome are defining specific

subgroups that might benefit from targeted therapy, such as TKIs for patients with ABL-class fusions. Lastly, international collaboration, as highlighted by the INTERFANT and ALLTogether consortia, will need to increase to properly investigate new treatment strategies and the biological determinants of treatment response in increasingly small subcohorts of patients.

CHAPTER 23

Chronic lymphocytic leukaemia and other chronic B-cell lymphoproliferative disorders

23

Emili Montserrat

Institute of Haematology and Oncology, Hospital Clinic, University of Barcelona, Barcelona, Spain

Classification

Chronic B-cell lymphoproliferative disorders include several entities arising from mature B lymphocytes, which involve primarily the blood, bone marrow and lymphoid organs such as the lymph nodes and the spleen. A constant finding in all these entities is the presence in peripheral blood of leukaemic cells in various degrees. Some of these conditions can be considered primary leukaemias. Others represent the leukaemic phase of B-cell lymphomas and are largely discussed in Chapter 26.

Table 23.1 lists chronic B-cell lymphoproliferative disorders with leukaemic expression as discussed in this chapter.

General aspects of diagnostic methodology

The first diagnostic step is to verify the presence of a non-transient blood lymphocyte count $>5 \times 10^9$/L since many benign conditions may cause moderate and temporary lymphocytosis. Next is the examination of a peripheral blood smear by an experienced haemato-pathologist. This is followed by the study of the immunophenotype (B or T) and determining whether the process is clonal or polyclonal. Once a monoclonal B-cell proliferation is confirmed, the diagnosis needs to be further clarified by using a panel of monoclonal antibodies and genetic markers (Table 23.2).

In those cases in which the absolute lymphocyte count is high ($>5 \times 10^9$/L) and the blood film and immunophenotype show unequivocal features of chronic lymphocytic leukaemia (CLL), lymph node histology is not required. If the diagnosis of lymphoma is a possibility, it is essential to perform a lymph node biopsy. Bone marrow biopsy can confirm a diagnosis of CLL or lymphoma and inform about the mechanism of anaemia or thrombocytopenia. For disorders with an enlarged spleen, such as hairy-cell leukaemia (HCL), splenic marginal zone lymphoma (SMZL) and the non-nodal, leukaemic mantle-cell lymphoma (MCL), spleen histology may be necessary to make the diagnosis. Fluorescence *in situ* hybridisation (FISH) allows the assessment of cytogenetic abnormalities in interphase cells. There is no specific genetic abnormality in CLL but FISH is important for excluding MCL with t(11;14)(q13;q32) and follicular lymphoma with t(14;18)(q32;q21). Next-generation sequencing techniques are unfolding the molecular heterogeneity of B-cell chronic lymphoproliferative disorders but are not employed in routine diagnosis. Finally, whenever possible, biological material not used for diagnostic purposes should be preserved, which can be useful for both research purposes and further studies of clinical interest for the patient.

Chronic lymphocytic leukaemia

Definition

CLL is a biologically and clinically heterogeneous disorder caused by the relentless accumulation in bone marrow, peripheral blood and lymphoid tissues of monoclonal B lymphocytes with a distinct immunophenotype (i.e. SmIg^{weak}, CD5^{+}, CD19^{+}, CD23^{+} and CD200^{+}) and a wide range of immune defects. CLL and small lymphocytic lymphoma (SLL) are the same mature B-cell neoplasm that differs in the extent to which the tumour involves blood (CLL) or lymphoid tissue (SLL). Within the SLL/CLL spectrum, about 10% of cases present as SLL and 90% as CLL. In many instances, SLL evolves to CLL over time. The median survival of patients with CLL is >10 years, but the individual prognosis is highly variable, ranging from a few

Table 23.2 Immunophenotypic and genetic markers in chronic B-cell lymphoproliferative disorders.

years to a normal lifespan. Despite important progress in its therapy, in most instances, CLL remains an incurable disease.

Epidemiology

CLL is the most frequent form of leukaemia in Western countries. The disease predominates in males (1.5–2:1) and the median age of patients at diagnosis is around 70 years. The incidence of CLL dramatically increases with age, reaching >20 cases per 100,000/year in individuals older than 70. In Europe, the incidence rate for all subtypes of leukaemia is 7.2 per 100,000/year, of which 34% of cases are CLL, translating to approximately 12,500 new CLL cases annually. Each year, CLL is responsible for approximately 6000 deaths across Europe. In the United States, the age-adjusted incidence rate is 4.2 cases per 100,000/year.

Genetic predisposition

The relative risk of developing CLL in patients' relatives is three to 8 times higher than in the normal population. The molecular basis of familial CLL is currently being unravelled by genome-wide association studies, including both families and sporadic cases. Familial CLL often co-segregates with other B-cell disorders, mainly lymphomas. Also, the prevalence of monoclonal B-cell lymphocytosis (MBL), a situation which may precede CLL, in the normal population is 3–12%, while in first-degree relatives of patients with CLL is 13–18%. While in Western countries CLL accounts for around 30% of all cases of adult leukaemia, in Asian countries (and in Asian-American people) and Japan CLL is an infrequent disease and remains so in the migrant population.

Pathogenesis

Neoplastic CD5+ B CLL cells are antigen experienced and express CD23, CD25, CD27, CD69 CD71, ROR1 and CD200. It is likely that they originate in haematopoietic stem cells (HSCs) found amid clonal haematopoiesis. The evolution from these progenitors to MBL and, ultimately, to overt CLL is the result of additional genetic and epigenetic abnormalities, B-cell receptor (BCR) stimulation, and microenvironment and T-cells crosstalk. Relevant genetic drivers of the disease are the deletion of miR15 and miR16 in chromosome 13q14, trisomy 12 and *MYD88* mutations. Over time, other mutations appear, including those involving *TP53, ATM, BIRC3, NOTCH1, XPO1* and *SF3B1*. Finally, in the most advanced cases, *C-MYC* and *CDKN2A* mutations can also be present.

Importantly, the immunoglobulin heavy chain variable region genes (*IGHV*) may be mutated or unmutated. Mutated *IGHV* (*IGHV*-M) (defined as <98% homology to germline IGHV sequence) CLL originates from post-germinal centre (GC) $CD5^+CD27^+$ B cells. Conversely, *IGHV*-unmutated (*IGHV*-UM) CLL appears to derive from pre-GC $CD5^+CD27^-$ B cells, which might arise from naive B cells or a separate lineage of precursor B cells, in a T cell-independent process (Figure 23.1). Of note, the *IGHV* gene repertoire is enriched in specific subtypes (e.g. *IGHV1-69*, *IGHV3-7* and *IGHV4-34*), suggesting a role for antigen stimulation and selection in CLL pathogenesis.

A key feature in CLL pathogenesis is the progressive accumulation of CD5 + B cells because of a failure in programmed cell death or apoptosis. Although most cells are in $G_{0/1}$ phase, there is a fraction of cells (0.1–1%) rapidly duplicating and renovating every day. The resistance of these cells to apoptosis is related to the upregulation of the antiapoptotic proteins such as BCL2 and MCL1 and downregulation of proapoptotic proteins such as BCLX. The microenvironment plays an essential role in protecting CLL cells from death through several molecules. This is demonstrated by the fact that *in vitro* CLL cells rapidly undergo apoptosis unless they are co-cultivated with stromal cells or in a stromal-mimicking milieu.

Immune defects

Hypogammaglobulinaemia affects ~25% of patients and tends to worsen over the course of the disease. In early stage, the absolute count of $CD8^+$T lymphocytes is increased, causing an imbalance of the $CD4^+/CD8^+$ ratio. T cells show an abnormal phenotype, with increased expression of exhaustion markers such as cytotoxic T lymphocyte antigen-4, lymphocyte activation gene 3, CD244, CD160 and PD-1. Functionally, these phenotypic changes correlate with a deficient immune synapse formation, significantly reduced cytotoxic and proliferative potential. Defects in NK cells, ADCC, monocytes and granulocytes are also found. Response to vaccination is suboptimal.

Clinical features

Approximately, 80% of patients are diagnosed while asymptomatic. In the rest, painless generalised peripheral lymphadenopathy (i.e. neck, axillae, and inguinal) is frequent. In contrast, mediastinal and retroperitoneal lymphadenopathy are less common. On some occasions, the investigation of bacterial infections, particularly pneumonia, or herpes virus infections may lead to the diagnosis. Rarely, the disease is discovered during the diagnostic workup of an autoimmune haemolytic anaemia (AIHA) or, even less frequently, an immune thrombocytopenia (ITP). Fatigue, fever, weight loss and drenching night sweats may affect a significant proportion of patients. A peculiar feature in some patients is high sensitivity to insect, mainly mosquito, bites. Rarely, CLL may involve extra haematological tissues, such as skin, liver, kidney or central nervous system; in such cases, however, disease transformation needs to be ruled out. In addition, vasculitis, hypercalcaemia and nephrotic syndrome are occasionally observed. Spontaneous regression of the disease

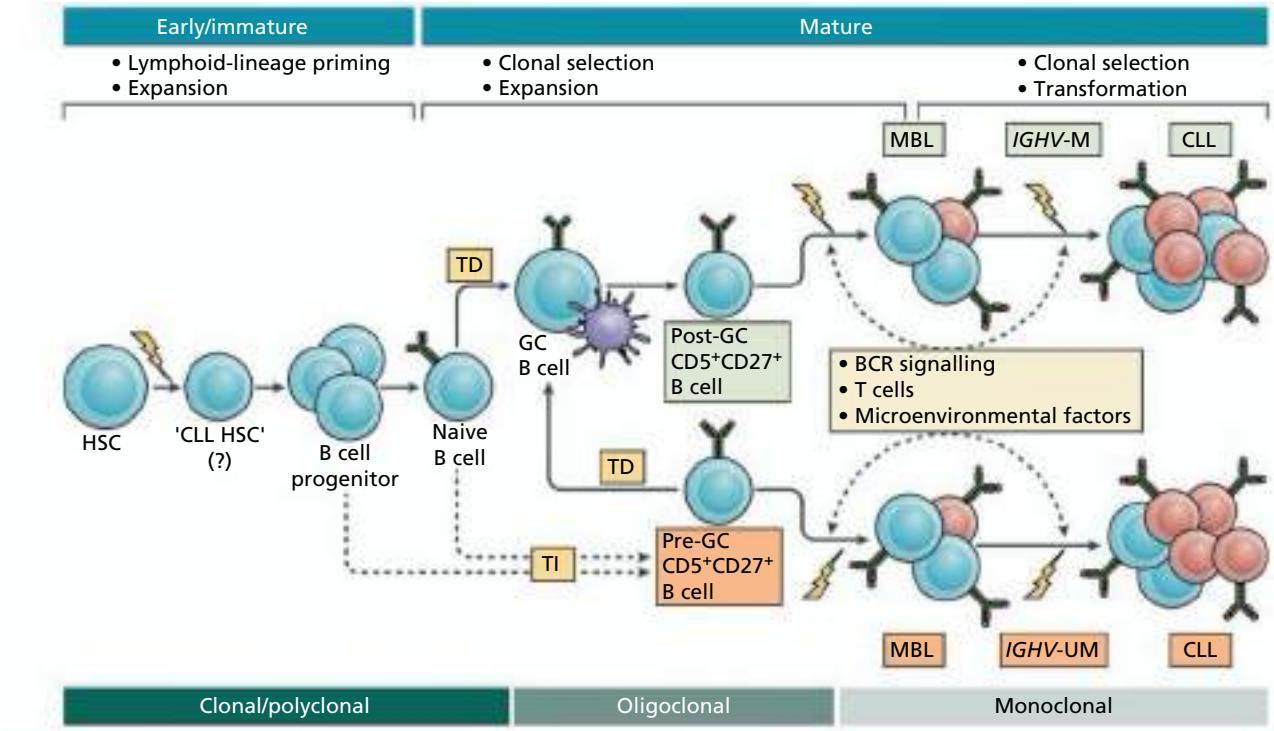

Figure 23.1 Genetic and epigenetic events leading to CLL. The genetic and epigenetic events leading to CLL have been suggested to occur in haematopoietic stem cells (HSCs). After HSCs acquire genetic and epigenetic lesions (indicated by lightning symbols), the cellular output of these lesions could be a polyclonal expansion of B cell progenitors. Subsequent antigenic stimulation might lead to oligoclonal selection and expansion of mature B cells. As mentioned above, CLL cells with mutations in the immunoglobulin heavy chain variable region genes (*IGHV*-M) seem to originate from post-germinal centre (GC) CD5+ CD27+ B cells, which are most likely derived from CD5+ CD27+ B cells that have undergone the GC reaction. Conversely, *IGHV*-unmutated (*IGHV*-UM) CLL seems to be derived from pre-GC CD5+ CD27− B cells, which might arise from naive B cells or from a separate lineage of precursor B cells, probably in a T cell-independent process. The evolution from these progenitors to monoclonal B lymphocytosis (MBL) and, ultimately, to overt CLL is dictated by additional genetic and epigenetic abnormalities (indicated by lightning symbols), B cell receptor (BCR) stimulation, microenvironmental factors and T cells. The dashed arrows indicate a hypothetical mechanism. TD, T cell-dependent antigen; TI, T cell-independent antigen (Source: From Bosch F and Dalla Favera R. Nature Reviews/Clinical Oncology 16 November 2019 (reproduced by permission)).

can be observed in 1–2% of patients per year. The remission, though, is rarely complete, most patients have persistent disease by flow cytometry and it is usually transient. The mechanisms behind spontaneous remissions are poorly understood but could involve immune-mediated reactions.

Patients with CLL may present concurrent diseases and fragility. The Cumulative Illness Rate Score (CIRS) is frequently employed to assess comorbidity. Particularly important is an impaired renal function (creatinine clearance <60 mL/min), which is associated with poor tolerance to fludarabine-based therapy and higher toxicity. Cardiac arrythmias, coagulation abnormalities and hypertension need to be taken into consideration when treatment with BTKi is considered.

Laboratory features

The hallmark of the disease is an increased white blood cell (WBC) count with a high percentage of lymphocytes and absolute lymphocytosis (Figure 23.2). A proportion of prolymphocytes (1–10%) are nearly always seen when WBCs are higher than 30×10^9/L. If the proportion of prolymphocytes is greater than 15% CLL is considered to be transforming into an aggressive (or accelerated) clinical form (Figure 23.3). Some patients have a mixed pattern of small and large cells and others have lymphoplasmacytoid features or even cells with nuclear clefts. These are often associated with other atypical features, such as $SmIg^{strong}$ and trisomy 12. *MYD88* L265P mutation is not detected.

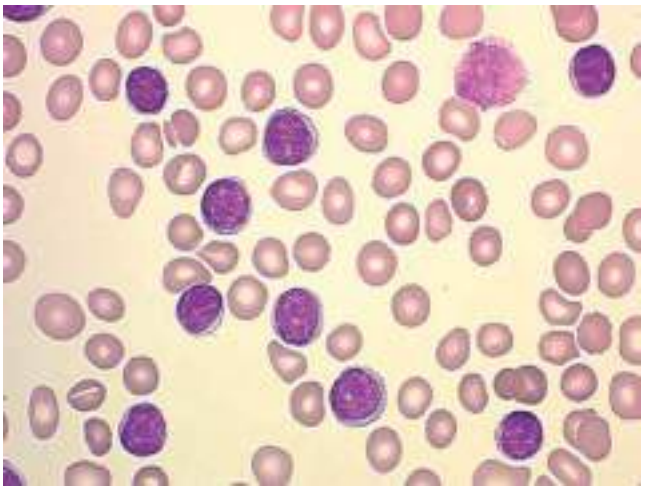

Figure 23.2 Blood film of a typical case of CLL. Small lymphocytes with scanty cytoplasm and tenuous nucleoli. In the upper right corner, a Gumprecht cell is observed.

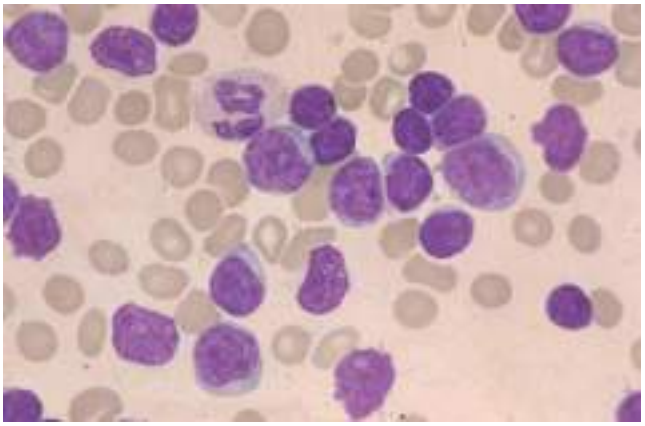

Figure 23.3 Blood film from a case of transforming CLL. Note the dual population of small lymphocytes and larger nucleolated prolymphocytes.

At diagnosis, anaemia is found in less than 10% of the subjects. Importantly, anaemia is not always due to the infiltration of the bone marrow by the disease; other causes such as autoimmunity, iron, folic acid or vitamin B12 deficiency may cause anaemia, particularly in the elderly and malnourished people. Likewise, thrombocytopenia is infrequent at diagnosis. A marked thrombocytopenia (e.g. $<20 \times 10^9$/L) in a patient with previous normal counts should raise the possibility of an immune origin, particularly in the absence of anaemia. Hypogammaglobulinaemia is frequent, particularly in advanced phases of the disease (20–40% of patients). IgM is the first immunoglobulin to decrease followed by IgG and, less frequently, IgA. Serum immunofixation can demonstrate an M component (usually of the IgM type) in 5–10% of cases. A positive direct antiglobulin test (DAT) is observed in around 5% of the patients at the time of diagnosis, with clinically apparent AIHA being less frequent.

Genetic and molecular features

CLL has no specific genetic lesions. The most frequent cytogenetic abnormalities are del(13q14), del(11q22-23), trisomy 12, del(6q) and del(17p13.1), which are associated with some peculiar clinical features and outcomes (Table 23.3). Del(17p) is observed in 5–50% of cases, depending on the characteristics of the studied population (e.g. untreated and treated). Historically, metaphase cytogenetic studies of CLL have yielded little information because CLL cells neither readily divide spontaneously in culture, nor do they respond to traditional B-cell mitogens. The stimulation of CLL cells with CpG oligodeoxynucleotide has facilitated the detection of cytogenetic abnormalities in up to 80% of patients. Thus, complex karyotypes (usually defined as either >3 or >5 aberrations) can be observed in 5–30% of patients, depending on the characteristics and phase of the disease, while chromosomal translocations are found in 20–30% of cases. In around 30% of cases, cytogenetic evolution occurs over the course of the disease. *TP53* mutations are usually observed in del(17p), but in 5–15% of cases, *TP53* mutations can occur in the absence of del(17p). Mutations of other genes such as *MYD88, NOTCH-1, SF3B1* and *BIRC3* can be observed in 5–15% of cases. Epigenetic lesions are the subject of many studies to better understand the landscape of genetic lesions in this disease. The *IGHV* gene repertoire is enriched by specific subtypes (e.g. *IGHV1-69*, *IGHV3-7* and *IGHV4-34*).

Pathology features

In typical cases, the histology of lymph nodes shows effacement of the architecture by small lymphocytes with a pseudo-follicular pattern of pale areas that correspond to proliferation centres. Proliferation centres contain numerous T cells, a fine network of dendritic cells and B cells with an increased expression of proliferation-associated markers and antiapoptotic molecules. There are patients whose lymph nodes have expanded proliferation centres (pseudo-follicles) with a high proliferation rate ('accelerated' or 'transforming' CLL). Differences observed in lymph node histopathology over the course of the disease are consistent with the concept of CLL as an evolving disorder, from typical CLL to 'accelerated'/'transforming' CLL and eventually disease transformation or Richter's syndrome (RS) (see Disease Transformation).

The spleen shows a diffuse infiltration, mainly affecting the white pulp.

The bone marrow displays a variable degree of infiltration by the disease but, in contrast to follicular lymphoma, there is no para trabecular infiltration. Four infiltration patterns have been described: nodular, interstitial, mixed (nodular + interstitial) and diffuse. While in early clinical phases of the disease nodular

Table 23.3 Cytogenetic and molecular features. Biologic and clinical correlations.

and interstitial patterns predominate, in advanced phase diffuse infiltration is the norm.

Diagnostic criteria

The diagnosis of CLL requires the following parameters:

- Presence in peripheral blood of $>5\times10^9$/L monoclonal B lymphocytes persisting for at least 3 months.
- Demonstration of the clonality of the population (κ/λ analysis).
- Characteristic immunophenotype: SmIg^{weak}, CD5$^+$, CD19$^+$, CD20^{weak} and CD23$^+$.

Based on the immunophenotypic characteristics and giving one point to each one of the following markers: CD5$^+$, CD23$^+$, FMC7^{weak}, SmIg (κ/λ staining) ^{weak} and CD79b^{weak}, Matutes and Catovsky showed that a score of 4–5 indicates almost invariably CLL, while a score <3 corresponds in most instances to non-CLL cases. FMC7 is a CD20 epitope and is now rarely employed as a marker. CD20 or CD79b can be used instead of FCM7 to obtain the diagnostic score. In line with this, the 'characteristic' CLL immunophenotype (i.e. SmIg^{weak}, CD5$^+$, CD19$^+$, CD20^{weak} and CD23$^+$) might be expanded to include other markers such as CD200.

Bone marrow aspirate and biopsy are not necessary for diagnosis but can be useful in complex cases and to provide information about the origin of cytopenias (i.e. bone marrow failure because of disease infiltration versus 'peripheral' mechanisms such as hypersplenism or autoimmunity). Moreover, the presence of cytopenia caused by a typical marrow infiltrate establishes the diagnosis of CLL regardless of the number of peripheral blood B lymphocytes or the lymph node involvement or organomegalies.

Differential diagnosis

Usually, the diagnosis of CLL is straightforward and does not present difficulties. In CLL, a small percentage (i.e. 1–10%) of atypical lymphocytes (e.g. prolymphocytes, lymphoplasmacytoid cells and cleaved cells or centrocytes) can be present in blood. If the percentage of atypical cells is >15% CLL is considered to be in 'transforming' or 'accelerated' phase. In such cases, trisomy12, FMC7 expression, *TP53* deletion, high rate of cell divisions (as shown with the antibody Ki-67) and many proliferating centres ('pseudo follicles') in lymph nodes and bone marrow can be found.

The diagnosis of SLL requires the presence of lymphadenopathy and the absence of cytopenias caused by a clonal marrow infiltrate. Additionally, the number of B lymphocytes in the peripheral blood should be $<5\times10^9$/L. In SLL, the diagnosis should be confirmed by histopathological evaluation of a lymph node biopsy or biopsy of other tissues. Some patients may present with enlarged lymph nodes that are not suspicious for solid tumours and with peripheral blood B lymphocytes $<5\times10^9$/L that carry a typical CLL immunophenotype. In these cases, a tissue or lymph node biopsy may not be necessary to establish the diagnosis of SLL.

Lymphoplasmacytic lymphoma (LPL) is characterised by a proliferation of *IGHV* mutated late-stage mature B-cells, with an admixture of small lymphocytes, plasmacytoid lymphocytes and plasma cells. A monoclonal IgM peak is a hallmark of Waldenström disease, a form of LPL. Neoplastic cells are IgM+, CD19+, CD20+, CD22+, CD25+, CD27+, FMC7+, CD5 variable, CD10−, CD23−, CD103− and CD108−. Plasma cells are typically CD138−. The diagnosis requires the exclusion of other B-cell disorders with plasmatic differentiation. *MYD*88(L265P) mutations are found in nearly all patients, and mutations of *CXCR4* are present in around 30% of cases. In some cases, a moderate increase of lymphocytes in blood is observed.

The diagnosis of *atypical CLL* should not be accepted without a comprehensive study to exclude a lymphoma in leukaemic phase. Because of this, when atypical lymphoid cells are present, it is important to consider the diagnosis of lymphoma evolving with tumour cells in blood. MCL can present with leukaemic involvement. The best method to exclude (or confirm) MCL is to test for t(11;14) by FISH and/or to demonstrate expression of cyclin D1 by immunohistochemistry. In contrast with nodal MCL, the leukaemic form is SOX (−) and CD200 (+). Other lymphomas can be excluded by histological criteria and the combination of peripheral blood morphology, immunophenotype and genetic features (Table 23.2).

A rare abnormality is *persistent polyclonal B-cell lymphocytosis*. This disorder is characterised by a median age at diagnosis of 40 years, a female predominance, a moderately increased and persistent lymphocyte count and occasional splenomegaly. The bone marrow is slightly infiltrated, sometimes showing intrasinusoidal distribution. Most patients are smokers and 90% have HLA-DR7 in their genotype. The cell markers show a non-clonal cell proliferation, $CD19^+$, $CD5^-$, $CD23^-$ and $CD27^+$. There are also increased levels of polyclonal IgM in serum. Despite its benign and non-clonal nature, several abnormalities have been shown in the B lymphocytes such as an extra copy of the long arm of chromosome 3 in the form of iso(3q) and also the presence of *IGH/BCL2* rearrangements. The blood picture is pleomorphic and frequently shows binucleated lymphocytes (Figure 23.4), which are characteristic of this condition. Persons with this abnormality should not receive therapy but be followed to detect an otherwise infrequent (around 3%) disease transformation.

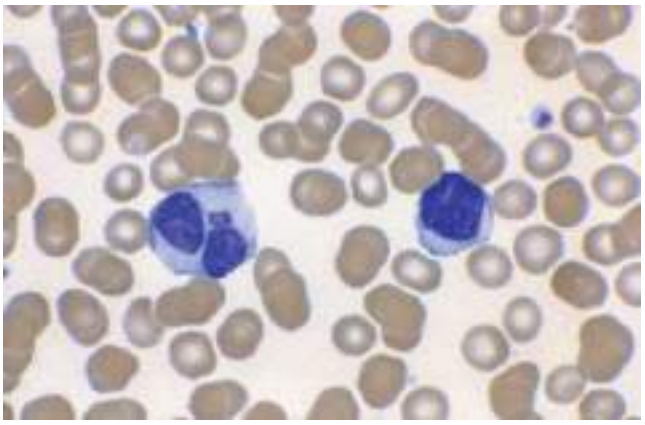

Figure 23.4 Blood film from a case of polyclonal B-cell lymphocytosis showing a binucleated cell characteristic of this condition.

Monoclonal B-cell lymphocytosis

In the absence of lymphadenopathy, organomegalies (detected clinically or by imaging studies), cytopenia and clinical symptoms, the presence of $<5\times10^9$/L monoclonal B lymphocytes in blood is defined as monoclonal B cell lymphocytosis (MBL). The prevalence of MBL in the normal population is 3–12% and is higher in first-degree relatives of patients with CLL and older subjects (13–18%). Its detection depends on the sensitivity of the flow-cytometry technique. The cut-off value of 5×10^9/L monoclonal cells for diagnosing MBL was selected arbitrarily to be consistent with CLL diagnostic guidelines and include patients in trials and is not based on substantial biological differences between MBL and Rai stage O CLL. Moreover, MBL represents a miscellaneous category ranging from patients with minute clonal B-cell populations detected in the general population or blood donors to patients referred for consultation. There are cases in which there is more than one B-cell clone, and others in which there is a mixture of monoclonal B cells and monoclonal T cells. Although the immunophenotype is in most cases identical to that of CLL, there are cases with an atypical immunophenotype (e.g. CD5-negative) or resembling SMZL, LPL, FL, non-nodal, leukaemic MCL or multiple myeloma, without fulfilling diagnostic criteria for overt malignancy.

MBL is classified by both the specific clonal B-cell immunophenotype (CLL-like MBL, non–CLL-like MBL or atypical MBL) and the size of the B-cell clone (low-count or high-count MBL). High-count MBL is defined by an absolute B-cell count $\geq0.5\times10^9$/L, makes up ~2% of all MBLs, and is typically identified in the clinic during the workup of lymphocytosis. High-count MBL has been shown to progress to CLL requiring

Table 23.4 Comparison of CLL, SLL and MBL.

	CLL	SLL	MBL
Clonal B-cells in peripheral blood	$\geq 5 \times 10^9$/L	<5x10^9/L	<5x10^9/L

CLL, chronic lymphocytic leukaemia; SLL, small lymphocytic lymphoma.
* Imaging studies recommended.
** Cases with cytopenia caused by the infiltration of bone marrow by lymphocytes are categorised as CLL, independently of the presence or not of lymphadenopathy and/or organomegaly.

treatment at a rate of 1–2% per year. Conversely, the clonal population can spontaneously regress over time. From the clinical standpoint, MBL has been associated with a higher tendency to suffer infections, immune defects and second neoplasias, although no striking differences exist with what occurs in Rai stage 0 CLL. Persons with MBL should be reassured their condition only needs periodic monitoring and that the possibility of evolving to CLL is remote. Terms such as 'leukaemia', 'pre-leukaemia' or 'cancer' should not be unnecessarily used when explaining the nature of the disease to the patient.

In Table 23.4, the differences between CLL, SLL and MBL are shown.

Autoimmune cytopenia

CLL is frequently accompanied by autoimmune cytopenia. *Autoimmune haemolytic anaemia* (*AIHA*) occurs in around 10% and immune thrombocytopenia (ITP) in 5–7% of the patients; *pure red-cell aplasia* (*PRCA*) and immune neutropenia are rare (<1% of the patients). AIHA can appear before or concurrently with the diagnosis of CLL, spontaneously over the course of the disease, while the patient is on therapy, or thereafter. AIHA and ITP may present together (Evan's syndrome).

The diagnosis of *AIHA* should be suspected in presence of anaemia of abrupt presentation or a significant worsening of previous anaemia accompanied by elevated LDH with or without increased bilirubin, low or undetectable haptoglobins and positive DAT. The examination of a peripheral blood smear is mandatory since it usually shows spherocytes. The absolute reticulocyte count may not be striking due to poor bone marrow function because of leukaemic infiltration or treatment toxicity. DAT is usually positive for IgG/IgG+C3. Cold-agglutinin disease (CAD) has also been described in CLL patients, in which case DAT will only show positivity for C3d, with agglutination at low temperature and in a few cases weak positivity for IgG.

It is accepted that treatment can trigger the appearance of AIHA, a fact already mentioned in seminal descriptions of CLL. However, the 1990s notion that fludarabine frequently caused AIHA was probably overrated as it was based on retrospective studies in highly selected, and heavily pre-treated patients. In fact, randomised studies in untreated patients demonstrated that the proportion of patients treated with fludarabine + cyclophosphamide (FC) or FC + rituximab (FCR) developing AIHA is significantly lower (1–5%) than with chlorambucil alone (12%) or fludarabine alone (11%). Targeted therapies (i.e. BCRi and BCL2i) are associated with AIHA in 2–5% of cases.

Immune thrombocytopenia (ITP) is most commonly an incidental finding on a routine blood count. Diagnosing ITP may present difficulties because there is no sensitive and specific diagnostic test. Nevertheless, thrombocytopenia can be considered immune-mediated when platelet counts suddenly decrease in the absence of splenomegaly, infection or CIT and the bone marrow shows abundant megakaryocytes. Staining with Factor VIII may help to reveal the presence of megakaryocytes in a massively infiltrated marrow. In advanced CLL, anaemia usually occurs before thrombocytopenia. Therefore, isolated thrombocytopenia, particularly if extremely low, is

more likely to be immune in origin. Response to corticosteroids may be the final, *post-hoc* diagnostic test. In those areas in which this is a prevalent problem, *Helicobacter pylori* infection should be excluded. Treatment should be that of primary ITP.

Erythroblastopenia or PRCA is defined by the lack, or maturation arrest, of red blood cell precursors in bone marrow, anaemia and low absolute reticulocyte count. In the presence of anaemia, the reticulocyte percentage can be misleadingly normal; therefore, the reticulocyte percentage corrected according to the haematocrit or, even better, the absolute reticulocyte count is more informative. The bone marrow shows characteristic defects of erythroblast maturation. In the presence of a bone marrow heavily infiltrated by lymphocytes, the identification of red cell precursors can be difficult. In this setting, anti-glycophorin immunohistochemistry may facilitate the identification of red cell precursors. Importantly, PRCA can be seen in association with other immune cytopenias, particularly AIHA. In addition, any patient with CLL and anaemia with a low reticulocyte count should be evaluated for viral infections that can be associated with PRCA, namely *cytomegalovirus, Epstein–Barr virus* and *parvovirus*.

Autoimmune neutropenia is exceedingly rare (<1%). Likely, most early reports of this complication did not occur in the context of *bona fide* CLL cases, but of misdiagnosed T-cell large granular lymphocytosis.

Prognosis

The *prognostic significance* of AIHA is controversial, but in some studies that when patients with advanced clinical stage (Binet C, Rai III, IV) are stratified according to the mechanism of the anaemia, those with 'immune' advanced stage do better than those with 'infiltrative' advanced stage, in which the cytopenia is due to a packed bone marrow. The reason for this difference, of important consequences in prognosis and clinical management, is patients with autoimmune cytopenia tend to respond well to corticosteroids, while those with a high tumour burden do not always respond satisfactorily to CLL therapy.

Treatment

Treatment of patients with CLL and autoimmune cytopenia is largely based on experts' opinions and analysis of retrospective series. In those patients with AIHA in the context of inactive CLL, the treatment should be the same as in idiopathic AIHA: initially with corticosteroids, and then, in patients who fail to respond or relapse quickly, anti-CD20 monoclonal antibodies. If there is no response to these two approaches, alternative immunosuppression (e.g. cyclosporine and azathioprine) should be considered. Good results have also been achieved with rituximab plus corticosteroids; rituximab, cyclophosphamide and dexamethasone; or rituximab, dexamethasone and cyclosporine.

For patients with ITP, corticosteroids are the mainstay of therapy with a response rate of around 80% after 1–3 weeks of therapy. Dexamethasone yields responses more quickly than prednisone but the long-term results are not different. Once a response is achieved the dose of corticosteroids should be tapered over a period of 4–8 weeks. Around 30% of patients are refractory to corticosteroids or suffer early (<6 months) relapse. Rituximab, cyclosporine and mycophenolate can rescue patients unresponsive to corticosteroids. The thrombopoietin receptor agonist eltrombopag may be effective in ITP associated with CLL, as in primary ITP, and is increasingly used as second-line therapy. Splenectomy can be considered in individual cases impossible to control by other measures. Intravenous immunoglobulin is of help when a rapid response is needed (e.g. a patient with thrombocytopenia and significant mucosa bleeding, pre-surgery), though as a single agent, it does not produce lasting effects. Antiplatelet agents such as aspirin, clopidogrel and prasugrel should not be given (or should be discontinued).

Supportive care should include blood product transfusion as clinically indicated, folic acid in AIHA and local measures to control bleeding in ITP.

Importantly, failure of autoimmune cytopenia to respond to conventional treatment is an indication for anti-CLL therapy.

Non-haematological autoimmunity is exceedingly rare, the only disorders that have been reliably linked to CLL being cold-agglutinin disease, paraneoplastic pemphigus and acquired angioedema.

Second neoplasias

Around 10–15% of patients with CLL develop other cancers. Melanoma, lung carcinoma, lymphoma, Kaposi sarcoma, CNS and gastrointestinal tumours are the cancer types most frequently observed. Skin cancers other than melanoma can be also found but at a frequency no different from that of the general population. Patients with CLL have a substantially increased risk for a rare skin tumour known as Merkel cell carcinoma, and *vice versa*. It is usually considered that there is no relationship between treatment and the incidence and type of secondary solid tumours. However, patients heavily pre-treated with cytotoxic agents (e.g. FCR) may present with secondary MDS/AML (.5% of cases).

Infections

Infections are frequent and the commonest cause of death in patients with CLL (40–60%). Their pathogenesis is multifactorial, including low IgG levels, impaired antigen presentation, immunosuppression and treatment-related myelotoxicity. Most infections are bacterial and frequently involve the respiratory tract. IgG replacement may be useful in patients with profound hypogammaglobulinaemia and repeated bacterial infections.

The pathogenesis of infections with purine analogues is related to T-cell abnormalities induced by these agents, with herpes virus infections being frequent. Infections by *Pneumocystis jirovecii, Listeria, Mycobacteria, Aspergillus* and *Candida* can be also observed. Importantly, anti-CD20 monoclonal antibodies (e.g. rituximab and obinutuzumab) carry a risk of hepatitis B reactivation amongst patients positive for hepatitis B surface antigen (HBsAg) or antibodies against hepatitis B core antigen (anti-HBc). All patients should be screened for hepatitis B before starting treatment. Patients with evidence of prior hepatitis B infection should be monitored for clinical and laboratory signs of reactivation during therapy and for several months after its completion. Anti-CD20 monoclonal antibodies should be discontinued in patients with hepatitis re-activation. Finally, although the overall risk of contracting COVID-19 does not appear to be different from the general population, patients with CLL have a higher risk of suffering severe forms of the disease.

Vaccination with inactivated high-dose influenza vaccines, haemophilus influenza, herpes zoster and conjugate pneumococcal vaccine may reduce the risk of infections. However, the serological response to such vaccines is low, particularly in previously treated patients and those treated with anti-CD20 monoclonal antibodies within the first year of exposure. Likewise, SARS-Cov-2 vaccination show a suboptimal response, but this is not a reason to omit vaccination; on the contrary, double vaccination is recommended.

Disease transformation (Richter's syndrome)

CLL can transform into B-cell diffuse large cell lymphoma (DLCL), an event historically known as Richter's syndrome (RS). RS occurs in about 5% of patients. There is no relationship between treatment modality and the risk of RS, but some studies suggest a higher risk of RS in treated patients. *IGHV* genes are frequently unmutated. Other biomarkers associated with RS are *NOTCH1*, *TP53, CDKN2A/B, MYC* mutations and stereotyped *IGHV* genes (#8 configuration). Akt activation may behave as an initiator of CLL transformation by inducing Notch signalling between RS cells and T cells.

RS is heterogeneous in its biology and prognosis. In 80% of cases, the transformation occurs in the CLL clone. The prognosis of these patients is poor, with a median survival inferior to 1 year. In the remaining 20% of patients, the DLCL arises in a CLL-unrelated B-cell clone, and the prognosis of these patients is like those with *de novo* DLCL.

Disease transformation should be suspected whenever the patient suffers a sudden worsening of the general status, fever, enlarging lymph nodes or extra nodal involvement. A sharply increasing LDH level is an important clue to suspect disease transformation. RS is often associated with monoclonal protein in the serum or free light chains in the urine. RS can be reliably suspected on clinical grounds but needs to be confirmed by biopsy. The diagnosis, however, may be difficult because RS can be localised in an isolated organ (e.g. spleen, lymph nodes of a given territory or in extra lymphatic tissues). Rarely, the transformation takes place in the bone marrow; in such cases, the large blast-like cells spill over to the peripheral blood and the morphology may resemble that of an acute leukaemia (Figure 23.5). 'Accelerated' CLL, in which a high proportion of proliferation centres ('pseudo follicles') are observed in lymph nodes should not be confused with RS, its prognosis being intermediate to classic CLL and RS. In contrast to uncomplicated CLL, PET/CT can show areas of hyperactivity corresponding to the transformed tissue, where it is more likely to identify RS.

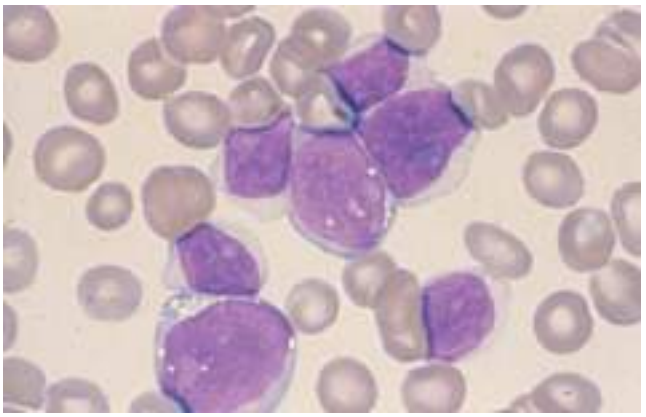

Figure 23.5 Large, blast-like atypical cells corresponding to a case of Richter syndrome with blood involvement.

Besides DLCL, cases of transformation into Hodgkin's lymphoma can be observed (5–10% of all RS cases). These are mainly observed in older men presenting with mixed-cellularity histological subtype and can be EBV-driven.

The treatment strategies for RS vary according to the type of disease transformation. In those cases in which the emerging DLCL is CLL-clonally related, the prognosis is poor (survival <1 year) and allogeneic stem cell transplantation (allo-HSCT) should be considered. Treatment with new BCR and BCL2 inhibitors and CAR T-cells is being investigated. In contrast, CLL-clonally unrelated DLCL has good prognosis and should be treated as *de novo* DLCL (e.g. R-CHOP). The prognosis of transformation into Hodgkin's lymphoma is heterogeneous and treatment should be risk-adapted; there are cases responding well to standard Hodgkin's lymphoma regimens.

Prognosis

The median survival of patients with CLL has improved over the last years and is now >10 years. This is mainly due to better therapies and an earlier diagnosis of the disease in routine blood analysis. The individual prognosis, however, is heterogeneous and ranges from a few months to a normal lifespan. This,

coupled with the lack of a truly curative therapy, makes prognostication an essential component in the management of patients with CLL.

Although somewhat overlapping, it is useful to distinguish parameters that predict disease progression, and hence need for therapy (*prognostic factors*), and those informing about the probability that an individual patient will respond to a given therapy (*predictive factors)* (see Treatment).

Importantly, the mere correlation of a parameter with a given outcome does not qualify it as an outcome marker. Outcome markers need to fulfil a number of requisites to be considered as such. These include standardisation, inter- and intra-patient reproducibility, specificity and sensitivity, identification of a substantial proportion of patients, independent prognostic value from other biomarkers for the same event and usefulness to manage patients. Moreover, determining outcome markers is only justified if patient's management will depend on their results.

Progression-free-survival (PFS) (a most frequent endpoint in clinical trials) is a treatment-related variable (the more effective the treatment, the longer the PFS) and, consequently, does not necessarily correlate with overall survival (OS), which depends on the effect of different treatments given during the course of the disease. Likewise, response predictors vary in function of the treatment modality.

Clinical stages

The clinical stages independently formulated by Rai and Binet in the 1970s continue being useful as a raw estimate of the tumour bulk. Clinical stages are based on the concept that neoplastic CLL cells accumulate first in blood, subsequently in lymph nodes and spleen, and eventually in bone marrow, leading to its functional failure (Table 23.5). In historical series, patients with low-risk disease (Binet A, Rai 0,) have a median survival longer than 15 years, those with intermediate-risk disease (Binet B, Rai I, II) have a median survival of 6–8 years and patients with high-risk disease (Binet C, Rai III, IV) have a median life expectancy of less than 5–6 years. Assigning a clinical stage to a given patient only requires a physical examination and a complete blood cell count; such simplicity is a great advantage that facilitates the application of clinical stages worldwide. Of note, Binet stages can be subclassified according to Rai stages, thus refining their prognostic significance (i.e. better survival: A0>AI>AII; BI>BII). The prognostic significance of clinical stages is steadily vanishing because of effective therapies.

Cytogenetics

Most patients with CLL (~90%) present with cytogenetic abnormalities that can be detected by FISH. Trisomy 12 and deletions at 13q14.2-q14.3 (including *DLEU2*, *MIR15A*/*MIR16-1*), 11q22.3 (*ATM*) and 17p13.1 (*TP53*) are the most frequent abnormalities. All these aberrations have important clinical correlates (Table 23.3). Döhner *et al*., in a seminal publication, proposed a hierarchical model of cytogenetic lesions for prognostic purposes. This model implies that patients are classified according to the worst cytogenetic abnormality, as shown in Table 23.3, independently of the number of lesions. It should be noted that del (13q14), present in up to 50% of cases, confer a good prognosis, provided they are found as the only change. Del(11q22-3) frequently involves the *ATM* gene and its prognostic significance mainly depends on whether or not the gene in the other allele is mutated. Del(17p3.1) is found in 5–30% of cases, its prevalence being higher in patients with advanced and heavily

Table 23.5 Rai and Binet clinical stages.

Rai	**0**	**I**	**II**	**III**	**IV**
Blood lymphocytosis	Yes	Yes	Yes	Yes	Yes
Lymphadenopathy	No	Yes	Yes/No	Yes/No	Yes/No
Spleen/liver enlargement	No	No	Yes	Yes/No	Yes/No
Hb <110 g/L	No	No	No	Yes	Yes/No
Platelets $<100 \times 10^9$/L	No	No	No	No	Yes
Median survival (years)	>15	10–11	7–9	3–5	3–5

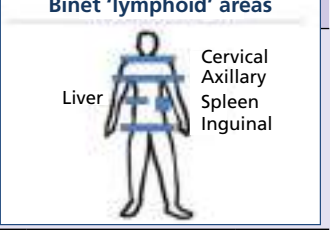
Blood lymphocytosis	Yes	Yes	Yes		
<3 lymphoid areas* enlarged	Yes	No	Yes/No		
> 3 lymphoid areas enlarged	No	Yes	Yes/No		
Hb <110g/L and/or Platelets $<100 \times 10^9$/L	No	No	Yes		
Median survival (years)	>15	7–9	3–5		



* cervical, axillary, inguinal lymph nodes (either uni- or bilateral), spleen and liver.

pre-treated CLL. In the case of complex karyotypes (defined as >3 or >5 genetic aberrations), the lesions usually include *TP53* mutations. Del (11q) and particularly *TP53* mutations are a strong predictor of response to CIT, while their impact on patients treated with BCRi or BCL2i is much lower (see Response biomarkers).

IGHV gene mutational status

The *IGHV* gene can be either mutated (<98% homology to the nearest germline sequence) or unmutated in a proportion of 50–60% and 30–50%, respectively. Importantly, *IGHV* mutational status separates CLL into two different clinic-biological forms. While patients with mutated *IGHV* genes (*IGHV*-M) usually have indolent disease not needing therapy and good prognosis, those with unmutated *IGHV* genes (*IGHV*-UM) tend to have rapidly aggressive disease, respond poorly to therapy and have short survival. *IGHV* mutational status correlates with other outcome biomarkers (Table 23.6). *IGHV* mutational status is thus not only a major marker of two different forms of disease, but also a central prognostic feature around, which revolve many other prognostic factors. The *IGHV* gene repertoire is enriched by specific subtypes (e.g. *IGHV1-69*, *IGHV3-7* and *IGHV4-34*). Some of these subgroups share a similar prognosis. For example, *IGHV3-21* gene usage (of stereotype subset # 2) may be associated with an unfavourable prognosis independent of the *IGHV* mutational status. As of today, assessment of *IGHV* stereotypes is not an element of the routine prognostic work up in CLL. Notably, the prognostic significance of *IGHV* mutational status was identified in cohorts of patients treated with CIT and has been virtually overcome with the use of BTKi and BCL2i, as discussed later (Table 23.6).

Gene mutations

The del(17p) at the *TP53* locus is observed in 5–50% of cases, depending on the clinical situation (i.e. early, untreated disease versus late, heavily treated and resistance to CIT) and in most cases correlates with a point mutation in the other allele, resulting in total inactivation of the *TP53* suppressor gene. In 2–5% of patients, however, *TP53* mutation can be present in the absence of del(17p). Prognostically, *TP53* mutations are the most important predictor of response to CIT. *TP53* mutations can be observed in small CLL subclones, bearing the same poor prognosis (see Response predictors). In turn, del(11q) deletions are usually monoallelic, frequently large and include a minimally deleted region (MDR) which encompasses the *ATM* gene in 30–40% of cases. *BIRC3*, a negative regulator of non-canonical NFKB signalling located at 11q22, has been found to be deleted or mutated in a mutually exclusive manner with *TP53*. *NOTCH1* and other mutations have been correlated with outcome and response to therapy. BTKi mutations and *BCL2* mutations are associated with resistance to therapy with ibrutinib and venetoclax, respectively. Not surprisingly, the higher the number of mutations and distorted genetic pathways, the poorer the prognosis. The importance of gene mutations in response to therapy is further discussed in the Treatment section.

Prognostic systems and scores

Prognosis is related to many factors, and thus a single parameter rarely predicts an outcome. Because of this, the prognostic assessment is based on the combination of different parameters in the form of stages, prognostic groups or scores.

Table 23.6 *IGHV* gene mutational status: biological and clinical correlates.

Mutated *IGHV*	Unmutated *IGHV*
Early stage (A, O)	Advanced stage (C, III, IV)
WBC count $<30\times10^9$/L	WBC count $\geq30\times10^9$/L
LDT >12 months	LDT ≤12 months
Low-risk genetics	High-risk genetics
del(13q)(isolated)	del(17p)
MYD88 mutations	del(11q)
CHD2 mutations	(+12)
Normal karyotype	Complex karyotype
	TP53, NOTCH1, SF3B1, BIRC3, POT1, XPO1 mutations
Low ZAP-70	High ZAP-70
Low B2M	High B2M
Low CD38	High CD38
Low thymidine-kinase	High thymidine-kinase
Median survival >15 years	Median survival: 6–7years

The CLL-International Prognostic Index (CLL-IPI) includes Rai stage, age, *TP53* status, *IGHV* mutational status and serum B2M and distinguishes four different prognostic subgroups predicting time to first therapy and OS. However, this and other similar models were developed in patients treated with CIT and poorly predict the outcome of patients receiving targeted agents such as BCRi or BCL2i. For example, age, Rai stage and *IGHV* mutational status have *no* prognostic significance in patients treated with ibrutinib, in whom adverse biomarkers are del(17p)/*TP53* mutation, high B2M, prior therapy and time interval from last therapy <24 months.

Moreover, prognostic and predictive models or scores apply to groups of patients but not to individual persons, and are far from being perfectly accurate. Thus, the most widely used accuracy indicator is the C-index in which a value of 0.0 indicates no accuracy at all, 1.0 is tantamount to a perfect prediction and 0.5 is like flipping a coin. The C-index of most outcome models is 0.70–0.80, meaning that the prediction may be wrong in 20–30% of the patients. These caveats emphasise that outcome markers complement, but cannot replace, clinical expertise and a thorough clinical judgement.

In Table 23.7, the most important outcome predictors for disease progression in global series of patients with CLL are shown.

As most patients with CLL are diagnosed in asymptomatic, early phases of their disease (Binet A, Rai 0) several models to predict disease progression in such patients have been proposed to (i) inform patients, (ii) decide frequency, modality and setting for patients' monitoring and (iii) select patients for clinical trials. Table 23.8 shows parameters associated with disease progression in asymptomatic Binet stage A disease according to different studies; such markers are otherwise superimposable to those in general series of patients.

Prognostic assessment in daily practice

In daily practice, the large and ever-increasing number of reputed outcome biomarkers can end up being, quite understandably, more confusing than helpful. Because of this, physicians routinely seeing patients with CLL should be aware that early clinical stage (Binet A, Rai 0), mutated *IGHV* genes, good-risk cytogenetics [del(13q)], normal serum B2M, low blood lymphocyte count (e.g. $<15\times10^9$/L) and a long LDT (e.g. >12 months) indicate good prognosis, with a survival close to the general population. And that advanced clinical stage (Binet B/C, Rai I–IV), unmutated *IGHV* genes, poor cytogenetics [del(11q), del(17p), complex karyotype], increased B2M, high blood lymphocyte count (e.g. $\geq15\times10^9$/L) and short LDT (e.g. <12 months) are associated with poor prognosis; of note, all these parameters are easily available in almost all locations. Likewise, physicians should keep in mind that currently the only biomarkers with a direct influence on treatment selection are unmutated *IGHV* and poor genetic features [i.e. del(17p)/*TP53* mutations; del(11q)]. Patients with any of these abnormalities should be treated with pathway inhibitors (i.e. BCRi or BCL2i) and not CIT.

Treatment

Criteria to start therapy

- Treatment should be only initiated in case of active/progressive disease (PD) as defined by the following parameters:
- Anaemia (Hb<110 g/L) and/or thrombocytopenia (platelets $<100\times109$/L) due to marrow failure.
- Massive (i.e. ≥6 cm below the left costal margin) or progressive or symptomatic splenomegaly.
- Massive (i.e. ≥10 cm in longest diameter) or progressive or symptomatic lymphadenopathy.

- Progressive lymphocytosis with an increase of ≥50% over a 2-month period, or lymphocyte doubling time (LDT) of <6 months.
- Causes of reactive lymphocytosis (e.g. infections and steroid administration) should be excluded. LDT is rarely (<10% of cases) the only criterion to start therapy.
- Autoimmune complications including anaemia or thrombocytopenia poorly responsive to standard treatment (i.e. corticosteroids).
- Symptomatic extra haematopoietic involvement (e.g. skin, kidney, lung or spine).
- Disease-related symptoms as defined by any of the following:
  - Unintentional weight loss ≥10% within the previous 6 months.
  - Significant fatigue (i.e. Eastern Cooperative Oncology Group performance status (ECOG-PS) ≥2: cannot work or unable to perform usual activities).
  - Fever ≥38.0 °C for ≥2 weeks without evidence of infection.
  - Night sweats for ≥1 month without evidence of infection.

Since the diagnosis of CLL rarely constitutes a medical emergency, the need for therapy and its modality should be decided after 1–3 months of observation, a period in which the diagnostic workup can be completed, the pace of the disease evaluated and the goals of therapy discussed with the patient.

Younger age or adverse biomarkers are not per se criteria to initiate treatment. Likewise, in the absence of other features of active disease, a high WBC count or hypogammaglobulinaemia with no infections do not justify treatment. In CLL, leukostasis due to a high WBC is exceedingly rare. However, if the WBC is $>300 \times 10^9$/L, a short intervention with chlorambucil or oral fludarabine to decrease the WBC and comfort the patient may be justified. As supported by several studies, patients benefit from being managed by experienced doctors at CLL referral centres.

Pre-treatment evaluation

The pre-treatment evaluation should include a complete medical history, physical examination to detect enlarged lymphoid areas, complete blood cell counts, DAT, renal function, general biochemistry and immunoglobulin levels. CT scans are not part of the routine assessment and should only be performed if clinically indicated (e.g. suspected retroperitoneal, lung or mediastinal involvement). A bone marrow biopsy can provide important information about tumour burden and origin of cytopenias, and is useful as baseline information. A normal creatinine clearance (>60 mL/min.) is required if fludarabine-based therapy is to be given, and hepatitis B serology should be performed in patients in whom treatment will contain an anti-CD20 antibody. Assessing comorbidity and frailty (geriatric assessment) is important since most patients with CLL are older.

Predictive biomarkers

The OS of CLL patients requiring treatment depends on the response to therapy and its degree. Patients achieving CR with undetectable minimal residual disease (uMRD or 'negative' MRD) upon therapy have an excellent outcome. Achieving uMRD CR largely overcomes the impact of adverse biomarkers. Predictive factors indicate the probability of response to a specific therapy. Importantly, genetic abnormalities, which are the most important predictive factor, can change over time in approximately 30–40% of patients; because of this, their study should be performed before initiating therapy, and should be repeated before changing treatment during the course of the disease. The most important predictive biomarker is del(17p)/*TP53* mutation that predicts a low probability of achieving a good and sustained response with CIT (i.e. chlorambucil; chlorambucil + rituximab; fludarabine; FC; FC + rituximab). This scenario has changed; thanks to the introduction of BTK inhibitors (BTKi) (i.e. ibrutinib and acalabrutinib), PI3K-delta inhibitors (i.e. idelalisib) and BC2L inhibitors (BCL2i) (i.e. venetoclax) that abrogate the negative impact of adverse response biomarkers, although the results are somewhat inferior in del(17p)/*TP53*-mutated cases. Likewise, unmutated *IGHV* predicts a shorter PFS in patients treated with CIT but not in those receiving small molecules. *NOTCH1*, *SF3B1* and *BIRC3* mutations have been correlated with inferior response to CIT, but they are not routinely tested. Patients carrying *NOTCH1* mutations do not benefit from adding anti-CD20 monoclonal antibodies to FC but this marker is not employed in daily practice. In patients treated with BTKi (i.e. ibrutinib and acalabrutinib) or BCL2i (venetoclax), *BTK* and *BCL2* mutations can be the cause of resistance to therapy and, hence, are worth of being determined in cases of treatment refractoriness. Of note, such mutations can be detected much time before actual clinical refractoriness appears. Besides abnormalities detected by FISH analysis, a complex karyotype (as defined by >3 or >5 abnormalities) is a biomarker of poor response to therapy and short OS (Table 23.9).

Minimal residual disease

Achieving a state of uMRD upon therapy is clinically important because patients in CR with uMRD have a longer PFS and OS than those with persistent MRD, independently of the treatment given. However, MRD is an arbitrary concept that depends on the technique used to assess it. Besides, high sensitivity flow-cytometry (FCM), high throughput sequencing can be useful to refine MRD detection. There are several factors such as type of therapy (containing or not anti-CD20 antibodies), site where MRD is evaluated (blood or bone marrow), time point at which MRD is assessed that complicate cross-comparisons of different studies. Pursuing MRD eradication as the treatment endpoint and MRD-guided therapies are only justified within clinical trials.

Table 23.9 Biomarkers predicting response to therapy. Differences between chemo(immuno)therapy and pathway inhibitors.

NOTCH1 mutations	+	NA
BTK mutations	Not applicable	++
BCL2 mutations	Not applicable	++

B2M, Beta 2 microglobulin; LDT, lymphocyte doubling time; PFS, Progression-free survival.

Objectives of treatment

CLL largely remains an incurable disease. The objectives of therapy are therefore to prolong survival (which ultimately depends on the response to different therapies administered over the course of the disease) and improve quality of life. Of note, endpoints used in clinical trials (e.g. CR rate, uMRD, PFS and time to next treatment [TTNT]) are not equivalent to treatment objectives, although there is a strong correlation between uMRD CR and OS.

Treatment approaches

Representative results that have contributed to build-up current treatment strategies in CLL are shown in Table 23.10.

As treatment modalities for CLL are ever-changing, patients should be included in clinical trials whenever possible. For patients not included in trials, the main treatment strategies are discussed below.

Management of asymptomatic disease

Large proportion of patients with CLL (40–60%) are asymptomatic at diagnosis. Several studies have shown that treatment of asymptomatic disease with agents such as chlorambucil, fludarabine or FC+rituximab results in a longer PFS but not a longer OS. The standard management of asymptomatic disease is, therefore, active surveillance. Several prognostic models based on *IGHV* mutational status and FISH cytogenetics [(del(17p)/del(11q)], may help to identify patients with early stage (Binet A, Rai 0) and different time-to-first therapy (TTFT) and OS. (see Prognosis and Table 23.8). These models are useful to inform patients, plan the frequency of follow-up visits (usually every 3–6 months initially and every 12 months thereafter) and select subjects for clinical trials. Monitoring should consist of physical examination and the assessment of blood cell counts, basic biochemistry, LDH serum levels and LDT. Imaging studies (e.g. CT) have no role in routine visits and should only be performed if clinically indicated.

Management of symptomatic disease

Front-line treatment

Chemo(immuno)therapy

The standard intervention has been CIT, namely the combination of fludarabine, cyclophosphamide and rituximab (**FCR**). The response rate with FCR is over 90%, including 30–40% of patients achieving uMRD. In a long-term follow-up of 300 patients initially treated with FCR, the 6-year OS was 77%, the median time to progression was 80 months and the treatment-related deaths <1%. Moreover, 50–60% of the patients with mutated *IGHV* and no adverse genetic features may remain in remission for >10 years ('functional' cure). However, FCR can only be safely given to younger persons (i.e. <65 years), fit, with no important comorbidity and normal renal function (creatinine clearance >40 mg/L). This excludes the majority of patients with CLL because they are older than 70 years, present comorbidities and have poor general status.

Frequent toxic events include fever and infections (including opportunistic), which may be observed up to 2 years after finishing treatment. There are other complications, such as HBV reactivation and, rarely, progressive multifocal leukoencephalopathy (PML), linked to treatment with rituximab. MDS/AML can be observed in a proportion (around 5%) of heavily pre-treated patients.

Beside FCR, other CIT regimens have been developed aiming at maintaining efficacy and reducing toxicity. The combination of **bendamustine and rituximab (BR)** is a popular regimen to treat patients >65 years old, although it is not as effective as BTKi (see below).

Although defining who is an older person is difficult and subject to frequent revision, 65–70 years of age is the cut-off used to separate 'younger' from 'older' patients. Although chronological age is less important than 'biological' age, only a small proportion of subjects older than 65–70 years can safely receive intensive cytotoxic therapy because of frailty or comorbidity. A Cumulative Index Rating Score (CIRS) >6 is used in some studies to identify patients for whom intensive treatment is not advised. With the increasing life expectancy of the general population, the group of very old patients

Table 23.10 Representative clinical trials in CLL.

	Patient number	Patients' treatment Status (TN or R/R)	Median Follow-up	ORR (CR) (%)	PFS (median/%)	OS (median/%)
FCR	408	TN	5.9 years	90 (44)	56.8 months	82% (@ 5 years)
BR	279	TN	58.2 months	96 (31)	42.3 months	80.1% (@ 5 years)

Acalabrutinib	179	TN	74.5 months	82	62% (at 72 months)	76% (at 72 months)
Acalabrutinib + Obinutuzumab	179	TN	74.5 months	945 (13)	78% (at 30 months)	84% (at 72 months)
Idelalisib + Rituximab	110	R/R	18 months	85.5	Median 20.8 months	Median 40.6 months
Venetoclax	127	R/R	14 months	79 (20)	25 months	84% (at 24 months)
Venetoclax + Rituximab	194	R/R	59.2 months	92.3 (26.8)	Median 53.6 months	82% (at 5 years)
Venetoclax + Obinutuzumab	216	TN	76.4 months	88	76.2 months	78.7% (at 6 years)
Zanubrutinib	214	TN No (17p+)	18 months	94.5	88.6% (at 24 months)	95.5% (at 24 months)

Note: This table is not intended to be a comprehensive analysis nor a cross-comparison of different trials, its purpose is merely informative.
Regular updates of CLL treatment results may be found at National Comprehensive Cancer Network (NCCN) (www.nccn.org/guidelines); European Society of Medical Oncology (ESMO)
www.esmo.org/guidelines; and National Institute for Health and Care Excellence (NICE) (www. nice.org.uk.guidance).

(e.g. >80 years) is increasing. This group calls for a cautious, tailored management based on a geriatric assessment and with quality of life as treatment goal; the inclusion of these patients in clinical trials is only justified if the treatment investigated is relatively non-toxic. Historically, chlorambucil has been the drug given to patients who cannot safely receive more intensive treatments. The dose usually given ranges from 40 to 70 mg/m^2 per month and is given intermittently (i.e. 10 mg/m^2 per day for 7 days or 0.5 mg per kg every 2 weeks, in monthly courses); the duration of the treatment depends on the degree of response but usually ranges from 6 to 12 months. Chlorambucil in association with anti-CD20 antibodies yields better results than Chlorambucil alone. Chlorambucil yields a small proportion of CRs (5–10%), and although it improves symptoms, survival is not substantially prolonged. However, in line with what has been discussed above, chlorambucil can be a plausible treatment in very old patients (e.g. >80 years) in which the aim of therapy is symptom control.

Targeted therapies

The advent of targeted agents has revolutionised treatment algorithms for CLL by allowing the use of chemo-free, generally well tolerated, and effective regimens for a wider range of patients than CIT candidates, and with better results. Importantly, targeted agents may overcome the negative impact of unmutated *IGHV* and del(17p)/*TP53* mutations on outcome.

Ibrutinib is a selective irreversible (covalent) BTK inhibitor, which is given continuously at a dose of 420 mg/day until disease progression or unmanageable toxicity. Ibrutinib given as single agent results in a 70–90% ORR in the front-line setting and 40–70% in previously treated patients. The CR rate increases over time (up to 35% in previously untreated subjects). Long-lasting responses are observed in patients without previous treatment (5-year PFS ~75%), whereas patients with relapsed or refractory CLL have shorter remissions (~40%). Importantly, ibrutinib may abrogate the poor prognostic impact of biomarkers such as unmutated *IGVH* and del(11q) and, to a lesser

degree, del(17p)/*TP53* mutations, particularly in previously treated patients. A series of randomised clinical trials have shown better outcomes in patients receiving ibrutinib alone or in combination with CD20 monoclonal antibodies as compared to chlorambucil ± anti-CD20 monoclonal antibodies, BR and FCR, mainly in patients with unmutated *IGHV*. The main toxicities of ibrutinib include infections, hypertension, atrial fibrillation and bleeding. Ibrutinib has shown to be effective in patients relapsing after venetoclax (and *vice versa* venetoclax is effective in patients refractory to ibrutinib). Altogether, around 50% had to discontinue ibrutinib therapy because of toxicity or disease progression. The time interval between treatment discontinuation and disease progression has been reported to be 25 months. Resistance to ibrutinib is usually linked to BTK^{C481S} mutation and *PLCG2* mutations, which occur in around 30% of patients.

Acalabrutinib is another irreversible BTK inhibitor, which shows a higher selectivity for BTK than ibrutinib. In clinical trials, acalabrutinib monotherapy or in combination with obinutuzumab significantly improved PFS as compared to obinutuzumab plus chlorambucil in elderly patients; and compared to rituximab with either idelalisibib or BR. Frequent side effects include hypertension, bleeding, atrial fibrillation, diarrhoea, headache and respiratory tract infection, although to a lesser degree than ibrutinib due to reduced off-target kinase inhibition. Therefore, acalabrutinib is a good alternative to ibrutinib when this latter agent causes unmanageable toxicity (but not in case of refractoriness). Results of trials comparing ibrutinib with acalabrutinib suggest similar efficacy but a lower frequency of cardiac events with acalabrutinib.

Zanubrutinib is another non-covalent BTKi recently approved by FDA and EMA for CLL treatment. As compared to ibrutinib and acalabrutinib treatment results are similar, if not better, and adverse events (i.e. hypertension, cardiac events), less frequent.

Pirtobrutinib is a new generation, non-covalent, BTKi which has demonstrated promising results in patients with relapsed/refractory disease, with an ORR of around 60% and a PFS of around 70% at 2 years from treatment initiation, including in patients previously treated with covalent BTKi showing BTK^{C481S} and *PLCG2* mutations Ongoing randomised studies will determine the position of pirtobrutinib in CLL treatment algorithms.

Idelalisib is an oral reversible inhibitor of phosphoinositide 3-kinases (PI3Ks), which inhibits the signalling of the BCR and other surface receptors. Because of inflammatory immune-mediated complications (hepatitis, colitis and pneumonitis), especially in untreated CLL patients and infections (i.e. *P. jirovecii* pneumonia and CMV reactivation), and lower efficacy when compared to BTKi, idelalisib is not used as front-line therapy but can be an alternative in patients who cannot tolerate BTKi. Treatment discontinuation has been reported in up to 80% of the patients, in most instances (~50%) because of toxicity.

Venetoclax is an orally administered, highly selective potent BCL-2 inhibitor, targeting the anti-apoptotic BCL-2 protein, which is present in high amounts in CLL cells. It yields a high CR rate (40–80%), including a substantial proportion of uMRD. To prevent tumour-lysis syndrome, venetoclax is initially administered following a weekly dose ramp-up schedule. Frequent severe adverse events include neutropenia, infections, anaemia and thrombocytopenia. Venetoclax can be used with obinutuzumab in patients who have not previously been treated or with rituximab in patients who have received at least one previous treatment. It can also be used on its own in·patients with del(17p)/*TP53* mutation) who cannot be treated with or are refractory to BCRi (ibrutinib and idelalisib); and patients who do not have these genetic changes, after treatments with chemoimmunotherapy as well as BCRi have both not worked. In clinical trials, the combination of venetoclax with ibrutinib and obinutuzumab has been shown to be extremely active in ongoing trials. Likewise, the 'triplet' venetoclax, ibrutinib and obinutuzumab has recently been shown to be highly effective in patients <70 years and no del(17) (uMRD CR:92.2%; PFS at 3 years 90.5%). Given these results, venetoclax-based combinations are likely to become the treatment of choice in many treatment settings, including upfront.

The main limitation of treatment with venetoclax is disease progression (~25% of cases). Resistance to therapy is usually associated with the acquisition of the Gly101Val point mutation in *BCL2* or other *BCL2* mutations at clonal and subclonal levels. However, these mutations are not found in all patients resistant to venetoclax, and other mechanisms, such as the upregulation of antiapoptotic proteins MCL-1 and BCL-xL might cause treatment resistance. In such cases, ibrutinib can be effective.

Front-line therapies for patients not included in trials are shown in Figure 23.6.

Relapsed/refractory disease

Importantly, disease relapse is not by itself a criterion to re-initiate treatment, only patients with relapsed *and* PD needing therapy (see Criteria to start therapy). There are patients with relapsed disease but no signs of progression in whom therapy can be postponed for prolonged periods of time. *TP53* status, serum B2M, advanced clinical stage, Hb level, LDH and time since last therapy <24 months are the most consistent outcome biomarkers in relapsed/refractory patients.

The introduction of pathway inhibitors (BCRi and BCL-2i) in CLL therapy has dramatically changed treatment strategies for this form of leukaemia, both upfront, as previously discussed, and at disease relapse. In patients having received effective

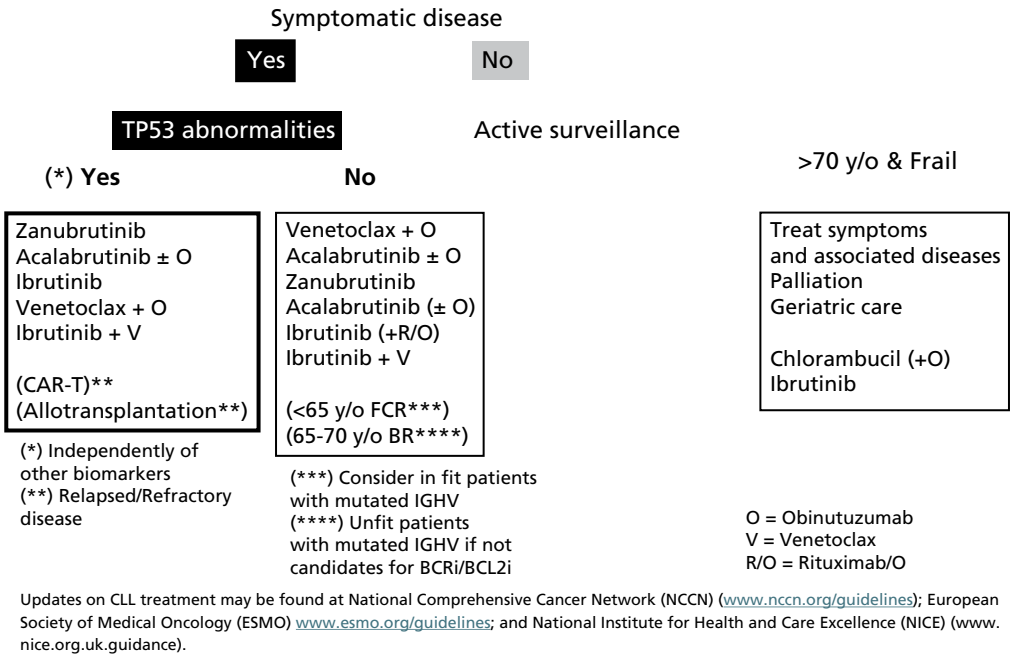

Figure 23.6 Treatment for patients with CLL.

front-line therapy (e.g. FCR), a PFS inferior to 2–3 years indicates poor-risk disease. Conversely, in patients with a longer PFS, the prognosis is considered to be better. In these latter patients, repeating the initial therapy has been considered a reasonable treatment approach. This notion, however, was generated when treatment possibilities for CLL were limited and poorly effective. Although repeating the initial therapy may be an option in selected patients, changing the type of therapy is in most cases a more logical approach.

Haematopoietic stem cell transplantation

While autologous transplants are considered not useful and have been virtually abandoned, allo-HSCT still has a role in the management of selected patients with CLL.

Allo-HSCT should be considered as an option in younger, fit patients with high-risk diseases having failed one or two pathway inhibitors and having a low transplant risk. According to the available evidence, fully myeloablative regimens offer no advantage over reduced-intensity conditioning regimens. Allo-HSCT exerts its therapeutic effect through the T-cell anti-leukaemia-mediated effect (graft-versus-leukaemia) and overcomes the negative impact of poor prognostic factors such as del(17p)/*TP53* mutations. The procedure-related mortality is around 10% at 1 year and 30% at 3 years from the transplant. Most deaths are due to graft-versus-host-disease and its complications. Disease relapses can be observed but are rare beyond 4 years from transplant. Transplant results are better in younger patients, with no comorbidity, transplanted in remission and receiving a transplant from a fully matched HLA donor.

Prior therapy with BTKi or BCL2i does not jeopardise transplant results. On the contrary, ibrutinib has been shown to be a safe and effective therapy as a 'bridge' to allo-HSCT. The experience with BCL2i is more limited and inconclusive. For idelalisib, an EBMT study has shown that prior therapy with this agent seems to increase the risk of suffering severe GVHD. Allo-HSCT should not be unnecessarily delayed nor considered as the last, desperate attempt to control the disease in refractory and heavily pre-treated patients, when the possibility of a successful transplant is remote.

CAR-T cells

T cells expressing CARs are highly targeted, move to tumour sites, undergo *in vivo* expansion and persist for long periods of time (Chapter 6). The most frequent antigen target for CAR-T cells is CD19. CART cells can trigger cytokine-release syndrome (hypotension, rigours, muscle aching, fever and anorexia) and CNS toxicity. To enable CAR T-cell expansion, chemotherapy is given before the infusion of CAR-T cells. Other important toxic events are profound and long-lasting hypogammaglobulinaemia and B-cell depletion. In CLL, despite overall response rates (ORR) of 60–95%, including MRD clearance in a large proportion of patients, the durable CR rates are relatively low, and only few long-term responses have been reported,

probably because of CLL-related immune defects that render CAR-T cells poorly effective.

Further studies refining CAR-T cell therapy for CLL are needed. Also, clinical expertise and a broad range of supporting measures are needed to carry out this form of therapy. CAR-T cells should only be given in the context of clinical trials in patients in whom allo-HSCT is not feasible or conveys a high risk to the patient.

Response categories

The following response categories are recognised:

- Complete response (CR)
  - CR undetectable ('negative') MRD
  - CR detectable ('positive') MRD
- Complete response incomplete (CRi)
- Partial response (PR)
- Stable disease (SD)
- Progressive disease (PD)

CR requires normalisation of blood counts and normal bone marrow as assessed by biopsy. Since clearing bone marrow disease can take time, the bone marrow biopsy should be performed 3 months after completing therapy. In clinical trials, it is recommended to further assess CR by measuring MRD. There are two types of CR: MRD-negative (undetectable) and MRD-positive (detectable), the outcome of patients with the latter not being as good as in those with uMRD CR. CT scan should be repeated only if abnormal at the start of therapy. Incomplete CR denotes cases with persistent anaemia, thrombocytopenia or neutropenia, due to myelotoxicity, who otherwise fulfil the criteria for CR. If the bone marrow is hypocellular, it is recommended the biopsy be repeated once the blood counts have recovered. Not infrequently, the degree of response improves over time. PR requires the regression of at least 50% organomegalies and abnormal blood cell counts. SD is defined as no major changes in the signs and symptoms present before starting therapy. PD is the appearance of signs or symptoms of active disease not present before starting therapy. Of note, treatment with BCRi results in a transient blood lymphocytosis that should not be confused with treatment failure and disease progression.

Other B-cell chronic disorders with leukaemic expression

Splenic marginal zone lymphoma

Two-thirds of patients with splenic marginal zone lymphoma (SMZL) (around 2% of all lymphomas) have circulating villous lymphocytes. However, a minority do not have villous cells and in some, the diagnosis can only be established after splenectomy.

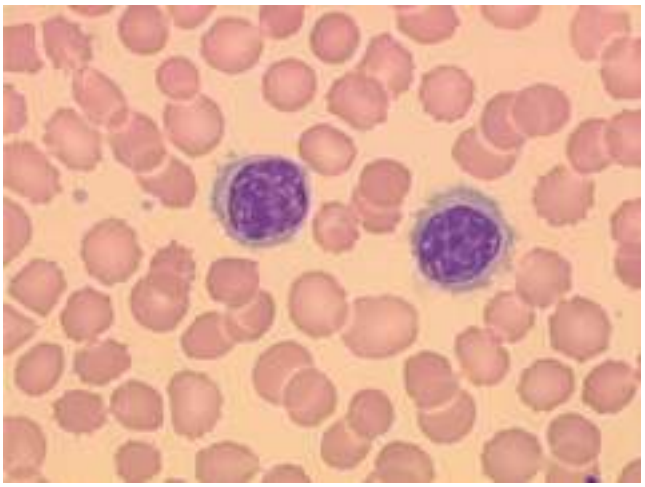

Figure 23.7 Lymphocytes from a case of SMZL. Villous lymphocytes are observed.

The median age of patients is around 70 years and the majority present with splenomegaly. Anaemia and/or thrombocytopenia are seen in 40% of cases. One-third have a serum monoclonal band, usually IgM below 30 g/L. The diagnosis is suspected on a typical blood film (Figure 23.7) showing small lymphocytes with an irregular membrane outline and short villi, often confined to one pole of the cells. The immunophenotype (see Table 23.2) is different from CLL. SMZL cells are negative for CD103 and CD123 but are always positive for CD11c.

Bone marrow aspirates may show the same cells as in the blood, with variable degrees of infiltration. A distinct pattern of intrasinusoidal infiltration is characteristic of SMZL, which can be highlighted with anti-B-cell antibodies (CD20 and CD79a). This pattern of infiltration is less common in other lymphomas and is not seen in CLL. The bone marrow infiltration can be nodular, interstitial and/or para trabecular. The spleen histology shows a characteristic bizonal pattern in the white pulp, with a central zone of small lymphocytes with scanty cytoplasm and a peripheral zone of larger cells with more dispersed chromatin and more abundant cytoplasm. The red pulp is always infiltrated by both the smaller and the larger cells. Plasmacytoid differentiation may be seen and transformation into large-cell lymphoma occurs in 10% of cases.

There is no unique cytogenetic abnormality in SMZL, but unbalanced translocations and deletions of 7q22–32 have been described in about 30% of cases. About 50% have a monoallelic deletion at 13q14. Trisomy 3 is found in around 15% of cases. Abnormalities of *TP53* are present in around 15% of patients and are associated with worse prognosis. The *MYD88* (L265P) mutation is found in almost 100% of cases of lymphoplasmacytoid lymphoma but is uncommon in SMZL.

An association with hepatitis C has been reported, particularly in the form of mixed cryoglobulinaemia, but its incidence

is unknown. Interferon (IFN)-α has been reported to induce CR in some hepatitis-C-positive SMZL patients. More recently, it was demonstrated that eradicating hepatitis C with direct active antivirals induced lymphoma responses in a proportion of patients. An association of SMZL with hyperreactive malaria and tropical splenomegaly has been described in African cases.

Rituximab is highly effective to reduce the spleen size and to control the disease and has virtually replaced splenectomy as mainstay of therapy. The latter, however, can be useful in cases in which there is not a good response to rituximab and can be a manoeuvre useful to establish the diagnosis and control the disease. In most cases, the OS is at least 10–15 years (see Chapter 27).

Hairy-cell leukaemia

Definition

HCL is an uncommon clinicopathological entity characterised by the accumulation in peripheral blood, bone marrow and splenic red pulp of small mature B lymphoid cells with abundant cytoplasm and 'hairy' projections. This, along with a reduction in normal blood cells, causes splenomegaly, anaemia, bleeding and an increased risk of infection. The so-called atypical or variant form of HCL (HCLv) was considered a provisional new entity in the 4th edition (2017) of the WHO classification system but in the 5th edition (2022) has been encompassed within a new entity: 'splenic B-cell lymphoma/leukaemia with prominent nucleoli'. Irrespective of the nomenclature, it should be separated from classical HCL (HCLc).

Epidemiology

HCL accounts for 2% of all leukaemia and affects males more frequently than females (ratio 4:1), usually over the age of 50 years. In a French study comprising the period 1996–2016, HCL represented 0.7% of all malignant haematological disorders and 3.0% of all leukaemias. The overall age-standardised incidence ratio (SIR) was 0.39/100,000 inhabitants in men and 0.09/100,000 in women, and it remained stable over the 20-year period analysed.

Pathogenesis

The *BRAF* V600E mutation is present in virtually 100% of cases of classical HCL and activates the RAF-MEK-ERK pathway leading to cell proliferation and accumulation. Also, important in the pathogenesis of HCL are several microenvironment-mediated cytokines and the exhaustion of the microenvironment itself.

Clinical features

In many cases, the diagnosis is made following investigation of a moderate pancytopenia. Fatigue is frequent and often underestimated. Other presenting features include infection (including opportunistic), bruising or mucosal bleeding. Splenomegaly is a characteristic feature but because of the now earlier diagnosis of the disease may be small or clinically undetectable, as compared to historical series (one-third of patients versus two-thirds). Lymphadenopathy is rare at diagnosis but can be observed in advanced and relapsed disease. Extranodal infiltration and nephrotic syndrome have been reported in a few cases. In contrast to CLL, the incidence of second cancers in patients with HCL does not appear to be increased compared to that of the general population.

Laboratory features

Anaemia is due to reduced bone marrow production and splenic pooling; haemolysis is exceptional. The WBC count may be low, normal or high (rarely $>20 \times 10^9$/L), but neutropenia and monocytopenia are almost always present, as is an increased MCV. Platelet counts are below 100×10^9/L in most cases.

The recognition of typical hairy cells in peripheral blood films is useful for suggesting the diagnosis. However, since the number of hairy cells in blood is typically low, a high degree of suspicion is required to make the diagnosis. Hairy cells are large, twice the size of a normal lymphocyte, with a barely discernible nucleolus and abundant cytoplasm that is characteristically villous ('hairy') in its outline (Figure 23.8). The nucleus is round, oval or slightly indented, and occasionally bilobed.

The typical HCL immunophenotype includes pan-B cell markers (CD19, CD20 and CD22) with co-expression of CD11c,

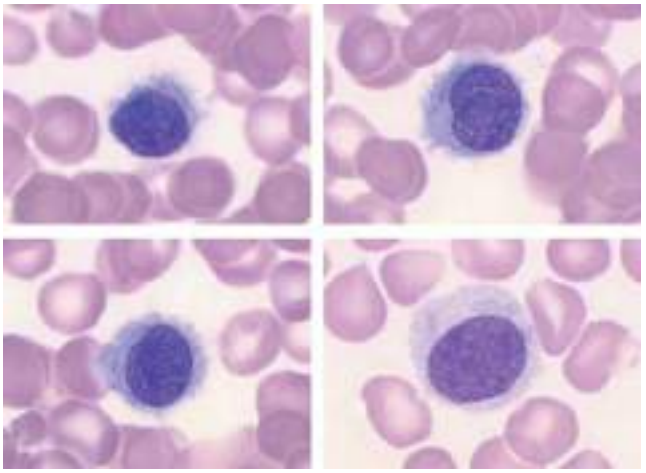

Figure 23.8 Individual hairy cells from blood films from two patients with HCL.

CD25, CD103, CD123 and CD200. *BRAF* mutations are found in virtually all patients (Table 23.2). Most cases (>80%) display mutated *IGHV* genes.

In most cases, bone marrow aspirates are unsuccessful ('dry tap') or yield scarce cellularity. The bone marrow biopsy shows diffuse interstitial infiltration of variable degrees; occasionally the infiltration is focal. A characteristic feature is the arrangement of the cellular infiltrate, which is loose, leaving plenty of space between cells, often with a clear zone around each cell, which is characteristic of this condition (Figures 23.9 and 23.10). Reticulin is always increased. Hairy cells stain strongly with anti-CD20. In 10–20% of cases, the bone marrow can be markedly hypocellular, which along with the pancytopenia may raise the possibility of aplastic anaemia as a diagnosis. In cases with hypoplastic marrows, immunohistochemistry (e.g. CD20, Annexin D1, DBA44, CD11c and VE1) is important for demonstrating clusters of hairy cells. Immunohistochemistry is also important to study MRD.

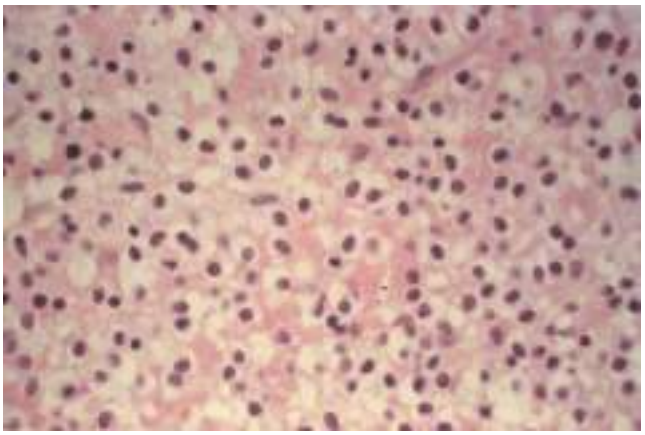

Figure 23.9 Bone marrow trephine section of a case of HCL showing the typical clear zone around the hairy cells in a paraffin-embedded section.

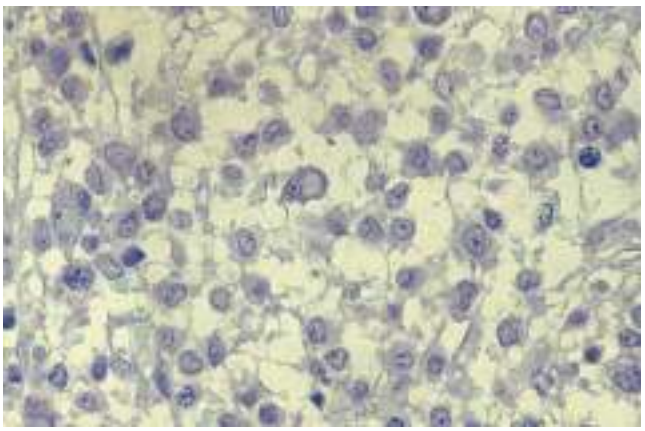

Figure 23.10 Bone marrow trephine from a case of HCL: section embedded in methacrylate giving good morphological detail of the hairy cells.

The spleen histology shows infiltration by mononuclear cells with a blunt nucleus in the red pulp with little residual white pulp, and formation of pseudo sinuses filled with erythrocytes.

The differential diagnosis of HCL in its classical form (HCLc) includes HCL atypical or HCLv, LPL, SMZL, B- cell prolymphocytic leukaemia (B-PLL) and splenic diffuse red pulp small B cell lymphoma (SDRPL) (Table 23.2).

Treatment

Treatment is only indicated in presence of active disease, as indicated by any of the following:

- Haemoglobin ≤110 g/L
- Platelet count $<100 \times 10^9$/L
- Absolute neutrophil count $<10 \times 10^9$/L.
- Splenomegaly
- Constitutional symptoms (i.e. fever, night sweats, fatigue and weight loss)

However, around 10% of patients present moderate asymptomatic pancytopenia and may be followed with no need for therapy for many years.

Front-line therapy

The purine nucleoside analogues, cladribine and pentostatin (PT), are the standard front-line treatment, with an ORR of 90–100% [complete response (CR) 70–90%] and no significant difference between the two agents. Remissions are durable (median, 15 years), and survival is close to that for an age-matched general population. In patients presenting with infection, this should be treated before commencing therapy. IFN (which is less myelotoxic than purine analogues) may be an option in case therapy cannot be postponed.

Cladribine (2-CDA) is effective in different schedules and by different routes (e.g. intravenous continuous infusion for 7 days, intravenous infusion over 2 hours on a 5-day regimen or alternatively subcutaneously on a once-per-day or once-per-week regimen.

PT is administered as a short 2 hours IV infusion every 2–3 weeks until remission is achieved (usually 8–10 injections). The dose may need to be modified based on renal function. Patients can experience nausea for up to 72 hours after the infusion.

Both pentostatin and cladribine cause temporary myelosuppression and a more prolonged immunosuppression. GCSF and prophylactic anti-infective agents (i.e. cotrimoxazole and acyclovir) may be initiated during treatment and continued for up to 6 months, or until adequate neutrophil and lymphocyte recovery. In the case of 2-CDA, it has been recommended to be

started after the 5-day course of treatment, since rashes can occur when the drugs are given concurrently. Allopurinol is not required.

Regarding classical therapies, splenectomy is now rarely performed because of the effectiveness of purine analogues in reducing the size of the spleen. Likewise, IFN is currently rarely given because of its side effects and inferior effectiveness in comparison with purine analogues. However, IFN may occasionally be useful in patients with serious infections and severe pancytopenia.

Rituximab monotherapy has not been formally tested in the first-line setting, but, based on the relatively low response rates seen in relapsed HCL, is not recommended as an alternative to purine analogues. Its use is reserved for patients unable to tolerate purine analogues or who present with an active infection. Nevertheless, rituximab may improve the remission rate when added to other agents. A study comparing 2-CDA with either concurrent or delayed rituximab (up to ≥6 months after detection of MRD in blood) resulted in a higher undetectable MRD CR rate in the concurrent arm. The use of this combination front-line is now standard in some centres, whereas others reserve the use of rituximab combinations for relapsed disease.

Treatment of refractory/relapsed disease

Resistance to therapy is exceedingly rare and should raise the possibility of an erroneous diagnosis. Patients with relapsed disease should only be treated if presenting symptoms, as in previously treated patients. Since almost all cases have a *BRAF* mutation, *BRAF* inhibitors (i.e. vemurafenib ± rituximab and dabrafenib) are effective to treat patients not responding to purine analogues or in relapse. Ibrutinib has been shown to be effective in this setting.

Non-nodal, leukaemic mantle cell lymphoma

Mantle cell lymphoma (MCL) signifies 3–10% of all lymphomas. MCL mainly affects older adults (median age, 60–65 years) with a male predominance. Broadly, two clinical forms of MCL are recognised: (i) nodal MCL (see Chapter 20) and non-nodal, leukaemic MCL included as an entity in the 5th WHO Classification 2022. Nevertheless, some degree of blood involvement can be demonstrated in almost 100% of cases if sensitive enough flow cytometry and molecular techniques are used. Close to 40% of cases evolving with splenomegaly have significant lymphocytosis, sometimes mimicking CLL (Figure 23.11). Most tumours have a classic morphology of small–medium-sized cells with irregular nuclei. However, the malignant lymphocytes may present with a spectrum of morphological variants, including small round (resembling CLL),

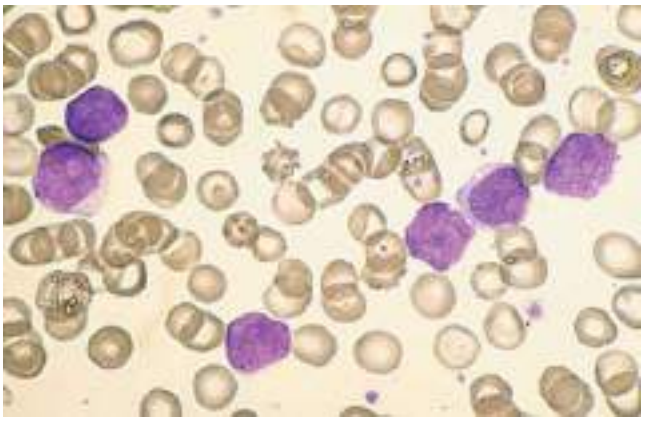

Figure 23.11 Blood film from a patient with mantle-cell lymphoma cells in peripheral blood. The cells are medium size, slightly irregular in shape and have a speckled nuclear chromatin pattern.

marginal zone-like, pleomorphic and blastoid cells. Blastoid cells, a high mitotic index and Ki-67 positive cells are all poor prognostic biomarkers. MCL are CD201, CD51 and positive for Cyclin D1 while being negative for CD10 and Bcl6. The hallmark chromosomal translocation t (11:14) (q13; 32) leads to the aberrant expression of cyclin D1 and identifies nodal. A few cyclin D1 negative cases have been identified. Overexpression of the transcription factor SOX11 has been described as a diagnostic marker for nodal MCL but is absent in non-nodal, leukaemic MCL. Biologic features such as the number of mitotic cells, a high Ki-67 proliferation index, *TP53* mutations and p16 deletions (*CDKN2A* mutation) are frequent in aggressive MCL subtypes such as the blastoid variant. On the contrary, low-density lipoprotein receptor protein 1 (LRPAP1) autoantibodies, present in around 13% of patients, correlate with a better outcome.

Marker studies show that MCL cells are always positive for CD5, CD19 and CD20, but negative for CD23 and CD200, although the latter may be absent in the leukaemic form (Table 23.2). The bone marrow biopsy shows a rather monotonous infiltration by slightly irregular cells. In contrast with CLL, no proliferating centres are seen. The pattern of bone marrow infiltration is often diffuse in advanced cases, but in other instances is nodular and/or paratrabecular (see Chapter 20).

The natural history of MCL often includes the worst features of both aggressive and indolent lymphoma: a rather aggressive clinical course and a pattern of resistant and relapsing disease with no sustained remissions. Historically, the median survival was 4–5 years; however, this is now 8–12 years; thanks to the availability of better therapies. On the other hand, not all cases of MCL require therapy at diagnosis. There are clinical forms biologically characterised by the expression of CD200, mutated *IGHV* genes, no del(17p)/*TP53* mutations and no expression of

SOX-1 in which the clinical course can be relatively indolent; these cases can be followed with no therapy for months, and their outcome is superimposable to those treated immediately after diagnosis. Treatment is as in nodal MCL.

Follicular lymphoma

Around 15% of patients with follicular lymphoma may have circulating lymphoma cells ($5–20 \times 10^9$/L). The proportion of patients with inconspicuous blood involvement is much higher, as demonstrated by flow cytometry or molecular techniques (BCL-2 detection). A minority of patients may present with a WBC count $>40 \times 10^9$/L) and extensive disease, generalised lymphadenopathy, hepatomegaly and a prominent splenomegaly. Usually, the circulating cells are small, with almost no visible cytoplasm, the nuclear chromatin is smooth without clumps of heterochromatin and no visible nucleolus, and the nuclear shape is angular and has a small cleft (Figure 23.12). Lymph node histology is essential for confirming a diagnosis of follicular lymphoma. Patients with high WBC and a marked proportion of lymphoma cells in blood have a poorer prognosis than those with a minor degree of spillover. Late-stage follicular lymphoma is characterised by multiple genetic lesions and may have circulating blasts (centroblasts); this corresponds with histological transformation to a large-cell lymphoma or the so-called blastic form of follicular lymphoma. The immunophenotypic characteristics of follicular lymphoma cells are shown in Table 27.2.

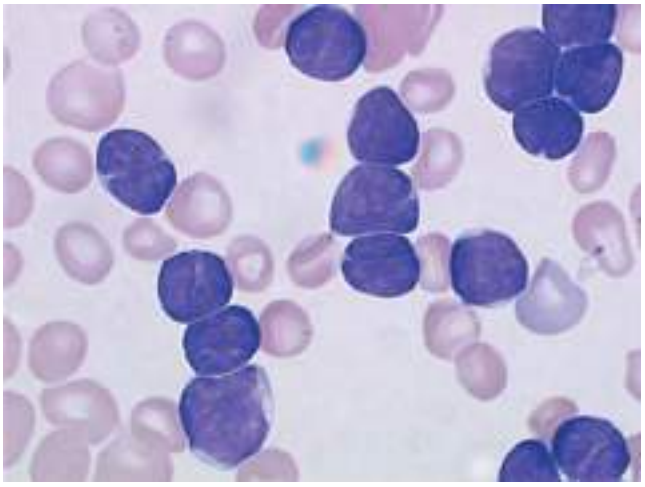

Figure 23.12 Blood film of a patient with follicular lymphoma presenting with significant lymphocytosis. The cells show a cleaved nucleus, angular shape, homogeneous chromatin pattern and high nucleus-to-cytoplasm ratio and small size.

Splenic B-cell lymphoma/leukaemia with prominent nucleoli (Hairy-cell leukaemia variant)

The so-called HCL variant (HCLv was included in the WHO classification (2017) as a provisional entity under the umbrella of splenic lymphomas. In the 5th Edition of the WHO classification (2022), HCLv falls under the term 'Splenic B-cell lymphoma/leukaemia with prominent nucleoli'. It affects older people, predominantly males and is characterised by the presence in peripheral blood of a large proportion of small to medium-sized villous lymphoid cells. The abnormal lymphoid cells have a polar distribution of the villi, and the nucleolus is small or not visible (Figure 23.13) The neoplastic cells in HCLv show intense expression of pan-B-cell markers, such as CD19, CD20, CD22 and CD79b, and also brightly positivity for surface light chains. CD11c, CD103 and, rarely, CD123 may be positive. CD25, CD200 and Annexin A1 are not expressed. The MCV is normal and there is no monocytopenia. Del (17p)/*TP53* mutation and del(11q)/*ATM* mutation may be present. In contrast to HCL, no *BRAF* V600E mutation is present. *MAP2K1* is the most frequently mutated gene, encoding *MAP2K1/MEK1* downstream from *BRAF*. HCLv frequently uses IGHV4-34 in unmutated conformation (approximately, 40% of cases), which is correlated with a higher disease burden. The WBC count can be high (e.g. $50–80 \times 10^9$/L). In contrast to HCL, the bone marrow aspirate is usually cellular and the bone marrow trephine shows a mixed pattern of predominantly interstitial and to a lesser extent, intrasinusoidal infiltration by leukaemic cells. HCL responds poorly to purine analogues given as single agents. For this reason, it is recommended that cladribine plus rituximab be used as first-line therapy. Small numbers of patients with HCLv have been treated with moxetumumab pasudotox (an anti-CD22 immunotoxin) with inferior results than seen in HCLv, which may be due to the

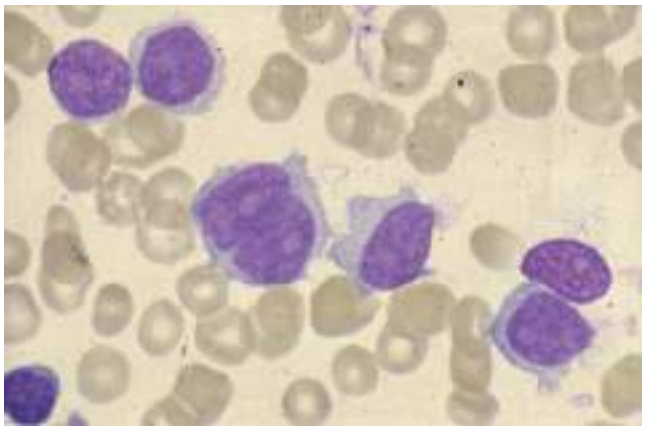

Figure 23.13 Blood film from a case of HCL variant showing large nucleolated villous cells, one of them binucleated.

presence of bulky disease. Trametinib (a MEK inhibitor) has been shown to have treatment activity. Splenectomy may be considered in refractory cases to improve symptoms and cytopenias. BTKi and BCL2i are emerging as treatment possibilities.

Splenic diffuse red pulp small B-cell lymphoma

The SDRPL is characterised by the presence of a large proportion of small-to-medium-sized lymphoid cells in peripheral blood with clumped chromatin and round nuclear outline and villous cytoplasm. The spleen shows a diffuse pattern of infiltration by monomorphous small cells with small round nuclei and pale cytoplasm. Bone marrow shows intrasinusoidal infiltration. The monoclonal B cells express CD11c, CD103 and CD123; CD25 and Annexin D1 are not expressed. This disease is more common in older men and usually presents with splenomegaly and moderate lymphocytosis. The differential diagnosis from other splenic lymphomas, such as SMZL can be difficult because of their similar clinical presentations and the absence of specific molecular markers. The diagnosis may eventually require the examination of the spleen histology. Splenectomy may be useful to control the disease.

Acknowledgements

This chapter is dedicated to the memory of the late Professor Daniel Catovsky who authored it in past editions. Thanks are due to Stefano Molica for helpful comments on novel CLL therapies. The author wishes to apologise to those colleagues whose contributions are referred to in this chapter but could not be quoted because of space limitations.

CHAPTER 24

T-cell lymphoma and lymphoproliferative disorders

24

Introduction

Chronic T-cell lymphoproliferative disorders are a group of neoplastic diseases that result from the clonal proliferation of mature post-thymic T-lymphocytes, being therefore clearly separated from diseases arising from T-cell (prethymic or thymus-derived) precursors, such as T-cell acute lymphoblastic leukaemia and lymphoblastic lymphoma.

The World Health Organization (WHO) classification provides clear definitions for the diagnosis of the major subtypes of T-cell lymphoproliferative disorders, which are classified on the basis of their clinical behaviour (indolent versus aggressive) and presentation (nodal, extranodal or leukaemic). In 2022, the classification of haematologic and lymphoid neoplasm was updated, now recognising 34 established entities of mature T-cell non-Hodgkin lymphomas and lymphoproliferative diseases. The classification underscores the great heterogeneity of T-cell neoplasms on account of morphological, immunophenotypical, clinical and molecular features of each disease entity. Furthermore, it provides the tools to better stratify patients in terms of prognosis and outcomes and to guide decisions before and throughout treatment. Table 24.1 reports the most recent WHO classification of mature T-cell neoplasms.

Mycosis fungoides and primary cutaneous CD30$^+$ T-cell lymphoproliferative disorders represent extranodal (cutaneous) diseases with a prolonged natural history; conversely, anaplastic large-cell lymphoma, angioimmunoblastic T-cell lymphoma and peripheral T-cell non-Hodgkin lymphoma, not otherwise specified, to cite the most relevant, represent the aggressive nodal counterpart. Enteropathy-associated T-cell lymphoma and hepatosplenic T-cell lymphoma have an extranodal presentation and usually behave aggressively, as well as some rarer cutaneous T-cell lymphoma entities, such as primary cutaneous aggressive epidermotropic CD8$^+$ T-cell lymphoma and cutaneous γ/δ T-cell lymphoma. T-prolymphocytic leukaemia and large granular lymphocyte leukaemia are indeed diseases with a primary leukaemic presentation, as they arise in the bone marrow and then evolve with a peripheral blood leukaemic presentation. Finally, Sézary syndrome may be considered as the leukaemic phase of a T-cell cutaneous lymphoma, since the tumour arises in an extranodal organ – i.e. the skin – but also displays a characteristic leukaemic picture.

This chapter focuses on the most significant clinical entities, by grouping together chronic T-cell leukaemias, peripheral T-cell non-Hodgkin lymphomas and cutaneous T-cell non-Hodgkin lymphomas, and provides the description of disease features and morphology, the basis for their diagnosis and the therapeutic approaches, with a closer look at new molecules and innovative treatment strategies.

Chronic T-cell leukaemias

Two distinct chronic T-cell lymphoproliferative disorders present with a primary leukaemic phase: T-prolymphocytic leukaemia (T-PLL) and large granular lymphocyte (LGL) leukaemia.

Table 24.1 The 2022 World Health Organisation (WHO) classification of mature T- and NK-cell neoplasms. Highlighted entities in bold are explained in the text.

Mature T/NK leukaemias	**T prolymphocytic leukaemia**
	T large granular lymphocytic leukaemia
	NK large granular lymphocytic leukaemia
	Adult T-cell leukaemia/lymphoma
	Sézary syndrome
	Aggressive NK-cell leukaemia
Primary cutaneous T-cell lymphoma	Primary cutaneous $CD4^+$ small/medium T-cell lymphoproliferative disorder
	Primary cutaneous acral $CD8^+$ lymphoproliferative disorder
	Mycosis fungoides
	Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorder – Lymphomatoid papulosis
	Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorder – Primary cutaneous anaplastic large cell lymphoma
	Subcutaneous panniculitis-like T-cell lymphoma
	Primary cutaneous γ/δ T-cell lymphoma
	Primary cutaneous $CD8^+$ aggressive epidermotropic cytotoxic T-cell lymphoma
	Primary cutaneous peripheral T-cell lymphoma, NOS
Peripheral T-cell lymphoma	Indolent T-cell lymphoma of the GI tract
	Indolent NK-cell lymphoproliferative disorder of the GI tract
Extranodal types	**Enteropathy-associated T-cell lymphoma**
	Monomorphic epitheliotropic intestinal T-cell lymphoma
	Intestinal T-cell lymphoma, NOS
	Hepatosplenic T-cell lymphoma
Peripheral T-cell lymphoma	**ALK-positive anaplastic large-cell lymphoma**
	ALK-negative anaplastic large-cell lymphoma
Nodal types	**Breast implant-associated anaplastic large-cell lymphoma**
	Nodal TFH cell lymphoma, angioimmunoblastic-type
	Nodal TFH cell lymphoma, follicular-type
	Nodal TFH cell lymphoma, NOS
	Peripheral T-cell lymphoma, NOS
EBV^+ NK/T-cell lymphomas and lymphoid proliferations	EBV^+ nodal T- and NK-cell lymphoma
	Extranodal NK/T-cell lymphoma
	Severe mosquito bite allergy
	Hydroa vacciniforme lymphoproliferative disorder
	Systemic chronic active EBV disease
	Systemic EBV^+ T-cell lymphoma of childhood

NOS, not otherwise specified; GI, gastrointestinal; TFH, T-follicular helper; EBV, Epstein-Barr virus.

T-prolymphocytic leukaemia

T-PLL is a rare, post-thymic, mature T-cell neoplasm, accounting for 2% of mature lymphoid leukaemias. It generally displays an aggressive clinical course, with only a minority of patients being asymptomatic at presentation. Disease progression may occur rapidly, even in asymptomatic patients. Older adults are generally affected (median age of 61 years), with a male predominance.

Clinical features

Splenomegaly, seen in almost two-thirds of patients, and marked peripheral blood lymphocytosis, with circulating prolymphocytes, are distinctive clinical aspects. Hepatomegaly and lymphadenopathies may be seen in up to half of patients, as well as skin nodules, maculopapular rash or erythroderma. Peripheral oedema (periorbital or conjunctival), pleuroperitoneal effusions or central nervous system involvement may also be present, especially during disease progression. Anaemia and thrombocytopenia are usually documented, along with a lactate-dehydrogenase elevation.

Diagnosis

Diagnosis is established on morphological, immunophenotyping and cytogenetic tests, as outlined in Table 24.2. All the three major criteria need to be fulfilled for the diagnosis, or alternatively the first two major criteria and one minor criterion.

Table 24.2 Requirements to establish the diagnosis of T-PLL.

Major criteria	Minor criteria
– More than 5×10^9/L cells of T-PLL phenotype in peripheral blood or bone marrow. – T-cell clonality (by polymerase chain reaction for *TCRB/TCRG*, or by flow cytometry). – Abnormalities of 14q32 or Xq28 or expression of *TCL1A/B* or *MTCP1*.	– Abnormalities involving chromosome 11 (11q22.3; *ATM*). – Abnormalities in chromosome 8. – Abnormalities in chromosomes 5, 12, 13, 22 or complex karyotype. – Involvement of T-PLL specific site (splenomegaly, effusions).

Prolymphocytes are medium-sized cells, displaying a high nuclear-to-cytoplasm ratio, with round, oval, irregular or convoluted nuclei and a single prominent nucleolus; the cytoplasm is agranular, with blebs (Figure 24.1). In up to 20% of cases, prolymphocytes may resemble small lymphocytes or show a cerebriform nuclear appearance. The bone marrow is invariably involved, with a diffuse and interstitial pattern, as well as the spleen, which shows an expansion of both red and white pulp. Tissue histology, however, is not mandatory for diagnosis. Immunophenotyping by flow cytometry demonstrates a positivity for CD7 (strong), CD5 and CD2, with lack of expression of terminal deoxynucleotidyl transferase (TdT) and CD1a. CD52 is expressed at high density. T-cell receptor α/β genes are rearranged in most of the cases, and just in a minority of instances a γ/δ rearrangement is detected. In virtually all cases, the Xq28 (*MTCP1* locus) or 14q32.1 (*TCL1* and *TCL1b* loci) regions are involved in translocations or inversions with *TCRA/D* at 14q11. The demonstration of either cytogenetic abnormality is a major criterion for diagnosis. Complex karyotype alterations or abnormalities involving chromosomes 8, 11, 5, 12, 13 and 22 may also be detected.

Therapy

Although in rare asymptomatic cases, an active surveillance programme may be pursued, systemic treatment is usually needed sooner rather than later due to the clinically aggressive and rapid natural history of the disease. More precisely, any the following are indications to treat: constitutional symptoms (fatigue, unintentional weight loss, drenching night sweats or fever without signs of infection), signs of bone marrow failure (haemoglobin <100 g/L, platelets $<100 \times 10^9$/L), rapidly enlarging nodes, spleen or liver, increasing lymphocytosis (doubling-time shorter than 6 months), extranodal involvement (including effusions or central nervous system involvement).

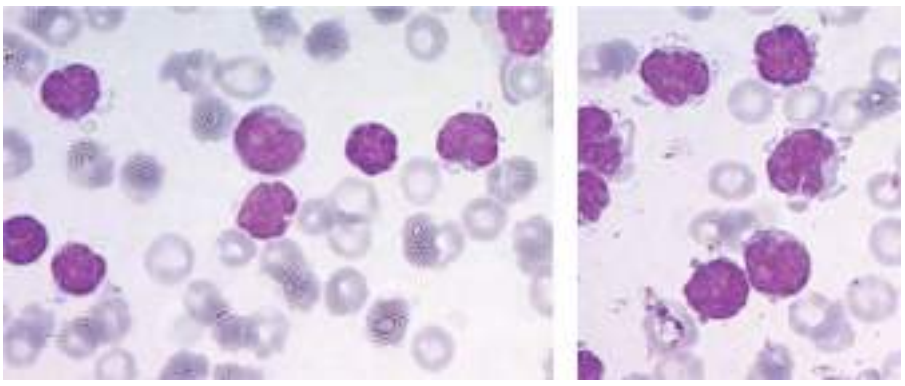
Intravenous alemtuzumab, a humanised anti-CD52 antibody, is the first-line treatment of choice, yielding up to an 80% of complete response in treatment-naïve patients. Although prolonged responses to alemtuzumab have been documented, all patients do eventually relapse: therefore, a consolidation with an allogeneic stem cell transplantation in first remission may offer a chance for a better long-term survival. Autologous stem-cell transplantation may also be beneficial for patients, but it does not result in a cure. Re-treatment with alemtuzumab at disease relapse is feasible if remission duration is longer than 6 months. Purine analogues, such as pentostatin, cladribine, nelarabine or fludarabine (alone or in combination with alemtuzumab) may be a reasonable treatment alternative, with some evidence of activity in T-PLL.

Prognosis

Response to alemtuzumab is the main outcome predictor: non-responders have a median survival of only 4 months. Five-year overall survival is only approximately 20%, with high white cell counts, older age and short lymphocyte doubling time being adverse prognostic factors.

Large granular lymphocyte leukaemia

LGL leukaemia is characterised by the clonal expansion of large granular lymphocytes, both of T (T-LGL) or natural killer (NKLGL) origin. The 2022 WHO classification includes T-LGL



(a) (b)

Figure 24.1 Peripheral blood smear showing T-prolymphocytes. (a) Nuclei are round to markedly irregular (indented, cerebriform), the chromatin is clumped, with inconspicuous nucleoli. (b) Blebs and cytoplasm protrusions are easily seen.

in the subgroup of mature peripheral T-cell and NK-cell neoplasms, along with a clinically distinct disease, which is the aggressive NK-cell leukaemia.

The frequency of the disease has never been accurately established; however, it ranges from 2 to 6% of the chronic lymphoproliferative disorders, being slightly more frequent in Asia than in North America and Europe. Men and women are equally affected, at a median age of 60 (range 12–87) years, with less than 25% of patients being younger than 50 years. Roughly 85% of LGL cases are of T-cell origin, while nearly 10% are described as chronic NK-LGL leukaemia. The aggressive NK-cell leukaemia is mostly reported in people of Asian origin, displaying a very poor outcome and a significantly high rate of treatment refractoriness.

The aetiology remains unclear, although a prolonged response to an antigenic (possibly viral) stimulus may be hypothesised. An initial oligoclonal proliferation of LGLs may lead to the emergence of a prevalent clone if the inciting antigenic drive persists due in part to the activation of the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway. Somatic mutations, particularly of *STAT3*, accelerate the clonal expansion and evolution of the leukaemic cells and lead to the production of pro-inflammatory cytokines that contribute to the development of cytopenias and autoimmune phenomena. Resistance of LGLs to apoptosis is also a key pathogenetic mechanism, which is mediated by the enhanced expression of the antiapoptotic molecule Mcl-1, the increased levels of IL-15 and the high expression of Fas and Fas-ligand (FasL) on neoplastic cells.

Clinical features

The disease displays a chronic and indolent course, although up to two-thirds of patients are symptomatic at diagnosis. Clinically relevant aspects are similar for both T- and NK-LGL and are represented by peripheral cytopenias, namely neutropenia and anaemia. Severe neutropenia can be asymptomatic for very long periods of time, albeit some patients show oral aphthous ulcerations or fever due to bacterial infections. Anaemia may be severe, due to multiple mechanisms, including autoimmune haemolysis and pure red cell aplasia, and may require transfusion support. Splenomegaly is reported in up to 50% of cases, without hepatomegaly or lymphadenopathy.

Rheumatoid arthritis is the most commonly associated autoimmune manifestation, in 11–36% of patients. A positive rheumatoid factor and the detection of antinuclear antibodies (along with polyclonal hypergammaglobulinaemia) is seen in 40–60% of cases, less frequently observed in NK-LGL. Less common autoimmune diseases include Sjögren syndrome, systemic lupus erythematosus, Behçet disease, autoimmune thyroid disorders and autoimmune thrombocytopenia.

Lymphocytosis ($>4\times10^9$/L) is seen in more than half of patients, with mean circulating LGLs varying from 0.5 to 10×10^9/L. Bone marrow involvement is documented in more than 70% of cases, without any linear correlation between the extent of marrow infiltration and the severity of symptoms or cytopenias.

Diagnosis

Diagnosis is established once an increased number of clonal LGLs is documented in a compatible clinical context, both morphologically and by immunophenotyping. LGLs are larger than quiescent lymphocytes and show an abundant cytoplasm with azurophilic granules and a reniform or round nucleus. A peripheral count of $>2\times10^9$/L LGLs is a diagnostic criterion; in case of lower LGL counts, a bone marrow biopsy (showing interstitial infiltration with linear arrays of CD8, granzyme B, perforin, TIA-1 positivity) is recommended to confirm the diagnosis. T-LGLs are CD3+, CD8+, CD57+, $CD5^{dim}$ and CD45RA+, and show evidence of clonal T-cell receptor γ gene rearrangement (which makes the distinction from reactive LGL proliferation). On the other hand, NK-LGLs are CD3–, CD2+, CD4–, CD8+, CD16+, CD56+ and CD57±.

Therapy

Therapy should be instituted in case of severe neutropenia (neutrophils $<0.5\times10^9$/L), recurrent infections (regardless of the absolute neutrophil count), symptomatic or transfusion-dependent anaemia or associated immune diseases (mainly rheumatoid arthritis). No standard treatment exists; however, immunosuppressive treatments represent the mainstay of therapy. Single-agent methotrexate (10 mg/m^2/week, orally) is adequate for patients with neutropenia and arthritis, to be administered for at least 4 months before response assessment and to be continued as long as the patient responds. For those with anaemia or pure red cell aplasia, oral cyclophosphamide at a daily dose of 50–100 mg for at least 4 months (up to 12 months in responding patients) is the treatment of choice, comparing favourably with methotrexate in terms of response rates (66 and 55%, respectively). Cyclosporine A (3 mg/kg/day) is an alternative first-line therapy in patients with anaemia and a suitable second-line, to be maintained indefinitely, as long as it is tolerated. Recent data suggests that Jak inhibitors are very active in cases which contain an activating *STAT3* mutation.

Prognosis

LGL leukaemia generally behaves indolently; it is difficult to evaluate the proportion of patients who will require a systemic therapy due to the worsening of cytopenias or the appearance of symptoms (33–80% in reported series). Aggressive NK disease, with high LGL peripheral counts and marrow infiltrate, massive organomegaly and lymphoma-related B symptoms display a poor prognosis, and patients appear refractory to any treatment.

Nodal peripheral T-cell non-Hodgkin lymphomas

Peripheral T-cell non-Hodgkin lymphomas (PTCL) are a distinct form of rare chronic T-cell lymphoproliferative disease, clearly separate from cutaneous T-cell lymphomas (CTCL), discussed below. The incidence of PTCL in the United States is less than 1 case per 100,000 people; worldwide, the prevalence of

each specific disease entity profoundly depends on the geographic region, although the biological reason for the observed discrepancies is still largely unknown. In Western countries, PTCL accounts for 15–20% of aggressive lymphomas, and 5–10% of all non-Hodgkin lymphomas. In Asia, however, incidence is higher, and 15–20% of all lymphomas are classified as PTCL or NK/T-cell lymphoma. PTCL-not otherwise specified (NOS) is the most common reported subtype in both North America and Europe, whereas NK/T-cell lymphoma and adult T-cell leukaemia/lymphoma are more common in Asia, the latter being specifically represented in Japan. Anaplastic large-cell lymphoma (ALCL) is more represented in the United States, whereas angioimmunoblastic T-cell lymphoma (AITL) is more frequent in Europe than in Asia or in North America.

In the context of the 2022 WHO classification, PTCL represent a group of mature T-cell aggressive diseases, primarily with a nodal origin (PTCL-NOS, ALCL, AITL being the most clinically relevant entities), although extranodal subtypes do exist – being far less common – described by their tissue tropism (e.g. enteropathy-associated T-cell lymphoma and hepatosplenic T-cell lymphoma).

Diagnostic accuracy amongst expert haematopathologists varies according to subtype. For example, diagnostic accuracy is very good (>97% agreement amongst experts) for anaplastic lymphoma kinase-positive ALCL, but poor (<85%) for the other lymphoma subtypes, being only 75% for the most common subtype, PTCL-NOS. Importantly, several cases previously characterised as PTCL-NOS can be reclassified into more recent WHO-recognised categories, such as AITL or ALCL. This underscores the role of recent biologic insights into the pathogenesis of these diseases, as well as more specific diagnostic markers and diagnostic criteria in enhancing the diagnostic accuracy and reproducibility for these entities.

PTCL are staged according to the Ann Arbor staging system, with the same techniques used for B-cell lymphomas. The majority of PTCL patients, with the exception of ALCL, present with an advanced (III or IV) stage disease. Positron emission tomography (PET) scanning has proved its usefulness in the staging of PTCL, although maximum standard uptake values in patients with PTCL seem somewhat lower than in aggressive B-cell lymphomas, and generally less pronounced for extranodal lesion than for nodal areas of disease. Data regarding the role of post-treatment PET scan are still inconclusive, since negative scans may not be always associated with significantly improved clinical outcomes.

The International Prognostic Index (IPI) remains the mainstay of the prognostic stratification of patients with PTCL, being inversely related to survival in a manner similar to B-cell lymphomas, although overall survival in each category is lower.

Peripheral T-cell non-Hodgkin lymphoma, not otherwise specified

PTCL-NOS is the most common subtype, accounting for at least 25–30% of PTCL. However, it does not represent a single entity, since as many as 20% of cases have shown a gene expression profile characteristic of other PTCL subtypes, such as AITL, ALCL, extranodal NK/T-cell lymphoma or adult T-cell leukaemia/lymphoma, sometimes with molecular markers suggesting a peculiar T-follicular helper (T_{FH}) origin. Moreover, another subgroup shows features of cytotoxic T-cells, thus suggesting a separate disease entity, with a worse prognosis than any other PTCL-NOS. The diagnosis of PTCL-NOS should then be established once other categories of PTCL have been excluded.

Clinical features

The disease tends to affect adult patients (median age at presentation is 60 years), with a male predominance. Children can also be affected. Nodal involvement is the most relevant feature at diagnosis, although any organ can be affected (including bone marrow, liver, spleen and skin). Advanced stage at presentation is relatively common (nearly 70% of cases); lymphoma-related symptoms, lactate-dehydrogenase elevation and poor performance status are documented in more than half of the cases; almost two-thirds of the patients present an intermediate to high IPI score.

Morphology and biology

Lymph node infiltration is generally diffuse, with neoplastic elements showing a variable morphology, ranging from small cells with irregular nuclei to large cells with prominent nucleoli and mitotic figures (Figure 24.2); cells with clear cytoplasm and occasionally Reed–Sternberg-like cells can also be encountered, along with an inflammatory background composed of small reactive lymphocytes, eosinophils, plasma cells and epithelioid histiocytes. A diffuse or interfollicular infiltrate of epithelioid histiocytes is particularly evident in the lymphoepithelioid (Lennert) variant. A subset of PTCL-NOS shows a vaguely nodular pattern, featuring a follicular lymphoma or a lymphocyte-predominant

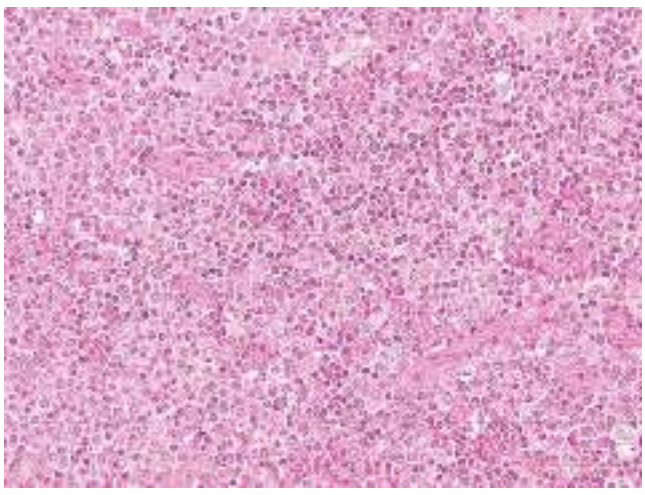


Figure 24.2 Peripheral T-cell lymphoma, not otherwise specified (haematoxylin and eosin stain, magnification 200×).

Hodgkin lymphoma pattern: such cases more often display a phenotype related to T_{FH} cells (as outlined in the paragraph on AITL). Neoplastic cells stain positively for CD2, CD3, CD5 and CD7, with a variable expression of CD4 and CD8; aberrant T-cell phenotypes, with lack of expression of some antigens, can also be observed. The CD30 antigen is variably expressed, mostly in large-cell variants. Rare cases of PTCL-NOS express the cytotoxic granule-associated proteins (perforin, granzyme B and TIA-1), specifically in the lymphoepithelioid variant.

Recently, gene expression profile studies have contributed to the dissection of PTCL-NOS into molecularly distinct entities, according to the overexpression of *GATA3* and *TBX21*. *GATA3* expression correlates with a worse prognosis (<20% of patients alive at 5 years), whereas cases with a *TBX21* signature have more favourable outcomes. Cases with a T_{FH} phenotype display recurrent genetic abnormalities in *TET2*, *IDH2*, *DNMT3A*, *RHOA* and *CD38*, as is seen with AITL: for this reason, they should be more correctly classified as nodal PTCL with a T_{FH} phenotype.

Prognosis

The IPI is significantly associated with treatment outcomes. Reported 5-year overall survival for IPI score 0/1 and 4/5 is 50 and 11% respectively with 5-year progression free survival of 33 and 6%. A newly introduced prognostic index specifically designed for PTCL (PIT) includes age, lactate-dehydrogenase elevation, performance status and bone marrow involvement, and better allows the stratification of patients into more specific prognostic groups, with a 5-year overall survival for the most favourable group (i.e. the one with no adverse factors) of 62, and of 18% for patients presenting with three or four adverse prognostic factors.

Angioimmunoblastic T-cell lymphoma

AITL makes up nearly 15–20% of cases of PTCL, being the second most common variety. AITL is a T_{FH}-derived neoplasm that originates from follicular helper T-lymphocytes: these cells are normally present in lymphoid follicles, being involved in the germinal centre reaction in close collaboration with B-lymphocytes. Given that a number of recurrent mutations and a peculiar gene signature characterise a significant proportion of AITL cases, as well as some cases of PTCL-NOS which manifest a T_{FH} phenotype (as said above), the 2022 WHO classification unifies under a common heading AITL, follicular T-cell lymphoma and nodal PTCL with T_{FH} phenotype.

Clinical features

The disease typically affects older adults (median age 65 years), and it is clinically characterised by an aggressive clinical course, an advanced stage at presentation (nearly 90% of patients show stage III/IV) and by the presence of lymphoma-related symptoms (in about 70% of patients since disease onset). Patients complain of a generalised lymphadenopathy, which is usually associated with hepatosplenomegaly and rash. Bone marrow is involved in 28% of cases. Lactate-dehydrogenase elevation, polyclonal hypergammaglobulinaemia and autoimmune manifestations (such as autoimmune haemolytic anaemia, cold agglutinin disease, rheumatoid factor positivity and anti-smooth-muscle antibody positivity) are frequently associated findings, as well as the presence of peripheral oedema, pleural or peritoneal effusions and joint pain.

Morphology and biology

From a histological point of view, the architecture of the lymph node appears completely effaced by a T-cell infiltrate, which extends beyond the node capsule, but characteristically sparing the subcapsular sinus, which appears dilated (Figure 24.3). The neoplastic cells show an aberrant expression of T-cell markers (CD2, CD3, CD5 and CD7) and display the phenotype of T_{FH} cells, with the positivity of at least three of the following markers: CD4, CD10, BCL-6, PD-1, CXCL13 and SAP. Reactive lymphocytes, eosinophils, plasma cells, follicular dendritic cells and histiocytes represent accompanying non-neoplastic populations, along with the presence of scattered large CD20+ immunoblastic cells, usually staining positively for EBV-encoded RNA (EBNA). A characteristic feature of AITL is a prominent vascular proliferation, as a consequence of the over-expression of the vascular endothelial growth factor (VEGF)-A gene, both in lymphoma and endothelial cells.

The AITL mutational landscape is complex: *TET2*, *IDH2*, *DNMT3A* and *RHOA* are amongst the most relevant mutated genes, possibly with a role in lymphomagenesis. *TET2* is mutated in half to three-quarters of the cases, along with *IDH2*; *RHOA* mutations can be found in up to 70% of the cases and occur with concomitant *TET2* mutations.

Prognosis

Rapid disease progression is seen in most patients, accompanied by frequent infectious complications, leading to a median survival of less than 3 years.

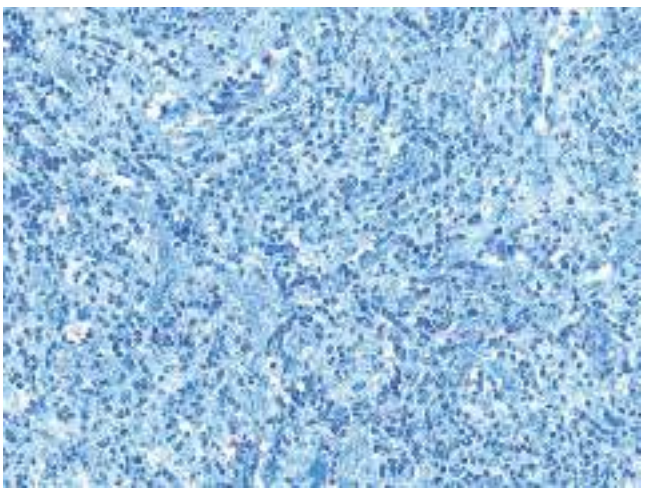

Figure 24.3 Angioimmunoblastic T-cell lymphoma (Giemsa stain, magnification 200×).

Anaplastic large-cell lymphoma

First described as a group of tumours displaying large cells with bizarre morphology, prominent sinusoidal invasion and Ki-1 antigen (nowadays recognised as CD30) expression, ALCL has been recognised as a distinct clinical entity since the third edition of the WHO classification, which grouped together a significant proportion of cases characterised by the expression of the anaplastic lymphoma kinase (ALK), and a smaller subcategory, lacking the expression of ALK (ALK-negative ALCL). When it became clear that ALK-positive ALCL represented a relatively homogeneous disease subtype, also displaying a better clinical course compared with ALK-negative ALCL, the two disease entities were clearly separated. The 2022 WHO classification recognises an ALK-positive ALCL and an ALK-negative ALCL, the latter being no longer conceived as a provisional subcategory but rather defined as a specific disease entity. These two entities display a markedly different prognosis when treated frontline with conventional therapy and are managed differently. The current WHO classification also recognises two more ALCL subcategories. The former has an exquisitely cutaneous presentation, thus defined primary cutaneous ALCL (pcALCL, discussed in the cutaneous T-cell lymphoma section). The latter is associated with breast prostheses and termed breast implant-associated (BIA) ALCL.

Clinical features

Nearly 70% of patients with ALCL present with an advanced stage, and the clinical scenario of ALK-positive and ALK-negative varieties is similar. Peripheral or abdominal nodal disease is associated in nearly one-third of patients with an extranodal involvement (especially in patients exhibiting the ALK-positive variant), with bone marrow, skeleton and lung being the most represented sites. BIA-ALCL mainly presents as seroma fluid between the breast implant and the fibrous capsule, with most of the cases being localised at onset. In a minority of cases, it develops as a growing mass, eventually with distant dissemination.

Biology and prognosis

In more than two-thirds of cases, the ALK protein is overexpressed, mainly due to the translocation of the *ALK* gene on chromosome 2 to the nucleolar phosphoprotein 1 (*NPM1*) gene on chromosome 5, most frequently as a result of the chromosomal translocation t(2;5)(p23;q35), although at least 11 variant translocations involving the *ALK* gene at 2p23 have been described. Patients with ALK-positive lymphoma are much younger (median age of 34 years) than those with the ALK-negative variant (median age of 58 years). The expression of the ALK protein makes a substantial prognostic difference in terms of overall survival and failure-free-survival, which both favour patients with ALK-positive ALCL compared with ALK-negative disease (5-year overall survival, 70 versus 49%, 5-year failure-free survival, 60 versus 36%). However, patients aged over 40 years tend to display a similar outcome in terms of survival, independently from the expression of the ALK protein.

The molecular biology of ALK-negative ALCL is far less known: in nearly one-third of cases, rearrangements of *DUSP22* can be found identifying a subset of patients with a more favourable outcome. Conversely, rearrangements of the *TP63* gene are associated with much worse outcomes.

Morphology

ALCL exhibits a wide range of cytological appearances, with no distinction on morphological grounds between the ALK-positive and the ALK-negative variants (Figure 24.4). Different morphological variants of ALK-positive ALCL are described: the common pattern is composed predominantly of pleomorphic large cells, with irregular, eccentric, kidney-shaped nuclei (hallmark cells); the normal lymph node architecture is frequently obliterated and an intrasinusoidal cell growth is often documented, mimicking a metastatic malignancy. The lymphohistiocytic pattern is characterised by the presence of tumour cells admixed with a variable amount of histiocytes, whereas the small cell pattern shows a predominance of small- to medium-sized neoplastic cells, with round or irregular nuclei and sometimes with a clear cytoplasm. The Hodgkin-like pattern has morphologic features

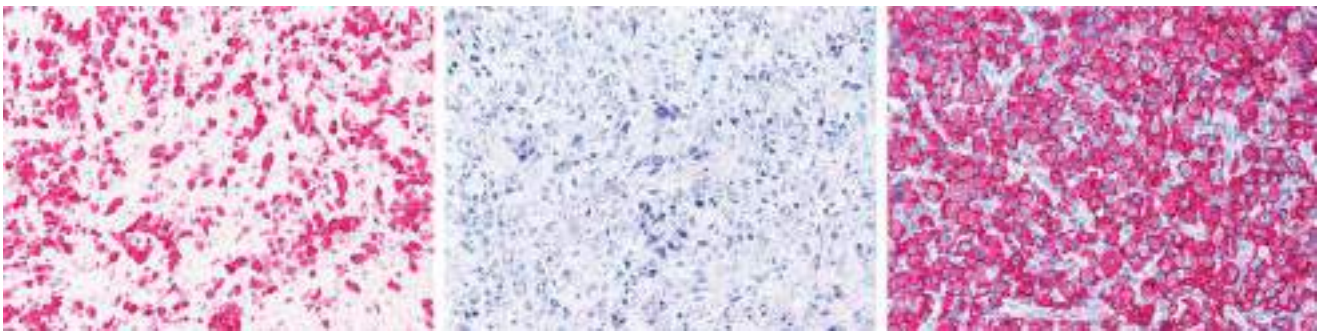

Figure 24.4 Anaplastic large-cell lymphoma (ALCL). (a) ALK-positive ALCL (immunohistochemistry for ALK protein, magnification 200×). (b) ALK-negative ALCL (Giemsa stain, magnification 200×). (c) ALK-negative ALCL (immunohistochemistry for CD30, magnification 200×).

mimicking nodular sclerosis classic Hodgkin lymphoma, with a significant number of tumour cells resembling Reed–Sternberg cells. Composite patterns may be seen in up to 20% of cases since features of more than one previously described pattern can be appreciated within a single lymph node specimen. The ALK-negative ALCL mostly shows a common type pattern of growth.

All ALCL are – by definition – positive for CD30, which is expressed on the cell membrane and in the Golgi region, predominantly in larger tumour cells. The great majority of ALCL cases express T-cell or NK-cell antigens, although several pan-T-cell antigens may be lost or unexpressed, yielding to an apparently T-null phenotype. The ALK staining may be cytoplasmic, nuclear or nucleolar, or it may be restricted to either the cytoplasm or the cell membrane. ALK expression is absent from all normal postnatal human tissues, except some rare cells in the brain although can be seen in some forms of lung cancer.

Extranodal peripheral T-cell non-Hodgkin lymphomas

Primary intestinal T-cell lymphomas

Enteropathy-associated T-cell lymphoma (EATL) is an aggressive disorder, frequently associated with coeliac disease; its incidence varies geographically, and it overlaps that of gluten-sensitive enteropathy, although not all patients with EATL have an overt coeliac sprue. EATL is most frequent in the sixth decade of life, with a similar incidence amongst men and women. It usually presents with abdominal pain, fatigue and anorexia, as well as with an exacerbation of typical symptoms of uncontrolled coeliac disease, such as diarrhoea and weight loss, together with hypoalbuminaemia and anaemia. Gastrointestinal ulceration, perforation, obstruction or haemorrhage may be frequent complications. The jejunum is mainly affected, although disease extension may be multifocal, also involving other intestinal segments.

Patients with EATL have a poor prognosis, one of the poorest of any subtype of PTCL, with a median 5-year overall survival of 20% and a progression-free survival of only 4%, which also remains dismal for those patients presenting with a more favourable IPI risk. Many patients, in fact, are unable to tolerate an aggressive chemotherapy approach.

Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL) is the second most common primary intestinal T-cell lymphoma. It occurs in older adults, at a median age of 61 years and with male predominance. In contrast to EATL, there is no definitive association with coeliac disease. The jejunum and ileum are the most commonly affected gastrointestinal segments, followed by the colon and the stomach. Extra-intestinal dissemination to mesenteric nodes or pelvic organs may also occur.

Nearly half of MEITL patients are asymptomatic, while a few shows gastrointestinal symptoms such as abdominal pain, weight loss, nausea or vomiting and diarrhoea. In some cases, the disease may have an acute onset due to intestinal perforation.

Hepatosplenic T-cell lymphoma

This subtype accounts for nearly 1.4% of PTCL, being more frequent in young men, who present with systemic symptoms, mainly fever, hepatic and splenic enlargement, along with peripheral cytopenias. It has been reported in the context of immune system disorders or alterations, including Crohn disease and solid organ transplantation. The tumour spreads to the spleen, the liver and the bone marrow, and infiltrates organs without forming growing and coalescent nodal masses.

The present treatments are largely unsatisfactory, and this disease displays a very poor prognosis, with a 5-year overall survival of 7% and progression-free survival of 0% although cures have been reported with early allogeneic stem cell transplantation.

Treatment of peripheral T-cell non-Hodgkin lymphomas

So far, the treatment strategies most widely applied in patients with PTCL are mainly derived from B-cell lymphomas. However, PTCL are biologically and clinically distinct from their B-cell counterparts, thus explaining the extremely different ranges of response to various therapies and the huge prognostic gap that exists between lymphomas of B or T origin.

The treatment approach for PTCL is discussed in this section. A chemotherapy-based first-line treatment is aimed at inducing a first clinical (complete) remission, which may be further consolidated with autologous or allogeneic stem cell transplantation (ASCT), depending on the specific PTCL subtype and IPI score at presentation. Although ASCT is frequently offered for consolidation of the first remission, its role is still a matter of discussion, as there is no randomised trial evidence of benefit.

Novel approaches are under consideration; on the one hand, to offer an alternative to those patients proving to be refractory after induction or relapsing after an autologous stem cell transplantation; on the other, to provide innovative treatment strategies to enhance the traditionally applied anthracycline-based induction schemes.

Induction chemotherapy

The cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP) regimen, administered every 21 days, or CHOP-like schemes, still represent the backbone of induction therapy and are still the most widely used worldwide. No randomised clinical trials are able to prove; however, its superiority over different treatment schemes. ALCL patients are those who best respond to CHOP and CHOP-like regimens, in comparison to other PTCL subtypes, with 5-year overall response rates higher than 60%. AITL patients have a 5-year overall survival of 32% and a failure-free survival of 18% when treated with CHOP, and in patients with PTCL-NOS there is no clear evidence that the use of an anthracycline-containing regimen during induction does any better compared with an anthracycline-free first-line therapy. Of

note, nearly 40% of patients with ALK-positive disease and more than 60% of those with an ALK-negative ALCL fail to respond to therapy, and taken as a whole, PTCL display 5-year overall survival rates lower than 40% when treated first-line with CHOP and CHOP-like strategies. There is some evidence that the combination of CHOP plus etoposide (CHOEP) can be more effective than CHOP alone in PTCL-NOS and ALCL, mainly in younger patients with no lactate-dehydrogenase elevation.

Autologous stem cell transplantation in first remission

Given that patients responding to frontline induction chemotherapy generally display a short duration of response and a high risk of relapse, ASCT can be considered a suitable consolidative strategy for patients in first complete remission and with chemosensitive disease, especially for those with intermediate to high IPI scores at disease presentation and with histologies other than ALK-positive ALCL. Unfortunately, many patients are older and some tend to progress when they are still on induction therapy, thus ASCT is not appropriate in many cases. A dose-dense approach followed by up-front ASCT has demonstrated a 5-year overall and progression-free survival of 51 and 44%, respectively, across a variety of PTCL, with the best results seen in ALCL, even in the ALK-negative subtype. Disease status at transplantation is a major predictor of success.

Recently, registry studies have collectively failed to demonstrate a clear survival advantage of ASCT over no further treatment after induction if patients achieve a complete response. No randomised trials have been designed to clarify whether upfront ASCT should be regarded superior to conventional chemotherapy only or if patients in complete response after induction strictly require a high-dose chemotherapy consolidation. Due to lack of conclusive results on this issue, upfront ASCT is still recommended by current guidelines for patients with chemosensitive PTCL-NOS, AITL and other rarer subtypes.

Treatment of relapsed and refractory disease

A variety of new agents have been investigated in relapsed or refractory PTCL patients, and some of them have obtained approval for the treatment of patients in such a disease context.

Four compounds are licensed by the Food and Drug Administration (FDA) in the United States for their specific use as single agents: pralatrexate, a novel antifolate agent; romidepsin and belinostat, both histone deacetylase (HDAC) inhibitors; and brentuximab vedotin (BV), an anti-CD30 drug-conjugated monoclonal antibody. The approval in Europe of both pralatrexate and romidepsin was rejected due to lack of evident clinical benefit and belinostat is not licensed in Europe, but it has been granted orphan designation status by the European Medicines Agency. All of these agents are effective in a minority of patients in the relapsed and refractory setting but have failed to impact survival. BV, however, has been granted approval for the treatment of relapsed and refractory systemic ALCL: in a phase 2 trial, it produced an objective response rate of 85%, with a complete response in 57% of the cases and 5-year overall survival and progression-free survival rates of 60 and 39%, respectively. Some activity, although under an off-label use, has also been demonstrated in PTCL-NOS and ALCL. BV is now being moved to frontline PTCL treatment in combination with chemotherapy according to the results of the ECHELON-2 trial (see next paragraph).

Besides approved agents, lenalidomide, bendamustine and gemcitabine have demonstrated efficacy in various subtypes of PTCL after failure of one or more previous treatments, with response rate closely resembling those of FDA-approved compounds.

Innovative frontline combinations

The standard CHOP regimen has been used as a backbone for new frontline combinations with drugs that have demonstrated efficacy when used as single agents in relapsed or refractory patients (see above). Theoretically, frontline combinations may improve complete response rates leading to a higher proportion of patients to receiving ASCT. Phase 1/2 trials combining pralatrexate, romidepsin, belinostat and the anti-CD52 monoclonal antibody alemtuzumab with CHOP and CHOP-like regimens have shown the feasibility of the proposed combinations, but have failed to show the superiority of any combination regimens over CHOP itself, both in terms of disease control and survival.

The only clearly positive study was ECHELON-2, a large double-blind multicentre randomised phase 3 trial that tested the combination of BV plus cyclophosphamide, doxorubicin and prednisone (BV-CHP regimen) versus standard CHOP in previously untreated subjects with CD30-expressing PTCL (at least 10% of the cells). 70% of patients had systemic anaplastic large cell lymphoma with the study design deliberately enriching for this cohort. The overall response rate was 83% in the experimental arm and 72% in the experimental arm, with a complete response in 68 and 56% of cases, respectively. The 3-year PFS was 57% for the BV-CHP arm and 44% for the CHOP arm, and the difference remained significant irrespective of any consolidative ASCT. This also translated into a significantly prolonged overall survival. Based on these results, BV was approved in November 2018 by FDA for the treatment of adult patients with previously untreated systemic anaplastic large cell lymphoma or other CD30-positive PTCL in combination with chemotherapy. In Europe, the licence is restricted to ALCL.

Allogeneic transplantation

The rationale behind allogeneic stem cell transplantation rests on both the fact that allogeneic haematopoietic stem cells are free of tumour contamination and that a graft-versus-lymphoma effect can be hypothesised since donor-derived immune cells

are potentially capable of mediating an anti-tumour effect. Once again, disease status at transplantation and chemosensitivity are outcome predictors: a high percentage (almost 70%) of patients who are in remission at the time of transplantation can be cured of their disease, while only 25–30% of refractory patients may take advantage of this procedure. No differences have been documented in the relapse rates when a myeloablative conditioning is compared to reduced-intensity conditioning regimens, although a higher rate of non-relapse mortality with the myeloablative approach still exists.

New drugs

Patients failing an initial treatment are generally hard to treat effectively with conventional chemotherapy and constitute an unmet medical need. New agents targeting specific molecular hallmarks of these disease entities may have a rationale in the treatment of relapsed and refractory patients.

Demethylating agents, above all azacitidine, can play a role in patients with a T_{FH} PTCL, including AITL, given the presence of recurrent mutations in *TET2*, *DNMT3A* and *IDH2*. The anti JAK1/2 inhibitor ruxolitinib may also have a role in patients with T-cell neoplasms given the presence of mutations within the *JAK* and *STAT* system in T-cell neoplasms: results are very preliminary, but encouraging. Phosphatidyl-inositol 3-kinase (PI3K) inhibitors are also under evaluation in heavily pretreated patients: PI3K inhibitors block mitogen and prosurvival signals from the tumour and its microenvironment and in turn activate an anti-lymphoma immune response. Duvelisib, an oral dual inhibitor of PI3Kδ and PI3Kγ, was applied as single agent in a phase 1 trial involving both PTCL and CTCL patients, producing encouraging results in both cohorts and across multiple histologies, including PTCL-NOS, EATL and AITL. Checkpoint inhibitors that target and disrupt the interaction of PD-1 with its ligands (namely PD-L1) causing T-cell activation against the tumour have significantly improved the therapeutic landscape in several malignancies. In PTCL, an increased expression of PD-L1 has been described in both neoplastic and stromal cells across various subtypes: This supports the therapeutic usage of checkpoint inhibitors in this setting. Results are still very preliminary and further efforts are required to clarify the role of PD-1 inhibitors in PTCL. Chimeric antigen receptor (CAR) T-cells in PTCL are still under development. However, as pan-T cell aplasia induces severe immunodeficiency, the application of CAR T-cells in T-cell lymphoma patients is contrasted by the lack of specific antigens discriminating malignant *versus* normal T-lymphocytes.

Cutaneous T-cell non-Hodgkin lymphomas

Cutaneous T-cell lymphomas (CTCL) represent the vast majority (more than 75%) of primary cutaneous lymphomas, which are by definition largely confined to the skin at diagnosis, without significant involvement of lymph nodes or other extranodal organs. Mycosis fungoides and Sézary syndrome are the most relevant disease entities, together accounting for more than two-thirds of CTCL.

The incidence of CTCL has been increasing and the disease becomes more common with increasing age. The median age at onset is in the mid-50s, and a fourfold increase in patients over 70. The highest incidence rates are described in males and African–Americans.

Establishing a correct diagnosis is mandatory to define the best treatment strategy, both at disease onset and in a context of refractory disease. A multidisciplinary approach, with the involvement of clinical haemato-oncologists, experienced pathologists and dermatologists, is therefore recommended at every step of patient management. Several new agents have already proved their efficacy within recently conducted clinical trials, but many innovative drugs are now under investigation in order to expand the therapeutic options available for the treatment of these rare entities.

The current CTCL classification is the product of the collaboration of the WHO and the European Organisation for Research and Treatment of Cancer (EORTC) and is summarised in Table 24.3. Below is a description of the most frequent CTCL subtypes along with some therapeutic recommendations.

Table 24.3 World Health Organization/European Organisation for Research and Treatment of Cancer (WHO/EORTC) classification of primary cutaneous T-cell lymphomas. Provisional entities are listed in italics. Highlighted entities are discussed in detail in this chapter.

Mycosis fungoides
Mycosis fungoides, variants and subtypes
Folliculotropic mycosis fungoides
Pagetoid reticulosis
Granulomatous slack skin
Sézary syndrome
Adult T-cell leukaemia/lymphoma
Primary cutaneous CD30+ T-cell lymphoproliferative disorders
Primary cutaneous anaplastic large cell lymphoma
Lymphomatoid papulosis
Subcutaneous panniculitis-like T-cell lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Primary cutaneous peripheral T-cell lymphoma, rare subtypes
Primary cutaneous γ/δ T-cell lymphoma
Primary cutaneous aggressive CD8+ aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous acral CD8+ T-cell lymphoma
Primary cutaneous CD4+ small/medium T-cell lymphoproliferative disorder
Primary cutaneous T-cell lymphoma, not otherwise specified

Mycosis fungoides

Mycosis fungoides represents the most frequent CTCL and consists of a mature neoplasm in which T-lymphocytes infiltrate the epidermis (early stages of the disease) or acquire the capacity to deeply proliferate and invade the dermis (plaques and tumour stages of the disease). It is a disease of the middle-aged and older adult.

Clinical features

The clinical history of this disease is characterised by an evolution over time in three different stages: the patch stage, the plaque stage and the tumour stage. The evolution reflects a progressively increased aggressiveness of the disease; it is associated with a different clinical appearance and prognosis, as well as with a particular treatment approach.

The patch stage is characterised by generally round to oval, flat or scaly cutaneous lesions – or patches – ranging from 1 to 10 cm in diameter, mainly appearing in areas of skin protected from sunlight (such as the buttocks, the groyne and the breasts, in women). Patches may present slight erythema, wrinkling or telangiectases; areas of hypo- or hyperpigmentation may occur (Figures 24.5 and 24.6). Patches may be confined to a limited skin area or may become disseminated. Patients at this stage are often asymptomatic, and this phase may behave indolently for several years or decades. Over time, cutaneous lesions may become infiltrated, and therefore flat or raised indurated lesions – or plaques – supervene. Plaques are red-to-brown in colour, often polycyclic and with a clear spot in the centre; sometimes they become ulcerated. An erythrodermic phase of the disease may be documented at either patch or plaque stage: the skin appears diffusely erythematous, infiltrated and desquamating (Figure 24.7); the face is also affected, although the

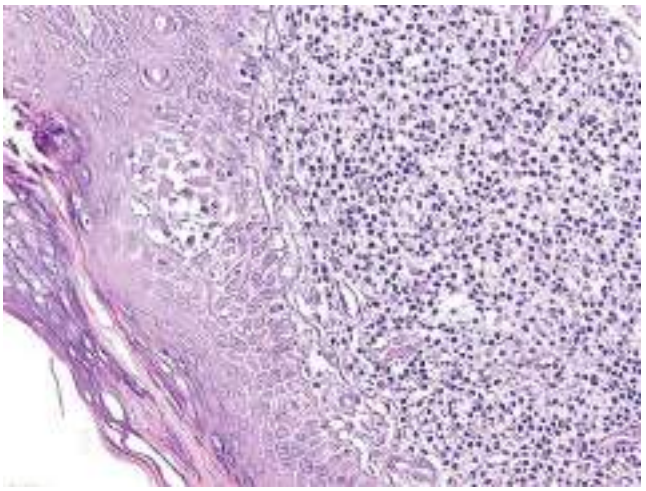

Figure 24.9 Histological appearance of plaques of mycosis fungoides (haematoxylin and eosin stain, magnification 200×).

elbow fold and the popliteal fossa seem to be characteristically spared. A thorough examination of peripheral blood is mandatory in this clinical context to correctly discriminate between an erythrodermic mycosis fungoides and Sézary syndrome. The tumour stage is characterised by the appearance of nodules or tumours on pre-existent patches or plaques (Figure 24.8): tumours are raised and plum coloured, with a smooth surface that usually ulcerates, and display a 'fungal' growth, hence the name of 'mycosis fungoides', first attributed by Alibert and Bazin to this disease. Along with the disease evolution to the tumour stage and the progressive appearance of new nodular lesions, the patient's general condition tends to worsen, and the prognosis becomes poor.

Morphology

The histopathologic appearance of the disease is extremely variable, depending on the stage. Early mycosis fungoides is not histologically recognisable with certainty: early patches feature small, isolated and scattered – or sometimes clustered – lymphocytes within the papillary dermis, with just a few within the epidermis. As infiltrates become denser, lymphocytes acquire an irregular (cerebriform) nucleus, surrounded by a small halo, and tend to invade the epidermis (epidermotropism), eliciting spongiosis or oedema between keratynocytes. Plaques contain a great amount of atypical, cerebriform, CD3+, CD4+, CD8– lymphocytes, infiltrating the epidermis, the papillary and the reticular dermis (Figure 24.9). Prominent collections of lymphocytes within the epidermis are termed Pautrier microabscesses; these are typical of plaques and rarely found in patches. Mycosis fungoides tumours show a diffuse infiltration of the dermis, with lymphocytes displaying a large variety of cytological appearance, although cells with cerebriform nuclei tend to predominate (Figure 24.10). Epidermotropism in this phase is scarce or totally absent. The CD30 antigen can be expressed in some plaques of

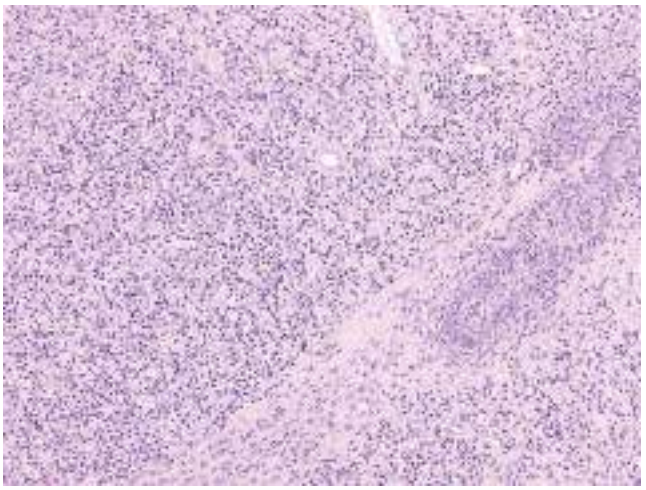

Figure 24.10 Histological appearance of tumours of mycosis fungoides (haematoxylin and eosin stain, magnification 100×).

mycosis fungoides, although it is mostly expressed in tumours harbouring larger amounts of anaplastic cells.

Staging system

Unlike the other B- and T-cell lymphomas, a revised TNM staging system is used for mycosis fungoides (Tables 24.4 and 24.5), which takes into account: the cutaneous involvement (T-stage), in terms of skin surface, presence of tumours or erythema; the involvement of peripheral lymph nodes (N-stage), which should be at least 1.5 cm in their major diameter, along with an evidence of T-cell receptor rearrangement (stages N1b and N2b) or not (stages N1a and N2a) and the involvement of visceral organs (M-stage), which requires pathological confirmation. The blood tumour burden is quantified by the B-parameter, and it reflects the amount of

Table 24.4 Description of TNM-B staging system categories for mycosis fungoides.

Skin	T_1	Limited patches, papules and/or plaques covering <10% of the skin surface. Further, stratify into T_{1a} (patches only) and T_{1b} (plaques ± patches).
	T_2	Patches, papules or plaques covering ≥10% of the skin surface. Further, stratify into T_{2a} (patches only) and T_{2b} (plaques ± patches).
	T_3	One or more tumours, ≥1 cm in diameter.
	T_4	Confluence of erythema, covering ≥80% of body surface area.
Nodes	N_0	No clinically abnormal peripheral lymph nodes: biopsy not required.
	N_1	Clinically abnormal peripheral lymph nodes (firm, irregular, clustered, fixed nodes, ≥1.5 cm in diameter)(*). Further, stratify into N_{1a} (clonally negative) and N_{1b} (clonally positive).
	N_2	Clinically abnormal peripheral lymph nodes(†). Further, stratify into N_{2a} (clonally negative) and N_{2b} (clonally positive).
	N_3	Clinically abnormal peripheral lymph nodes(††). Either clonally positive or negative.
	N_X	Clinically abnormal peripheral lymph nodes; no histological confirmation.
Viscera	M_0	No visceral organ involvement.
	M_1	Visceral involvement (requires histological confirmation; involved organ should be specified).
Blood	B_0	Absence of significant blood involvement: ≤5% of peripheral blood lymphocytes are atypical (Sézary) cells. Further, stratify into B_{0a} (clonally negative) and B_{0b} (clonally positive).
	B_1	Low blood tumour burden: >5% of peripheral blood lymphocytes are atypical (Sézary) cells, but criteria for B_2 are not met. Further, stratify into B_{1a} (clonally negative) and B_{1b} (clonally positive).
	B_2	High blood tumour burden: $\geq 1 \times 10^9$/L Sézary cells clonally positive.

* Histopathology Dutch (lymph node effacement scale) grade 1 or National Cancer Institute (number of atypical lymphocytes within the involved node) LN_{0-2}.
† Histopathology Dutch grade 2 or National Cancer Institute LN_3.
†† Histopathology Dutch grade 3–4 or National Cancer Institute LN_4.

Table 24.5 TNM-B staging system for mycosis fungoides.

	T	N	M	B
I A	1	0	0	0–1
I B	2	0	0	0–1
II A	1–2	1–2	0	0–1
II B	3	0–2	0	0–1
III A	4	0–2	0	0

IV A_1	1–4	0–2	0	2
IV A_2	1–4	3	0	0–2
IV B	1–4	0–3	1	0–2

circulating Sézary cells (less or equal to 5% versus more than 5%), with at least 1×10^9/L Sézary cells required to diagnose a high tumour burden Sézary syndrome.

Therapy

The treatment of this peculiar kind of cutaneous T-cell lymphoma is specifically stage-adapted (see Table 24.5), which means that different treatment options are applied for each stage of the disease. Patients with an early-stage mycosis fungoides, which is characterised by a slow progression and an indolent course, may take advantage of skin-directed therapies, although lacking a curative intent, whereas more advanced stages require systemic approaches, with either more conventional chemotherapeutic drugs or newer agents.

TNM stage I disease, consisting of patches and/or plaques, requires a skin-directed approach: photochemotherapy, using a psoralen compound as a photosensitising agent and ultraviolet light type A (PUVA), is nowadays the most widely adopted treatment strategy, along with narrow-band ultraviolet light B (UVB) phototherapy (wavelength of 311–313 nm) if patches represent the most relevant cutaneous lesions. Recombinant α_2-interferon may be used with PUVA therapy as a second-line therapy, in order to produce more durable and profound clinical responses; this combination also represents a suitable treatment of stage IIA disease (with patches and/or plaques and lymph node involvement). Unilesional mycosis fungoides may also be treated with conventional external beam radiation therapy.

TNM stage IIB (tumour-stage disease) may be treated either with total skin electron beam irradiation (TSEBI), which yields only 40% satisfactory clinical response, or with systemic

monochemotherapy, usually with gemcitabine or liposomal doxorubicin. The orally bioavailable retinoid Bexarotene is an alternative systemic agent. It is a selective agonist of the retinoid X receptor, which consequently exerts its function through the recruitment of transcription factors, and induces apoptosis and cell cycle arrest in CTCL cells.

Stage III disease (erythroderma) can be first treated again with the combination of recombinant α_2-interferon and PUVA; possible alternatives or second-line options are represented by TSEBI, gemcitabine, liposomal doxorubicin or bexarotene.

Stage IV disease, which is characterised by extracutaneous involvement, requires an immediate systemic chemotherapy: gemcitabine or doxorubicin used as monotherapy should be preferred to polychemotherapy with cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP) or CHOP-like regimens, which appear significantly more toxic and display poor disease control.

Histone deacetylase inhibitors (HDACi) are active in patients with advanced-stage mycosis fungoides and in those who relapse or progress. Through the inhibition of the enzymatic removal of acetyl groups from histonic and non-histonic proteins, these molecules control the epigenetic regulation of gene transcription, ultimately regulating cell-cycle and apoptosis-related proteins. Vorinostat and romidepsin, the former being orally available and the latter being administered intravenously, have both shown a rate of response of 30–40% in Phase 2 studies, with a median duration of response varying from nearly 200 days to more than 1 year.

The anti-CD30 immunoconjugate BV demonstrated its activity in CD30+ CTCL within initial phase 2 trials displaying a response rate of 73% and a complete response rate of 35%. The randomised phase 3 ALCANZA trial involving patients with previously treated mycosis fungoides and cutaneous ALCL, BV used as single agent demonstrated superior activity in disease control over standard treatments (oral methotrexate or oral bexarotene). More than half of the patients treated with BV obtained a response lasting at least 4 months compared to roughly 12% of those receiving standard treatments. These results granted BV approval in patients with mycosis fungoides and cutaneous ALCL who have received at least one previous systemic treatment line

Allogeneic transplantation can be a suitable treatment option for younger patients failing at least two previous lines of standard therapy; durable remissions may be obtained as a consequence of a putative graft-versus-lymphoma immune effect, yielding 5-year progression-free and overall survival rates of 34 and 53%, respectively.

Sézary syndrome

Sézary syndrome, first described in 1938 by Sézary and Bouvrain, who identified a population of large lymphocytes in the peripheral blood, with grooved and lobulated 'cerebriform' nuclei (*cellules monstrueuses*), is regarded as the leukaemic form of mycosis fungoides, clinically characterised by the triad: erythroderma (diffuse reddening of the skin), generalised lymphadenopathy and atypical T-lymphocytes (Sézary cells) in peripheral blood, skin and lymph nodes. Like mycosis fungoides, it is a disease of the middle-aged and elderly, although much less common.

Clinical features

Erythroderma is the most relevant clinical aspect; it either tends to evolve gradually over months or even years from a preexisting non-specific dermatitis, or it may abruptly develop *de novo*. Sometimes, erythroderma may reflect an evolution of a patch or plaque stage mycosis fungoides (see above). Skin is red and scaly, and may become doughy, as well as fissurated. Hyperkeratosis of palms and soles is also a distinguishing feature, along with onychodystrophy and sometimes alopecia.

Morphology

Sézary cells are clonal mature T-helper lymphocytes, generally CD3+, CD4+ and CD8–; an aberrant loss of T-cell antigens, such as CD2, CD3, CD4, CD5 and CD7 is frequently observed and T-cell receptor rearrangement found by polymerase chain reaction provides proof of clonality. Histologically, skin changes resemble those of mycosis fungoides, although epidermotropism is seen to a lesser extent. Sometimes, however, skin specimens can be non-diagnostic for mycosis fungoides at all, because there can be more spongiosis and lymphocytes are often small.

Diagnosis

The integration of clinical features, histology, cytology, immunophenotyping and molecular assays is necessary to make a correct diagnosis of Sézary syndrome. In the presence of erythroderma, Sézary syndrome is diagnosed when the absolute count of Sézary cells is $\geq 1 \times 10^9$/L (or Sézary cells represent more than 20% of circulating lymphocytes). Clonal rearrangement of the T-cell receptor is required to establish the diagnosis. Alternatively, one of the following criteria should be satisfied, if a count of Sézary cells cannot be performed: increased CD4+ or CD3+ cells, with a CD4/CD8 ratio $\geq$10, aberrant immunophenotypes (CD4+/CD7– ratio $\geq$40% or CD4+/CD26– ratio $\geq$30%).

Therapy

Extracorporeal photopheresis (ECP) represents the treatment of choice, and it is performed for two consecutive days every 2–4 weeks. During ECP, pooled leucapheresis and plasmapheresis

products are treated with 8-methoxypsoralen, then exposed to ultraviolet light type A (UVA) as they pass through a disposable narrow cassette, *ex vivo*. Irradiated leucocytes are subsequently re-infused: psoralens covalently bind to DNA after irradiation with UVA, therefore leading to the induction of apoptosis. In parallel, ECP seems also to induce dendritic cell differentiation, which in turn translates into an enhanced antigen presentation and the initiation of a host immune response against the tumour. Overall responses to ECP are around 60% and complete responses are seen in about 20% of the cases, with durable responses seen in patients lacking a significant nodal or visceral involvement. ECP can also be combined with TSEBI, α_2-interferon or bexarotene therapy. Systemic chemotherapy based on chlorambucil, methotrexate, fludarabine, gemcitabine or doxorubicin as single agents should be considered in patients with high tumour burden (>2600 Sézary cells/μL), advanced disease with significant nodal or visceral involvement, or relapsed disease.
