The humanised anti-CC chemokine receptor 4 (CCR4) monoclonal antibody, mogamulizumab, demonstrated a response rate of 47% in Sezary syndrome patients and 29% in mycosis fungoides within early phase trials, demonstrating the rapid clearance of malignant cells from the bloodstream. In the phase 3 randomised MAVORIC trial where mogamulizumab was compared to vorinostat, superior outcomes in terms of response rate (35 versus 6%) and progression-free survival (8 versus 3 months) were demonstrated in favour of the former. These findings led to the FDA approval of mogamulizumab for mycosis fungoides and Sezary syndrome patients who have failed at least one prior systemic therapy.

Primary cutaneous CD30+ lymphoproliferative disorders

These cover a wide spectrum of indolent T-cell lymphoproliferative disorders, primarily localised in the skin and account for nearly 30% of CTCL, thus representing one of the most frequent disease entities.

They are clinically characterised by a chronic clinical course, with cutaneous lesions sometimes showing a relapsing-remitting behaviour or spontaneous regressions, always featuring the presence of large and atypical CD30+ cells, variably represented within the histological specimen. Primary cutaneous anaplastic large-cell lymphoma (pcALCL) and lymphomatoid papulosis (LyP) represent the two extremities of the spectrum and are discussed in more detail.

Primary cutaneous anaplastic large-cell lymphoma

This is the second most common type of CTCL, being most frequently seen in middle-aged men (median age at presentation is 60 years, with a male/female ratio of 2–3:1). It clinically presents with solitary and localised papules, nodules or tumours, frequently ulcerated, involving the skin of the trunk, face, extremities and buttocks. Multifocal involvement is rather uncommon. Lesions may show a spontaneous complete or partial regression; however, skin relapses are frequent. Extracutaneous dissemination is rare, with regional lymph nodes being the most commonly affected organs other than the skin.

Tumour cells are large, with an anaplastic (abundant cytoplasm, round to oval or irregularly shaped nuclei with prominent nucleoli), pleomorphic or immunoblastic cytomorphology; the infiltrate involves the dermis, without epidermotropism. Cells mostly display a CD4+ T-cell phenotype, CD8+ in a minority of cases, with possible loss of CD2, CD5 or CD3; CD30 is by definition expressed by a majority (>30%) of the neoplastic cells, without CD15 expression. Cytotoxicity markers, such as TIA-1, perforin and granzyme B are frequently expressed.

The prognosis is good, with a 5-year disease-free survival higher than 90%, although relapses are frequent. Patients with multifocal skin lesions and patients with involvement of regional nodes show a similar prognosis to those presenting with a single skin lesion. Localised lesions favourably respond to radiation therapy, and surgical excision may be curative in some cases. Systemic therapy is required for multifocal disease: as demonstrated in the ALCANZA study (see above), BV produces much more significant results than conventional agents like low-dose methotrexate, α_2-interferon or bexarotene.

Lymphomatoid papulosis

LyP is a chronic, recurrent, self-healing skin disease, which mainly affects middle-aged men (with a male/female ratio of 2–3:1). It is clinically characterised by the presence of papular, papulonecrotic or nodular skin lesions, mainly affecting the trunk and the extremities, at different stages of development and with a relapsing-and-remitting course over 3–12 weeks, leaving behind superficial scars. In about 20% of the patients, LyP is associated – or followed by – another malignant lymphoma, such as mycosis fungoides, pcALCL or Hodgkin disease.

LyP has a very heterogeneous appearance upon examination of skin biopsy: for this reason, it has been classified into six distinct subtypes, termed A–E. Type F denotes a folliculotropic variant of LyP not recognised by the current WHO and WHO-EORTC classifications. A newly recognised subtype harbouring the *DUSP22-IRF4* rearrangement has also been described (Table 24.6).

The prognosis is excellent; no treatment is required for localised lesions, while topical steroids, low-dose methotrexate or PUVA phototherapy may be suitable in cases of disseminated disease. BV has an approval for the treatment of LyP, but it is exceedingly rarely required.

Table 24.6 Morphologic and immunophenotypic classification of lymphomatous papulosis, with details on differential diagnoses.

Type A	Most common type, up to 75% of the cases. Wedge-shaped dermal infiltrate of large atypical CD4+/CD30+ lymphocytes within an inflammatory background. Differential diagnosis is with Hodgkin lymphoma, popular mycosis fungoides and transformed mycosis fungoides.
Type B	Small CD4+/CD8-/CD30± lymphocytes with cerebriform nuclei and epidermotropism. Overlaps with mycosis fungoides, clinical correlation necessary to establish the diagnosis.
Type C	Nearly 10% of the cases. Closely resembles type A but it lacks the accompanying inflammatory *pabulum* of neutrophils, eosinophils and histiocytes. Differential diagnosis is with pcALCL, adult T-cell leukaemia/lymphoma, PTCL-NOS and transformed mycosis fungoides.
Type D	Epidermotropic infiltrates of small- to medium-sized pleomorphic lymphocytes expressing cytotoxic markers such as granzyme, perforin and TIA-1. Overlaps with aggressive epidermotropic CD8+ cytotoxic lymphoma, primary cutaneous γ/δ T-cell lymphoma or pagetoid reticulosis.
Type E	Angioinvasive infiltrate of atypical CD30+ lymphocytes in superficial and deep dermis, in a mixed inflammatory background. Differential diagnosis with extranodal NK/T-cell lymphoma nasal type and pcALCL.
Type F	Perifollicular infiltrates of CD30+ atypical cells with folliculotropism, with or without follicular mucinosis. Differential diagnosis with folliculotropic mycosis fungoides and transformed mycosis fungoides.
DUSP22-IRF4	Lymphomatoid papulosis with chromosomal rearrangements of the *DUSP22-IRF4* locus on 6p25.3. Heavy epidermotropism and dense dermal infiltrates of CD3+ lymphocytes.

Conclusions

T-cell lymphoproliferative disorders are classified on the basis of their clinical behaviour and presentation, thus distinguishing them into either indolent or aggressive nodal, extranodal and leukaemic diseases. Although infrequent, they represent a big challenge for the treating haematologists, since their prognosis is rather disappointing when the current treatment strategies are applied, and relapse rates are still relevant. A precise clinical and histological diagnosis, as well as the presence of a multidisciplinary team, are the key elements to assure the best patient management. The application of molecular techniques and immunological markers has clarified some aspects of the pathogenesis of these diseases and has provided the rationale for the development and approval of new specific treatment approaches.

Introduction

Hodgkin lymphoma (HL) is an uncommon, relatively aggressive B-cell malignancy with several unique features. Unusually for a cancerous disorder it has a particular predilection for young people, being the most common cancer in the teenage and young adult population. It has a unique pathology characterised by rare, malignant Reed-Sternberg cells within a pronounced inflammatory background. It also has a significant role in the history of cancer treatment: it was one of the first cancers to be cured with the application of linear accelerator-based radiotherapy techniques, followed by similar successes with combination chemotherapy approaches. Often regarded as a success story of modern medicine, HL is one of the more curable malignancies with a sound evidence base of randomised clinical trials guiding modern treatment approaches. Current research focuses on improving outcomes for higher risk groups such as the elderly and those with relapsed disease, and risk-adapting treatment enabling a more personalised approach with de-intensification of therapy where appropriate to reduce late toxic effects.

Pathological features

HL is classified into two broad groups according to the most recent editions of the *World Health Organisation Classification of Tumours of Haematopoietic and Lymphoid Tissues* (2016, 2022); classical HL (cHL) and nodular lymphocyte-predominant HL (NLPHL). Classical HL accounts for the vast majority of cases of HL (95%) compared to NLPHL. Classical HL and NLPHL have distinct pathogenesis, prognosis, clinical features and management. Whilst it may be argued that the WHO classification system which keeps the two entities together is inappropriate (compared with the International Consensus Classification 2022 which has reclassified NLPHL as nodular lymphocyte-predominant B-cell lymphoma), molecular analysis has demonstrated a closer relationship between NLPHL and cHL than between NLPHL and subtypes of non-Hodgkin.

Classical Hodgkin lymphoma

An accurate histological diagnosis of cHL is made by recognising the morphological and immunophenotypic characteristics of the Hodgkin/Reed-Sternberg (HRS) cell within the appropriate cellular background. Systematic immunohistochemical evaluation of both the tumour cell compartment (HRS cells and its variants) and the associated cellular background is important to accurately distinguish cHL from the main competing differential diagnoses; diffuse large B-cell lymphoma (DLBCL) (in particular T-cell/histiocyte-rich diffuse large B-cell lymphoma and primary mediastinal B-cell lymphoma), anaplastic large-cell lymphoma (ALCL) and peripheral T-cell lymphoma not otherwise specified (PTCL-NOS).

Hodgkin and Reed-Sternberg cells

Classic HRS cells are very large (20–50 μm) and can either have one nucleus (termed Hodgkin cells) or be multinucleate (termed Reed-Sternberg cells). HRS nuclei typically contain large, eosinophilic, inclusion-like nucleoli (Figure 25.1). The classic 'owl's eye' appearance describes a binucleate HRS cell with two mirror-image

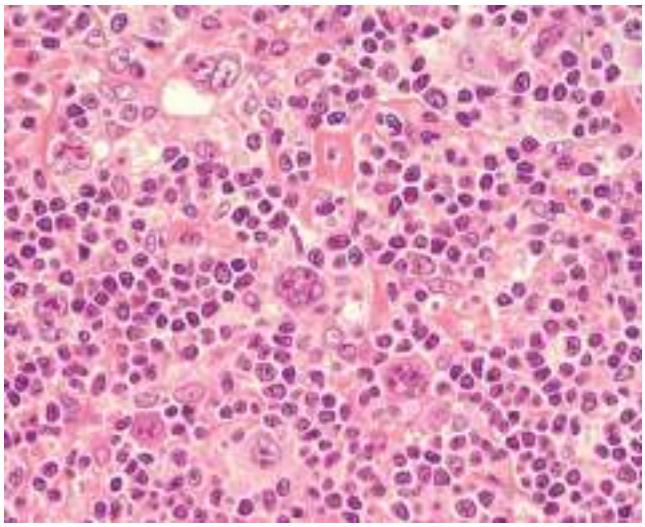

Figure 25.1 Classical Hodgkin lymphoma with numerous multinucleate Hodgkin Reed–Sternberg cells with prominent nucleoli.

nuclei containing eosinophilic nucleoli and a thick nuclear membrane. In most histological subtypes, the HRS cells make up only a small proportion of the cellularity of the tumour (typically 1% or less). High levels of circulating tumour DNA can be detected in most patients with Hodgkin lymphoma at diagnosis and this suggests that there is a high proliferation rate of tumour cells, with a very high rate of apoptosis possibly accounting for the relative scarcity of HRS cells seen histopathologically.

The immunohistochemical hallmark of the HRS cell is positive membrane staining for CD30 (with a paranuclear focus of staining within the Golgi) (Figure 25.2). CD15 is also present in about 70% and useful for the diagnosis. Due to the disruption of the normal B-cell gene expression programme, HRS cells show different immunohistochemical staining characteristics to both normal and malignant B-lymphocytes of other B-lymphoproliferative disorders. Therefore, whilst HRS cells usually stain strongly for MUM1, they show weak (albeit positive) expression of the master B-cell transcription factor PAX5. CD20 may be positive in approximately 20% of cases, but this is usually patchy and weak. CD45 expression is negative in HRS cells; however, due to the surrounding CD45-positive haemopoietic compartment, this feature can sometimes be difficult to appreciate.

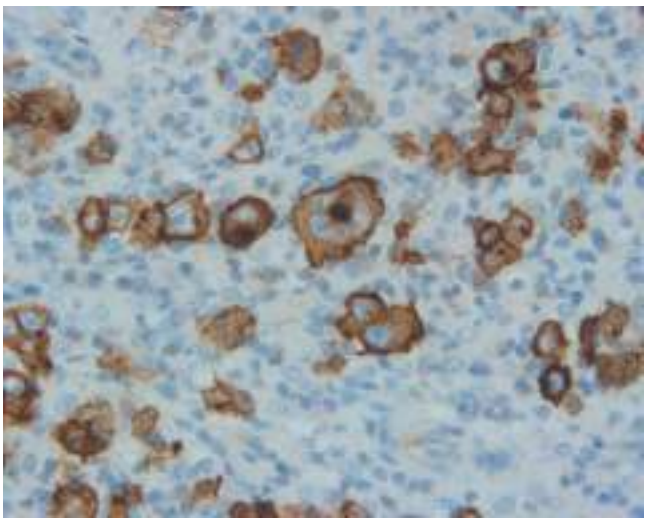

Figure 25.2 CD30 immunohistochemistry of classical Hodgkin lymphoma showing membrane and Golgi apparatus staining of the Hodgkin Reed–Sternberg cells.

Tumour microenvironment

A hallmark feature of cHL is the exuberant tumour microenvironment (TME). The HRS cells have a complex and symbiotic relationship with the TME as evidenced by frequent rosetting of HRS by T-cells of the TME. PD-L1/L2, expressed by HRS cells, interacts with PD-1 expressing T-cells and other immune effector cells such as macrophages, to protect the HRS cells from immunological harm. Numerous cytokines and chemokines are produced by HRS cells, which attract a range of often suppressor-type immune cells including T-lymphocytes (predominantly CD4+ (TH2 and Treg)), macrophages, plasma cells and eosinophils. The cytokines and chemokines produced by HRS cells induce the surrounding inflammatory milieu to produce their own cytokines, leading to propagation of the TME. The immune cells within the microenvironment in turn provide signalling to the HRS cells via surface receptors that activate intracellular pathways, including NF-κB, which contribute to the malignant phenotype of the HRS cells.

Associated histological features

Within cHL, four histological subtypes exist based largely on features of the microenvironment.

- Nodular sclerosis (NS): approx. 70–75% of cases. This is characterised by fibrous bands arising from a thickened capsule that runs throughout the node and compartmentalise the tumour into nodules (Figure 25.3). Lacunar HRS cells are typical of this subtype and are present within a heterogenous cellular background that consists predominantly of CD4+ T-lymphocytes, but also includes histiocytes, eosinophils, plasma cells and neutrophils (Figure 25.4).
- Mixed cellularity (MC): approx. 20–25% of cases. This subtype is named after the heterogenous inflammatory infiltrate that surrounds the HRS cells, consisting of lymphocytes, plasma cells, epithelioid histiocytes and eosinophils. Whilst there may be interstitial fibrosis in the MC subtype, broad bands of compartmentalising fibrosis are not present. The majority of MC cases are EBV-positive.
- Lymphocyte-rich (LR): approx 5% of cases. Compared to the T-cell-predominant lymphocytic infiltrate in NS and MC cHL, this subtype contains a cellular background containing both B

Figure 25.3 Low-power view of lymph node from patient with nodular sclerosis subtype classical Hodgkin lymphoma showing broad bands of fibrosis and thickened capsule.

and T lymphocytes. In addition, there is usually a relative paucity of neutrophils and eosinophils. This form is distinguished from NLPHL by the presence of typical HRS cells, which show membrane staining for CD30 and CD15 (which are not seen in NLPHL).

- Lymphocyte-depleted (LD): <1% of cases. True LD cHL is a very rare entity that histologically may be characterised by either large numbers of HRS cells or rare HRS cells in a densely fibrotic background stroma. The LD histological subtype was reported to be associated with a poorer prognosis; however, many cases were probably misclassified and included cases of ALCL.

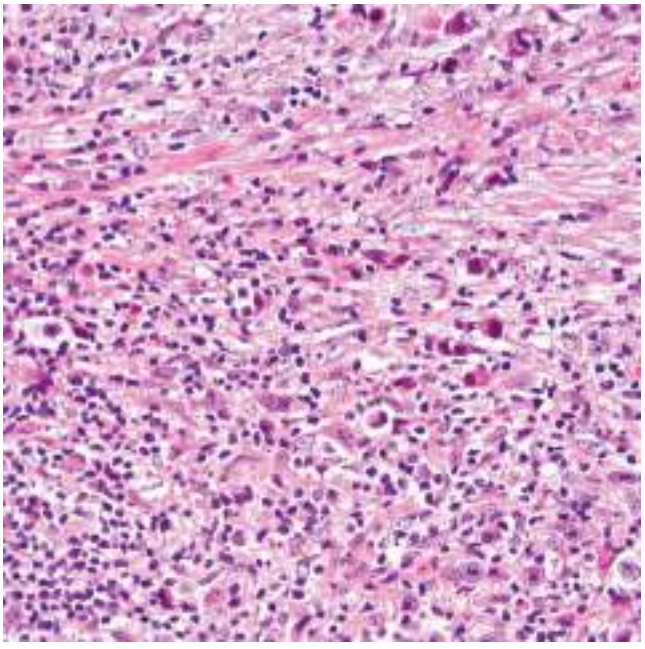

Figure 25.4 Nodular sclerosis classical Hodgkin lymphoma with prominent eosinophils.

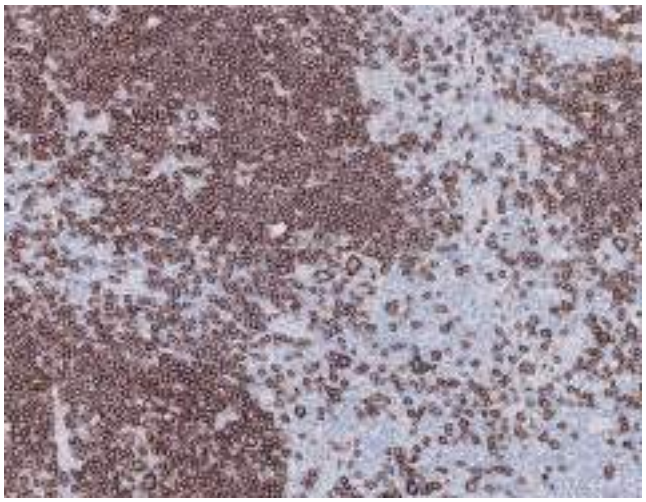

Figure 25.5 Nodular lymphocyte predominant Hodgkin lymphoma stained for CD20 showing nodules of small B cells with scattered larger CD20 positive LP cells.

Nodular lymphocyte-predominant Hodgkin lymphoma

Typically, NLPHL shows a nodular pattern composed largely of small reactive B-cells with infrequent single, scattered LP cells mostly located within the B-cell-rich nodules (Figure 25.5). The lymphocyte-predominant (LP) cells themselves display a fairly typical B-cell phenotype with positivity for CD20, CD79a, PAX5, OCT2 and BOB.1. CD10 is usually negative helping to distinguish them from germinal centre B-cells. CD30 and CD15 are also negative. LP cells can be fairly small, making them hard to spot within the rich B-cell background. However, they typically have a rosette of T-cells which can aid identification. Variant histologies have been described which may differ in terms of clinical presentation and disease course. In general, cases in which the LP cells are found frequently outside of B-cell-rich nodules are thought to be associated with more aggressive disease.

NLPHL can be a challenging diagnosis to make especially when small biopsies are obtained. Wide-bore core, or preferably excision node, biopsies are particularly important for this condition. Progressive Transformation of Germinal Centres (PTGC) is a cause of benign peripheral lymphadenopathy which can uncommonly occur before, during or after a diagnosis of NLPHL. Repeat biopsies are therefore indicated in patients with PTGC who develop newly enlarged lymph nodes. A repeat biopsy is also indicated for patients with NLPHL who relapse after initial therapy or who develop extranodal disease or a rapidly enlarging nodal mass as NLPHL can also transform into T cell/histiocyte-rich large B-cell lymphoma requiring a different treatment approach.

Pathogenesis

Classical Hodgkin lymphoma

Cell of origin

cHL is a B-cell lymphoma although the HRS cell has lost many B-cell associated surface markers such as CD20 and CD79a. This meant the cell of origin for HRS cells was in dispute for many years until clonal rearrangement of immunoglobulin loci was demonstrated within microdissected HRS cells. Somatic hypermutation was also noted within the immunoglobulin loci suggesting transit through the germinal centre. Indeed, some cases appeared to have mutations that would reduce the expression of immunoglobulin, a process that would normally lead to cell death. This led to the concept of HRS cells being crippled germinal centre B-cells which had received an aberrant survival signal preventing normal apoptosis.

Molecular pathogenesis

Genes involved in normal B-lymphocyte growth and differentiation are suppressed in HRS cells. Instead, numerous aberrant intracellular signalling pathways contribute to the malignant phenotype of HRS cells including the following:

- HRS cells show constitutive activation of the NF-κB pathway, which is associated with apoptosis resistance. The molecular basis for this observation includes gains and amplification of the genes encoding the NF-κB factor Rel as well as the kinase MAP3K14 and Bcl3. Mutations in negative regulators also occurs, such as the genes *TNFAIP3* and *NFKBIA*. Other mechanisms can also activate the NF-κB pathway in HRS cells such as signalling through CD40 and the EBV-encoded protein LMP-1 (which can mimic CD40 activation).
- The JAK-STAT pathway is overactive in HRS cells, important in mediating cytokine signalling. Mechanisms of JAK-STAT over-activity include chromosomal gains at 9p24.1-24.3 leading to multiple copies of the *JAK2* gene and inactivating mutations in the negative regulators *SOCS1* and *PTPN1*.
- Numerous other signalling pathways are active in HRS cells. These include the NOTCH pathway, PI3K/AKT pathway and MAPK/ERK pathway. The extent of pathway activation appears greater than for other lymphoma subtypes.
- Immune evasion is a key feature of HRS cells. In addition to harbouring the *JAK2* locus, 9p24.1 contains the *PDL1* and *PDL2* loci resulting in overexpression of the checkpoint proteins PD-L1 and PD-L2 on the surface of HRS cells. This results in protection from killing by PD-1-expressing T-cells and other immune effector cells. Furthermore, frequent inactivating mutations in *B2M* reduce MHC class I expression and therefore recognition by CD8+ T-cells.
- HRS cells have been shown to have deacetylated histones (H3), increased H3K27 trimethylation and DNA methylation patterns, leading to silencing of tumour-suppressor genes and the extinction of the normal B-lymphocyte expression profile.

Role of Epstein-Barr virus

Epstein-Barr virus (EBV) can be detected in HRS cells in a variable proportion of cases of HL, depending on age, sex, race and histological subtype. HRS cells that have destructive mutations of their immunoglobulin loci rearrangements are almost always EBV-positive. This likely represents a mechanism by which the HRS cell bypasses the need for a functional B-cell receptor by using EBV-encoded proteins. EBV infection and expression of latent EBV-associated proteins (LMP1) is also associated with activation of NF-κB as well as JAK/STAT pathways.

Nodular lymphocyte predominant Hodgkin lymphoma

Far less is known about the pathogenesis of NLPHL partly due to the rarity of the disease and difficulty obtaining the rare LP cells from a clinical sample. LP cells harbour clonal rearrangements of immunoglobulin genes and ongoing somatic hypermutation, suggesting a germinal centre B-cell derivation. Similar to HRS cells in cHL, LP cells frequently have an active JAK-STAT signalling pathway which can be due to mutations in *SOCS1*, the negative regulator of JAK2. NF-κB is also often deregulated although pathway mutations are much less commonly seen than in cHL. The microenvironment is composed in most cases of small reactive B-cells although double-positive CD4+ and CD8+ T-cells are seen along with a CD69+ T-cell population, both of which are uncommon in cHL. The rosetting T-cells are typically PD-1+ and PD-L1, expression has been described both on the LP cells and on epithelioid histiocytes in close proximity to LP cells. EBV is not thought to have role in NLPHL pathogenesis although recently IgD-expressing cases have been described to have reactivity to a protein from the bacterium Moraxella catarrhalis.

Clinical features

Classical Hodgkin lymphoma

cHL has an annual incidence of 2–3 per 100,000 in developed countries and has a median age at diagnosis of 35–40 years. It can occur at any age but typically has a bimodal age distribution, with most cases occurring in younger patients but with a second peak in the elderly. cHL usually presents in one of the following ways:

1 Enlarging lymphadenopathy: painless, non-tender, slowly progressive lymphadenopathy in the neck or axillae is a typical presentation. Less commonly, infra-diaphragmatic disease can predominate with palpable inguinal or even pelvic enlarged lymph nodes

2 Complications of lymphadenopathy: compression or invasion of thoracic structures due to a large mediastinal mass is

Table 25.1 Ann Arbor staging system with Cotswolds modifications.

Ann Arbor stage	Criteria
Stage I	Involvement of a single lymph node region (Figure 25.7) or lymphoid structure*
Stage II	Involvement of two or more lymph node regions or lymph node structures on the same side of the diaphragm
Stage III	Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement. Involvement of liver and bone marrow always considered stage IV
Additional classifiers	
B	Presence of B symptoms defined as • Unexplained weight loss of more than 10% of the body weight during the 6 months before initial staging investigation • Unexplained, persistent or recurrent fever with temperatures above 38 °C during the previous month • Recurrent drenching night sweats during the previous month
E	Limited extranodal extension from adjacent nodal site or apparent discrete single extranodal deposit (excluding liver and bone marrow)
X	A node or nodal mass greater than 10 cm (by largest dimensions of a single node or conglomerate nodal mass). For mediastinal disease, maximum width is equal to or greater than one-third of the internal transverse diameter of the thorax at the level of T5/6 on chest X-ray.

* e.g. spleen, thymus, Waldeyer's ring.

relatively common. Resulting symptoms include chest pain, cough, superior vena cava obstruction (with facial plethora and engorged neck veins) and a chest wall mass due to direct invasion. Less commonly, porta hepatis nodal enlargement can result in biliary tree obstruction leading to jaundice or deranged liver function tests.

3 Systemic symptoms: cHL is a highly inflammatory tumour and is associated with numerous systemic symptoms. Three such symptoms – fever, weight loss and drenching night sweats – are termed 'B' symptoms and have implications for Ann Arbor staging (Table 25.1).

4 *Other symptoms* may occur which are not considered B symptoms. These include fatigue, itch and alcohol-induced pain in affected nodal areas. Other very rare systemic associations include vanishing bile duct syndrome and paraneoplastic cerebellar degeneration.

Nodular lymphocyte predominant Hodgkin lymphoma

NLPHL has a median age at presentation of 35–40 years and shows a male predominance with a 3:1 male: female ratio. Typically, patients present with peripheral lymphadenopathy with no other symptoms and over three-quarters of patients have early-stage disease at diagnosis. The possibility of transformation to high-grade non-Hodgkin lymphoma should be considered in those presenting with B-symptoms, splenic or extra-nodal disease.

Investigations

Classical HL is diagnosed by morphological and immunohistochemical identification of the HRS cell within an appropriate cellular background. The optimal tissue for diagnosis of cHL, and indeed almost all subtypes of lymphoma, is an excisional lymph node biopsy. There is an increasing tendency to perform core biopsies on lymph nodes for the investigation of lymphoma and whilst these are sufficient to make a diagnosis in most cases, there is a risk of a false-negative biopsy due to sampling error. Fine needle aspirates are never acceptable for the diagnosis of cHL and should not be performed if cHL is the suspected diagnosis.

Investigations that are performed in the diagnostic work-up of patients with cHL (and suspected cHL) include:

- Full blood count: typical findings include mild anaemia, leukocytosis and lymphopenia. Eosinophilia and microcytosis are less common associations.
- Renal and liver function tests: to assess baseline organ function, for risk stratification (albumin) and as a screen for hepatic dysfunction due to HL infiltration.
- Erythrocyte sedimentation rate (ESR): for risk stratification in early-stage and paediatric cHL
- HIV serology: the incidence of cHL is increased in patients with HIV
- Echocardiogram/nuclear medicine assessment of cardiac function: to assess for baseline abnormalities that preclude anthracycline treatment

• Respiratory function tests: for patients at significant risk of bleomycin-related lung toxicity or with pre-existing lung disease. The presence of a large mediastinal mass can confound results.

Staging and risk stratification

HL is highly 18-fluorodeoxglucose (FDG) avid, therefore positron emission tomography (PET) imaging is the standard of care for disease staging, usually performed together with CT (Figure 25.6). Approximately 15–20% of patients will be 'up-staged' to a higher disease stage by PET, when compared with CT alone, with implications for treatment selection. PET has high sensitivity for extranodal disease, therefore bone marrow biopsy is no longer routinely required for staging of cHL.

Ann Arbor staging

The Ann Arbor staging system was first developed for cHL in 1971 and remains the principle system for cHL staging for both adult and paediatric cHL today (Table 25.1, Figure 25.7). It is a relevant prognostic factor and is widely used to stratify patients for different treatment approaches. Staging via the Ann Arbor classification involves a thorough history to detect the presence of B-symptoms, examination of affected lymph node groups and radiological investigations to accurately determine the extent of nodal and extranodal involvement. Based on the Ann Arbor stage, patients are usually divided into either early-stage HL (ESHL) or advanced-stage HL (ASHL).

Early-stage Hodgkin lymphoma

ESHL broadly refers to Ann Arbor stage I or II disease. Many groups treat stage IIB as advanced-stage disease, particularly if additional risk factors are present (e.g. extranodal extension and/or mediastinal bulk).

ESHL is often further stratified into 'favourable' and 'unfavourable' or 'intermediate-risk' subgroups according to the presence of specific clinical risk factors, such as the presence of mediastinal bulk extranodal disease, ≥3–4 involved nodal areas, elevated erythrocyte sedimentation rate and/or B symptoms. This distinction has been made in many of the large prospective randomised trials in ESHL to guide treatment selection. Importantly, the criteria used to define favourable and unfavourable are not standardised between international groups, and whilst the criteria are similar, there are important differences (Table 25.2).

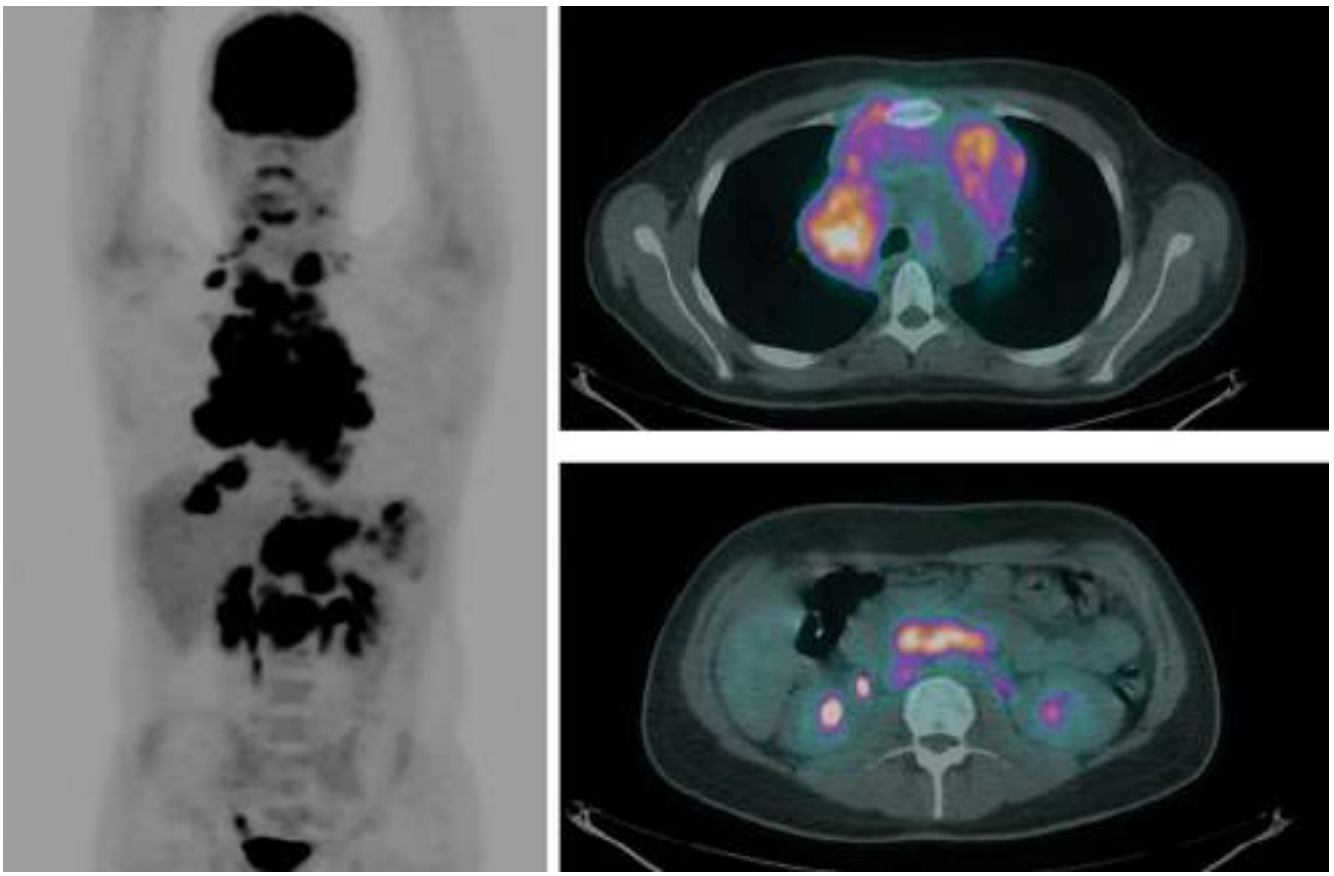

Figure 25.6 PET scan images of patient with stage III Hodgkin lymphoma showing FDG-avid cervical, mediastinal, mesenteric and retroperitoneal lymphadenopathy.

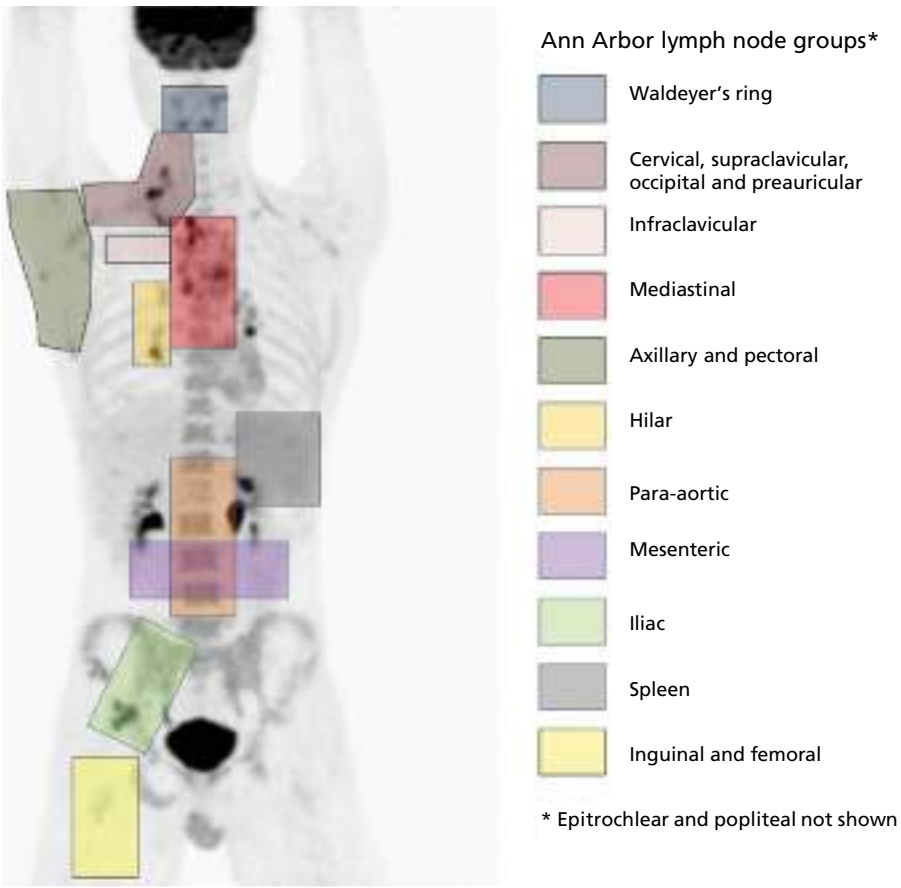

Figure 25.7 Ann Arbor lymph node groups.

Advanced-stage Hodgkin lymphoma

ASHL broadly refers to any patient with Ann Arbor stage III or IV disease. Many prospective trials in ASHL also include patients with stage II disease with high-risk features (e.g. a large mediastinal mass or B symptoms), given that treatment pathways are often shared with ASHL. The International Prognostic Score (IPS), also known as the Hasenclever score, is widely used as a prognostic tool in ASHL (Table 25.3).

Table 25.2 Different definitions of early-stage favourable and unfavourable (or intermediate stage) Hodgkin lymphoma.

EORTC criteria		GHSG criteria	
Early-stage favourable	**Early-stage unfavourable Presence of one or more of the following**	**Early-stage favourable**	**Early-stage unfavourable Presence of one or more of the following**
No large mediastinal adenopathy	Large mediastinal adenopathy	No large mediastinal adenopathy	Large mediastinal adenopathy
ESR <50 without B symptoms	ESR ≥50 without B symptoms	ESR <50 without B symptoms	ESR ≥50 without B symptoms
ESR <30 with B symptoms	ESR ≥30 with B symptoms	ESR <30 with B symptoms	ESR ≥30 with B symptoms
Age ≤50 yrs	Age >50 yrs	No extranodal lesions	Extranodal lesions present
1–3 lymph node sites involved	≥4 lymph node sites involved	1–2 lymph node sites involved	≥3 lymph node sites involved

EORTC, European Organisation for the Research and Treatment of Cancer; GHSG, German Hodgkin's Study Group.

Table 25.3 Outcomes in patients with advanced-stage classical Hodgkin lymphoma using the international prognostic score (patients treated with ABVD or ABVD-like regimens).

International prognostic score	5 yr FFP (%)	5 yr OS (%)
0	88	98
1	84	97
2	80	91
3	74	88
4	67	85
≥5	62	67

Score one point for each of albumin <4 g/dL, haemoglobin <105 g/L, male sex, age ≥45 years, stage IV disease, leucocytosis ($\geq 15 \times 10^9$/L), lymphopenia (<8% of WCC and/or $<0.6 \times 10^9$/L).

Principles of Hodgkin lymphoma treatment

There are three main therapeutic modalities used to treat cHL: conventional chemotherapy, radiotherapy and targeted agents.

Multiagent chemotherapy

cHL is highly chemosensitive and was one of the first malignancies to be cured by multiagent chemotherapy. Combination chemotherapy remains the mainstay of cHL treatment today. Regimens used in frontline treatment usually contain an alkylating agent (e.g. dacarbazine or procarbazine), an anthracycline (usually doxorubicin) and a vinca alkaloid (e.g. vinblastine or vincristine). The most commonly used chemotherapy regimens used for upfront treatment of cHL in adults are ABVD (doxorubicin, bleomycin, vinblastine and darcarbazine), the more intensive escalated BEACOPP regimen (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine and prednisolone) and AVD combined with the antibody-drug conjugate brentuximab vedotin (AVD-BV).

Radiotherapy

Radiotherapy is a highly effective modality for the treatment of cHL. Indeed, radiotherapy alone was used as curative therapy for cHL in the 1950–60s. In modern practice, it is predominantly used for localised disease control, particularly for ESHL where it is given as combined modality therapy following multiagent chemotherapy. It also has a role for treatment of refractory disease and palliation.

Older-style radiotherapy fields (e.g. mantle field and subtotal nodal irradiation) typically encompassed widespread nodal areas, as well as normal tissue, resulting in considerable delayed toxicity. Advances in disease staging, together with more effective combination chemotherapy regimens, have enabled a dramatic reduction in field size and radiotherapy dose, therefore modern involved site radiotherapy is far safer. Improvements in radiotherapy techniques, including shielding, deep inspiration breath holding and advances in planning technology, have further refined treatment and reduced exposure to normal tissue. Proton beam therapy is increasingly being used for younger patients with cHL and is predicted to reduce toxicity further for some patients, although long-term data on efficacy compared with standard photon radiotherapy are currently lacking.

Targeted agents

One of the most effective new cHL therapies to emerge is brentuximab vedotin (BV). BV is an antibody-drug conjugate consisting of an anti-CD30 antibody conjugated to the antimicrotubule agent monomethyl auristatin E (MMAE). Ligation of CD30 by BV triggers receptor-mediated endocytosis, leading to lysosomal degradation of BV and release of MMAE within target cells.

PD-1 inhibitors are another very promising class of drugs, with higher single-agent response rates seen in cHL than in solid organ malignancies. This is in part due to the near-universal overexpression of PD-1 ligands on HRS cells, although the mechanism of action is complex and still not completely understood. PD-1 inhibitors are hypothesised to act by stimulating adaptive anti-tumour immunity, although HRS cells frequently downregulate surface major histocompatibility complex (MHC) expression, which hinders effective cytotoxic T-cell responses. PD-1 inhibitors may also block important survival signals between HRS cells and the tumour microenvironment.

Other immunotherapeutic agents in development include CD30-directed chimeric antigen receptor T-cell (CAR-T) therapy, the anti-CD25 antibody-drug conjugate camidanlumab tesirine and bispecific antibodies.

Response assessment, early PET response and response-adapted treatment

PET is the gold standard for response assessment in HL. Residual masses are a common finding after cHL treatment but do not necessarily confer an increased risk of progression if there is no FDG uptake on PET. Therefore, CT alone has limited accuracy for response assessment.

Consensus response assessment criteria for lymphoma are based on PET assessment using the semi-quantitative five-point Deauville scale (Table 25.4). In most situations, a Deauville score of 4–5 is considered 'positive', i.e. uptake greater than normal liver, whilst a Deauville score of 1–3 signifies complete metabolic response (CMR). However, the threshold used to

Table 25.4 Deauville score for the standardised reporting of PET scans in lymphoma.

Deauville score 1	No uptake above background
Deauville score 2	Uptake less than or equal to mediastinal blood pool
Deauville score 3	Uptake greater than mediastinum, but less than or equal to liver
Deauville score 4	Uptake greater than liver
Deauville score 5	Uptake markedly greater than liver and/or new sites of disease
Deauville score X	New areas of uptake unlikely to be lymphoma

define PET-positivity has shifted over recent decades, with many older clinical trials using a more conservative threshold of PET-positivity (e.g. Deauville score 3–5).

Mid-chemotherapy or interim PET response assessment is one of the strongest predictors of outcome in cHL. For the majority of patients (75–90%) who achieve CMR after two cycles of chemotherapy, PFS rates are high (at least 80–95%, depending on treatment and disease stage). However, patients with a positive interim PET scan have inferior outcomes, with PFS rates generally below 50% for ASHL patients receiving ABVD alone. Several trials have investigated interim PET-based response adaptation of treatment with escalation for interim PET-positive patients and de-escalation for PET-negative patients.

Risk-stratified treatment

Similar to response-adapted treatment, risk-stratified treatment attempts to reserve more intensive and toxic therapy from the outset for high-risk patients whilst reducing the intensity of treatment for those with a low-risk

The success of this approach is dependent on accurate assessment of disease risk at diagnosis. Until recently, this has been solely reliant on clinical risk stratification, with different treatment pathways for ESHL patients with 'favourable' and 'unfavourable' baseline characteristics. However, the predictive value of pretreatment clinical risk stratification is suboptimal, particularly in the context of recent advances in PET. In ASHL, some centres recommend more intensive approaches (e.g. eBEACOPP) for patients with a higher baseline risk according to the IPS.

Several promising biomarkers have the potential to improve risk stratification and response adaptation further and hence the precision of recommended treatment pathways. These include advanced PET metrics such as baseline metabolic tumour volume, reflecting overall tumour burden. Circulating tumour DNA and serum cytokines (e.g. CCL17/thymus activation-regulated cytokine (TARC)) may enhance the accuracy of interim response assessment. Further validation is required before incorporating these biomarkers into routine clinical practice.

Frontline treatment

Early-stage favourable cHL

Standard treatment for ESHL without adverse risk factors usually consists of combined modality treatment with ABVD plus radiotherapy. The German Hodgkin Study Group (GHSG) HD10 trial demonstrated that two cycles of ABVD plus 20Gy radiotherapy were equally as effective as four cycles of ABVD plus 30Gy radiotherapy. The subsequent HD13 trial demonstrated that reducing chemotherapy further (i.e. by omitting bleomycin and/or dacarbazine) was associated with inferior disease control. Therefore 2x ABVD plus 20Gy radiotherapy is considered a standard of care.

This combined modality approach is very successful, with overall survival rates >95% at 5–10 years. There is, however, some concern about the late effects of radiotherapy, including secondary malignancy and cardiovascular disease. The NCIC HD.6 trial compared subtotal nodal radiotherapy +/− ABVD with ABVD alone. Radiotherapy was associated with fewer relapses but inferior overall survival at 12 years, largely due to late treatment-related mortality. It is expected that modern involved-site radiotherapy, using lower doses and smaller radiotherapy fields, will markedly reduce the incidence of late toxicity. Nevertheless, these findings instigated a series of trials investigating whether radiotherapy can be omitted altogether for selected patients.

Three key clinical trials have evaluated response-adapted treatment in favourable ESHL. The RAPID, HD16 and H10 trials all randomised patients with PET complete metabolic response (CMR) after ABVD to receive either radiotherapy consolidation or no further treatment (Table 25.5). These trials demonstrated that radiotherapy improves progression-free survival by 4–12%. However, overall survival rates were universally high (≥97%) at 5 years, irrespective of whether radiotherapy consolidation was given. Follow-up remains too short to evaluate the incidence of late treatment-related toxicity, therefore the role of radiotherapy remains a matter of considerable debate. Combined modality therapy remains the standard of care when the risks of radiotherapy are low, however, ABVD alone (three to four cycles) is a reasonable option for patients with higher risk of radiotherapy toxicity who achieve CMR.

Early-stage unfavourable (or intermediate stage) cHL

For patients with ESHL plus risk factors, combined modality therapy has generally been considered standard of care, with 4× ABVD plus 30Gy radiotherapy the most widely applied strategy over recent years.

The GHSG HD14 trial compared four cycles of ABVD with more intensive '2 + 2' chemotherapy, consisting of two cycles of escalated BEACOPP plus 2 ABVD, followed by radiotherapy in

Table 25.5 Outcomes of selected trials in early-stage and advanced-stage classical Hodgkin lymphoma.

Trial	Treatment	Interim PET status	Progression-free survival
Early-stage favourable			
UK NCRI RAPID	ABVD ×3 + RT	CMR (DS 1–2)	94.6% at 3yr
	ABVD ×3		90.8% at 3yr
EORTC/FIL/LYSA H10	ABVD ×3 + RT	CMR (DS 1–2)	99.0% at 5yr
	ABVD ×4		87.1% at 5yr
GHSG HD16	ABVD ×2 + RT	CMR (DS 1–2)	93.4% at 5yr
	ABVD ×2		86.1% at 5yr
Early-stage unfavourable/intermediate risk			
GHSG HD17	BEACOPP(esc) ×2 + ABVD ×2 + RT	CMR (DS 1–2)	97.6% at 5yr
	BEACOPP(esc) ×2 + ABVD ×2		96.0% at 5yr
EORTC/FIL/LYSA H10	ABVD ×4 + RT	CMR (DS 1–2)	92.1% at 5yr
	ABVD ×6		89.6% at 5yr
	ABVD ×2 + BEACOPP(esc) ×2 + RT	PET-positive	90.6% at 5yr
Advanced-stage			
UK NCRI RATHL	ABVD ×2 + AVD ×4	CMR (DS 1–3)	84.4% at 3yr
	ABVD ×2 + BEACOPP ×4	PET-positive	67.5% at 3yr
GHSG HD18	BEACOPP(esc) ×4	CMR (DS 1–2)	92.2% at 5yr
	BEACOPP(esc) ×6–8	PET-positive	89.7% at 5yr
LYSA AHL2011	BEACOPP(esc) ×2 + ABVD	CMR (<1.4× liver uptake)	89.4% at 5yr
	BEACOPP(esc) ×6	PET-positive	70.7% at 5yr
ECHELON-1	ABVD ×6	N/A	76% at 3yr
	AVD+BV ×6	N/A	83.1% at 3yr

BEACOPP(esc), escalated BEACOPP; CMR, complete metabolic response; DS, Deauville score; RT, radiotherapy.

both arms. The more intensive 2 + 2 approach resulted in lower relapse rates but greater toxicity, with no difference in overall survival. The H10 trial evaluated an alternative, PET-adapted strategy, reserving escalated BEACOPP for patients with a suboptimal interim response to ABVD. Patients with a positive PET after two cycles of ABVD were randomised to receive two more cycles of ABVD or two cycles of escalated BEACOPP, followed by radiotherapy in both arms. The latter was associated with superior PFS and a trend towards improved OS.

There is a desire to reduce use of radiotherapy in this group, given that many patients have multiple nodal sites and/or mediastinal bulk and are therefore at greater risk of late toxicity. The GHSG HD17 trial demonstrated that radiotherapy is not required for patients who achieve CMR (Deauville score 1–2) after 2 + 2 chemotherapy. The H10 trial evaluated whether radiotherapy can be safely omitted after ABVD, randomising patients with early CMR to receive either 4× ABVD plus radiotherapy, or 6× ABVD alone. PFS was marginally higher in the radiotherapy arm (2.5% difference at 5 years) and therefore the trial did not demonstrate non-inferiority of a radiotherapy-free strategy. However, given the modest PFS difference, many clinicians feel that it is reasonable to omit radiotherapy after ABVD for patients with CMR where the risks of late toxicity are high. Such patients usually receive response-adapted chemotherapy in line with the advanced-stage RATHL trial.

Treatment selection for 'unfavourable-risk' ESHL patients is complex, balancing cure rates against the acute and delayed toxicities of escalated BEACOPP and radiotherapy, respectively. Response-adapted treatment is now a routine part of care, with interim PET directing treatment intensification after ABVD and/or application of radiotherapy.

Advanced-stage cHL

There are three main approaches for the treatment of adult advanced-stage cHL:

1 Begin treatment with ABVD: Continuing to six cycles remain a standard approach, although many centres will perform a PET scan after two cycles and adapt according to response. The UK

NCRI RATHL trial demonstrated that if patients achieve a negative PET scan at this stage (Deauville score 1–3), omission of bleomycin from the subsequent four cycles results in non-inferior outcomes and reduces toxicity. For patients with a positive PET scan (Deauville score 4 or 5), the trial intensified treatment to a BEACOPP regimen. Although results were better than some historical comparisons using ABVD alone, this arm was not randomised and a 3-year PFS of 67.5% was disappointing. Furthermore, some retrospective data challenges the efficacy of escalation.

2 Begin treatment with escalated BEACOPP: Multiple studies have confirmed escalated BEACOPP to be superior to ABVD in terms of disease control but whether there is an overall survival benefit is less clear. Initial trials of up to eight cycles showed significant toxicity including increased myelotoxicity with more febrile neutropenia and blood product support, and longer-term issues such as a higher risk of infertility and incidence of second malignancy. However, the recent HD18 trial demonstrated that for patients with a negative interim PET scan (defined as Deauville 1–2), four cycles in total were not inferior to six or eight cycles with a significant improvement in short-term toxicity. The impact on late toxic effects is yet to be demonstrated although it is expected to be less. For Deauville score 3–5 after two cycles, patients continued to a total of six cycles. Many centres now treat Deauville 3 as negative with this approach based on outcomes equivalent to the Deauville 1–2 group. Another large, randomised trial called AHL2011, randomised patients with a negative PET scan after two cycles of escalated BEACOPP to continue to six cycles, or to de-intensify to four cycles of ABVD. There was no difference in survival endpoints in the two arms. Although this lengthens the duration of treatment, it reduces toxicity and appears to improve fertility. Whilst this wasn't tested in AHL2011, many centres also omit bleomycin for the four cycles of ABVD.

3 Replace the bleomycin with brentuximab vedotin (BV) and use AVD-BV for six cycles. This is based on the ECHELON-1 trial which randomised over 1300 patients between 6 cycles of ABVD and 6 cycles of AVD-BV. There was no PET response adaptation within this trial. AVD-BV was associated with a 4.9% improvement (corresponding to a 23% risk reuduction) in the 2-year modified PFS. On longer follow-up, a significant overall survival benefit has also emerged with AVD-BV. As expected, there was more neuropathy and febrile neutropenia with AVD-BV necessitating the use of GCSF support, but less lung toxicity. Although licensed in a number of countries, funding remains an issue in some territories due to the cost of BV. Recent trials comparing BrECADD (an intensive brentuximab containing regimen) with escalated BEACOPP and comparing AVD plus nivolumab with AVD-BV have both shown progression free survival benefits and are likely to change frontline treatment approaches in the future.

Radiotherapy in advanced-stage disease

Compared with early-stage disease, radiotherapy has less of an established role in advanced-stage disease. For patients treated with an escalated BEACOPP approach, 30 Gy radiotherapy is given to patients with a residual mass of >2.5 cm which is PET-positive at end of treatment. With this approach, the outcome of patients with an end-of-treatment positive PET was only 6% lower than for the PET-negative group. For patients treated with an initial ABVD approach, the situation is less clear. The RATHL study did not include any protocol-defined radiotherapy and very few patients received it. Whereas initial bulk disease has often been thought to benefit from radiotherapy, a randomised trial of radiotherapy or observation for patients with initial bulk but an interim negative PET scan after two cycles of ABVD showed no benefit for radiotherapy. The trial was small and underpowered however and may mask a clinically significant benefit. Whilst not assessed in a trial, irradiation of sites that are positive on interim or end-of-treatment PET would seem sensible although the risks and benefits of this approach for an individual patient should be discussed with a radiation oncologist.

Paediatric and TYA approaches

Classical HL is the most common malignancy within the teenage and young adult (TYA) age group (13–24 years). Given that the majority of patients are cured with frontline cHL treatment, paediatric regimens have been designed with a strong focus on late effects, fertility preservation and survivorship, aiming to reduce cumulative doses of anthracyclines, bleomycin, alkylating agents and radiotherapy.

The most widely studied treatment in under-18s is the Euronet approach. Patients are stratified into low, intermediate and high-risk groups according to stage, ESR, tumour volume and the presence of extranodal disease. All patients receive two cycles of OEPA (vincristine, etoposide, prednisolone and doxorubicin) followed by one to four cycles of COPDac (cyclophosphamide, vincristine, prednisolone and dacarbazine), dependent on baseline risk group. Radiotherapy is given to slow responders on interim PET, where lower doses are generally employed (19.8Gy) than adult protocols. Progression-free survival rates are 85–90% with this approach.

For older TYA patients (18–24 years), the optimum treatment approach is unknown. Several studies have demonstrated that these patients have comparatively lower progression-free survival rates than paediatric and older adult cHL patients treated with the same regimens. Delays in diagnosis, psychosocial issues and treatment-related side effects may all contribute to this observation.

Treatment of older patients

An estimated 20–30% of patients presenting with cHL in the UK are over the age of 60. Older patients are consistently underrepresented in trials however and there is no defined standard of care in this population. In the German HD10 and HD11 trials in

early-stage disease, only 9% of participants were over the age of 60. Analysis of this subset highlighted that toxicity frequently resulted in failure to deliver protocol-defined therapy and the treatment-related mortality was 5%. Survival was also 10% lower in older patients even with adjustments for deaths not related to cHL or treatment. The risk of bleomycin toxicity is of special concern in older patients with rates of up to 25% reported in some series. The German Hodgkin Study Group do not recommend the use of eBEACOPP in patients 60 years of age or older due to significant morbidity and mortality. A common approach is to use an anthracycline regimen (such as AVD) in fit older patients whereas to use an anthracycline-free regimen (such as modified ChlVPP) in frail patients. Where available, incorporating BV concurrently or sequentially with AVD is an effective approach. Radiotherapy is particularly important in older patients, partly due to relatively poor tolerance of chemotherapy and also due to a low risk of late toxicity, particularly second cancers. Defining optimal treatment in this group is a major aim in cHL clinical research.

Treatment of nodular LP Hodgkin lymphoma

Some countries will enrol NLPHL patients within clinical trials primarily aimed at cHL and draw little distinction between HL treatment approaches. However, it is increasingly clear that the natural history of NLPHL is similar to low-grade non-Hodgkin lymphoma. Long remissions but late relapses are well described, and the prognosis is generally excellent. Treatment approaches are increasingly reflecting this understanding. High-grade transformation to diffuse large B-cell lymphoma (often the T-cell rich subtype) occurs in approximately 10% of patients.

- Early-stage disease: Local treatment approaches are generally applied in this setting such as surgical excision (often as part of the diagnostic process) followed by active surveillance or radiotherapy.
- Advanced disease: For asymptomatic patients, active surveillance is a reasonable approach with an immunochemotherapy combination (such as R-CVP) for those with symptomatic disease. High-grade transformation to diffuse large B-cell lymphoma is a concern for patients with splenic disease, extranodal disease or variant histologies and R-CHOP is often used in this setting.

Relapsed and refractory disease

Treatment of relapsed and refractory (R/R) cHL consists of two or three phases: remission induction, transplant consolidation, and in some instances, maintenance therapy. This approach is potentially curative for at least 50% of patients, if fit and transplant-eligible. Adverse risk factors include extranodal disease, primary refractory cHL or relapse within 12 months of frontline treatment, tumour diameter ≥5 cm and poor performance status.

Remission induction typically involves use of intensive, non-cross-resistant and multi-agent chemotherapy. There are multiple different options, which have never been directly compared in clinical trials, therefore the optimum regimen is unknown. The majority are platinum-based, including GDP (gemcitabine, dexamethasone, cisplatin), ICE (ifosfamide, carboplatin, etoposide) and ESHAP (etoposide, methylprednisolone, cytarabine and cisplatin). Other options include IGEV and BeGEV (ifosfamide or bendamustine plus gemcitabine and vinorelbine). Published response rates vary, but around 50% of patients achieve CMR after two to three cycles of chemotherapy.

Targeted agents are increasingly used in R/R cHL. Brentuximab vedotin (BV) and PD-1 inhibitors (nivolumab and pembrolizumab) are both licensed as monotherapy for R/R cHL, producing high overall response rates, although CMR rates are more modest (typically 20–35%). These are most widely used for patients with insufficient response to initial salvage chemotherapy but are being investigated at earlier stages in the treatment pathway. The KEYNOTE-204 trial demonstrated that PD-1 inhibition with pembrolizumab results in superior PFS and more durable responses compared with BV. The combination of BV or PD-1 inhibitors with salvage chemotherapy as second-line treatment results in high CMR rates (70–90%), but the benefit of these combinations have not been proven within randomised clinical trials.

For fit, non-comorbid patients, the aim is to consolidate with high-dose chemotherapy- most commonly LEAM or BEAM (lomustine or carmustine plus etoposide, cytarabine and melphalan)- followed by autologous stem cell transplant (ASCT). Evidence of chemosensitivity is a prerequisite; PET response to induction chemotherapy is the strongest determinant of outcomes following ASCT. Patients with CMR prior to ASCT have long-term PFS rates of approximately 80%, compared with <50% for patients without CMR. Therefore, ASCT is usually reserved for patients with CMR, or at least very good partial response, to induction chemotherapy. Consolidation radiotherapy is often given together with, or instead of, ASCT for patients with limited-stage disease at relapse or residual PET-positive sites.

An alternative option is allogeneic transplantation (alloSCT) consolidation. There is good evidence for a graft-vs-lymphoma effect in cHL, with low relapse rates following alloSCT, including in patients with suboptimal response (<CMR) prior to transplant. Transplant-related mortality rates have fallen over recent decades, but continue to undermine the feasibility of this approach. AlloSCT is largely reserved for patients who relapse after ASCT or are refractory to multiple lines of therapy with few or no subsequent salvage options.

The AETHERA trial demonstrated that maintenance therapy after ASCT with BV (up to 16 cycles) improves PFS for BV-naïve patients with high-risk R/R cHL (relapse within 1 year and/or extranodal disease). This trial has been criticised for a lack of

mandatory PET assessment prior to ASCT and there is no demonstrated overall survival benefit. Considering the risk of peripheral neuropathy and cost, use of maintenance BV post-ASCT remains contentious. Other maintenance strategies, including PD-1 inhibitor maintenance, are currently under investigation.

Late effects and survivorship

With high cure rates in a relatively young patient population, late treatment-related effects are a major concern for cHL patients and a cause of significant morbidity and excess mortality. The risk of late toxicity depends on patient age, exposure to certain chemotherapy agents, radiotherapy dose and field. The incidence of many late effects, particularly secondary malignancy and cardiovascular disease, increases with time and is often only apparent >10 years after completion of therapy. Therefore, relative mortality rates remain elevated beyond disease cure for most cHL survivors. Indeed, for patients with ESHL and those with ASHL treated with intensive regimens, patients are more likely to die from treatment-related effects than cHL itself.

Secondary malignancies

HL survivors have an approximately fourfold increased risk of developing solid organ malignancy compared to the general population. The most common secondary malignancies are breast, lung and gastrointestinal tract cancers. Radiotherapy increases the risk of secondary solid organ malignancy at exposed sites, with a dose-response relationship. Certain chemotherapy agents are also known to increase the risk of specific malignancies, such as gastrointestinal cancers following procarbazine treatment. Lifestyle factors can modify cancer risk, with a strong association between secondary lung cancers following chest radiotherapy and smoking history.

One of the strongest determinants of secondary malignancy risk is the age at which the patient received treatment. The relative risk of breast cancer risk increases 15–25-fold for patients receiving radiotherapy to breast tissue before age 20, whilst patients aged over 40 have a similar risk to the general population. Sex hormones are a major contributor and these patients should avoid hormonal contraceptives/replacement therapy wherever possible, particularly oestrogen-containing. Breast cancer risk after radiotherapy is lower in patients who have received sterilising chemotherapy with secondary ovarian failure. In the UK, annual breast screening is offered to all lymphoma patients who have received radiotherapy to breast tissue, starting 8 years after treatment or at age 30 years (whichever is later).

Secondary MDS/AML is an uncommon but potentially devastating effect of treatment. It generally occurs 3–10 years after treatment and is related to use of alkylating agents, topoisomerase inhibitors and radiotherapy. It affects approximately 2% patients treated with escalated BEACOPP, compared with <1% with ABVD.

Cardiovascular disease

Cardiomyopathy is a well-established side effect of anthracycline chemotherapy and increases with cumulative dose. Exposure of the heart to radiotherapy confers additional risks of ischaemic and valvular heart disease. As a result, patients treated for cHL have an increased risk of cardiac mortality, depending on patient age and treatment delivered. The risk is greatest in those aged <20 years at diagnosis (up to fourfold increase), and older patients with pre-existing cardiac comorbidities. For paediatric and TYA patients (≤21 years) treated with ≥250 mg/m^2 doxorubicin, the risk of cardiac failure by age 40 is approximately 10%. Concomitant cardiovascular risk factors (e.g. hypertension, hypercholesterolemia, smoking and obesity) compound this risk and should be proactively screened and managed. Surveillance echocardiography is recommended for high-risk paediatric and TYA cHL survivors.

Infertility and premature ovarian failure

The risk of infertility and ovarian failure relates to the cumulative dose of alkylating agents, (e.g. cyclophosphamide and procarbazine) and in rare instances, pelvic radiotherapy. For women of childbearing potential, this is an important consideration in treatment selection. Fertility is preserved in most patients treated with ABVD alone but may be reduced in patients aged ≥35 years. However, 20–30% of ASHL patients will require treatment intensification or further lines of chemotherapy after ABVD, where fertility is often compromised. Women receiving escalated BEACOPP have markedly reduced ovarian reserve and high rates of sustained amenorrhea. This is most evident in women aged ≥30 years, who have <50% chance of regular menstruation following ≥six cycles of escalated BEACOPP, with over a third developing significant menopausal symptoms post-treatment. Fertility preservation should be considered in all young patients with newly-diagnosed cHL, where feasible.

Men are at greater risk of infertility after exposure to alkylating agents than women. There is a ~50% risk of severe oligospermia at 5 years following just two cycles of escalated BEACOPP, rising to >90% after six cycles, whilst the risk of infertility with ABVD alone is generally low (<20%). Pretreatment semen cryopreservation is straightforward for most patients and can mitigate this to an extent. Paediatric trials have shown that substituting procarbazine for dacarbazine markedly reduces the risk of male infertility without significantly compromising efficacy. This substitution is currently

being evaluated in adult regimens, with some centres switching to BEACOPDac rather than BEACOPP.

Other late effects

Osteonecrosis of the hips and/or knees is an uncommon but potentially serious late effect. It is strongly associated with corticosteroid use, age and sex. It is rarely seen after ABVD alone, but occurs in 1–2% patients treated with regimens such as BEACOPP and OEPA/COPDac, increasing to 3% in adolescent males. There is no evidence for any preventative measures, apart from reducing corticosteroid use where possible. Management of established osteonecrosis is supportive.

Conclusion

The high cure rates in cHL are one of the major successes in haemato-oncology. There are now multiple valid treatment options for both ESHL and ASHL. Personalised treatment decisions require multidisciplinary input from both haemato-oncologists and radiation oncologists, taking into account patient preferences and goals. Going forwards, a major priority is to improve the toxicity profile of treatment whilst maintaining high cure rates. To improve the precision of current risk-adapted approaches, more accurate patient risk stratification is required, potentially incorporating novel imaging and circulating biomarkers. There have been major advances in our understanding of the pathogenesis of cHL, particularly with respect to interplay with the immune microenvironment. These have the potential to revolutionise the treatment of cHL over the coming decades, with immunotherapy currently being evaluated in the frontline setting and an ultimate goal of reducing reliance of cytotoxic chemotherapy.

CHAPTER 26

Indolent non-Hodgkin lymphomas

26

Kim Linton[1] and William Townsend[2]

[1]The Christie Hospital NHS Foundation Trust, Department of Medical Oncology and The University of Manchester, Division of Cancer Sciences, Manchester, UK
[2]University College Hospitals NHS Foundation Trust, Department of Haematology and University College London Clinical Trials Centre, London, UK

Introduction

Indolent or low-grade B-cell non-Hodgkin lymphomas (NHL) are a heterogenous group of malignancies with distinct epidemiology, pathogenesis, morphologic, immunophenotypic and clinical features. Despite these differences, they share many similarities in their disease course and treatment paradigms.

Low-grade lymphomas predominantly affect older patients and their collective incidence has increased in line with an ageing population and improved diagnostics. Although still regarded as incurable malignancies, survival rates have dramatically improved with modern treatment approaches including the introduction of anti-CD20 monoclonal antibodies. Improved survival coupled with a rising incidence resulted in a 33% increased prevalence of between 2000 and 2016, reflecting a high burden of disease and a growing need for low toxic therapies to extend the array of treatment options for patients living with low grade lymphomas. In recent years, there have been significant advances in our understanding of lymphoma pathogenesis and many new and promising novel therapies have emerged. Ongoing research is now aimed at deepening our understanding of the biological determinants of risk to delineate patient groups and develop risk-adapted therapies incorporating novel agents to overcome treatment resistance.

This chapter will summarise current management and future directions for follicular lymphoma, marginal zone lymphomas, lymphoplasmacytic lymphoma/Waldenström macroglobulinaemia and mantle cell lymphoma. Chronic lymphocytic leukaemia (CLL)/small lymphocytic lymphoma (SLL) and hairy-cell leukaemia are also mature B-cell malignancies with similarities to the above entities; they are covered in Chapter 23 and T-lymphoproliferative disorders are covered in Chapter 24. Chapter 20 covers the histology and classification of low-grade NHL, but salient features will be highlighted in the relevant sections below.

Follicular lymphoma

Follicular lymphoma (FL) is the second most common B-cell lymphoma accounting for ~20% of non-Hodgkin lymphomas, with an annual standardised incidence of ~3.5/100,000 in Western countries and 0.4–1.1/100,000 in Asia. The median age at diagnosis is 65 years, with a slight male preponderance.

FL typically follows an indolent relapsing and remitting clinical course over many years, with progressively shorter remissions. Therapy resistance or transformation to high-grade disease occurs in 20–30% of patients. A further 20% of patients experience early treatment failure and death; progression of disease within 24 months of the start of first-line immunochemotherapy (POD24) has recently emerged as a powerful predictor of survival with validity across modern immunochemotherapies. POD24 confers a 5-fold increased risk of death at 5 years (50% for POD24 versus 90% for non-POD24), in part attributable to a higher rate of transformation associated with early treatment failure.

Notwithstanding inferior survival for high-risk FL, overall survival has improved considerably in the past 10–15 years with the introduction of therapeutic anti-CD20 monoclonal antibodies and improvements in diagnostics and supportive care. Population-based studies now report median survival exceeding 20 years, challenging the paradigm that FL is an incurable malignancy.

Pathogenesis of FL

FL arises from a common progenitor cell (CPC), typically harbouring the hallmark t(14;18)(q32;q21) chromosomal translocation arising from errors during V(D)J recombination. This leads to constitutive expression of the anti-apoptotic proto-oncogene *BCL2* (B-cell lymphoma-2) and malignant transformation of germinal-centre (GC) B-cells, with effacement of nodal architecture by large, uniform follicles demonstrating various degrees of diffuse neoplastic growth.

Deregulated *BCL2* alone is insufficient for FL to develop. Additional genetic and epigenetic alterations are required. These are typically early clonal events in the CPC pool involving recurrent inactivating mutations of histone modifiers *KMT2D* (*MLL2*) in 79–89% and gain of function *EZH2* mutations in 17–27% of cases. Inactivating mutations of *CREBBP* (32–70%) and *EP300* (9–19%) tend to characterise high-risk FL. Other important epigenetic modifiers in FL include *ARID1A* and *MEF2B*. Mutations affecting NF-κB signalling, B-cell development and cell cycle regulation often occur later. Epigenetic modulation is a fundamental principle in FL pathogenesis and epigenetic-based therapies targeting these early and stable events represent attractive targets for FL and transformed FL.

The CPC undergoes independent and divergent subclonal evolution leading to disease relapse and high-grade transformation, which are additionally linked to upregulation of *MYC*, mutation of *TP53* and other genetic events.

Malignant B-cells exist within a rich tumour microenvironment (TME) composed of various T-cell subsets, macrophages and follicular dendritic cells. The composition and complex interactive 'cross talk' between lymphoma and immune cells are responsible for much of the clinical variability of this disease. Early evidence for the powerful prognostic role of the TME came from a pivotal gene expression profiling study demonstrating superior survival for increased T-cell infiltration (immune response 1 signature) and inferior survival for increased macrophages and dendritic cells (immune response 2 signature). There is considerable interest in further characterising the composition and spatial heterogeneity of the TME to discover predictive patterns associated with treatment resistance and response, with ongoing studies applying highly multiplexed image analysis and other novel approaches of investigation.

Clinical and pathological features of FL

FL commonly presents with painless lymphadenopathy. This is usually asymptomatic but may cause local symptoms or organ compromise. In a large retrospective review, including 4167 patients enrolled in clinical trials, 78% of patients had advanced-stage disease, 19% had B symptoms (weight loss, night sweats or fever), 52% had bone marrow involvement and 38% had extranodal disease outside the bone marrow. CNS involvement is rare in FL, and LDH is elevated in 20% of cases.

FL diagnosis is based on the histomorphologial and immunohistochemical features of FL cells obtained from a needle core or surgical excision biopsy. Malignant cells express B-lineage and Germinal centre (GC) markers (CD10 and BCL6), and most (85%) are BCL2-positive. Bone marrow involvement has a characteristic paratrabecular pattern.

FL GCs contain a monomorphic population of centrocytes without clear zonation. The number of centroblasts per high-power field (HPF) determines histological grade; 0–15 per HPF constitutes grades 1–2 (now collectively termed 'low-grade') and occurs in 75% of cases; >15 per HPF constitutes grade 3, which is further separated into grades 3a (20%) and 3b (5%). Outcomes for grades 1–3a are similar, whereas grade 3b FL has an aggressive course analogous to DLBCL and is clinically managed as such, with the possibility of cure. The proliferation index, as measured by Ki67, usually reflects histological grade and is typically <20% in low-grade FL and >20% in grade 3 disease.

Staging and baseline investigations in FL

Disease staging at diagnosis determines the extent of disease for prognostic assessment and treatment planning and involves imaging of the neck, chest, abdomen and pelvis by CT or PET-CT and a bone marrow aspirate and trephine biopsy. The Lugano 2014 classification system has largely replaced the Ann Arbor system, classifying stage I–II as early or limited stage disease and stage III–IV as advanced stage disease.

FL is uniformly fluorodeoxyglucose (18F) (FDG) avid and FDG-PET is more accurate than CT for staging nodal and extranodal sites, upstaging 18–30% of patients and altering FLIPI score. PET-CT is now the preferred imaging modality for routine staging of FL in updated treatment guidelines, especially for evaluation of early-stage disease to confidently exclude dissemination before recommending involved field radiotherapy (discussed later). FDG-PET is not reliable for assessing bone marrow infiltration in FL, and bone marrow biopsy therefore remains an important component of staging, even when FDG-PET is performed.

Other baseline investigations include full blood count, serum biochemistry, lactate dehydrogenase (LDH), β-2-microglobulin (β2M), immunoglobulins and protein electrophoresis, uric acid and virology for hepatitis B, hepatitis C and HIV. Measurement of creatinine clearance and cardiac function may be required depending on patient age, co-morbidities and therapy choice.

Prognostic markers in FL

Baseline prognostic assessment in newly diagnosed FL is based on clinical and laboratory parameters, with the FLIPI

Table 26.1 Outcomes according to risk group defined by the FLIPI, FLIPI2 and PRIMA-PI scores.

Prognostic tool	**FLIPI**		**FLIPI2**		**PRIMA-PI**	
Adverse risk factors	• Age >60 yrs • Stage III–IV • Hb <120 g/L • LDH >ULN • >4 nodal sites		• Age >60 yrs • BM involvement • Hb <120 g/L • β2M >ULN • Nodes >6 cm		• BM involvement • β2M >3 mg/L	
Risk	**Risk factors**	**5-yrs OS (%)**	**Risk factors**	**3-yrs PFS (%)**	**Risk factors**	**5-yrs PFS (%)**
Low	0–1	91	0–1	91	β2m ≤3, BM neg	74
Intermediate	2	78	2	69	β2m ≤3, BM pos	59
High	3-5	53	3–5	51	β2m >3	39

β2M, Beta-2 microglobulin; BM, bone marrow; Hb, haemoglobin; LDH, lactate dehydrogenase; ULN, upper limit of normal; OS, overall survival; PFS, progression-free survival.

(Follicular Lymphoma International Prognostic Index) and, to a lesser extent, FLIPI-2 scores being the most commonly used (Table 26.1).

The FLIPI score was developed from a retrospective analysis in the pre-rituximab era to predict overall survival (OS). It incorporates age, stage, number of involved nodal groups, haemoglobin level and serum LDH. Three identifiable risk groups had a 10-year OS of 71% for low-risk (0–1 points), 51% for intermediate-risk (2 points) and 36% for high-risk (3–5 points).

A revised system, FLIPI2, was developed prospectively in 2009 to provide a simplified tool to predict progression-free survival (PFS), a more reliable clinical endpoint not confounded by subsequent therapy. The majority (59%) of patients in this study received rituximab-containing regimens, most commonly cyclophosphamide, doxorubicin, vincristine, prednisolone (CHOP)/CHOP-like. FLIPI2 determines risk according to age, haemoglobin, presence of bone marrow infiltration, β2-microglobulin, and greatest diameter of largest involved lymph node, the latter providing an easier tool to assess tumour bulk. Three-year PFS was 91% for low-risk (0–1points), 69% for intermediate-risk (2 points) and 51% for high-risk (3–5 points).

Recently, the PRIMA Prognostic Index was developed as an age-independent score based on just two factors – β2-microglobulin and bone marrow infiltration, predicting 5-year PFS rates of 74, 59 and 39% for high-, intermediate- and low-risk FL (see Table 26.1). PRIMA-PI improved risk stratification by overcoming the effect on poor survival of non-relapse mortality in patients aged over 60, identifying a smaller proportion of high-risk patients aged over 60 with greater specificity than FLIPI and FLIPI2. The discriminatory power of PRIMA-PI was shown to be as good as FLIPI.

FLIPI and FLIPI-2 are helpful for describing the distribution of risk in clinical trial populations but their application has not resulted in the development of risk-adapted therapy and they cannot guide choice of therapy. All three tools (FLIPI, FLIPI-2 and PRIMA-PI) were developed and/or validated in a majority of patients treated with CHOP/R-CHOP; their validity across all modern immunochemotherapy regimens is not known.

There is considerable interest in developing baseline prognostic indices to predict POD24 as a validated surrogate for OS. FLIPI and FLIPI2 only predict 50–60% of POD24 events. A novel 11-point model integrating clinical variables and treatment factors from the GALLIUM trial demonstrated superior risk stratification compared to FLIPI and FLIPI2, and improved POD24 sensitivity to 73%, warranting independent validation.

Other promising predictive/prognostic biomarkers in development include total metabolic tumour volume (TMTV) and molecular minimal residual disease (MRD) assessed on circulating tumour cells (CTCs) and cell-free DNA (cfDNA). Models incorporating biological determinants of risk include the m7-FLIPI, which combines FLIPI and performance status with the mutational status of seven genes (*EZH2*, *FOXO1*, *EP300*, *CREBBP*, *CARD11*, *MEF2B* and *ARID1A*), and a 23-gene signature developed from PRIMA trial data reflecting B-cell biology and the TME. Both demonstrated similar sensitivity for POD24 as FLIPI and neither has yet been adopted into routine clinical practice.

Depth of response to induction immunochemotherapy currently provides the most accurate prognostic information for FL patients. A subanalysis of the GALLIUM trial showed that FDG-PET was more predictive of outcome than conventional CT imaging for post-induction response assessment. Using Lugano 2014 response criteria, patients who failed to achieve complete metabolic response (CMR) had a 5-fold increased risk of progression and early death compared to CMR patients (2.5-year progression-free survival 87.4 versus 54.9% and OS 96.6 versus 84.0% for CMR versus non-CMR patients). CMR patients were further stratified by MRD remission status determined by

polymerase chain reaction (PCR) quantification of *BCL2-IGH* rearrangement. Ongoing studies are evaluating the utility of post-induction PET to guide response-adapted therapy to overcome adverse disease biology and are combining models for improved risk prediction; promising results have been reported for combining baseline TMTV plus FLIPI2, TMTV plus end of induction (EOI) PET and MRD plus EOI PET, to mention a few.

Management of early-stage FL

Early-stage disease represents 10–20% of new FL diagnoses. Radiotherapy historically cured ~50% of stage I patients and 25% of stage II FL, including nodal and extranodal presentations staged by CT. Long-term outcomes for this study, involving mostly regional and extended field radiotherapy, were superior for stage I disease (15-year cause-specific survival 87% for stage I versus 54% for stage II) and lymphomas <3 cm in size (15-year rate 49 versus 29% for <3.0 versus ≥3.0 cm). Late relapses beyond 10 years are extremely rare and when they occur, are typically outside the radiotherapy field – perhaps suggesting that occult disseminated disease was present at the time of treatment. More sensitive FDG-PET upstages 23–60% of early-stage cases and, in combination with bone marrow staging, is recommended to confidently identify early-stage cases suitable for radiotherapy; a strategy which has significantly improved long-term disease-free survival compared to historic controls in the CT staging era.

Modern radiotherapy has also evolved to incorporate lower doses and smaller radiation fields, without loss of disease control. One randomised trial, mostly of patients with previously untreated early-stage FL, showed similar outcomes for low-dose involved field radiotherapy (IFRT) (24Gy) and standard doses at the time (40Gy). Very low-dose radiotherapy (4Gy) has also been assessed and, whilst this achieves good disease control and symptomatic relief in the palliative setting, 4Gy is inadequate for long-term disease control.

Despite excellent outcomes for radiotherapy alone, its use is variable. According to a recent National LymphoCare study, over half of early-stage patients in the US received systemic therapy, alone or in combination with radiotherapy. The benefit of systemic therapy in early-stage FL was evaluated in a randomised trial comparing 30Gy IFRT with or without six cycles of cyclophosphamide, vincristine and prednisolone (CVP), with rituximab added latterly for a minority of patients. Combined modality treatment delivered superior PFS and reduced relapses outside the radiation field. There were also fewer transformation events and deaths, however longer follow-up is needed to confirm a significant survival benefit. Nevertheless, results were still excellent for patients treated with IFRT alone (10-year PFS 41%), without the added toxicity of chemotherapy.

A recent retrospective multicentre study produced similar results in patients rigorously staged with FDG-PET and bone marrow biopsy and treated with modern radiotherapy protocols (including IFRT in 50%). Five-year freedom from progression (FFP) and OS rates were 68.9 and 96%, respectively. Five-year FFP was significantly superior for stage I versus stage II disease (74.1 versus 49.1%), confirming that curative potential of radiotherapy for truly localised FL was underestimated in the pre-PET era. The same study demonstrated universally high ORR (96%), PFS and OS rates regardless of treatment modality (radiotherapy alone at doses ≥24Gy, immuno-chemotherapy or combined modality treatment), underscoring the value of radiotherapy alone in these patients.

Taken together, 24Gy IFRT is the recommended approach for early-stage FL, including stage I and contiguous stage II suitable for a single-volume radiotherapy field, and is expected to cure most patients. Chemotherapy or combined modality therapy should be reserved for patients with symptomatic early-stage FL that is unsuitable for single-volume IFRT (including patients with non-contiguous stage II disease) or when radiotherapy increases the risk of serious or long-term toxicity.

Active surveillance should be offered to patients with asymptomatic early-stage disease unsuitable for RT, or when localised disease has been completely excised, the latter being associated with long-term remissions in 80% of cases without additional therapy. Expanding knowledge in the field, and development of biological predictors for progression, may determine a subset of higher-risk patients for whom combined modality therapy may be more beneficial.

Management of asymptomatic low tumour burden advanced-stage FL

Most patients (85%) present with advanced-stage FL. Their need for immediate therapy depends on the presence of high tumour burden features, most commonly evaluated by GELF (Groupe d'Etude des Lymphomes Folliculaires) criteria developed in the pre-rituximab era. The presence of at least one criterion constitutes 'high tumour burden' disease and is sufficient to recommend treatment: a single site of disease >7 cm in maximal diameter, ≥ three nodal sites each ≥3 cm in diameter, systemic or B symptoms, splenomegaly, organ compromise or significant cytopenias (neutrophils $<1.0 \times 10^9$/L and/or platelets $<100 \times 10^9$/L).

Asymptomatic patients with non-bulky disease and no GELF criteria are regarded as having low tumour burden FL. They can be managed with active surveillance as delaying treatment until needed does not compromise disease-specific survival, OS or quality of life. Results of an early, pivotal UK-NCRI trial informed this approach, showing no OS benefit for immediate chlorambucil versus active surveillance in 309 patients. Patients managed with active surveillance delayed systemic therapy for 2–3 years, with ~20% not requiring therapy at 10 years, increasing to 40% for patients aged over 70.

Active surveillance was compared to rituximab monotherapy in a second randomised UK-NCRI study of 379 patients followed for 16 years. Short-course rituximab (weekly doses for 4 weeks) prolonged PFS and doubled the number of patients not requiring therapy within 3 years compared to active surveillance (78 versus 46%), again with no impact on OS. This study provided further evidence that active surveillance does not compromise survival, whilst also proffering short-course rituximab as a reasonable option for patients seeking active therapy to delay immunochemotherapy. Short-course rituximab was subsequently shown to be cost-effective compared to active surveillance, mainly due to the large proportion of patients never requiring systemic therapy.

The value of maintenance rituximab after short-course rituximab induction in low tumour burden FL was evaluated in the RESORT trial. Patients responding to induction rituximab were randomised to maintenance rituximab, 3 monthly until progressive disease, or rituximab re-treatment at relapse, delivered as weekly doses for 4 weeks at each progression until treatment failure. Time to treatment failure (TTTF) was significantly longer for maintenance versus re-treatment (4.8 versus 1.4 years); however, this came at a cost of significant exposure to rituximab (median 18 doses for maintenance versus 4 doses for re-treatment patients) and did not produce a survival benefit. Interestingly, in this trial, 50% of patients randomised to the re-treatment arm remained in remission 3 years after short course induction rituximab. Those that relapsed demonstrated very high response rates to subsequent single-agent rituximab at first and second relapse (61 and 67%, respectively), suggesting that acquired rituximab resistance was not a frequent occurrence in this cohort.

Whether active surveillance is still appropriate in the modern era of novel therapies is an important question that has not yet been addressed; it will be necessary for future trials to determine if novel agents with an acceptable safety profile could change the natural course of this disease to improve survival compared to active surveillance.

Management of symptomatic high tumour burden advanced-stage FL

Patients with advanced-stage FL require therapy when they become symptomatic or meet GELF (or similar) criteria. Modern FL regimens consist of induction immuno-chemotherapy followed by consideration of maintenance therapy in responding patients. Response to first-line therapy, and in particular depth of metabolic response, is the strongest determinant of survival and complete remission produces very long life expectancy exceeding 30 years. Achieving complete metabolic response by post-induction PET has therefore become the most important goal of therapy, alongside symptom control and prolonging time to next treatment.

Induction therapy

Induction therapy has evolved considerably in the past decade, with many studies demonstrating a survival benefit for adding rituximab (R) to first-line chemotherapy. Adding rituximab to CVP (cyclophosphamide, vincristine and prednisolone) significantly improves 4-year OS from 77 to 83%; and adding rituximab to CHOP (cyclophosphamide, doxorubicin, vincristine, prednisolone) significantly improves 2-year OS from 90 to 95%. A large meta-analysis confirmed these findings, concluding a significant improvement in OS for R-chemo compared to various chemotherapy combinations (HR 0.63, 95% CI 0.51–0.79).

Whilst the benefit of adding rituximab to chemotherapy is definitive, the optimal chemotherapy regimen for combination remains unresolved despite evidence from several phase 3 randomised trials. The FOLL05 trial demonstrated inferior TTTF for R-CVP compared to R-CHOP or R-FM (rituximab, fludarabine, mitoxantrone). R-FM was associated with increased toxicity, including neutropenia, infections and second malignancies. This together with a higher rate of myelodysplasia and impaired stem cell mobilisation reported elsewhere led to fludarabine withdrawal from common use in the management of FL. The STiL NHL1 trial showed that bendamustine in combination with rituximab (BR) was more effective and less toxic than R-CHOP (PFS 69.5 versus 31.2 months, HR 0.58, $P < 0.001$), with no difference in OS after 9 years of follow-up. The BRIGHT trial showed that BR was non-inferior to R-CHOP/R-CVP (ORR 97 versus 91%, $p = 0.0102$; CR 31 versus 25%, $p = 0.0225$); OS was not evaluated. Toxicity profiles were different, with RCHOP/RCVP causing more neuropathy and alopecia, and BR caused more vomiting and drug hypersensitivity.

GALLIUM, an recent international randomised phase 3 trial, compared rituximab (R) with the more potent type II anti-CD20 monoclonal antibody obinutuzumab (Gazyvro®, G), both in combination with investigator choice chemotherapy (bendamustine, CHOP or CVP). The study enrolled 1202 previously untreated high tumour burden FL patients. Responding patients (achieving CR/PR to induction therapy) received a maintenance phase of the same antibody for 2 years or until progressive disease. At 34.5 months median follow-up, G-chemo achieved longer PFS than R-chemo (median not reached versus 47.1 months, HR 0.66 (95% CI, 0.51–0.85) $p = 0.0012$) and reduced the POD24 event rate by 46%. This effect was consistent across patient subgroups; however, the trial was not powered to compare different chemotherapy regimens. G-chemo also prolonged time to next treatment (TTNT) and event free survival (EFS: 3-year EFS 87.1 versus 81.2%, HR 0.68, $p = 0.0094$), with a non-significant trend for improved OS. In terms of toxicity, G-chemo caused more grade 3–5 adverse events (76 versus 69%), driven mainly by cytopenias, infections and infusion-related reactions.

CMR was consistently high for both antibodies at a rate >2.5 times higher than CT-assessed CR, but G-chemo increased MRD responses >90%, irrespective of chemotherapy backbone. This was not the case for R-chemo, which produced MRD responses in 76% (R-CVP), 78% (R-CHOP) and 90% (BR) of cases. This trial resulted in the swift approval of obinutuzumab as an alternative to rituximab for first-line treatment of FL in combination with chemotherapy. The observation that obinutuzumab could be combined with less intensive chemotherapy (such as CVP) subsequently led to an anecdotal increase in the use of G-CVP over combinations with other chemotherapies, especially bendamustine, which was associated with significantly more grade 3–4 infections and fatal adverse events than CHOP or CVP, regardless of antibody partner. CHOP in combination with rituximab is generally the preferred choice for clinically suspected or confirmed high-grade transformation, there being no demonstrated benefit of obinutuzumab over rituximab in studies of high-grade NHL.

The novel immunomodulatory agent, lenalidomide, produces high response rates when delivered in synergistic combination with rituximab (R2 regimen). The question of replacing chemotherapy with novel agents was addressed by the RELEVANCE trial, a multicentre, international phase 3 trial designed to demonstrate superiority for R2 over R-chemo (BR, R-CHOP or R-CVP); 1030 previously untreated patients meeting GELF criteria were enrolled, 72% received R-CHOP and 23% received BR in the standard arm. A 2-year maintenance rituximab phase was included in both arms. Both treatments produced remarkably similar outcomes and neither demonstrated superiority for co-primary endpoints (CR at 120 weeks 48 versus 53%, $P = 0.13$; 3-year PFS 77 versus 78%, $P = 0.48$). Grade 3–4 adverse events were also similar with ~30% of patients in both arms not completing therapy, but individual toxicity profiles differed between treatments. R-chemotherapy caused more high-grade neutropenia and febrile neutropenia and R2 caused more high-grade cutaneous reactions. Longer follow-up with more mature survival data are needed to assess long-term outcomes and determine whether R2 should become an option in future for first-line treatment.

Based on current evidence, six to eight doses of either rituximab or obinutuzumab in combination with six cycles of bendamustine, CHOP or CVP is the current standard of induction treatment for previously untreated FL meeting GELF criteria. This is expected to achieve 87–89% ORR by CT assessment and 3-year PFS of 73% (R-chemo) and 80% (G-chemo). In view of the increased risk of infections, patients receiving bendamustine should have extended anti-microbial prophylaxis until recovery of CD4+ T-lymphopenia.

Options for patients unable to tolerate full course immunochemotherapy include attenuated chemotherapy with full-dose rituximab/obinutuzumab, rituximab plus chlorambucil or single-agent rituximab where this is funded. Table 26.2 summarises key trials for frontline induction therapy for symptomatic advanced-stage FL.

Maintenance and consolidation therapy after induction

Up to 2 years of anti-CD20 monoclonal antibody maintenance (with the same antibody used for induction; rituximab or obinutuzumab) provides an option to delay disease progression in patients responding to induction immunochemotherapy.

The landmark PRIMA trial randomised 1019 patients with previously untreated, advanced-stage FL to maintenance rituximab or observation following response to induction R-CHOP, R-CVP or R-FCM. Results demonstrated a clear PFS advantage for maintenance rituximab (375 mg/m^2 every 2 months for 2 years), with updated results reporting a median PFS of 10.5 years for maintenance versus 4.1 years for observation, $P < 0.0001$. Benefits were evident across all FLIPI risk groups and post-induction response categories (PR/CR), but maintenance had no impact on OS, which was high in both arms (10-year OS 80%). These findings were confirmed in a meta-analysis of nine trials of rituximab maintenance involving 2586 patients with FL. The lack of survival benefit suggests that rituximab re-treatment is as effective as maintenance therapy for overall disease control and survival, supported by data from the RESORT trial discussed earlier. Rituximab is now also licensed for subcutaneous delivery, providing a convenient and efficient alternative to intravenous administration, without loss of disease control. This advantage is limited to rituximab as obinutuzumab can only be given intravenously.

Maintenance rituximab improves PFS, but at an increased risk of toxicity which is manageable in most patients but serious in some. Collective results of several trials demonstrate a 5–15% increased risk of neutropenia and delayed post-induction IgG recovery, leading to a >3-fold increased risk of grade 3–4 infections. Considering a lack of a survival benefit for maintenance therapy, clinicians should therefore carefully weigh the benefits and risks of maintenance therapy for individual patients, especially those at increased risk of complications, such as older or co-morbid patients, or those receiving bendamustine-based treatment, where the additional benefit of maintenance has not been assessed in a randomised study.

The advent of more effective induction immunochemotherapy and excellent outcomes for patients achieving CMR has led to investigation of PET-response adapted approaches to determine if maintenance improves disease control in CMR patients. The Italian FOLL12 trial investigated a standard maintenance approach of 2 years' maintenance rituximab given to all CR/PR patients versus a PET-response adapted approach whereby CMR and MRD negative patients omitted maintenance. The results demonstrated a reduction in PFS control when rituximab was omitted but did

Table 26.2 Summary of results of key trials randomised trials of first-line induction therapy for symptomatic advanced stage FL.

not directly evaluate the effect of maintenance versus no maintenance in CMR patients. This question, along with investigating the role of novel agents to improve outcomes in <CMR patients with the addition of lenalidomide to maintenance schedules, is being addressed in the ongoing UK-NCRI PETReA trial.

The optimal duration of maintenance is not known. Results from low-risk/low tumour burden studies suggest no benefit for extended duration maintenance (up to 5 years) or for prolonged maintenance over re-treatment at relapse, and it seems reasonable to extrapolate these data to high tumour burden FL; accordingly, it is standard practice for maintenance therapy to be delivered for 2 years.

Radio-immunotherapy consolidation with ^{90}yttrium-ibritumomab tiuxetan or ^{131}iodine-tositumomab has been an option to improve CR and PFS in patients responding to induction. Although effective and generally well tolerated, an increased risk of myelodysplasia has been observed and this, coupled with specialist delivery requirements, led to declining use largely superseded by maintenance antiCD20 monoclonal therapy.

Autologous stem cell transplantation (ASCT) consolidation in first remission is not recommended for FL patients based on results of four randomised trials comparing ASCT to observation, mostly performed in the pre-rituximab era. All but one of these trials demonstrated significant improvements in PFS, but this did not confer a survival benefit, partly due to excess toxicity (including secondary malignancies) in the ASCT arms and the success of salvage therapy in patients not receiving ASCT. In the current era of highly efficacious induction therapy and maintenance therapy, which has a low toxicity profile, there is no role for more toxic ASCT consolidation in first remission; ASCT does however remain an important therapeutic option at relapse (discussed later).

Management of relapsed FL

Most patients with advanced-stage FL will experience one or more relapses of disease. A biopsy should be performed to exclude high-grade transformation, especially in cases of early treatment failure after highly effective first-line immunochemotherapy with bendamustine or CHOP, or when transformation is clinically suspected. A recent competing risk analysis demonstrated a 23% risk of transformation for POD24 patients compared to just 3.4% for patients without POD24; risks increased to 42% for patients progressing within 12 months. Suspicions for transformation should not be based on FDG-PET uptake alone, as many FL cases have increased FDG uptake without a high-grade component. Management of transformed FL is discussed below.

There are many options but no standard treatments for relapsed FL. Management of localised or asymptomatic advanced-stage relapse without GELF criteria is the same as the first-line setting. For localised recurrence, 24 Gy is highly effective but lower doses (4 Gy) may be appropriate, especially for symptom control. Active surveillance is appropriate for asymptomatic, advanced-stage disease without GELF criteria. Patients with symptomatic advanced-stage, non-transformed relapse should be considered for immunochemotherapy or novel therapy when GELF criteria are met. Re-treatment with single-agent rituximab is also an option, especially for low tumour burden disease or elderly patients, resulting in a median TTTF of 4 years; however, rituximab monotherapy is not universally reimbursed in this setting, with most clinicians offering immunochemotherapy when patients become symptomatic, with dose reductions if patients are frail or elderly. There are no evidence-based guidelines for optimal therapy sequencing, thus choice of therapy is an individualised decision based on previous treatment received, associated toxicity, quality of response and duration of remission. Patient age, co-morbidities and preference, as well as the availability of options, are central to these decisions.

Non-cross-resistant immunochemotherapy is the mainstay of treatment for relapsed FL. Re-treatment with R-bendamustine or R-CVP may be considered if a prolonged remission (>2 years) was previously achieved, but there is limited scope to repeat anthracycline-based treatment such as R-CHOP due to an excess risk of cardiotoxicity. Rituximab plus lenalidomide (R2 regimen) was recently licensed for relapsed/refractory FL from the second treatment line onwards based on results of the AUGMENT and ongoing MAGNIFY trials demonstrating a PFS advantage over rituximab monotherapy and a median PFS of 39–40 months. In the first relapse setting, expected response rates for treatment are 85% for R-CHOP, 82% for BR and 78% for R2.

The positioning of R2 in the treatment pathway for relapsed/refractory FL has not been established as there have been no direct comparisons with immunochemotherapy at relapse. The option is attractive to both older and younger patients, with equivalent efficacy and safety outcomes reported for patients aged over and under 70 years, and provides a rational non-chemotherapy option for patients with early treatment failure, most of whom will be chemo-refractory. Median PFS for the POD24 subset treated with R2 in the AUGMENT trial was 30.4 versus 39.4 months for non-POD24 patients. R2 is also suitable for rituximab refractory patients, as it synergises with rituximab for enhanced antibody-dependent cell-mediated cytotoxicity to overcome resistance.

When previous remissions lasted less than 2 years, an alternative, non-cross-resistant immunochemotherapy or novel therapy is preferable; the main choice of chemotherapy backbone for immunochemotherapy is CHOP or bendamustine. Some centres may use a platinum-containing regimen for transplant candidates (discussed later) who have previously received CHOP-based therapy, or progressed on standard regimens. Obinutuzumab in combination with bendamustine, followed by obinutuzumab maintenance, is an option for patients with rituximab-refractory disease, defined as resistance or relapse within 6 months of any rituximab-based regimen. This offers a median PFS of 29.2 months compared to 14 months for bendamustine monotherapy according to results of the GADOLIN trial, which also demonstrated an OS benefit compared to bendamustine monotherapy.

Several randomised trials and a meta-analysis have demonstrated that rituximab maintenance leads to significant improvements in both PFS and OS over observation alone after second-line therapy, including patients who have previously received rituximab-containing immunochemotherapy. The largest trial reported an improvement in median PFS from 14.9 to 51.5 months, but it should be noted that these patients had not received maintenance after first-line therapy. In practice, a second round of maintenance is seldom applied, mainly due to risks of cumulative toxicity with prolonged B-cell depletion. Maintenance after re-induction at relapse is generally reserved for patients with high-risk disease who have not previously received maintenance therapy.

Several PI3-kinase inhibitors were FDA/EMA approved for relapsed and refractory FL, including idelalisib, copanlisib, duvelisib and umbralisib. These agents, which target the deregulated PI3K pathway important for B-cell receptor signalling, cellular proliferation and anti-tumour immunity, typically produce ORR rates of 40–60%, but CR rates are low (4–20%) and median duration of response is ~10–14 months in heavily pre-treated patients (median of 3–4 prior lines of therapy). The major limitation of these agents is their safety profile, with an increased risk of severe infections and autoimmune side effects, especially with continuous and long-term dosing, mandating the use of antimicrobial prophylaxis and monitoring for infections. Intermittent dosing schedules are under investigation to improve safety and preserve efficacy, and next-generation agents with improved specificity, such as umbralisib, appear to have improved toxicity profiles. Access to these agents varies considerably; none are

currently available in the UK and most licenses have been withdrawn due to unacceptable safety profiles.

Tazemetostat, an oral inhibitor of the enhancer of zeste homologue 2 (EZH2), was recently FDA-approved for relapsed/refractory FL harbouring *EZH2* mutations or from the third treatment line onwards without available standard options. Results from a phase 2 trial demonstrated higher response rates for *EZH2*-mutant FL compared to wild type (ORR 69 versus 35%) but PFS rates were similar (median PFS 13.8 versus 11 months ($EZH2^{MUT}$ versus $EZHT^{WT}$).

Radioimmunotherapy (RIT) is an effective alternative to immunochemotherapy for relapsed FL, but there are no direct comparisons of RIT in the relapsed setting against other modalities. Zevalin (^{90} Yttrium-ibritumomab tiuxetan) produces high response rates with durable remissions in heavily pretreated (albeit rituximab-naïve) patients, but restricted access to (few) specialist centres and the availability of novel treatment alternatives has largely replaced this agent.

All patients with relapsed/refractory FL should be considered for experimental therapies if clinical trials are available. Emerging novel therapies for the treatment of FL are discussed below.

Transplantation in relapsed FL

Both autologous and allogeneic haematopoetic stem cell transplant (HSCT) have a role in a subset of patients with relapsed or transformed FL.

Several non-randomised studies from the pre-rituximab era suggested that ASCT prolongs PFS in relapsed FL compared to historical controls treated with standard chemotherapy. Results of the European CUP trial also showed a survival benefit for ASCT after CHOP re-induction (2-year OS, 71 versus 46%, HR 0.4, $P = 0.026$). Several studies indicate a plateau in the survival curves approximately 10 years after ASCT, with 12-year OS of 48% in one study suggesting that some patients may be cured.

Recent retrospective observational studies highlight an emerging role for ASCT in FL patients with early treatment failure after first-line immunochemotherapy. One study showed a 20–25% improvement in 5-year survival for ASCT compared to observation in POD24 patients treated mostly with immunochemotherapy. Another study identified a survival benefit only for patients undergoing ASCT within 1 year of early treatment failure. Although retrospective and subject to selection bias, these studies highlight the potential value of ASCT as an early management strategy for high-risk relapsed FL. Myelodysplastic syndrome (MDS), acute myeloid leukaemia (AML) and other second malignancies account for the majority of late non-relapse mortality after ASCT and must be considered when weighing options, especially with increasing availability of alternative novel options.

Allogeneic HSCT offers the possibility of cure for a subset of younger patients with high-risk relapsed FL and a suitable donor. Reduced-intensity conditioning (RIC) HSCT is preferable to myeolablative conditioning for FL, due to its lower transplant-related mortality (TRM) and enhanced graft-versus-tumour effect. Several retrospective and registry studies of RIC allogeneic HSCT in FL suggest a relapse rate of 10–44% and TRM of 11–40% at 3 years, delivering 3-year OS rates of 50–65%. At present RIC allogeneic HSCT is recommended for patients who relapse after prior ASCT. While it is tempting to consider alloSCT in younger patients with early relapse and high-risk disease characteristics, there have been no prospective trials assessing autologous versus allogeneic transplantation and the advent of highly effective novel therapies may soon challenge the role of alloSCT in this setting.

Novel therapies for FL

A burgeoning array of novel agents is in clinical development for FL, with a strong emphasis on improving outcomes for high risk and multiply relapsed FL. Some are already available for routine use, including lenalidomide, rituximab and tazemetostat (discussed earlier).

Bispecific monoclonal antibodies simultaneously targeting CD20 and CD3, and CD-19 directed chimeric antigen receptor T-cell (CAR-T) therapies are amongst the most promising emerging agents. Impressive ORR and CR rates have been reported in early phase trials of high risk and heavily pre-treated patients, but long-term efficacy and safety are pending mature follow-up data. The four leading bispecific antibodies (mosunetuzumab, glofitamab, odronextamab and epcoritamab) demonstrate ORR of 62–92% and there are other similar molecules in development too. Most patients achieve CR (50–60%), and for these patients, responses appear to be durable. Recent data for CAR-T therapies are also very encouraging; axicabtagene ciloleucel (ORR 94%, CR 80%, median PFS not reached after 17.5 months of median follow-up) and tisagenlecleucel (ORR 83%, CR 65%, median PFS not reached after 9.9 months median follow-up). Predictable toxicities of these immune-activating therapies include cytokine release syndrome and immune effector cell-associated neurotoxicity syndrome (ICANS), mostly low-grade in FL, and cytopenic complications necessitating specialist delivery units to manage these patients.

Other novel agents with high activity in FL include the antibody-drug conjugates loncastuximab tesirine (CD19-directed), polatuzumab vedotin (CD79B-directed), the radioimmunoconjugate lutetium (177Lu) lilotomab satetraxetan (CD37-directed).

Since the success of the R2 combination, there has been considerable interest in combining lenalidomide with other novel agents, including the bispecific antibodies, obinutuzumab and novel antibody-drug conjugates. The combination of obinutuzumab and lenalidomide (GALEN regimen) produces durable remissions, with 2-year PFS exceeding 65%.

Table 26.3 Suggested algorithm for management of FL.

- Grade 3b and transformed FL: treat as high-grade lymphoma.
- Early-stage disease confirmed by comprehensive staging (bone marrow aspirate and trephine and FDG-PET scan, if available): 24 Gy involved field radiotherapy; other options should only be considered within clinical trials.
- Advanced-stage asymptomatic low tumour burden disease: active surveillance or short course rituximab monotherapy, with choice depending on patient wishes and goals of treatment.
- Symptomatic advanced-stage disease: six to eight cycles of rituximab or obinutuzumab in combination with six cycles of chemotherapy. Obinutuzumab-chemo prolongs PFS compared to rituximab-chemo. The chemotherapy options are bendamustine, CHOP or CVP; Bendamustine and CHOP, are superior to CVP. Fludarabine-based treatments are no longer recommended.
- Patients who are unable to receive full-dose immunochemotherapy: attenuated chemotherapy with full-dose rituximab/obinutuzumab or rituximab alone.
- Consolidation of first remission with rituximab/obinutuzumab maintenance for 2 years is recommended in most instances, with evidence that this prolongs remissions and time to next treatment, but no evidence that it prolongs survival.
- Relapsing patients should be re-staged and repeat biopsy performed to exclude high-grade transformation. Treatment depends on stage at relapse, prior treatments and duration of previous remission and is dictated by the availability. Options include R-chemotherapy, obinutuzumab-bendamustine, Rituximab-lenalidomide. Tazemetostat and several Pi3 kinases are licensed but availability is variable.
- ASCT is a useful treatment option for patients achieving second or subsequent remissions and should be considered early in the disease course and for high-risk patients.
- Allogeneic haematopoietic stem cell transplantation after reduced-intensity conditioning can be considered in younger patients, with a suitable donor, who have aggressive early relapsed disease, especially after prior ASCT.
- Transformation has an inferior prognosis and optimal treatment is unknown. Options include RCHOP and salvage regimens (e.g. RGDP) with ASCT in patients achieving remission, except in treatment naïve patients presenting with high-grade transformation at first diagnosis.
- Novel therapies are highly promising, and good-quality randomised trials are required to understand how these treatment options should best be used. Patients should be enrolled on a clinical trial wherever possible.

BTK, BCL2 and PD1/PDL1 checkpoint inhibitors, which have broad clinical activity and application across a wide range of lymphomas, have generally yielded disappointing results in FL when delivered as single agents. Some combination strategies are still under investigation, and biological insights are emerging.

With such a large array of promising emerging therapies, it is likely that the treatment landscape for FL will undergo significant transformation in the coming years. The major challenge will be to determine the role and place of novel agents in modern treatment pathways and to develop surrogate endpoints and novel predictive and prognostic biomarkers for personalised approaches and optimal patient selection. Table 26.3 provides a suggested algorithm for management of FL.

Management of transformed FL

Transformation to high-grade lymphoma, most commonly to DLBCL, but occasionally Burkitt lymphoma, occurs at a rate of ~3% per year or 15–28% at 10 years. There is considerable variation in reported rates of transformation, in part due to differences in the definition of transformation (whether histologically confirmed or clinically suspected). The large co-operative ARISTOTLE study, involving 11 groups and 10,000 patients, recently reported a 10-year cumulative incidence of 7.7% for high-grade transformation defined as a biopsy-proven first event after first-line therapy. In this study, the addition of rituximab significantly reduced the risk of transformation; however, prior rituximab treatment had no impact on survival rates after transformation, which was reported to be 32% at 10 years – an improvement compared to historic controls.

High-grade transformation often occurs relatively early in the disease and may be accompanied by B symptoms, high LDH and nodal or extranodal masses growing rapidly and often discordantly from other involved areas.

There is limited evidence to direct optimal therapy for transformed FL. CHOP should be offered to patients who have not previously received anthracyclines, alternatively, platinum-based salvage regimens may be preferred, usually in combination with rituximab for CD20-positive tumours. Radiotherapy consolidation after immunochemotherapy is an option for limited-stage disease. Consolidation with high-dose therapy followed by ASCT is often performed for transplant-eligible patients undergoing high-grade transformation after previous treatment for FL; however, previously untreated patients with transformed FL at the time of initial diagnosis have a good outcome following R-CHOP (analogous to *de novo* DLBCL) and ASCT consolidation in first remission may be avoided in these cases.

Marginal zone lymphomas

Marginal zone lymphomas (MZLs) arise from chronically stimulated immune cells within expanded marginal zones of secondary lymphoid follicles. Pathogenesis is linked to genetic factors, autoimmune conditions and infections leading to chronic antigenic stimulation and inflammation.

MZL accounts for 7–8% of mature B-cell neoplasms. The incidence is increasing over time and rises sharply with age for all subtypes; in the UK, the median age at diagnosis is 72 years and although individual subtypes are rare, MZL may collectively now be more common than FL. There are three genetically, clinically and therapeutically distinct histological subtypes – extranodal lymphomas of mucosa-associated lymphoid tissue (MALT; 61%), nodal MZL (NMZL; 30%) and splenic MZL (SMZL; 9%). All are characterised by the presence of mature B-cells expressing surface immunoglobulin, CD20 and pan-B-cell markers, typically negative for CD5 and CD10, and with variable CD23 expression. Histological subclassification and differential diagnosis from other indolent B-cell lymphomas may be difficult in cases presenting with atypical (usually CD5 positive) histology or disseminated disease involving nodal and extranodal sites, peripheral blood, bone marrow and spleen.

The best staging system for MZL is controversial as neither the Ann Arbor system nor the 2014 Lugano classification is ideal. CT is routinely used for staging and response assessment, in addition to site-specific investigations for MALT lymphomas. The use of FDG-PET in MZL is an open question due to heterogeneity of FDG uptake. Recent data indicate that most MZL lesions are detectable by PET, especially nodal subtypes, and PET may upstage a proportion of patients compared to CT; however, the impact of PET staging on treatment decisions and the prognostic value of PET for treatment response remain investigational. At this time, PET in MZL is generally reserved for cases with suspected high-grade transformation.

First-line systemic therapy for MZL

The management of MZL follows similar general principles to other low-grade B-NHLs, with additional roles for anti-infective therapy and surgery in selected subtypes. Localised disease (stage l and contiguous stage ll) can be treated with potentially curative radiotherapy; advanced-stage asymptomatic disease can be observed, without compromising OS; and symptomatic advanced-stage disease, at initial presentation or relapse after antibiotics or local therapy, is typically treated with rituximab or rituximab-containing immuno-chemotherapy, with novel targeted therapies beginning to emerge. The choice of chemotherapy depends on patient age, fitness and preference. MZL subanalyses of larger randomised trials in indolent B-NHL have largely informed clinical practice as there have been few subtype-specific studies in MZL due to the rarity of individual subtypes.

MALT lymphoma

MALT lymphomas can involve any mucosal site and presentation depends on disease location; B symptoms are rare. Gastric MALT is the most common site (33%), followed by intestine (3–9%), salivary glands (16%), orbit (10–12%) and lung (6–10%). MALT lymphomas often remain localised for many years, but disseminated disease at presentation may occur in 25 and 46% of cases of gastric and non-gastric MALTs, respectively, dictating the need for comprehensive staging. Dissemination can be either to other sites of mucosal tissue or to lymph nodes, bone marrow, spleen or liver. Nodal and bone marrow involvement at presentation confers a worse prognosis. MALT lymphomas typically follow an indolent course, but transformation to high-grade disease occurs in about 10% of cases.

Gastric MALT

The pathogenesis of gastric MALT is strongly linked to chronic inflammation secondary to *H. pylori* infection. It typically presents with non-specific upper gastrointestinal tract symptoms (dyspepsia, epigastric pain and bleeding) or anaemia and is diagnosed at endoscopic biopsy. Endoscopic biopsies should be taken from each region of the stomach and duodenum to provide samples for histopathology, cytogenetics to detect the t(11;18) translocation, and examination for *Helicobacter pylori*, which can be confirmed histologically, by urea breath test or by faecal serological testing.

Early-stage gastric MALT can be successfully controlled by *H.pylori* eradication alone, typically consisting of a proton pump inhibitor in combination with amoxicillin and clarithromycin. The approach is most effective for localised disease and when t(11;18) is not detected. Infiltration beyond the mucosa reduces the success of *H. pylori* eradication, irrespective of t(11;18) translocation status, indicating the need for reliable assessment of gastric wall depth in determining the need for additional systemic therapy. Invasive depth is evaluated histologically or by endoscopic ultrasound.

Although more effective for localised tumours with detectable *H.pylori* infection, significant responses have also been reported in *H.pylori* negative and advanced gastric MALT, possibly due to a false negative test, infection by other Helicobacter species, or when disseminated disease is dependent on *H.pylori* for disease progression. For these reasons, current guidelines recommend *H. pylori* triple eradication therapy as an inexpensive initial treatment for all cases of gastric MALT, irrespective of *H. pylori* status, disease stage or t(11;18) status.

Eradication of *H. pylori* induces complete histological remission in approximately 78% of early-stage gastric MALT lymphomas, with 5-year OS exceeding 95%. The median time to histological remission is 6 months, but can take up to 24 months after eradication, advocating the need for endoscopy surveillance every 3–6 months for up to 2 years to confirm eradication of infection and assess for histological regression. Even when histological CR is achieved, a population of monoclonal B-cells remains detectable by PCR in ~50% of patients, but this alone does not necessitate additional treatment. Similarly, no additional therapy is required for patients with histological evidence of residual disease if they are asymptomatic; they too should be managed with active surveillance endoscopies.

Involved site radiotherapy should be considered for localised disease with persistent *H.pylori* infection or symptoms after eradication therapy, which is more likely in tumours genetically driven by the t(11;18) translocation. 30Gy involved field radiotherapy to the stomach is highly effective for patients with stage I/II disease, providing a 5-year disease-free survival of 93%. Relapses are more frequent for tumours located at sites other than the gastric body. The LY03 trial showed no clinical benefit of adding chlorambucil after *H. pylori* eradication.

Rituximab alone or in combination with chemotherapy (discussed below) should be considered for symptomatic patients with localised or advanced-stage disease if eradication therapy has failed and radiotherapy is not an option.

Non-gastric MALT lymphoma

Non-gastric MALT lymphomas can arise at many sites, often in response to chronic infection, inflammation or autoimmune disease. Ocular adnexal MALT lymphoma is linked to infection with *Chlamydia psittaci*, extrandodal MZL of the skin to *Borrelia burgdorferi*, MALT lymphoma of the thyroid to Hashimoto's thyroiditis and salivary gland MALT lymphoma to Sjogren's syndrome. Disseminated disease is more frequently identified in non-gastric than gastric MALT lymphomas.

The management of non-gastric MALT lymphoma depends on site, stage and presence or absence of symptoms. Anti-infective therapy may be effective. An analysis of 7 studies (4 retrospective) comprising 131 patients, mostly with ocular adnexal lymphoma receiving doxycycline for *Chlamydia psittaci*, reported an ORR of 45% at a median follow-up of 25 months. Best responses were achieved in patients with evidence of infection, although interestingly responses were also reported in cases without detectable *Chlamydia psittaci*. Similar responses to antibiotics have not been observed in MALT lymphoma occurring at other sites.

Radiotherapy is effective in early-stage disease, with 25–35 Gy producing local control and long-term freedom from disease in most cases. A recent retrospective study in 68 patients with early-stage non-gastric MALT, predominantly stage I treated with 24–30 Gy involved field or involved site radiotherapy, reported excellent PFS and OS rates of 79 and 95% at a median follow-up of 5 years. Interestingly, in this study auto-antibodies or autoimmune events were detected in 38% of patients, and 24% of patients were *H.pylori* positive.

Patients with advanced-stage symptomatic disease should be considered for systemic therapy (discussed below); radiotherapy retains a role for the management of localised symptoms.

Splenic marginal zone lymphoma

Splenic marginal zone lymphoma (SMZL) is a rare disorder, comprising less than 2% of lymphoid neoplasms. It typically presents with splenomegaly, moderate lymphocytosis and bone marrow involvement with associated cytopenias. B symptoms are present in one-third of patients. Circulating lymphocytes have characteristic cytoplasmic projections, and are termed villous lymphocytes. Splenic hilar lymph nodes may be infiltrated, but peripheral lymph nodes and extranodal sites are usually spared. A paraprotein, usually IgM, is detectable in up to 25% of cases, and autoimmune phenomena occur in 20% of patients, including autoimmune haemolytic anaemia, ITP and cold agglutinin disease. Diagnosis depends on splenic histology or peripheral blood flow cytometry demonstrating typical cell morphology, with an MZL immunophenotype and intrasinusoidal CD20-positive cells in the bone marrow. Features are not unique and diagnosis often requires exclusion of other B-cell NHLs.

There are no pathognomonic chromosomal aberrations associated with SMZL. Pathogenesis is also linked to deregulated genes involved in splenic marginal zone B-cell differentiation (NF-kB signalling genes *NOTCH2* and *KLF2*), and chronic antigenic stimulation evidenced by a highly restricted Ig gene repertoire. Hepatitis C virus (HCV) infection is associated with up to 36% of SMZL cases in areas such as Japan where HCV is endemic.

SMZL generally follows an indolent course, even when the bone marrow is involved, with a median OS of 11.2 years – however ~30% have an inferior outcome and up to 10% transform to high-grade lymphoma.

The HPLL prognostic score was recently proposed and independently validated for lymphoma-specific survival (LSS) in SMZL, incorporating haemoglobin <95 g/L, platelet count $<80 \times 10^9$/L, elevated LDH, and extrahilar lymphadenopathy. Groups A (no risk factors), B (1–2 risk factors) and C (3–4 risk factors) had a 5-year LSS of 95, 87, and 68%, respectively. POD24 was shown to have an independent association with OS in SMZL in a recent retrospective analysis of SMZL with bone marrow involvement.

Therapy is generally reserved for patients with symptomatic or advanced-stage disease, defined by 2008 Splenic Lymphoma Study Group (SLSG) consensus criteria as the presence of one or more of the following: symptomatic cytopenias, progressive or bulky splenomegaly, rapidly rising lymphocyte count,

B symptoms and/or involvement of nodal or extranodal sites >2 cm. Patients with early/asymptomatic SMZL, characterised by the absence of these features, may be managed with active surveillance, with up to 50% of asymptomatic patients never requiring treatment.

For decades, splenectomy has been the principal treatment for symptomatic patients or those with cytopenias, providing patients are fit for surgery and there is no nodal dissemination beyond the splenic hilum. ORR to splenectomy ranges from 60 to 100%, with a median duration of response (DOR) of 4 years, 5-year PFS 35–61% and median TTNT of 8 years. Splenectomy resolves cytopenias and improves quality of life ~90% of patients but does not impact bone marrow infiltration or lymphocytosis. Splenic irradiation may be an option for patients with poor performance status or as a palliative measure. There may also be a role for interferon-α (IFN), with or without ribavirin, in patients with SMZL and concurrent HCV infection. Such patients may achieve durable partial and occasional complete remissions, and new IFN-free regimens with direct-acting antiviral agents are in development.

Rituximab monotherapy produces similar outcomes to splenectomy and is increasingly used instead of splenectomy and in those unsuitable for this approach due to significant cytopenias. A retrospective evaluation of rituximab induction in 108 patients meeting SLSG criteria produced very high responses (ORR 92%), mostly CR/CRu (CR unconfirmed) (65%), with 10 year FFP and OS rates of 64 and 85%, respectively. A maintenance phase of rituximab for 1–2 years improved 9-year FFP from 42 to 76%, with no impact on survival or PFS advantage for 2 versus 1 year of maintenance.

Rituximab in combination with chemotherapy should be considered for patients with symptomatic progressive disease after splenectomy, rituximab monotherapy or anti-viral therapy (discussed later).

Nodal marginal zone lymphoma

There are no specific guidelines for managing nodal marginal zone lymphoma (NMZL) and recommendations tend to follow those for FL, i.e. in localised disease, radiotherapy is effective and may be curative, in advanced-stage asymptomatic disease, a watch-and-wait approach is acceptable, whilst in symptomatic advanced-stage disease, chemotherapy in combination with rituximab is frequently used.

First-line systemic therapy for symptomatic advanced-stage MZL

Systemic therapy should be considered for symptomatic advanced-stage disease or localised disease that has failed appropriate local therapy or antibiotics. Several trials have demonstrated the value of 'light touch' rituximab or chlorambucil monotherapy and low-intensity immunochemotherapy (R-chlorambucil and RCVP), especially for MALT and SMZL histologies. Table 26.4 summarises the key first-line trials of immunotherapy and immunochemotherapy for advanced stage MZL.

IELSG-19, a randomised trial in gastric and non-gastric MALT lymphomas (including 40% stage l patients who had failed prior local therapy), demonstrated excellent outcomes for monotherapy using rituximab or chlorambucil; ORR 78–85% and median EFS >5 years. Combining these agents improved ORR (to 95%) and EFS (not reached), but 5-year survival was universally excellent (89–92%) with no difference between treatments. In a phase 2 study in advanced MZL, first-line RCVP also produced high ORR and 3-year PFS of 88 and 59% in MALT and NMZL lymphomas.

The benefits of bendamustine over other chemotherapies are less clear in MZL as it is for other low-grade B-NHLs. Two small single-arm phase 2 trials identified promising activity for BR in MALT lymphomas (MALT2008-01, $n = 60$), including patients with localised antibiotic-resistant gastric MALT, and SMZL (IELSG36 BRISMA, $n = 56$). These trials reported very high response rates (90–100%), EFS was 88% at 4 years for MALT lymphomas and PFS was 90% at 3 years for SMZL. It should be noted that over half of patients in the BRISMA trial had low-risk (HPLL Group A) disease, and neither studies were randomised, making it difficult to ascertain if BR is superior to rituximab monotherapy or less intensive immunochemotherapy. Subset analyses of MZL enrolled on the randomised BRIGHT ($n = 46$) and StiL 2003 ($n = 67$) trials in indolent B-NHL reported a trend towards higher response rates for BR compared to RCHOP/RCVP, but there was no difference in PFS for BR versus RCHOP. These results should be interpreted with caution in these small, inadequately powered analyses.

The GALLIUM randomised trial of obinutuzumab versus rituximab in combination with CVP, CHOP or bendamustine (B) demonstrated no advantage for obinutuzumab in a subset analysis of 195 enrolled MZL patients (nodal, 66; extranodal, 61; splenic, 68), most of which (83%) had advanced stage disease. Both antibodies produced high 3-year PFS rates of 75–78%, but obinutuzumab was associated with a higher frequency of high-grade toxicity (82 versus 77%) and fatal adverse events (11.9 versus 6.5%). Obinutuzumab should not be combined with chemotherapy for treatment of MZL.

Fifty-eight percent of MZL patients in the afore-mentioned GALLIUM trial received maintenance therapy; however, the role of maintenance therapy in MZL is an evolving question. A non-randomised phase 2 trial from the CISL group demonstrated a 20% improvement compared to historic controls for 2 years of maintenance after RCVP (3y PFS 81 versus 59%). The randomised MAINTAIN trial demonstrated a superior 2-year PFS for maintenance versus no-maintenance after BR (not reached versus 92 months, $p = 0.008$) at a median follow-up of

Table 26.4 Summary of results of key trials of immunotherapy and immunochemotherapy in the first-line treatment of advanced-stage marginal zone lymphoma.

First author, year of publication (trial)	Treatment, *n*	Subtype, *n*	Median follow-up (months)	ORR, CR (%)	PFS/EFS (%)	OS (%)

76 months. No difference in OS was observed between the groups. Final results of this trial are awaited; however, these early data suggest that maintenance therapy may confer a PFS (but not OS) advantage in MZL patients and could be considered for selected patients.

Management of relapsed MZL

Treatment pathways for relapsed MZL are similar to relapsed FL pathways. Immunochemotherapy has historically been the therapy of choice, resulting in ORR rates of 85–93% and CR rates of 54–78%. Many patients with MZL are elderly or experience excess toxicities with standard approaches, leading to considerable interest in novel approaches. Single-agent rituximab, chlorambucil or R-chlorambucil are options for relapsed MALT lymphomas based on the IELSG-19 trial, which enrolled a minority (8%) of patients with relapsed/refractory MZL; interestingly, their OS was similar to first-line patients. BR is very active in relapsed MALT, achieving ORR rates of 93%, but at a cost of almost 30% grade 3–4 haematological toxicity. Bortezomib is also active, achieving ORR 48%, CR 31%. Patients with relapsed/refractory SMZL (including those who progress after splenectomy or rituximab monotherapy) may have rituximab re-treatment or immunochemotherapy. Patients with relapsed/refractory NMZL follow similar pathways to relapsed/refractory FL.

Bruton's tyrosine kinase (BTK) plays a critical role in the pathogenesis of MZL, and several BTK inhibitors have been developed in relapsed/refractory MZL. A pivotal phase 2 trial of ibrutinib monotherapy led to FDA approval based on an ORR of 48% (although CRs were rare at 2%) and median PFS of 14.2 months, with 38% of patients still on treatment at 19 months. Outcomes were best for SMZL and MALT. In the recently completed MAGNOLIA trial, zanubrutinib (a second-generation BTK inhibitor) demonstrated very promising activity and was granted FDA priority review based on an ORR of 74%, CR 24% and 9 month PFS of 67%. Results were even better in high-risk subsets, including patients aged over 75 years (ORR 89%), refractory to last therapy (ORR 71%) or those with NMZL (ORR 84%). Zanubrutinib also had a favourable safety profile compared to other novel agents

in development and has now received a European and UK license. It is likely to have a key future role in the management of relapsed/refractory MZL.

Lenalidomide in combination with rituximab (R2) is an FDA-approved option for relapsed/refractory MZL based on data from the AUGMENT and MAGNIFY trials. Interestingly, adding lenalidomide to rituximab improved ORR (65 versus 44%) but not PFS compared to rituximab alone in the MZL subset analysis of the AUGMENT trial, attributed to the small size and imbalance in baseline characteristics. R2 does not have approval for relapsed/refractory MZL in the UK and EU.

Other novel agents with emerging activity in MZL include the PI3k inhibitors (although most have now been withdrawn from the market) and axicabtagene ciloleucel; but whilst the latter has demonstrated promising utility, a higher rate of CRS and ICANS was reported for MZL compared to FL suggesting the need for and judicious patient selection when considering these experimental therapies. Similarly, CD3–CD20 bispecific antibodies may be expected to be active in MZL but higher rates of CRS may be anticipated especially in SMZL, based on emerging safety data.

Waldenström macroglobulinaemia

Waldenström macroglobulinaemia (WM) is a clinical syndrome that occurs in patients with clonal proliferation of post-germinal-centre IgM-secreting lymphoplasmacytic cells in the bone marrow or other organs and a detectable IgM paraprotein. Lymphoplasmacytic cells express IgM, CD19 and CD20 and a mutation in the *MYD88* gene – *L265P* – leading to downstream activation of the BTK pathway and activation of NFκB and other pathways in >90% of cases. Mutations in *MYD88* also occur in a small proportion of MZL cases. *CXCR4* is mutated in ~30% of cases. The presence or absence of *MYD88* and *CXCR4* mutations are increasingly used to predict response and choice of therapy.

WM is mainly a disease of the elderly, with a median age at presentation exceeding 70 years, more common in males, and an incidence in the UK of 0.55/100,000 per year. With modern therapeutic approaches, WM has a median survival from diagnosis of over 8 years.

Like other low-grade lymphomas, WM may be asymptomatic at diagnosis but wide-ranging symptoms and clinical manifestations can occur due to bone marrow infiltration, lymphadenopathy and IgM paraproteinaemia. High IgM levels >50 g/L may cause hyperviscosity syndrome, with symptoms including fatigue, headache, blurred vision, mucosal bleeding, impaired cognition or reduced level of consciousness requiring urgent management. Other clinical manifestations include haemostatic abnormalities, polyneuropathies (which may be related to anti-myelin-associated glycoprotein (MAG) antibodies), cryoglobulinaemia, cold agglutinin haemolytic anaemia (CHAD), acquired von Willebrand's disease and, rarely, consequences of light-chain tissue deposition such as amyloidosis. Approximately one-third of patients present with lymphadenopathy, splenomegaly or hepatomegaly. Rarely, there is direct central nervous system (CNS) involvement, termed Bing Neel syndrome (BNS), occurring in ~1% of patients. The clinical manifestations of BNS are varied and can occur at any point in the disease course. It is important to distinguish BNS from the more common peripheral neuropathy seen in patients with WM. There are no established diagnostic criteria for BNS; leptomeningeal enhancement on magnetic resonance imaging (MRI) is common but not essential, and cerebrospinal fluid (CSF) examination typically reveals WM cells with the *MYD88* mutation.

Table 26.5 Risk stratification in Waldenström macroglobulinaemia according to the International Prognostic Scoring system for WM.

Risk group	Number of risk factors	Median survival (months)
Low	0–1 (except age)	143
Intermediate	Age (alone) or any two risk factors	99
High	3–5	44

Risk factors: Age >65 years, haemoglobin ≤115 g/L, platelet count ≤100 × 10^9/L, β2M >3 mg/L, monoclonal IgM >70 g/L.

WM is risk stratified according to the International Prognostic Staging System for WM (IPSSWM), which defines three risk groups based on age, haemoglobin, thrombocytopenia, paraprotein level and β2M (see Table 26.5). Of note, data used to generate this risk score included historically treated patients and median survival may be longer for patients diagnosed today.

Response in WM is based on the International Workshop on WM (IWWM) guidelines and includes assessment of serum paraprotein, bone marrow infiltration, lymphadenopathy/organomegaly (if present at baseline), as well as assessment of lymphoma signs and symptoms. Assessment of bone marrow is particularly important and serum IgM alone should not be used to assess response. Responses can be delayed in WM and the timing of response assessment needs to be carefully considered.

Management of Waldenström macroglobulinaemia

Active surveillance is appropriate for asymptomatic patients, but most patients eventually require treatment. In one study, 59% of patients progressed within 5 years, and 75% eventually required treatment. Indications for treatment defined by the IWWM include constitutional symptoms, symptomatic

lymphadenopathy or splenomegaly, hyperviscosity syndrome, cytopenias due to marrow infiltration and IgM-related syndromes (including CHAD and neuropathy). Anaemia is the most common indication for treatment. Patients presenting with hyperviscosity should be considered for urgent plasmapheresis.

There is a range of treatment options for patients with symptomatic WM, albeit with relatively few randomised controlled trials to guide choice and sequencing. With many new therapies emerging, individual therapy choices depend on patient factors and comorbidities, disease factors (such as symptoms, risk factors and mutational status of *MYD88* and *CXCR4)* and availability of treatments.

Previously, alkylating agents such as chlorambucil were the mainstay of treatment for symptomatic WM, producing remissions in 50–75% of patients. Subsequent studies demonstrated that rituximab monotherapy was effective, achieving responses in up to 60% of previously untreated patients with a median PFS of 14–24 months and a favourable side effect profile compared to alkylator therapy. Rituximab can cause a sudden rise in serum IgM and viscosity in some patients, so-called 'IgM flare', therefore close monitoring for hyperviscosity is recommended and rituximab should be avoided when IgM exceeds 40 g/L.

Later studies demonstrated that combining rituximab with chemotherapy deepens remissions compared to either chemotherapy or rituximab alone. R-fludarabine, RCHOP, R-cyclophosphamide-dexamethasone (DRC) and BR all demonstrated response rates >90% with major response rates >75% and durable remissions. BR achieves a median PFS of 65 months and is often favoured due to its efficacy and favourable toxicity profile. In patients with a high paraprotein concentration, rituximab is deferred until the second or third cycle to mitigate IgM flare; alternatively, pre-emptive plasmapheresis may be used alongside systemic therapy. Response to immunochemotherapy does not seem to be related to *MYD88* or *CXCR4* mutational status.

Evidence from previous retrospective series suggested that maintenance rituximab after immunochemotherapy improves outcomes but a randomised trial of maintenance or observation in patients achieving at least PR to BR found no significant difference in PFS or OS. Accordingly, maintenance rituximab should no longer be considered for these patients.

Proteasome inhibitors such as bortezomib are effective in combination with rituximab, with or without dexamethasone. Treatment-emergent peripheral neuropathy is partially mitigated by administering bortezomib subcutaneously but care should be taken in patients with pre-existing neurological manifestations of WM. Newer proteasome inhibitors, carfilzomib and the orally available ixazomib, have been assessed in combination with rituximab and dexamethasone, demonstrating high activity with different safety profiles.

Several recent non-randomised trials showed that the oral BTK inhibitor, ibrutinib, is highly active in WM leading to EU and FDA licensing for patients with symptomatic disease. In these trials, ibrutinib monotherapy achieved responses in >90% of patients whether used upfront or at relapse, with a major response in >70% of patients, often durable, and 5-year PFS >50% in one trial. Ibrutinib monotherapy is less effective in patients with wild-type *MYD88* and mutated *CXCR4*; immunochemotherapy may be preferred in these patients.

Rituximab plus ibrutinib has also been assessed but not yet directly compared with ibrutinib monotherapy. This combination produces rapid and deep remissions and may also be effective in patients without *MYD88* mutation. Ibrutinib crosses the blood–brain barrier with case reports of efficacy in BNS. Important toxicities of ibrutinib include bleeding, atrial fibrillation, hypertension and respiratory tract infections. Several other BTK inhibitors are in development; these have different side effect profiles and may be more effective, but carefully conducted trials are needed to understand their role in the treatment pathway.

Management of relapsed WM depends on prior therapy, duration of remission and patient fitness. It is reasonable to retreat with the same regimen provided there was a good response previously and if retreatment is funded. An alternative regimen should be considered for patients with short previous remissions (<1 year).

Stem cell transplantation for Waldenström macroglobulinaemia

The role of stem cell transplantation in WM remains unclear with a lack of high-quality evidence to guide its use. Autologous SCT may be considered in second or subsequent relapses in high-risk patients, although it is now generally considered that SCT should not be offered to BTKi-naïve patients. There is evidence to suggest a graft-versus-disease effect in WM and, therefore, allogeneic HSCT may be appropriate in selected younger patients, with a 5-year PFS of 49–56% and OS of 62–64% reported. The 3-year non-relapse mortality was 33% after myeloablative conditioning and 23% after reduced-intensity conditioning in the largest registry series reported to date. The emergence of many new treatment options in WM makes it difficult to define the place of SCT in the contemporary management of WM. IWWM guidelines for managing WM are summarised in Table 26.6.

New approaches in WM

As with other low-grade B-cell NHLs, many new treatment approaches are in development and the treatment landscape is likely to change in coming years. Agents under investigation in WM include the BCL2 inhibitor venetoclax, second and later-generation BTK inhibitors, CXCR4 antagonists, CD3-CD20 bispecific antibodies and CAR-T cell therapy. Carefully conducted, academic clinical trials with international

Table 26.6 Guidelines for management of Waldenström macroglobulinaemia.

The IWWM published updated recommendations for treatment WM in 2020 to incorporate ibrutinib in first-line treatment options. Suggestions for the management of WM, taking into account the 2020 iteration of the IWWM recommendations, are presented below whilst acknowledging that choice of therapy will depend on local availability:

- First-line treatment for symptomatic patients should be BR, bortezomib-rituximab-dexamethasone, cyclophosphamide-dexamethasone-rituximab, or ibrutinib (+/− rituximab). For patients who are $MYD88^{WT}$ or $CXCR4^{mut}$ ibrutinib alone is unlikely to be effective – inrutinib with rituximab or an immunochemotherapy regimen should be considered instead.
- CHOP and purine analogue based treatments are not recommended in most cases.
- Avoid bortezomib in patients with neuropathy
- Avoid carfilzomib in patients with cardiac disease or age >65 years
- Avoid purine analogues in patients who may be stem cell transplant candidates
- Patients with relapsed disease can be treated with an alternative first-line regimen or with the same regimen if previous duration of response was >1 year.
- Autologous SCT may be considered for patients with high risk, refractory or relapsed disease if they have previously had BTKi.
- Allogeneic transplantation should usually only be undertaken in the context of a clinical trial.
- Plasmapheresis should be considered as interim therapy until definitive therapy can be initiated.
- Patients with WM should be enrolled into clinical trials whenever possible.
- Patients should be stratified according to the IPSSWM.
- Response assessment should be according to the IWWM criteria.

collaboration are necessary to understand which of these therapies are most beneficial, how best to sequence them, and to determine the optional duration of treatment.

Mantle cell lymphoma

Mantle cell lymphoma (MCL) comprises approximately 5% of all non-Hodgkin lymphomas (NHLs). It typically occurs in older patients with a median age at diagnosis of 65 years and is more common in males. The natural history and prognosis of MCL are highly variable ranging from truly indolent disease with a long overall survival and no need for urgent therapy to a rapidly progressive illness requiring prompt intervention. Relapses are inevitable with contemporary strategies but, as with the other B-NHLs, the myriad of emerging therapeutic approaches stands to change the treatment paradigm. The median overall survival was historically only 3–5 years (substantially shorter than other low-grade B-NHLs) but with modern approaches median OS exceeding 8 years has been reported for intensively treated patients. Further improvements are anticipated with the advent of targeted treatments.

Most cases of MCL are characterised by the t(11;14)(q13;q32) translocation leading to over-expression of cyclin D1 and cell-cycle dysregulation. In rare cases, cyclin D1 is not expressed. Upregulation of the neural transcription factor SOX11 has been identified in 90% and may be helpful in diagnosing cyclin D1 negative cases.

Presentation with advanced-stage disease including extranodal involvement occurs in >90% of cases, commonly involving the bone marrow and gastrointestinal tract. CNS involvement is rare at presentation but may occur at relapse. MCL is typically FDG-avid and therefore FDG-PET scanning is frequently used for staging and response assessment.

Two distinct subtypes of MCL were defined in the 2016 revised WHO classification of lymphoid malignancies: nodal MCL (80–90%) and non-nodal MCL (10–20%). In nodal MCL, IGH is unmutated, SOX11 is over-expressed and the disease typically behaves aggressively. Blastoid MCL is a variant of nodal MCL with a high proliferation rate and aggressive clinical course. Non-nodal MCL is characterised by a leukaemic presentation with splenomegaly, IGH is mutated and SOX11 absent. Non-nodal MCL typically follows an indolent trajectory.

Prognosis of MCL

Patients with MCL can be stratified into three main prognostic groups according to the MCL International Prognostic Index (MIPI), which incorporates age, performance status, LDH and leucocytosis. Low-risk MIPI patients have a median OS >5 years, whilst OS in intermediate- and high-risk MIPI groups is only 51 and 29 months, respectively. Additional factors affecting prognosis include Ki67 score, β2M and CNS involvement. Ki67 was incorporated into the MIPI score to give a 'biological MIPI' (MIPIb). Despite significant inter-observer variability in Ki67 quantification, a high proliferation index is widely accepted as a poor prognostic factor. *TP53* mutations occur in ~10% of cases at diagnosis and have also recently been identified as a strong predictor of poor outcome in MCL that may be used to direct treatment strategies. Patients with *TP53* mutations often have other high-risk features (high Ki67 and high MIPI). Minimal residual disease (MRD) assessment was also found to be highly predictive of response in several trials and may in

future be used to tailor or adapt therapy, but has not yet been widely adopted in routine clinical practice.

First-line management of MCL

The management of MCL is undergoing rapid change, as increased understanding of disease pathogenesis is leading to molecularly targeted therapies.

Whilst most patients require treatment at presentation, ~25% of patients may initially be observed, with retrospective data showing that this delays initiation of therapy for a median of 12 months. This approach is most often applied for non-nodal MCL (see above), but patients with asymptomatic nodal presentations may also be observed initially.

The choice of first-line treatment depends on patient factors (age, fitness and comorbidities), and assessment of disease features (symptoms, MIPI and *TP53* status). The most important assessment is whether or not the patient is fit for autologous stem cell transplantation (ASCT).

If fit for ASCT, treatment with rituximab in combination with chemotherapy followed by consolidation ASCT is appropriate. For this fit population, there is no agreed international standard of care but incorporation of cytarabine, an anthracycline and rituximab are considered essential.

In the second Nordic Mantle Cell Lymphoma trial (MCL2), 160 patients were treated with dose-intense R-CHOP (R-maxi-CHOP), alternating with cycles of rituximab plus high-dose cytarabine, followed by consolidation ASCT. The CR rate after ASCT was 90% and with a median follow-up of 11 years, median OS and PFS were 12.7 and 8.5 years, respectively. The success of this regimen may be due to the intensive use of cytarabine and *in vivo* purging with rituximab prior to stem cell harvest. Despite never having been assessed in a prospective randomised trial, this approach is still widely followed for patients considered fit for intensive treatment.

A similar approach is six cycles of alternating R-CHOP/DHAP (rituximab plus dexamethasone, high-dose cytarabine and cisplatin) and consolidation ASCT, shown in the randomised 'MCL Younger trial' to be superior to R-CHOP followed by ASCT. The R-CHOP/DHAP and MCL2 (Nordic) approaches have not been compared in a randomised trial and the choice between these two similar regimens is largely determined by centre preference.

Another approach for fit patients is rituximab, hyperfractionated cyclophosphamide, vincristine, doxorubicin and dexamethasone, alternating with high-dose methotrexate and cytarabine (R-Hyper-CVAD). This regimen is used without consolidation ASCT and achieves very high response and survival rates in phase 2 studies, but it is associated with significant toxicities limiting its widespread use.

Although many studies have shown that patients with *TP53* mutations have significantly worse outcomes with intensive upfront treatment approaches there is as yet no internationally agreed approach for treating such patients. Wherever possible such patients should be entered into trials of novel approaches.

Rituximab maintenance every 2 months for 3 years after consolidation ASCT significantly prolongs PFS (4-year PFS 83 versus 64%) and OS (4-year OS 89 versus 80%, HR 0.5) and should be offered as standard of care unless contraindicated.

There are a number of first-line treatment options for patients who are unfit for ASCT, with no established gold standard. The European MCL network trial demonstrated that R-CHOP was superior to R-FC (rituximab, fludarabine and cyclophosphamide), partly due to lower toxicity. The StiL trial demonstrated a PFS advantage for BR over R-CHOP in 94 patients with MCL, with a median PFS of 35 versus 22 months; therefore, BR is often used in this cohort. Adding cytarabine to bendamustine and rituximab (R-BAC) is very effective but relatively intensive in this older population and requires judicious patient selection. If the proteasome inhibitor bortezomib is available, it can be combined with rituximab, cyclophosphamide, doxorubicin and prednisolone in the VR-CAP regimen, which has demonstrated improved OS over R-CHOP albeit maintenance rituximab was not given after induction. Single-agent rituximab has low efficacy in MCL and should only be considered if chemotherapy is contraindicated.

The European MCL network trial for elderly patients included a second randomisation to rituximab or interferon maintenance and reported both a PFS and OS benefit for rituximab maintenance. Rituximab maintenance should therefore be considered in patients who have responded to induction treatment but are unfit for more intensive therapies. Although maintenance has only been assessed after R-CHOP, it is widely applied after varied induction regimens.

Many new therapies for MCL are being assessed and it is likely that firstline treatment options will expand in coming years. For example, ibrutinib in combination with rituximab is being assessed in first-line treatment of MCL in older pts in a UK-NCRI randomised trial against R-bendamustine or R-CHOP.

Relapsed disease and novel treatments

There are no standard treatments for relapsed MCL. Treatment decisions are based on duration of response to prior treatments, disease characteristics e.g. *TP53* status, performance status, drug availability and patient preference. Therapeutic options in relapsed disease are changing, with the introduction of numerous targeted therapies; some of which are now also being investigated in the first-line setting. Wherever possible, patients with relapsed disease should be enrolled in clinical trials.

The BTK inhibitor ibrutinib, now licensed in relapsed or refractory MCL, delivers an ORR of ~65% and median PFS of 12–13 months when used as monotherapy. Median OS is however short at only 25 months and very short for those who progress on treatment, indicating the challenges of relapsed disease. Ibrutinib is more effective when used early in the relapsed pathway with superior PFS and OS in second line compared to later

lines in a large retrospective analysis. Accordingly, for many patients, ibrutinib should be considered at second line. Ibrutinib may be combined with rituximab to deliver potentially superior disease control. Whether used as monotherapy or in combination with rituximab, outcomes are inferior for patients with *TP53* mutation and high Ki67.

Second-generation BTK inhibitors acalabrutinib and zanubrutinib have received FDA approval for relapsed MCL and have a more favourable side effect profile than ibrutinib. Head-to-head comparisons have not been performed to compare efficacy. Other BTK inhibitors in development include pirtobrutinib, a highly selective non-covalent BTK inhibitor with very promising results in early-phase trials. Understanding how to combine these drugs with other active agents in MCL in both relapsed and frontline treatment is a major research area.

If a BTK inhibitor is not available or a patient has progressed after BTKi there are a number of other options to consider. Bortezomib is active as monotherapy or in combination with chemotherapy such as CHOP or R-CHOP in the relapsed setting. Lenalidomide is also effective either as monotherapy or in combination with rituximab delivering response rates of 35–50% and some durable remissions. Lenalidomide in combination with BTK inhibitors and other agents is under investigation. Venetoclax has very high single-agent activity achieving response rates of 75%, including patients who have failed BTK inhibitors.

CAR-T cell therapy with brexucabtagene autoleucel (formerly KTE-X19; Tecartus) was approved in 2021 for relapsed MCL based on results of the ZUMA-2 trial. In this trial of 71 patients very high response rate of 85% (CR 59%) were achieved, with 12-month PFS and OS rates of 61 and 83%, respectively. These impressive results led to approval of Tecartus. Mature follow-up will determine if initial response rates translate into long-term disease control. Other CAR-T cell products are in development and it is hoped that toxicities will be more manageable to allow this treatment to be delivered to older, frailer patients with comorbidities. Efforts to incorporate CAR-T therapies into the MCL treatment pathway should focus on those who have progressed after BTK inhibitors, especially those with adverse risk factors such as *TP53* mutation.

Reduced-intensity allogeneic stem cell transplantation can be considered for young, fit patients with relapsed disease and high-risk features. A retrospective analysis of reduced-intensity allogeneic HSCT for 70 MCL patients reported to BSBMT showed a 5-year relapse risk of 67%, PFS of 14% and OS of 37% with a TRM of over 20% at 1 year.

Given the numerous new treatment options in MCL, it is clear that wherever possible, patients should be enrolled into clinical trials to understand how best to combine and sequence these exciting new treatments to improve outcomes for patients with MCL. Focusing efforts on risk stratification and improving outcomes for those with high-risk disease is a priority.

Introduction

The term aggressive (often termed high-grade) non-Hodgkin lymphoma (NHL) originally referred to one of three categories defined by the International Working Formulation (IWF) classification system introduced in 1981 and included just three histological subtypes: large cell immunoblastic lymphoma, lymphoblastic lymphoma and Burkitt lymphoma. Today a number of clonal heterogeneous pathological entities fall under this broad umbrella term describing lymphomas that are highly proliferative. The term 'aggressive lymphoma' is now preferred to 'high-grade lymphoma' as since 2016, high-grade B-cell lymphoma is a specific entity, distinct from other aggressive lymphomas. Aggressive lymphomas exhibit distinct epidemiology, aetiology, pathogenesis, morphologic, immunophenotypic and clinical features. Paradoxically, despite the aggressive nature of the disease, a significant number of patients can be cured with intensive combination immunochemotherapy regimens. Recently, significant strides have been made in our understanding of the molecular pathogenesis of lymphomas and how this can be potentially translated into novel therapeutic strategies.

Aggressive NHL can also be broadly subcategorised into B-cell and T-cell disorders, depending on the immunophenotype of the malignant clone. This chapter will focus on the pathogenesis, clinical diagnoses and management of aggressive B-cell NHL. Common T-cell lymphomas are covered in Chapter 24.

Epidemiology

Aggressive B-cell NHL represents approximately 45% of all NHL diagnoses with diffuse large B-cell lymphoma (DLBCL) being the most common. The annual incidence rate varies markedly with lymphoma subtype and age, some being more prevalent in children and younger adults whilst others are more common in elderly individuals. The overall incidence of NHL has increased in the Western World over recent decades, rising by 39% in the UK between 1993–1995 and 2015–2017. This rise is in part explained by improved diagnostic techniques but is predominantly driven by increased life expectancy and a significant rise in incidence in older adults. There remains a slight male predominance.

Classification of aggressive B-cell lymphomas

The classification of aggressive B-cell lymphoma is dependent on morphological, immunophenotypic, genetic and molecular features, which form the basis of the World Health Organisation (WHO) classification system (Table 27.1). The most recent version of this classification in 2022 clarified a number of new entities as well as revising existing lymphoma subtypes to reflect increased understanding of pathogenesis and advancement of molecular diagnostics. Precise subtype classification is discussed

Table 27.1 Classification of aggressive, mature B-cell lymphomas in accordance with WHO 2022 classification.

Diffuse large B-cell lymphoma (DLBCL), NOS
Germinal-centre B-cell type
Activated B-cell type
Large B-cell lymphoma with IRF4 rearrangement
T-cell/histiocyte-rich large B-cell lymphoma
Primary cutaneous DLBCL, leg type
EBV+ diffuse large B-cell lymphoma
DLBCL associated with chronic inflammation
Fibrin-associated large B-cell lymphoma
Lymphomatoid granulomatosis
Fluid overload-associated large B-cell lymphoma
Primary mediastinal large B-cell lymphoma
Primary large B-cell lymphoma of immune-privileged sites:
Primary large-B cell lymphoma of the central nervous system (CNS)
Primary large B-cell lymphoma of the vitreo/retina
Primary large B-cell lymphoma of the testis
Intravascular large B-cell lymphoma
ALK+ large B-cell lymphoma
Plasmablastic lymphoma
Primary effusion lymphoma
HHV8+ diffuse large B-cell lymphoma
Burkitt lymphoma
High-grade B-cell lymphoma lymphoma with 11q aberrations
Diffuse large B-cell lymphoma/high-grade B-cell lymphoma, with *MYC* and *BCL2* rearrangements
High-grade B-cell lymphoma, NOS
Mediastinal grey zone lymphoma
Transformations of indolent B-cell lymphomas

in detail in Chapter 20. Although most aggressive B-cell lymphomas fall into well-defined categories, there remain subgroups of patients with intermediate or overlap features that present a diagnostic and therapeutic challenge. Ongoing developments in the molecular basis of these disorders will likely refine the current classification system in the future.

Many of the subtypes share the same principles with regard to diagnosis and management. The bulk of this chapter will focus on the most common subtype, diffuse large B-cell lymphoma not otherwise specified (DLBCL, NOS). There will also be short sections describing other subtypes.

Aetiology

With the exception of a handful of aggressive NHL subtypes, the causative factors that underpin lymphomagenesis are unknown. Certain infectious agents are known to play a role in the pathogenesis of specific high-grade lymphomas such as Epstein–Barr virus (EBV) in Burkitt lymphoma, post-transplant lymphoproliferative disorders and plasmablastic lymphoma or human herpesvirus-8 (HHV8) in primary effusion lymphoma and multicentric Castleman's disease. Immunosuppression as a result of human immunodeficiency virus (HIV) or after allogeneic stem cell or orthotopic transplantation is a well-recognised risk factor. Familial aggregation of high-grade lymphomas has rarely been reported suggesting there is no clear genetic susceptibility. Scant epidemiological studies have implicated occupational exposure to insecticides and pesticides as a risk factor in the development of specific lymphomas. However, the exact impact of these factors and their putative role in contributing to lymphomagenesis has not been clarified.

Diagnosis

The diagnosis of aggressive B-cell NHL is made based on a combination of clinical features, radiological assessment, tissue histology and, more recently, molecular confirmation.

Clinical features

Aggressive B-cell NHLs present in a variety of ways. Localised or widespread painless lymphadenopathy is often evident and may be accompanied by B symptoms (unexplained fever of 38 °C or higher, drenching night sweats and loss of more than 10% of body weight in 6 months). Given the rate of tumour proliferation, patients can present with compression symptoms and/or organ dysfunction due to rapidly enlarging lymphadenopathy or extra-nodal masses. Superior vena cava syndrome caused by a bulky mediastinal mass is also more frequent in certain subtypes of NHL such as primary mediastinal B-cell lymphoma. Neurological presentation due to CNS infiltration is typically seen with Primary CNS lymphoma (PCNSL) but rare in systemic lymphomas, although not an uncommon feature of Burkitt lymphoma. Unlike indolent NHL, bone marrow involvement is less common, occurring in less than 20% of cases and has been associated with poorer outcomes. Patients can present with symptoms secondary to deranged haematological or biochemical parameters such as anaemia and hypercalcaemia.

Laboratory investigations

Histological diagnosis from either excision or core biopsy of a lymph node, bone marrow or extranodal mass is essential. Core biopsies are increasingly used in routine clinical practice due to improved radiologically guided sampling techniques and low procedural complications, but excision is sometimes required to obtain larger tissue sections in complex cases. Fine-needle aspiration (FNA) is rarely performed now and can lead to a delay in

diagnosis due to the inadequate tissue obtained, except in suspected cases of Burkitt lymphoma, when a diagnosis can be made on the morphology and immunophenotype, and therapy can be urgent. Immunohistochemistry is routinely performed on tissue sections of lymph nodes and, increasingly, cytogenetic immunoglobulin rearrangement and gene mutation testing.

Anaemia at diagnosis is usually indicative of widespread disease and may reflect a non-specific manifestation of malignancy. However, it can also be due to hypersplenism or bone marrow infiltration. The white count is variable. Overspill of lymphoma cells into the blood can occur in aggressive lymphoma, representing the so-called 'leukaemic phase' but this is infrequent and usually seen in later stages of disease. Hypoalbuminaemia is another feature associated with a systemic disturbance and is indicative of a poor prognosis. A raised level of lactate dehydrogenase (LDH) is usually associated with advanced disease and was identified as an independent prognostic factor in 1993 (within the International Prognostic Index) and remains so today (Table 27.2).

Table 27.2 Clinical prognostic scoring systems in patients with DLBCL.

Prognostic Index and Risk groups	Proportion of patients (%)	5-year overall survival (%)
IPI		
Low (0–1)	34	88
Low-intermediate (2)	23	76
High-intermediate (3)	23	67
High (4–5)	20	54
R-IPI		
Very good (0)	9	93
Good (1–2)	48	81
Poor (3–5)	43	61
Age-adjusted IPI (patients ≤60 years)		
Low (0)	22	83
Low-intermediate (1)	32	69
High-intermediate (2)	32	46
High (3)	14	32
NCCN-IPI		
Low (0–1)	13	92
Low-intermediate (2–3)	41	84
High-intermediate (4–5)	36	63
High (6–8)	10	49

Factors in IPI and R-IPI: Age >60 years, LDH > upper limit normal (ULN), Stage III or IV, ECOG performance status >1, no. of extranodal sites >1.
Factors in age-adjusted IPI: Stage III or IV, LDH > ULN, ECOG performance status >1.
Factors in NCCN-IPI: Age: >40 to ≤60 (1 point), >60 to ≤75 (2 points), >75 (3 points). LDH radio: >1 to ≤3 (1 point), >3 (2 points). Stage III or IV (1 point). ECOG performance status >1 (1 point). Extranodal disease: bone marrow, CNS, liver or GI tract, lung (1 point).

Staging

The Ann Arbor staging system, initially developed for Hodgkin lymphoma, is used in adults with B-cell NHL (see Chapter 25). Historically a staging bone marrow biopsy (BMB) was performed at baseline. The presence of high-grade disease in the bone marrow is prognostically important, and may direct the need for CNS prophylaxis or identify concomitant low-grade disease. However, most guidelines now suggest BMB can be omitted where baseline PET imaging has been performed. Radiography with computerised tomography (CT), magnetic resonance imaging (MRI) or PET scanning are used for initial staging of the disease and are of value in monitoring response to therapy and detection of residual disease or relapse. As treatment may differ for patients with stage I disease and more advanced stages, especially in the context of DLBCL, a PET scan at diagnosis can have significant therapeutic implications. At the end of therapy, PET has been incorporated into the revised response criteria.

Cerebrospinal fluid (CSF) examination including cytological assessment by cytospin and immunophenotyping should be considered if there are clinical signs of CNS disease, if there are radiological features suggesting CNS invasion or in cases exhibiting features associated with very high risk of CNS relapse.

Treatment

Treatment of aggressive B-cell NHL is mainly based on the histological findings, although therapeutic decisions are influenced by the patient's age, co-morbidities, performance status and disease extension. There are also a number of subtypes with distinct clinical and pathological features and therapeutic strategies that will be discussed separately. Often these lymphoma subtypes are potentially curable and thus access to timely sophisticated diagnostic services and expert clinical opinion is necessary to ensure accurate diagnosis and tailored therapy.

Particular considerations prior to therapy

A formal assessment of cardiac function is recommended for older patients and those with risk factors for cardiovascular disease prior to anthracycline therapy. Accurate analysis of renal function should be considered before the administration of high-dose methotrexate, platinum-containing regimens and high doses of other renally-excreted agents. Serology for HIV and hepatitis B (HBsAg, HBcAb and HBsAb) and hepatitis C should be performed in all patients as appropriate concomitant antiviral therapy may be indicated during and after therapy and can improve outcome and reduce morbidity of therapy.

Diffuse large B-cell lymphoma

The updated WHO classification from 2022 (Table 27.1) continues to recognise large B-cell lymphoma, not otherwise specified (DLBCL, NOS) as an entity in its own right. However, the principles of diagnosis, prognostication and management of DLBCL apply to several other subtypes including high-grade B-cell lymphoma (HGBL), and as a result, DLBCL is often used as an umbrella term for all related entities.

DLBCL is by far the most common NHL, representing approximately 30% of all newly diagnosed NHL and 85% of all aggressive B-cell lymphomas. According to the latest Haematological Malignancy Research Network's registry data, the overall annual incidence for DLBCL in the UK is 8.2 per 100,000 with a median age at diagnosis of 69.7 years and slight male predominance (1.2:1). Although DLBCL is potentially curable, it remains a challenging lymphoma to manage because of the biological and clinical heterogeneity of the disease and the poor outcomes in patients not responding to first-line treatment.

Aetiology

The majority of DLBCL cases have no underlying causative factor and arise *de novo*. However, a small proportion occurs as a result of transformation from a previously indolent disorder such as follicular lymphoma, marginal zone lymphoma or chronic lymphocytic leukaemia. Indeed, transformations of indolent B-cell lymphoma are now a separate entity within the WHO 2022 update. A small proportion of cases are associated with risk factors occurring in the setting of an underlying immunocompromised state including concomitant infections with EBV and HIV, post-solid organ transplantation and in elderly patients.

Pathogenesis and molecular basis of DLBCL

DLBCL is a clonal neoplasm of large B-lymphoid cells with a diffuse growth pattern. There is a growing appreciation of the marked biological heterogeneity of DLBCL, NOS through advances in technology leading to continued evolution of the classification of this disorder.

Cell-of-origin based typing

Pivotal gene expression profiling (GEP) studies in the early 2000s provided the first biological-based cell-of-origin (COO) classification reflecting the different stages of B-cell development from which the malignant B-cells arose. This approach identified two distinct binary groups: germinal-centre B-cell (GCB-DLBCL) and post-germinal centre-activated B-cell (ABC-DLBCL). Notably, about 10–15% of DLBCLs fell into an 'unclassified' COO subtype. The derivation of each subtype from differing COO explained their distinctive molecular features, clinical characteristics and prognostic information and thus the 2016 revision of the WHO classification recognised these two COO-based subtypes of DLBCL.

The GCB-DLBCL subtype expresses genes reminiscent of normal germinal-centre B-cells such as CD10 and LMO2. They are characterised by high expression of the transcriptional repressor gene, *BCL6*, which can also be translocated or mutated in DLBCL and exhibit highly mutated immunoglobulin genes with ongoing somatic hypermutation (SHM), further evidence that supports its germinal-centre origin. In contrast, ABC-DLBCL corresponds to post-GC B-cells characteristically expressing several genes that are normally upregulated in plasma cells but are blocked from terminal differentiation into plasma cells by additional genetic alterations that interfere with Blimp1, the master regulator of plasmacytic differentiation.

Genetically, ABC and GCB-DLBCLs are driven by their dependence on different oncogenic pathways. Chronic B-cell receptor (BCR) signalling and constitutive NF-κB activation are pathogenic hallmarks of ABC-DLBCLs, mediated through distinct genetic alterations in components of the *BCR* (*CD79A* and *CD79B*), *CARD11*, *MYD88* and *TNFAIP3*. On the other hand, GCB-DLBCLs primarily harbour genetic alterations in chromatin-modifying enzymes (*EZH2*, *CREBBP* and *KMT2D*). Additionally, approximately 40% of GCB-DLBCLs have a t(14;18) *BCL2* translocation that leads to constitutive overexpression of *BCL2* and over 50% of GCB-DLBCLs harbour *BCL2* mutations.

Importantly, COO-based stratification of DLBCL patients showed clinical prognostic relevance, with GCB-DLBCL demonstrating more favourable responses and overall survival (OS) rates compared with ABC-DLBCL, independent of the IPI, following treatment in the pre-rituximab era. Moreover, even in the setting of combination immunochemotherapy, the worse outcome for ABC-DLBCL was not abrogated (3-year progression-free survival (PFS): 74% GCB; 40% ABC; 3-year OS: approximately 80% GCB; 45% ABC, $P < 0.001$). These significant differences in outcomes inspired a number of clinical studies attempting to tailor treatment in accordance with the COO subtype, with particular emphasis to improve ABC-DLBCLs (see section *Treatment: First-line – advanced-stage disease*).

Molecular-based typing

The dawn of higher-resolution genomic technologies has brought about a more in-depth understanding of the underpinning molecular heterogeneity in DLBCL-NOS. Unlike the COO derived from GEP, these recent studies utilise broad genomic approaches including exome, targeted gene sequencing and copy number analyses to identify subtypes based on genetic alterations. With nearly 2000 primary DLBCL cases across three recent studies, a molecular classification-based approach was developed using the genetic attributes together with iterative

statistical modelling to identify subtypes based on the enrichment of driver mutations and specific biological pathways. Although, in each of these studies, the molecular classifiers were developed using different technologies, approaches and statistical methods and each with its own independent nomenclature, there was broad consensus across the studies lending weight to the robustness and validity of the molecular subtypes identified. Between five and seven molecular subtypes were described in each of these studies. The key molecular groups consistent across the three studies include:

1 MCD subtype (equivalent to C5 and MYD88 subtypes in the parallel studies): Characterised by mutations in *MYD88* L265P and *CD79B* leading to NF-κB activation and chronic BCR signalling and immune editing through mutations in *HLA A-C* genes. The majority of this subtype are ABC-DLBCL cases and frequently have extra-nodal site involvement including the testes, breast and CNS. Notably, PCNSL and primary testicular lymphomas have overlapping genetic profiles with this subtype.
2 EZB subtype (equivalent to C3 and BCL2): The majority of which are GCB-DLBCL cases characterised by *BCL2* translocations, frequent mutations in histone modifiers such as *CREBBP*, *EZH2* and *KMT2D*. Follicular and transformed follicular lymphoma share many genetic features with this subtype. A recent gene expression-based signature, molecular high grade (MHG) or double hit (DHITsig), that identifies a poor prognostic group of GCB-DLBCLs, is a subset within the EZB group, the majority of which expectedly harbour *MYC* aberrations.
3 BN2 subtype (equivalent to C1 and *NOTCH2*): Characterised by *BCL6* translocations and activating *NOTCH2* mutations. This subtype consists of DLBCLs that are mostly ABC-DLBCL or unclassified DLBCL. The genetic profile shares similarities to marginal zone lymphomas.
4 ST2 subtype (closely related to C4; *TET2/SGK1* and *SOCS1/SGK1*): Frequent truncating mutations in *SGK1* and *TET2* comprising predominantly of GCB-DLBCLs.

Additional groups identified but not aligned across the studies perhaps due to differences in methodology include:

- A53 subtype (equivalent to C2) comprised both ABC- and GCB-DLBCL cases and typified by widespread genomic instability including *TP53* mutations and multiple copy number alterations.
- N1 subtype was identified in only one study and is the rarest subtype occurring in less than 2% of DLBCLs, characterised by *NOTCH1* mutations and predominantly ABC-DLBCLs.

These genetic subtypes are linked to distinct clinical outcomes following R-CHOP therapy. The worst outcomes occur in the N1 (5-year OS 22%), EZB-MYC+ subset and *MCD/C5/MYD88* (approximate 5 years OS 40%) groups. Intermediate outcomes are seen in the BN2/C1/NOTCH2 and A53 groups (approx. 5 years OS 50%) whereas the most favourable outcomes are in patients within the ST2 and EZB-MYC- groups (approx. 5 years OS 60–65%). Altogether, these studies suggest a step-change beyond the existing binary COO framework to a modern molecular taxonomy classification system in DLBCL (Figure 27.1) with the potential for improved risk stratification and patient selection for novel therapies that can target distinct biological dependencies and vulnerabilities.

Role of the microenvironment in DLBCL

Less attention has been paid to the microenvironment in DLBCL although there is increasing evidence that a lymphoma-promoting niche and immune-modulation are relevant. Escape from immune surveillance is a common feature in DLBCL through loss of MHC class I and class II molecules; some of this is driven via genetic mechanisms including recurrent alterations in *EZH2*, *CREBBP* and *B2M*. Another immune escape mechanism is increased expression of PDL1/PDL2 on malignant cells occurring in a subset of DLBCLs. This might identify a cohort of patients that may respond to anti-PD1 therapy. More recently, transcriptomic analyses of the microenvironment of 4655 DLBCLs suggest that DLBCLs can be categorised into four major microenvironment groups each associated with characteristic biological features and clinical behaviour. This together with the molecular subtypes may facilitate alternative therapeutic approaches beyond the conventional R-CHOP.

Clinical prognostic factors

Despite advances in the treatment of DLBCL, the outcome of patients with DLBCL remains variable. Although potentially curable, about 40% of patients will die with relapsed or refractory disease. There is therefore a pressing need to identify patients for whom standard treatment measures are inadequate so that alternate therapeutic strategies can be employed. Clinical prognostic features remain surrogates for the underlying biological differences in patients; however, they continue to be the most widely used methods for delineating risk groups in clinical practice.

Table 27.2 summarises the most frequently used prognostic scoring systems in DLBCL. The International Prognostic Index (IPI) was devised in 1993 and remains the most widely used prognostic tool. It incorporates five clinical parameters determined at diagnosis, resulting in four risk groups with predicted 5-years OS ranging from 26 to 73%. An age-adjusted IPI was also defined for patients <60 years old and a revised IPI (R-IPI) outlined in the rituximab era with 3 risk groups identified. More recently, clinical data from the National Comprehensive Cancer Network (NCCN) database has allowed an 'enhanced IPI' tool to be devised. This tool accounted for the continuous nature of specific variables such as LDH as well as the specific prognostic impact of particular extra-nodal sites. Four risk groups were developed and compared favourably with the IPI, with the NCCN-IPI being better at discriminating low- and high-risk

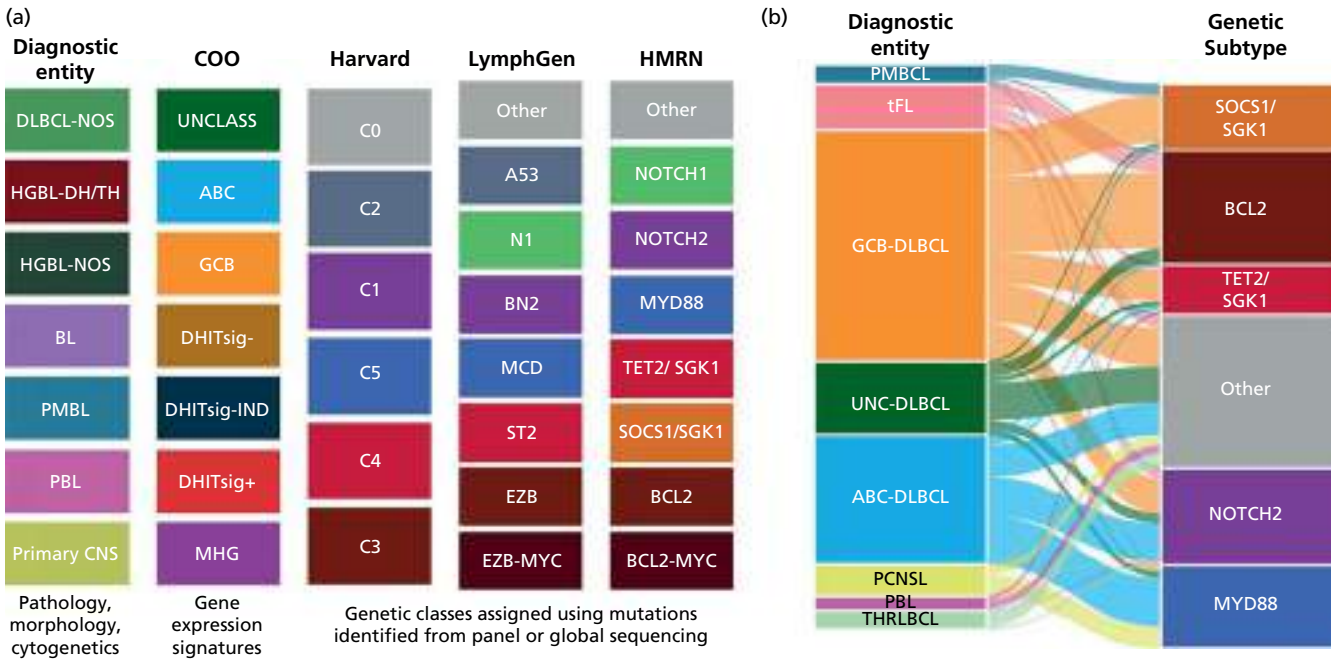

Figure 27.1 Evolution of the molecular classification DLBCL and related lymphoma entities. (a) Column 1 shows diagnostic entities closely related to DLBCL. Column 2 represents the subtypes defined by GEP. Columns 3–5 demonstrate the three recent studies (Harvard, LymphGen and HMRN) that have led to the molecular subtypes of DLBCL; (b) As an example, the HMRN classification is used to illustrate how the molecular subtypes relate to the diagnostic entities. (Source: Morin RD, Arthur SE, Hodson DJ (2021) Molecular profiling in diffuse large B-cell lymphoma: why so many types of subtypes? *B. J. Haem*., Open Access, https://doi.org/10.1111/bjh.17811/ British Society for Haematology and John Wiley & Sons Ltd/CC BY 4.0.).

subgroups compared to the IPI. Despite the validity of the various IPI risk models, they remain limited in their ability to predict which patients will follow a very aggressive course.

Treatment: first-line – limited-stage disease

Definitions of limited-stage disease vary, but it is commonly described as stage I or II disease that is anatomically localised, non-bulky (largest mass <7.5–10 cm) and without associated 'B' symptoms. Twenty-five to thirty percent of DLBCL present with limited-stage disease, and whilst the prognosis is excellent with modern therapy, a pattern of delayed relapse has been recognised.

Prior to the development of effective combination chemotherapy, radiotherapy was often employed as a single-modality treatment with some durable remissions. However, a significantly improved disease-free survival (DFS) and OS in limited-stage DLBCL patients who received combined modality treatment with brief chemotherapy course (three cycles of R-CHOP) followed by consolidative radiotherapy has been reported in a prospective randomised trial. The 5-year OS and PFS for stage I and II disease treated with R-CHOP and consolidative radiotherapy were 92 and 82%, respectively; whereas without radiotherapy, OS and PFS were 73% ($P = 0.0007$) and 68% ($P = 0.0003$), respectively. Until recently, abbreviated immunotherapy (three-to-four cycles of R-CHOP) followed by involved field radiotherapy (IFRT) has been widely accepted as the preferable approach for all early-stage DLBCL with non-bulky disease, especially at sites of presenting disease where radiation is well tolerated with lower risks of late toxicities. An alternative approach is following a full course of immunochemotherapy (six cycles of R-CHOP), omitting radiotherapy if the site of disease carries a risk of significant toxicity.

Recent trials have focussed on trying to minimise toxicity by identifying a subgroup of low-risk patients where abbreviated chemotherapy alone may be sufficient. The FLYER trial, published in 2019, showed that four cycles of R-CHOP plus two additional doses of rituximab was non-inferior to six cycles of R-CHOP in young patients with limited-stage, non-bulky DLBCL and age-adjusted IPI of 0. There was no OS difference between the groups and adverse events were reduced in the four-cycle group. Whether the two additional doses of rituximab confer any benefit is unclear, and it is crucial that this approach is restricted to patients meeting the strict criteria employed in the FLYER trial. Further trials are ongoing investigating whether using a PET-adapted approach can refine this approach further, with some initial results suggesting that early

PET response (after two cycles) can identify patients who benefit from abbreviated chemotherapy.

Primary extranodal DLBCLs have traditionally been included in many of the large studies focussing on early-stage disease; however, involvement with certain organs with DLBCL has distinct therapeutic implications when occurring as primary sites of disease.

Testicular

Testicular involvement by DLBCL is associated with a worse clinical outcome than many other subtypes of DLBCL, in particular with a high risk of CNS relapse. Management of this DLBCL subtype is often based on the protocol used in the phase II IELSG10 study which involved 6(-8) cycles of R-CHOP-21, four doses of intrathecal methotrexate and radiotherapy to the contralateral testis for all patients and to regional lymph nodes for stage II disease. Outcomes in the 53 patients enrolled were better than historical controls, with 5-year PFS and OS of 74 and 85% respectively, and cumulative incidence of CNS relapse of 6%.

On the basis of these results, and an increased recognition of the role of intravenous (IV) methotrexate in CNS prophylaxis, the subsequent IELSG30 trial had the same chemotherapy/radiotherapy protocol but incorporated two courses of IV methotrexate ($1.5\,g/m^2$) at the end of R-CHOP chemotherapy (in addition to four doses of intrathecal liposomal cytarabine). Recently presented data from this study (n = 54) reported no CNS relapses during the median 6 years of follow-up although late extranodal relapses were observed. A PFS of 88% at median follow-up of 5 years was reported.

Breast

DLBCL is the most common subtype of primary breast lymphoma. Data to inform treatment of breast DLBCL is largely retrospective, but several studies have reported high rates of relapse both in the ipsilateral or contralateral breast and in the CNS. As a result, CNS prophylaxis is often recommended as well as radiotherapy due to the local relapse risk. Six cycles of immunochemotherapy are usually delivered, with one retrospective study from the pre-rituximab era showing benefit for patients receiving more than three cycles.

Gastric

Patients with gastric DLBCL are generally treated with a similar approach to other sites of localised disease, either with six cycles of R-CHOP alone or three cycles of R-CHOP followed by radiotherapy. Surgery is generally avoided unless required for complications such as perforation, obstruction or bleeding. Some small studies have reported induction of remission with eradication of *Helicobacter pylori* (HP) alone in gastric DLBCL, both in cases with and without evidence of underling mucosa-associated lymphoid tissue (MALT) lymphoma. If this approach is followed, close monitoring for treatment failure is critical, with early institution of chemotherapy/radiotherapy if remission is not achieved.

Bone

Although bone involvement is seen reasonably frequently in advanced-stage DLBCL, lymphoma affecting bone as the only site of disease is relatively rare. Optimal therapy for primary bone DLBCL is not well-defined, guided mainly by retrospective studies either before or after the introduction of rituximab. The use of radiotherapy is controversial, with disagreement between studies regarding its potential benefit. Three cycles of R-CHOP with radiotherapy (in truly localised disease) or six cycles of R-CHOP with or without radiotherapy are the most frequently employed strategies for this entity.

Treatment: first-line – Advanced-stage disease

Patients with more advanced stages of disease (Stage 2B to Stage 4) should receive combination immunochemotherapy. Several studies have shown the benefit of adding Rituximab to chemotherapy making R-CHOP or R-CHOP-like regimens the gold standard in advanced-stage DLBCL. In recent years, several large phase III trials have attempted to improve on outcomes with R-CHOP, with a summary of selected key completed clinical trials in first-line DLBCL outlined in Table 27.3. Broadly speaking, these attempts have involved either intensification of immunochemotherapy, use of consolidative autologous stem cell transplant (ASCT) or, more recently, addition of a novel agent 'backbone' to (R)-CHOP. The positive trials will be discussed below. Approaches which have failed to show a benefit include intensification of R-CHOP given every 21 days to that given every 14 days; use of the infusional and dose-adjusted DA-EPOCH-R regimen (see Table 27.4); replacement of rituximab with obinutuzumab; addition of ibrutinib to R-CHOP in non-GC subtype of DLBCL; maintenance rituximab following R-CHOP; consolidative autologous stem cell transplant following R-CHOP and incorportation of lenalidomide maintenance in older patients with DLCBL following R-CHOP induction.

Intensified chemotherapy approaches

The only regimen to date conferring an overall survival benefit over R-CHOP in a randomised study has been dose-intensive R-ACVBP (see Table 27.4) followed by sequential consolidation (rituximab, ifosfamide, etoposide and cytarabine). The LNH03-2B trial, published in 2011, demonstrated significantly improved survival with this regimen in patients aged <60 years with low-intermediate risk compared to standard R-CHOP (3 years PFS 87 versus 73%, HR 0.48, p = 0.0015; 3 years OS 92 versus 84%, p = 0.0071). However, significant toxicities, in particular haematological, have limited its application in the real-world setting, especially in older patients.

Table 27.3 Selected key phase III trials in first-line DLBCL.

Study	Regimen	No. of patients	Criteria	Age	Outcome
MInT	**A.** R-CHOP-like x6 Versus **B.** CHOP-like x6	824	aaIPI: 0 or 1	18–60 years	3 years EFS: 79% (A) versus 59% (B)* 3 years OS: 93% (A) versus 84% (B)*

Table 27.4 Chemotherapy protocols used in high-grade NHL.

ACVBP	Doxorubicin, cyclophosphamide, vindesine, bleomycin, prednisolone
BEAM/ mini-BEAM	BCNU, etoposide, cytarabine, melphalan
CHOP	Cyclophosphamide, doxorubicin, vincristine, prednisolone
CODOX–M/ IVAC	Cyclophosphamide, doxorubicin, high-dose methotrexate/ifosfamide, etoposide and high-dose cytarabine
DHAP	Dexamethasone, high-dose cytarabine and cisplatin
DVIP	Dexamethasone, etoposide, ifosfamide and cisplatin
EPOCH/ DA-EPOCH	Etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin
ESHAP	Etoposide, cytarabine, methylprednisolone, cisplatin
GCVP	Gemcitabine, cyclophosphamide, vincristine, prednisolone
GemOx	Gemcitabine, oxaliplatin
Hyper CVAD	Hyperfractionated cyclophosphamide, vincristine, doxorubicin and dexamethasone
ICE	Ifosfamide, carboplatin, and etoposide

Based on results from the MiNT study, conducted prior to the use of PET scans in response assessment, R-CHOP with the addition of radiotherapy to sites of primary bulky disease was previously recommended for young patients with low or intermediate risk IPI. In recent years, the value of consolidative radiotherapy has been questioned, with large retrospective datasets and sub-analyses from prospective trials demonstrating patients with a complete metabolic response (CMR) on post-treatment PET have favourable outcomes without the use of radiation therapy.

For patients with a high-risk IPI score of 3–5 for which the PFS of <50% at 3 years following R-CHOP is unsatisfactory, there remains no consensus on the appropriate treatment strategy. In the UK, a single arm National Cancer Research Institute (NCRI) phase II study explored the feasibility of using the intensified R-CODOX-M/R-IVAC regimen (see Table 27.4) in patients <65 years with high risk DLBCL (IPI 3–5). Outcomes in this high-risk cohort (9% CNS involvement and 53% performance status (PS) ≥2) were promising with 3-year PFS and OS 68.4 and 76.2% respectively. However, toxicity was significant with treatment-related mortality (TRM) of 4.3%, highest in patients >50 years and PS≥2. These results require confirmation in a randomised study before its use can be adopted widely; however, it remains an option for selected high-risk patients deemed fit enough for such an intensive approach.

Addition of novel agents

An increased understanding of the molecular heterogeneity of DLBCL has provided the basis for pre-clinical studies identifying subtypes which may benefit from the addition of targeted novel agents. Several phase 3 trials have now been performed using the 'R-CHOP + *X* versus R-CHOP' design (see Table 27.3). The first of these trials, reported in 2019, investigated the addition of Bortezomib, a proteasome inhibitor which causes inhibition of the NF-κB pathway and has activity thought to potentially benefit patients with ABC subtype DLBCL. GEP at diagnosis was used to classify COO, and this information was combined with IPI classification to allow stratified randomisation between R-CHOP alone and R-CHOP + Bortezomib from cycle 2 onwards. The initial report did not suggest a survival improvement although on longer follow-up this was seen for

patients with the activated B-cell subtype and so-called molecular high-grade group. The lack of availability and standardisation of GEP has limited use of this approach.

The phase III POLARIX trial has recently demonstrated superior PFS with substitution of vincristine with the antibody-drug conjugate Polatuzumab vedotin (pola-R-CHP) for patients with intermediate- or high-risk DLBCL. Patients in the pola-R-CHP arm had 2 year PFS of 76.7% compared to 70.2% in the R-CHOP arm, with fewer patients (22.5 versus 30.3%) requiring subsequent anti-lymphoma therapy. However, there was no OS difference between the two arms (2 year OS 88.7 versus 88.6%), possibly reflecting the efficacy of novel therapies in the second-line setting and beyond such as CAR T-cells. There was no stratification based on COO or molecular subtyping, although interestingly post-hoc subgroup analyses suggested a possible benefit for patients with ABC-subtype DLBCL. The biological rationale for this is unclear. As a result of these findings, Pola-R-CHP has been approved in the USA and Europe, however the additional cost of Polatuzumab vedotin and the lack of OS benefit seen may hinder its widespread application.

Special considerations – DLBCL in the elderly

Approximately 50% of DLBCL diagnoses occur in patients older than 60 years with this number expected to rise alongside the increasing age of the population. Patients older than 60 years represent a heterogeneous population with varying levels of general health, co-existing co-morbidities and an increased susceptibility to treatment toxicities. A comprehensive geriatric assessment is increasingly performed prior to treatment decisions to ensure all these factors are considered. With key randomised trials in DLBCL frequently excluding patients >80 years, this patient group can be very challenging to manage with no firmly established standard of care.

Results of the GELA study (LNH98-5) demonstrated that the addition of rituximab to CHOP-21 improves PFS and OS in patients aged 60–80 years. As a result, R-CHOP-21 remains the standard therapy for fit patients under the age of 80 without cardiac dysfunction, whilst omission of anthracycline is commonly considered in those that have proven cardiac dysfunction. For this latter cohort of older patients with cardiac co-morbidities, a phase II study has demonstrated efficacy using a regimen where anthracycline is substituted with gemcitabine, R-GCVP, with an ORR of 61% and 2-year PFS and OS of 49.8 and 55.8% respectively. Alternative options in this setting include substituting doxorubicin with etoposide (R-CEOP) or rituximab, gemcitabine and oxaliplatin (R-GemOx).

For patients older than 80 years without significant cardiac dysfunction, a phase II trial from the LYSA group demonstrated that dose reduction of R-CHOP – so-called R-miniCHOP – is deliverable for very elderly patients with 4-year DFS of 57.9% and a clear plateau in survival curves. Of note, the TRM rate was 8%, highlighting the need for judicious supportive care and attention to dose-reductions in this group. Subsequent trials have investigated the use of pre-phase therapy with vincristine and prednisolone, with results demonstrating a significant improvement in performance status prior to definitive chemotherapy, and reduction in toxicity including neutropenia and neutropenic fever. Routine G-CSF prophylaxis is often recommended for all patients over 65 years old in a further attempt to reduce risk of infective toxicity.

A systematic review of 13 retrospective studies and 5188 patients published in 2021 demonstrated that higher R-CHOP dose intensity was associated with improved survival in those aged <80 years, but subgroup analyses of patients aged ≥80 years showed that survival was not affected by reduced dose intensity. Acknowledging the limitation of mainly retrospective studies informing this analysis, it supports the broadly accepted approach of attempting full dose R-CHOP in those aged <80 years and reserving R-miniCHOP for those aged ≥80 years or with significant co-morbidity.

CNS prophylaxis

Systemic disease progression is the primary cause of treatment failure in DLBCL; however, relapse within the CNS occurs in approximately 5% of patients. The outcome of those who develop CNS relapse is extremely poor, with a median survival of less than 6 months. However, prophylactic treatment aimed at preventing this devastating outcome remains a very controversial area with little robust evidence to guide practice.

The definition of 'high-risk' for CNS relapse has been modified over the years, with the most widely adopted model for patient selection being the 'CNS-IPI', developed by the German High-Grade Lymphoma Study Group. Univariable and multivariable analyses of a training cohort of 2164 patients from prospective trials were performed with validation in a large registry cohort, resulting in a model consisting of the established IPI factors plus involvement of kidney and/or adrenal glands (see Table 27.5). Patients with a high CNS-IPI score (four to six points) are frequently offered CNS prophylaxis, but this remains an imperfect approach given that ~90% of patients in this group will receive prophylaxis unnecessarily.

Other risk factors warranting consideration for CNS prophylaxis, independent of the CNS-IPI, are the presence of three or more extranodal sites or particular extranodal site involvement including testicular, renal, adrenal, breast and uterine. Previous data suggested that ABC-subtype DLBCL (established by GEP) or 'double hit' HGBCL also conferred an increased risk of CNS relapse. The new molecular classification of DLBCL may also allow more precise identification of subgroups with high CNS risk. Another area of interest is the use of circulating tumour DNA (ctDNA) analysis in CSF at diagnosis to detect occult CNS disease with much higher sensitivity than traditional CSF analysis by flow cytometry.

Intrathecal (IT) chemotherapy was previously considered the CNS prophylaxis of choice for selected patients, but there is now

Table 27.5 Central nervous system international prognostic index.

CNS-IPI risk group	2-year rates of CNS relapse (%)	Proportion of patients: training cohort (%)	Proportion of patients: validation cohort (%)
Low (0–1 points)	0.6	46	31
Intermediate (2–3 points)	3.4	41	46
High (4–6 points)	10.2	12	23

CNS-IPI risk categories with corresponding 2 year rates of CNS relapse and proportion of patients in each category from the training (clinical trial patients) and validation (BCCA registry) cohorts (Schmitz *et al.* 2016). 1 point is scored for any of the following: age >60 years, LDH >normal, ECOG performance status >1, stage III/IV disease, extranodal involvement ≥2 sites, kidney and/or adrenal involvement.

cumulative evidence to suggest it has limited efficacy and therefore is generally not recommended in isolation. Intravenous high-dose methotrexate (HD-MTX) with folinic acid rescue has instead been widely adopted as CNS prophylaxis despite a lack of prospective data supporting its use and the risk of toxicity and interruptions to systemic therapy. Recently, two large retrospective analyses have addressed this topic. The first analysed 1384 patients receiving HD-MTX CNS prophylaxis either 'intercalated' between cycles or delivered at end of R-CHOP therapy. There was no difference in CNS relapse rate between the two approaches, with intercalated delivery introducing significant risk of R-CHOP delay, and the overall rates of relapse seen in high-risk patients were similar to published cohorts receiving no CNS prophylaxis. The second analysis of 2300 patients deemed at high risk of CNS relapse found no reduction in risk between patients who did (n = 410) and did not (n = 1890) receive HD-MTX. Taken together, these analyses suggest that HD-MTX is unlikely to significantly reduce rates of CNS relapse for the majority of patients deemed at high risk by traditional criteria, and if it is used it should be deferred until end of systemic therapy to avoid treatment delays.

In summary, current methods for identifying high-risk patients and the agents used for prophylaxis are suboptimal. Future studies are likely to focus on using modern diagnostic technology to identify 'molecular high-risk' patients, with incorporation of novel agents capable of penetrating the CNS and thus preventing the devastating consequences of CNS relapse.

Role of interim PET/CT in response assessment

Unlike in Hodgkin lymphoma where the prognostic utility of interim PET-CT is established, its role in DLBCL remains debatable. Initial studies using PET-CT for response assessment after two, three or four cycles of immunochemotherapy suggested an association between the result of the interim scan and patient outcome. However some studies have demonstrated interim PET-CT assessment in DLBCL to have low prognostic and positive predictive value with a high number of false positive interim scans confirmed by a biopsy of the FDG-positive site. What is evident in comparing these studies is a current lack of standardisation for the appropriate time point for interim response assessment (two, three or four) and the response criteria used, as different grading systems from visual assessment scales (such as the Deauville five-point scale) to quantitative measures (such as change in standardised uptake value; SUV) are employed and subject to wide inter- and intra-observer variability.

The most robust trial to date in this area is the PETAL study which enrolled 862 patients with aggressive B or T-cell lymphomas and included an interim PET-CT after two cycles of (R)-CHOP. PET-CT response was defined according to reduction in SUV. A positive interim PET-CT was associated with poor EFS (<50%) which was independent of IPI risk group. Crucially, however, patients with a positive interim PET-CT who were randomised to receive an intensified 'Burkitt-like' therapy instead of (R)-CHOP had no improvement in survival outcomes but did experience increased toxicity.

Greater harmonisation of interim PET-CT interpretation is required before this response modality can be transitioned to the standard of care. Studies are ongoing combining ctDNA assessment with interim PET-CT imaging to better identify true high-risk patients. However, there must be a prospectively evaluated strategy to improve outcomes for these patients before these assessments can be recommended in routine clinical practice.

Treatment: relapsed or refractory DLBCL

Up to 40% of patients do not respond to first-line therapy and fall into one of three categories: those relapsing after achieving CR, those achieving PR with residual disease or refractory patients. The majority of the progressions occur within the first 18 months, with rare relapses occurring more than 5 years after diagnosis. Once a patient inadequately responds to initial chemotherapy, the prognosis is poor with historical data reporting long-term OS of less than 10%. However, the treatment landscape for such patients has been transformed in recent years by the development of novel treatments, in particular chimeric antigen receptor (CAR) T-cell and bi-specific T-cell engager (BiTE) therapies.

High-dose chemotherapy and ASCT

Until recently, second-line chemoimmunotherapy followed by ASCT was recommended for patients considered fit enough as established from the results of the landmark prospective PARMA trial published in 1995, which demonstrated the superiority of intensified treatment in patients with chemo-sensitive relapse. PET-CT following second-line therapy and prior to ASCT is highly prognostic, with excellent outcomes seen in

patients with Deauville score 1–3 pre-ASCT. However, a CMR is not necessarily required to proceed to ASCT, as demonstrated in a recent retrospective analysis of 249 patients undergoing ASCT with a PET-positive partial response, where the 5-year PFS was reported at approximately 40%.

The second-line chemotherapy of choice, however, remains a subject of debate. The majority of favoured regimens include rituximab with either one or both of a platinum compound or ifosfamide. A prospective phase III trial showed there was no difference in survival between second-line regimens R-ICE (rituximab, Ifosfamide, carboplatin and etoposide) and R-DHAP (rituximab, dexamethasone, high-dose cytarabine and cisplatin). Another randomised prospective study comparing R-GDP to R-DHAP demonstrated similar response rates and survival between regimens but increased toxicity with R-DHAP.

Eligibility for high-dose therapy and ASCT is generally determined by medical fitness, comorbidities, performance status and patient preference. Age is often considered an important factor, with patients over 70 years old often not proceeding to ASCT unless they are exceptionally fit. A recent retrospective analysis demonstrated that toxicity of ASCT, in particular cardiovascular, was increased in a cohort of patients >70 compared to those aged 60–69. However, non-relapse mortality was comparable across the two groups and therefore age alone should not be considered a reason to withhold this therapy in selected patients.

There is no clear consensus regarding management of patients where ASCT is deemed unsuitable, either due to patient fitness or due to lack of response to second-line chemotherapy. Until recently, options for patients not deemed fit for ASCT were limited to less intensive chemotherapy regimens such as R-GemOx, palliative oral chemotherapy combinations, steroid monotherapy as palliation or best supportive care alone. However, with increased recognition of the more favourable toxicity profiles of novel cellular therapies and targeted agents (see below), less fit patients may also be considered for these approaches subject to local availability and thus focus on appropriate sequencing of therapies has become increasingly important.

CAR T-cell therapy

CAR T-cells are genetically modified T cells formed by combining the antigen-binding site of an antibody with the intracellular domain of a T-cell activation receptor. The first approved products for treatment of B-cell lymphomas involve autologous T-cells targeting CD19; however, several trials are ongoing investigating the use of other targets (including CD20 and CD22) and allogenic 'off-the-shelf' products. Initial approvals in most countries recommended consideration of CAR T-cells after failure of second-line therapy; however recent results of some of the phase III trials comparing CAR T-cells to chemotherapy and ASCT have led to approval of CAR T-cells for patients with disease which is refractory to R-CHOP or relapsing within 1 year.

Manufacture of CAR T-cells is complex and expensive, involving leukapheresis to obtain autologous T lymphocytes which are genetically modified (using viral vectors) with a gene encoding a CAR designed to direct the T cells against lymphoma cells. This modification occurs *ex vivo*, with subsequent expansion in a centralised production facility, before being transported back to the patient and infused. Managing patients in this period while the product is being manufactured can be challenging due to the aggressive nature of relapsed/refractory DLBCL, and some form of 'bridging' therapy (either corticosteroids, immunochemotherapy, radiotherapy or a combination of the above) may be required.

The therapy itself can also be associated with significant side effects, including neurological toxicity (immune effector cell-associated neurotoxicity syndrome, ICANS) and cytokine release syndrome (CRS). CRS is a severe systemic response to the activation and proliferation of CAR T-cells and is observed in a variable proportion of patients, depending on the product, but typically is transient and responds well to treatment including corticosteroids and tocilizumab (a monoclonal antibody against interleukin-6 receptor). ICANS is a neuropsychiatric syndrome that is usually seen in the context of CRS and can result in seizures and diffuse cerebral oedema in the most severe cases. Management is supportive, consisting primarily of corticosteroids and anti-epileptic medications.

There are currently three commercially available anti-CD19 CAR-T products – axicabtagene ciloleucel, tisagenlecleucel and lisocabtagene maraucel. They have all been FDA-approved following pivotal phase II trials but at present none have been compared directly in a randomised study. The three products have subtle differences in molecular structure, manufacturing processes and toxicity profiles. However, the efficacy appears to be broadly similar between products, with overall and complete responses reported in the range of 50–82% and 40–54% respectively. The longevity of these responses is less clear, although updated follow-up from the phase II study of axicabtagene ciloleucel has demonstrated that 44% of patients were alive at 4 years.

Despite the significant toxicities associated with CAR T-cell therapy, there is increased recognition that these are manageable and reversible for the majority, and overall the process is likely to be better tolerated than high-dose salvage chemotherapy and ASCT. As a result, patients previously deemed unfit for further treatment due to ineligibility for ASCT can now be considered for CAR T-cell therapy. The challenges going forward include reducing the manufacturing time of the products, investigating 'off-the- shelf' products which can be infused rapidly, reducing toxicities, identifying the optimal timing for such an approach and reviewing the response to other treatment modalities if CAR-T is ineffective. Finally, a major consideration is the socioeconomic considerations of such an expensive therapy, which may not be feasible in many healthcare settings with more limited resources.

Bispecific T-cell engagers (BiTEs) and bispecific antibodies

BiTEs are a new class of immunotherapy which conceptually function as linkers between T-cells and specific target antigens in an MHC-subtype independent manner. They consist of a protein fragment containing two separate single-chain variable regions. One end recognises CD3, expressed on all T-cells, while the other end recognises the target tumour antigen. The result is induction of cytotoxic T-cell-mediated tumour eradication. Bispecific antibodies are conceptually similar, but in this case, a whole antibody is engineered to have Fab portions which recognise two separate antigens, most commonly CD3 and CD20.

Following impressive results in patients with acute lymphoblastic leukaemia, a number of BiTE and bispecific antibody products have now been investigated for management of relapsed/refractory DLBCL. Initial BiTE products, e.g. blinatumomab, were cumbersome to deliver (continuous infusion) and associated with significant neurotoxicity. Several bispecific antibodies targeting CD3 and CD20 have now been developed which have longer half-lives, allowing delivery every 3–4 weeks, with subcutaneous administration possible for some. Although these therapies are associated with toxicities similar to those seen with CAR T-cells, namely CRS and ICANS, the rates of grade 3 and 4 toxicities are significantly lower than in CAR T-cells. Both glofitamab and epcoritamab are licensed in Europe for use in the third line plus treatment setting for DLBCL. Future trials directly comparing bispecific antibodies to CAR T-cell therapy, and earlier incorporation of these agents in the DLBCL treatment algorithm, are awaited with great interest.

Other novel therapies in relapsed/refractory DLBCL

One regimen being used increasingly in patients deemed unsuitable for ASCT is the combination of rituximab, bendamustine and polatuzumab vedotin (R-BP). Polatuzumab is an antibody-drug conjugate (ADC) targeting the B-cell antigen, CD79B. When compared to rituximab-bendamustine in a phase II trial of 80 patients, R-BP demonstrated significantly improved response rates and OS. Bendamustine does result in significant and often prolonged lymphopenia so consideration regarding appropriate timing of its administration is imperative. Loncastuximab tesirine is another ADC which instead targets CD19 and has demonstrated impressive response rates in a phase 2 trial, including in patients treated with prior CAR T-cell therapy.

Tafasitamab is humanised anti-CD19 monoclonal antibody, which demonstrated efficacy when combined with the immunomodulatory agent Lenalidomide in a phase 2 trial. Selinexor, a selective inhibitor of the nuclear export protein XPO1, has shown modest activity as a single agent for relapsed/refractory DLBCL, but is hindered by a significant toxicity profile. Other agents including venetoclax (BCL2 inhibitor), ibrutinib and tazemetostat (EZH2 inhibitor) have demonstrated limited efficacy as single agents but trials are ongoing investigating their use in combination therapies.

Despite showing efficacy in Hodgkin lymphoma, and in primary mediastinal B-cell lymphoma, programmed cell death protein 1 (PD-1) inhibitors have thus far failed to show significant benefit in DLBCL.

DLBCL in HIV-positive patients

People living with HIV (PLWH) have an increased risk of developing DLBCL, the second most common tumour in individuals with HIV. The development of DLBCL is related to older age, low CD4 cell count and no prior treatment with combination anti-retroviral therapy (ART). Patients tend to present with advanced-clinical stage, B symptoms and extra-nodal involvement. Factors associated with survival in the post-ART era are the IPI score and in some studies, a low CD4 cell count, but overall outcomes for PLWH have recently been demonstrated to be similar to HIV-negative counterparts with equivalent age-adjusted IPI.

Use of ART

The introduction of ART has led to better control of HIV viral replication and improved immune function. Previously, opinions differed as to whether ART should be continued during chemotherapy or not, with some concerns regarding potential adverse pharmacokinetic and pharmacodynamic interactions with chemotherapy and the potential for increased toxicity. However, with modern ART agents, these concerns regarding toxicity have not been realised, and there is now general acceptance that ART should be continued or initiated wherever possible. A combined approach to care involving HIV physicians and haemato-oncologists is essential, particularly when considering switching ARV agents to avoid chemotherapy interactions.

Choice of immunochemotherapy

There is much debate on whether R-CHOP or infusional regimens, such as DA-EPOCH-R, are most efficacious as first-line treatment in HIV-positive patients. However, there has been no randomised study comparing these regimens specifically in PLWH. A pooled analysis of US studies suggested that DA-EPOCH-R resulted in superior response rates and survival compared to R-CHOP, but the former regimen was used during a later time period (2002–2006) than the R-CHOP study (1998–2002), suggesting other variables, including supportive care and antiretroviral drug options, may have differed.

The role of rituximab in HIV-associated DLBCL has been controversial ever since a randomised phase III study of CHOP ($n = 50$) versus R-CHOP ($n = 99$), conducted in the US was published. Although there was a trend to improved response rate

with rituximab, (58 versus 47%, $p = 0.15$), a significant reduction in progression of lymphoma on treatment, and in death due to lymphoma, an increased death rate from infectious complications, particularly (9/15) in those with a CD4 count below 50 cells/mm^3, was observed. However, maintenance rituximab was included every 3 months in those who responded to R-CHOP. Subsequent phase II studies of R-CHOP (without maintenance rituximab) from Europe did not show an increased risk of infectious deaths, instead showing that rituximab was beneficial. A meta-analysis of prospective studies has confirmed the benefit in response rate and OS of the addition of rituximab to chemotherapy. Thus, the addition of rituximab to chemotherapy is now recommended for all patients with DLBCL with appropriate anti-microbial prophylaxis, pre-emptive G-CSF and prompt treatment of opportunistic infection.

Preventing CNS relapse

Historical data suggested high rates of both CNS involvement at baseline and of CNS relapse during or shortly after treatment for HIV-associated DLBCL. However, earlier estimates included patients with HIV-associated BL where CNS involvement is much more prevalent. Furthermore, it is unlikely that HIV infection itself is an independent risk factor for CNS relapse in DLBCL, but patients tend to present with other features which are known to increase the risk (*see section on* 'CNS prophylaxis' *above*). As a result, many guidelines now recommend applying the same criteria for PLWH as non-HIV-associated DLBCL when making decisions about CNS prophylaxis.

Relapsed/refractory disease

Treatment of refractory or relapsed DLBCL in the pre-ART era was disappointing with few clinically useful responses. Two large, retrospective, multi-centre studies performed by the EBMT have confirmed the feasibility and efficacy of HDT and ASCT for PLWH who respond to second-line chemotherapy. Thus, in the ART era, PLWH with chemosensitive relapsed DLBCL should be considered for ASCT according to the same criteria adopted for HIV-negative patients.

The pivotal trials of anti-CD19-directed CAR T-cell therapy in DLBCL excluded HIV-positive patients, and as a result, there was initial hesitancy in using this therapy for PLWH. However, there is now growing evidence suggesting the products can be manufactured adequately with comparable safety and efficacy to HIV-negative patients, and as a result, this can be considered in line with approvals for HIV-negative DLBCL.

Allogeneic stem cell transplantation in DLBCL

With the advent of CAR T-cells and other novel therapies, the role of allogeneic stem cell transplant in DLBCL is diminishing. There is no certainty regarding the existence of a strong graft-versus-lymphoma (GvL) effect in aggressive NHLs, whereas mortality following transplantation remains high. Traditionally, allogeneic transplant was considered for patients with chemosensitive disease who fail to adequately mobilise autologous stem cells or who relapse after ASCT. However, such patients will now be offered CAR T-cell therapy or other novel agents in countries where these are available, although allogeneic transplant remains a potential option where these treatments have failed or are not accessible. The choice of conditioning regimen employed should be individualised, based on balancing the risks of toxicity with a myeloablative approach versus the greater risk of relapse with reduced-intensity conditioning.

High-grade B-cell lymphoma with MYC and *BCL2* rearrangements (Double-hit lymphoma)

The previous WHO classification of haematopoietic and lymphoid tumours from 2008 included a borderline category named 'B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma', often referred to informally as 'high-grade lymphoma unclassifiable' or HGLUC. This category was used to describe high-grade B-cell malignancies that had intermediate cytological features between DLBCL and BL. Many cases in this category were found to be so-called 'double hit lymphoma (DHL)', carrying translocations of *MYC* and either *BCL2* or *BCL6*, or, more rarely, 'triple hit lymphoma (THL)', involving *MYC*, *BCL2* and *BCL6* translocations. The majority of DHL or THL are GCB-DLBCLs with genetic profiles similar to the molecular EZB subtype except *MYC-BCL6* DHLs, which are mostly ABC-DLBCLs. Clinical studies indicated that many DHLs were clinically aggressive with associated poor outcomes with standard DLBCL therapy (R-CHOP). Moreover, there was recognition that DHLs were morphologically heterogeneous, with some being diagnosed as DLBCL and some as HGLUC. As a result, the 2016 revision of the WHO classification created a unifying category, 'High-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* rearrangements'. In the 2022 update, this has been modified to only include *MYC* and *BCL2* rearrangements. Due to the distinct characteristics of lymphomas with MYC and BCL6 rearrangements (without *Bcl2* rearrangements), this would now be placed under 'DLBCL, NOS' or 'HGBCL, NOS' depending on the cellular morphology. Importantly, this category includes only those cases with *MYC*/*BCL2* translocations identified by FISH – cases with overexpression of *MYC* and *BCL2* by immunohistochemistry are known as 'double-expressors'. Double-expressors account for around 25% of DLBCL cases and have been shown to have an inferior outcome with R-CHOP, but at present, this is not a specific diagnostic category in itself and treatment is as per non-double expressor DLBCL.

Incidence and clinical presentation

Initial estimates of both frequency and outcomes of DHL were skewed due to non-universal application of FISH testing, with early studies often only analysing cases exhibiting high-risk features. However, a large analysis from the Lunenburg Biomarker Consortium has provided the most robust estimates for DHL incidence, as well as providing insight into the heterogeneity of this diagnostic category. In over 2,000 DLBCL cases with biopsy material available for FISH analysis, *MYC* translocations were identified in 11% of patients. Of these cases, 53% had a concomitant rearrangement of *BCL2* and/or *BCL6*. Outcomes for *BCL2*-DHL, *BCL6*-DHL and THL were similar with all having inferior PFS and OS compared with those patients without translocations. Interestingly, this adverse prognostic impact was only observed in patients with DHL/THL cases in which *MYC* was translocated with an immunoglobulin chain (IG) partner.

Patients with DHL/THL frequently present with high-risk clinical features, including advanced stage, B symptoms, raised LDH and multiple extranodal site involvement. CNS involvement at diagnosis has been reported as frequently as 10%, although such figures are likely to be inflated by lack of universal FISH testing. Conversely, there are patients with DHL who present without high-risk features – such cases are likely to be underreported, and may represent a group who have similar outcomes with R-CHOP to non-DHL DLBCL.

Treatment and prognosis

Outcomes with standard R-CHOP therapy are significantly poorer for DHL, with one series from British Colombia reporting 5-year PFS and OS of 18% and 27%, respectively. Accepting the caveats of retrospective data and possible under-utilisation of FISH, there is general acceptance that R-CHOP is insufficient therapy for these patients and there has been much focus on use of intensified immunochemotherapy regimens for DHL.

Evidence to support the use of intensified regimens for DHL includes a systematic review and meta-analysis of 11 retrospective studies whereby treatment with DA-EPOCH-R resulted in improved PFS in 394 patients with DHL compared to R-CHOP therapy. However, this PFS improvement did not translate to superior OS. A multicentre study of 159 patients with DHL reported that more intensive front-line therapy (DA-EPOCH-R, R-HyperCVAD, R-CODOX-M/IVAC) was associated with improved 3-year PFS compared with R-CHOP, but again no difference in OS was demonstrated.

DA-EPOCH-R has been prospectively evaluated in a single arm, phase II trial of 53 patients with untreated *MYC* rearranged aggressive B-cell lymphomas. With median follow-up of 55.6 months, 4-year event-free and overall survival were 71.0 and 76.% respectively, with similar outcomes between those with single *MYC* translocation and those with DHL/THL. The only randomised phase III study comparing DA-EPOCH-R to R-CHOP thus far had very low numbers of patients with DHL/THL so no definitive conclusions could be drawn from this data on potential superiority of DA-EPOCH-R.

The UK NCRI phase 2 study of R-CODOX-M/R-IVAC in high-risk DLBCL patients included 59/116 patients where FISH results were available – 12% of these cases had DHL. The outcomes for the DHL patients were similar to the whole study cohort which had 2-year PFS/OS of 67.9 and 76.0%, respectively. This regimen has significant toxicity (TRM 4.3% in this study) but is used in some centres for DHL, particularly as it incorporates CNS penetrating agents.

Given the poor outcomes in DHL treated with R-CHOP, many centres previously advocated consolidative therapy with high-dose chemotherapy and ASCT in first complete response (CR). However, a large US analysis of patients with DHL who achieved first CR following completion of front-line therapy (with either R-CHOP or more intensive regimens) demonstrated that ASCT did not improve relapse-free survival (RFS) or OS. Patients treated with R-CHOP had inferior RFS compared to those receiving intensive therapy but similar OS, and sub analyses suggested a benefit of ASCT specifically for the R-CHOP treated group. However, these data do not advocate an approach of R-CHOP induction followed by ASCT as patients are less likely to achieve CR with R-CHOP, but importantly there does not appear to be benefit of ASCT consolidation in those achieving CR and in those undergoing intensive induction.

Conclusion and future directions

Although intensified front-line therapy has not been definitively proven in a prospective trial to improve outcomes for DHL/THL, the outcomes with R-CHOP alone are unsatisfactory and there is sufficient cumulative evidence to support intensified regimens for these patients. With more sophisticated molecular diagnostic techniques and classification, recognition of these high-risk patients is likely to move beyond simply using FISH to identify the three described translocations. Recent studies have used RNA sequencing to identify a gene expression signature associated with the presence of DHL. When applied to large cohorts of DLBCL patients, most cases of DHL (by FISH) are identified with this technique but many non-DHL cases exhibiting similar high-risk features and poor outcomes are also picked out. Identifying a more homogenous group of poor-risk patients in this way may enable focussed attempts at improving outcomes with prospective trials incorporating novel agents, intensified immunochemotherapy, or both.

Primary mediastinal (thymic) large B-cell lymphoma

Primary mediastinal large B-cell lymphoma (PMBL) is an aggressive lymphoma that accounts for 2–4% of all NHLs. PMBL is recognised as a separate entity in the WHO classification of

lymphoid neoplasms, with distinct clinic-pathological features from DLBCL. It characteristically presents with a large anterior mediastinal mass frequently accompanied by clinical complications such as pericardial or pleural effusions and superior vena cava obstruction as a result of local intrathoracic tumour invasion. Extra-thoracic involvement and bone marrow infiltration are rare, although at relapse, there is a significantly high incidence of extra-nodal site involvement. The median age at presentation is in the third to fourth decade with a female predominance. Interestingly, PMBL shares not only clinical and pathological features with classical Hodgkin lymphoma (cHL) but also molecular similarities, with GEP demonstrating greater resemblance with cHL than with DLBCL.

Genetic and molecular features

The cell-of- origin of PMBL is unclear although the pattern of somatic hypermutation of typical gene targets such as *BCL6* and the immunoglobulin heavy chain gene (IgVH) and GEP supports derivation from thymic B-cells with a germinal centre or post-germinal centre origin. Key molecular pathways and biological mechanisms involved in PMBL include deregulated NF-κB, Janus kinase–signal transducers and activators of transcription (JAK-STAT) signalling and immune surveillance. A number of these genetic and molecular aberrations are shared by cHL.

Gains and amplification of chromosome 2p16.1 containing the gene locus for *REL,* occur in over 50% of patients, with increased NF-κB activity seen in these cases. Additionally, truncating mutations and deletions of *TNFAIP3*, a negative regulator of NF-κB signalling, occurs in 36% of PMBL, promoting constitutive NF-κB activation.

The *JAK2* gene at chromosome 9p24.1, is amplified in up to 75% of PMBL cases and is a major molecular hallmark of the disease. Other components of the JAK-STAT signalling pathway are altered in PMBL including recurrent mutations in *PTPN1*, encoding a protein tyrosine phosphatase, the tumour suppressor gene, *SOCS1* and *STAT6*.

MHC Class II antigens such as HLA-DR are downregulated on the surface of PMBL cells and correlate with a diminished number of infiltrating cytotoxic T-cells and an inferior outcome. Translocations in the transcriptional regulator of MHC II class expression, *CIITA*, occur in 38% of PMBL and shown to suppress HLA class II expression *in vitro*. Highly recurrent genomic rearrangements involving T-cell anergy-inducing programmed death ligands (PDL1 and PDL2) lend further support to the role of escape from immune surveillance as a feature of PMBL.

Treatment and prognosis

Initial therapy is critical in treating PMBL; however, there has been limited prospective trial activity in PMBL making it difficult to establish a standard of care. This is further compounded by the dilemma of how to deliver a therapy with the highest cure rate yet minimise long-term morbidity and sequelae in this young population. Currently, therapies for PMBL consist of a multi-agent anthracycline- and rituximab-containing backbone. Multiple retrospective studies have suggested improved response rates and remission duration with the addition of rituximab, as well as prospective data from PMBL patients treated within the MInT trial. There remains a lack of consensus worldwide on the optimal chemotherapy backbone for PMBL. R-CHOP and DA-EPOCH-R are the two most widely used worldwide, although there has been no randomised controlled trial comparing the two regimens specifically in PMBL.

Data supporting R-CHOP in PMBL is derived from either retrospective analyses or from post-hoc subgroup analyses from large DLBCL trials. The MiNT trial of CHOP-like therapy with or without rituximab (Table 27.3) included 87 patients with PMBL. The rituximab arm had significantly improved EFS (78 versus 52%) and a trend towards improved OS (89 versus 78%) compared with CHOP only. The majority (61%) received involved field radiotherapy. The UK NCRI R-CHOP 14 versus R-CHOP 21 trial included 50 patients with PMBL, with 5-year PFS and OS of 79.8 and 83.8%, respectively. There was a trend towards survival benefit in the R-CHOP 14 arm in this study, and recent non-randomised data from the IELSG37 study supports the recommendation of R-CHOP on a 14-day rather than 21-day cycle in PMBL.

DA-EPOCH-R has been evaluated prospectively in PMBL, albeit only in a single centre phase II trial of 51 patients. The outcomes in this study were very encouraging with 5-year EFS of 93% and OS 97%, although toxicity was significant with 13% of cycles resulting in admission for neutropenic fever. Only two patients received radiotherapy due to locally progressive disease, suggesting that use of DA-EPOCH-R may obviate the need for consolidative radiotherapy if CMR is attained. More recently, the IELSG37 randomised question has shown that radiotherapy does not provide a significant benefit to patients achieving a CMR after R-CHOP. The vast majority of patients with a positive PET scan did receive radiotherapy however and omission of radiothearpy in, for example, patients with a Deauville 4 response, remains controversial.

Relapse of PMBL is infrequent compared to DLBCL with the majority of treatment failures occurring within the first 6–12 months after therapy completion, and rarely beyond 2 years. A repeat biopsy is advocated to confirm histology at the time of recurrence. Broadly speaking, the approach for PMBL relapse, similar to DLBCL, is salvage therapy followed by consolidation with ASCT in those deemed fit enough, although radiotherapy should be considered if omitted from initial therapy where relapse is localised. Patients with PMBL were included in the initial trials of the CAR T-cell products axicabtagene ciloleucel and lisocabtagene maraleucel and therefore these agents can be considered where available, with indications in line with DLBCL. In keeping with the frequent expression of PD-L1 in PMBL, there is also some promising data with the use of immune checkpoint inhibitors (e.g. pembrolizumab, nivolumab) as well as Brentuximab in the relapsed/refractory setting.

Primary central nervous system lymphoma

Primary central nervous system lymphoma (PCNSL) is rare form of NHL comprising 2–4% of all central nervous system (CNS) tumours. It encompasses lymphoma exclusively involving the brain, spinal cord, eyes, meninges and cranial nerves, with 90–95% classified histologically as DLBCL. Depending on the location involved, PCNSL can present with a variety of symptoms. Intracranial lesions are the most common manifestation of PCNSL and the majority present with focal neurologic symptoms, but nonspecific neuropsychiatric symptoms are also observed. Primary vitreoretinal lymphoma can present with blurred vision and symptoms mimicking uveitis.

The median age of presentation of PCNSL is around 70 years. The majority of PCNSL are sporadic and an increasing incidence has been recognised in recent years, particularly in older patients (>60 years). A minority are attributable to immunosuppressed states, including HIV infection or iatrogenic immunosuppression following organ transplantation, and the tumours in this setting are biologically different and usually EBV positive. In the era of effective ART, the frequency of HIV-associated PCNSL has diminished.

The involvement of critical sites within the CNS presents both diagnostic and therapeutic challenges, with outcomes inferior to systemic DLBCL. Neurocognitive dysfunction and impaired performance status are frequent at clinical presentation, whilst histological confirmation is inherently risky and often yields small tissue biopsies. Moreover, choice of cytotoxic therapy is limited by the inability of many drugs employed for systemic NHL treatment to penetrate the blood–brain barrier (BBB) efficiently. Since the initial description of PCNSL in 1975, treatment algorithms have evolved from whole-brain radiotherapy (WBRT) as a single-modality treatment towards a multiagent, high-dose, MTX-based chemotherapy approach and consideration for consolidation with chemotherapy with or without ACST in fit patients. WBRT is used less commonly in frontline consolidation and reserved more often to treat relapsed disease. Given the rarity of PCNSL, data from randomised studies are scarce, but a number of clinical trials performed over the last decade have addressed key questions addressing optimal induction, consolidation and maintenance strategies.

Diagnosis and prognosis

The diagnosis of CNS lymphoma can be a particular challenge because of lesional response to corticosteroids and radiological features that are shared with other pathologies. Multimodal gadolinium-enhanced MRI remains the standard of care for diagnosis and therapeutic monitoring of PCNSL. At initial diagnosis, PCNSL in immunocompetent individuals classically demonstrates avidly enhancing lesions (up to 60%, 75% of which are multiple). Most are supratentorial (80%), in a periventricular or deep cerebral white matter distribution. The majority of PCNSL are diagnosed via stereotactic biopsy or, less commonly, by flow cytometric analysis of CSF. A number of biomarkers, such as interleukin-10 (IL-10) and myeloid differentiation primary response L265P mutation (mut-*MYD88*), detected in CSF, show promise in detecting PCNSL both at initial diagnosis and relapse. Recently, the value of detection of ctDNA at diagnosis and response assessment has been highlighted. Whole body 18FDG PET-CT has an increased sensitivity for detection of systemic DLBCL over conventional CT staging and has an important role in the exclusion of systemic lymphoma at presentation.

Age and baseline performance score are the main determinants of prognosis in PCNSL and both are incorporated into prognostic scores.

Genetic and molecular features

The pathobiology of PCNSL has arisen through observations from small and heterogeneously treated populations. The majority of PCNSLs type as the ABC cell-of- origin. There is a high incidence of recurrent mutations in genes that drive BCR and NF-κB signalling including *MYD88* and *CD79B*. The serine/threonine kinase, PIM1, involved in cytokine signalling and cell proliferation is also frequently mutated as are deletions of 6p21, involving the HLA locus (56–79%), representing a potential mechanism for immune escape. The genetic features of PCNSL align very closely to the newly identified MCD/C5 molecular group in DLBCL. Notably, EBV-associated PCNSL usually occurring in the context of immunosuppression are rare but have a distinct biology with nearly complete absence of the above genetic features described.

Treatment – remission induction

Chemotherapy regimens incorporating HD-MTX are considered the standard of care as induction therapy for newly diagnosed PCNSL, achieving high rates of initial response and improved survival outcomes when combined with other cytostatic agents. There is general consensus that MTX should be administered as a rapid infusion (2–4 hours) at a dose of at least 3 g/m^2 to maximise therapeutic CSF concentrations, at an interval of 14–21 days. Over recent years, a growing number of clinical studies investigating intensive immunochemotherapy approaches have included older patients. For example, the MATRix regimen comprising rituximab, HD-MTX, cytarabine and thiotepa has proven to be effective in patients up to the age of 70 years in the IELSG32 trial. Other popular regimens include HD-MTX, carmustine, etoposide and prednisone (MBVP); HD-MTX, vincristine, and procarbazine (MVP); and HD-MTX, temozolomide, and rituximab (R-MT).

Several studies have evaluated the additional value of BBB-penetrating alkylating agents, such as temozolomide and

procarbazine, providing non-cross-resistant agents that, unlike antimetabolite chemotherapy, are also cytotoxic to cells in G0 of the cell cycle.

Treatment: consolidation

One of the paradigms in the treatment of patients with PCNSL is that induction therapy should be followed by consolidation treatment to achieve long-term remissions. The rationale for HDT-ACST in PCNSL is the delivery of BBB-penetrating agents into the CNS, in several-fold higher concentrations compared to conventional therapy, which cannot be achieved without autologous stem cell rescue. Various single arm and randomised trials provide a robust body of evidence for the use of HDT-ASCT in younger PCNSL patients <65-70 years with 3–5 years survival ranging between 69 and 87%. A recent retrospective study which included 603 patients demonstrated superiority of thiotepa-based conditioning associated with better 3-year PFS (75 versus 58% with BEAM), notably the upper limit of age for HDT-ASCT was 77 years.

WBRT following HD-MTX-based induction chemotherapy is associated with delayed neurotoxicity, particularly with increasing age and increased doses of WBRT, and this is associated with significant morbidity and mortality. There is increasing reluctance to use this consolidation therapy at first response although the efficacy and toxicity of reduced dose (rd) WBRT (23.4 Gy) with no boost in patients with radiographic CR after induction has been assessed in some prospective and retrospective studies. However, the safety of rdWBRT in elderly patients remains to be determined, since few patients older than 60 years completed neuropsychological evaluation.

Consolidation with a nonmyeloablative chemotherapy has also been suggested as potentially less toxic, less resource-consuming consolidation strategy in patients with PCNSL. Two randomised Phase II trials have assessed the efficacy and toxicity of this strategy compared to HDT-ASCT and preliminary results from one study suggest less intensive chemotherapy consolidation may be less effective although more data is awaited.

However, with a median age of 68 years, a significant proportion of patients with PCNSL are not eligible for consolidation treatment. For this population, maintenance treatments have been and are being evaluated in several studies. Agents such as procarbazine, temozolamide, rituximab, obinutuzumab, nivolumab, ibrutinib and lenalidomide are being explored.

Relapsed PCNSL

While PCNSL is chemo and radiosensitive, relapse is as common as 50% in the first 2 years highlighting the need for improved durable therapies. Currently, there exists no standard treatment approach for patients with relapsed and refractory PCNSL. Published data are largely restricted to small, uncontrolled, retrospective studies, in which outcomes are influenced by a number of parameters, including prior therapies and response durations. In studies where eligible patients have proceeded to HDT-ASCT, available data support the use of thiotepa-based HDT-ASCT in relapsed PCNSL.

Studies addressing the efficacy of agents such as temozolomide, pemetrexed, bendamustine, topotecan, lenalidomide, pomalidomide, temsirolimus, ibrutinib, PI3K inhibitors, a dual PI3K/mTOR inhibitor and other agents targeting B-cell signalling are ongoing. Immunotherapies with CAR T-cells are also being evaluated in PCNSL.

Trials involving new therapies should include robust assessment of neurocognitive functioning and quality of life metrics as the minimisation of neurotoxicity is a primary goal in PCNSL treatment.

Burkitt lymphoma

Burkitt lymphoma (BL) was first described in Ugandan children by Denis Burkitt in 1958. BL is a highly aggressive mature B-cell lymphoma that constitutes less than 2% of all NHL diagnoses in the UK. It represents the most frequent B-cell lymphoma in children accounting for 30–50% of all paediatric lymphomas. There are three clinical variants recognised: endemic, sporadic and immunodeficiency-associated BL.

The endemic BL variant occurs predominantly in equatorial Africa and Papua New Guinea, mainly affecting children with an estimated incidence of 3–6 cases per 100,000 children per year and a peak incidence of 4–7 years. The risk factors for endemic BL are incompletely understood. However, EBV is widely accepted to be a contributing factor with the EBV genome detected in about 95% of endemic BL cases. Infection with plasmodium falciparum malaria has also been linked as a risk factor for endemic BL. The ubiquity of EBV and malaria in these regions suggest that these factors alone cannot explain all endemic BL cases. Sporadic BL is distributed worldwide, occurring mainly in children and young adults. EBV can be detected in about 30% of sporadic BL cases.

Presentation varies according to the clinical subtype but extranodal site involvement is a common feature. CNS involvement (typically leptomeningeal rather than parenchymal) may occur at presentation, particularly when there is advanced-stage disease. In endemic BL, the jaw and facial bones are characteristically affected. For sporadic BL, presentation with intra-abdominal masses is more common, with jaw tumours rarely seen. Lymph node presentation is seen more commonly in adults than children.

Genetic and molecular features

BL is derived from a germinal-centre cell-of- origin yet has a unique gene expression profile that distinguishes it from DLBCL. Recent characterisation has shown that BL most closely resembles

cells from germinal-centre dark zones, whereas the GCB subtype of DLBCL is more akin to cells from germinal-centre light zones.

The molecular hallmark of BL is the translocation t(8;14)(q24;q32) or its variants t(2;8) and t(8;22), occurring in nearly all affected individuals irrespective of the clinical variant. These chromosomal translocations juxtapose the *MYC* oncogene at 8q24 with one of the three immunoglobulin loci partners: Ig heavy chain (IGH) at 14q32, kappa light chain (IGK) at 2p12 or lambda light chain (IGL) at 22q11, leading to deregulation of MYC expression. While *MYC* rearrangement is a diagnostic feature of BL, it is not specific and occurs less commonly in DLBCL and other aggressive lymphomas. A recently discovered entity that shares morphological, phenotypic and gene expression profiles to sporadic BL but lacks MYC rearrangement was included in the WHO 2016 update, Burkitt-like lymphoma with 11q aberration. These lymphomas are characterised an 11q aberration (typically proximal gains and telomeric losses, see Figure 27.2), complex karyotypes and a mutational landscape that differs from sporadic BL. The WHO 2022 update updated the terminology subtly to reflect this, classifying such cases as 'High-grade B-cell lymphoma with 11q aberrations'.

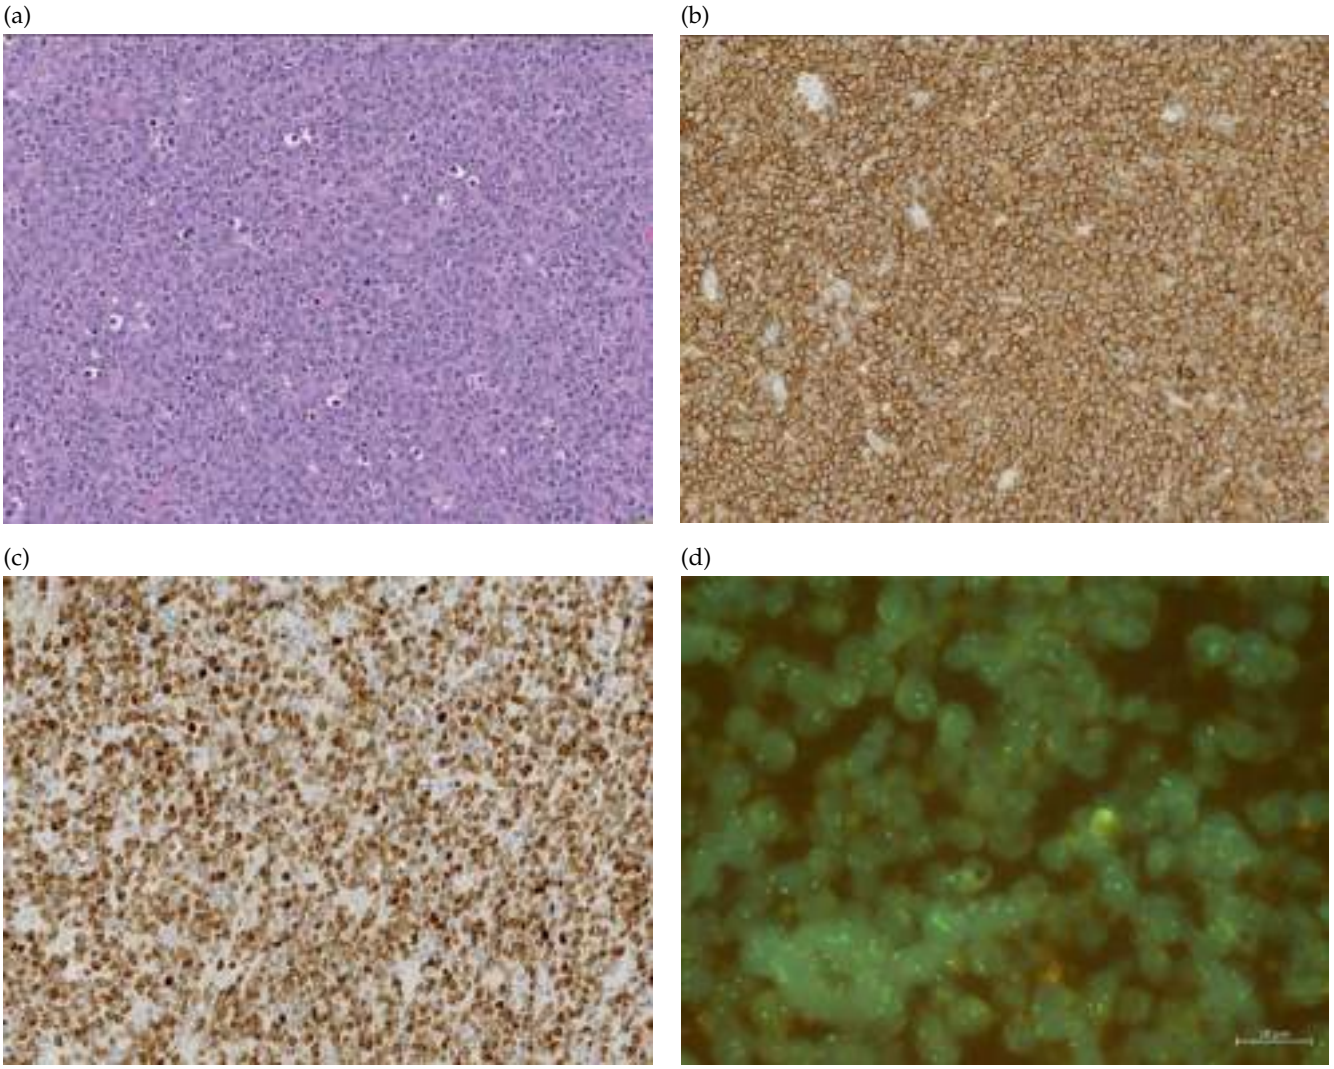

Figure 27.2 High-grade B-cell lymphoma with 11q aberration (previously known as Burkitt-like lymphoma with 11q aberration in WHO 2016 classification). (a) H&E staining demonstrating high-grade lymphoma morphology with 'starry-sky' appearance due to presence of scattered tangible-body laden macrophages. (b) Uniform positivity of CD20 on immunohistochemistry confirming B-cell lineage. (c) Ki-67 immunohistochemistry positive in >90% of cells. (d) FISH using 11q gain/loss triple-colour probes showing two to three green signals in the 11q23.3 region but only one orange signal at the 11q24.3 region, confirming the presence of typical 11q gain-loss pattern. (Source: Au-Yeung RKH, Padilla LA, Zimmermann M *et al.* (2020) Experience with provisional WHO-entities large B-cell lymphoma with *IRF4*-rearrangement and Burkitt-like lymphoma with 11q aberration in paediatric patients of the NHL-BFM group./JOHN WILEY & SONS, INC. / CC BY-NC 4.0.)

Current models for BL assume that IG-MYC translocation is an early genetic event and additional cooperating oncogenic events are required to drive lymphomagenesis. *MYC* and *TP53* mutations occur in approximately 60% and 40% of BL cases, respectively. Recent genomic sequencing studies have revealed novel activating mutations in the transcription factor, *TCF3* and inactivating mutations in its negative regulator, *ID3*, affecting up to 70% of cases. Additionally, activating mutations in *CCND3* (encoding cyclin D3) have been identified in 38% of sporadic BL. Together, these recurrent oncogenic mutations cooperate with *MYC* to promote proliferation, survival and growth of BL cells.

Treatment and prognosis

Until recently, estimating prognosis for adults with BL was challenging because the international prognostic index (IPI) used for other aggressive lymphomas lacked prognostic discrimination in BL. However, a recent multicentre analysis of >1000 patients with BL identified variables showing the strongest prognostic association with PFS, resulting in creation of the BL International Prognostic Index (BL-IPI). The BL-IPI is made up of the following four risk factors; age ≥40 years, performance status ≥2, serum LDH >3× upper limit of normal and CNS involvement. The score was validated in an external data set whereby 3-year PFS estimates were 96, 82 and 63% for low (score 0), intermediate (score 1) and high risk (score ≥2) groups, respectively. This scoring system will be useful in the clinical setting for prognostication and also for designing clinical trials in BL, which will largely focus on reducing toxicity for low-risk patients who have excellent long-term outcomes and incorporating novel agents for poor-risk groups.

Therapies in BL are typically more intensive than DLBCL. Due to the high proliferation rates of the tumour, a dose-intense, short-duration treatment strategy is employed to avoid rapid growth and development of resistance between chemotherapy cycles. Effective treatment of patients with BL is therefore based on a multi-drug combination chemotherapy of anti-metabolites and alkylating agents (e.g CODOX–M/IVAC regimen, hyper CVAD; Table 27.4) and includes drugs which highly penetrate the blood–brain barrier, such as methotrexate and cytarabine. Prospective trials in adults and children have now demonstrated that addition of rituximab to chemotherapy is associated with improved survival and this is now universally recommended in BL. With the above rituximab-containing regimens, CR and 3 year-PFS rates are in the region of 80–94% and 70–90% respectively. Addition of granulocyte-colony stimulating factors (G-CSF) is required in these regimens to maintain dose intensity and reduce the duration of severe neutropenia.

In recent years, the less dose-intense regimen DA-EPOCH-R has been used in BL with good clinical outcomes. A single arm, multicentre study published in 2020 investigated using a risk-adapted approach with DA-EPOCH-R in 113 adults with untreated BL. Low-risk patients received three cycles with no CNS prophylaxis, and high-risk patients received six cycles with intrathecal CNS prophylaxis (or extended intrathecal treatment if leptomeninges involved). At median follow-up of 59 months, EFS/OS were 84.5 and 87.0% respectively, and EFS was 100 and 82.1% in low- and high-risk patients. Notably, involvement of the CSF was the most significant risk factor for early TRM or treatment failure in this study, and a recent multicentre retrospective analysis of 641 patients demonstrated that intensive regimens containing CNS penetrating agents were associated with lower rates of CNS relapse compared to DA-EPOCH-R. Larger studies are required to evaluate this regimen in adult BL, but it may be an acceptable option for patients who may not tolerate more intensive regimens.

The risk for tumour lysis syndrome (TLS), especially after initiating chemotherapy, is relatively high, reflecting the high proliferation rate of tumour cells. Vigorous hydration with alkalinisation, accompanied by administration of recombinant urate oxidase (rasburicase) (or a uric acid synthesis inhibitor such as allopurinol) is very important in preventing/reducing the severity of this complication (see also Chapter 55). Hypercalcaemia is also frequent at presentation and needs appropriate therapy with hydration and bisphosphonates.

Relapses in BL typically occur within the first 12 months following treatment. Although BL is a highly FDG-avid tumour, there is currently no consensus on its usefulness for response assessment, and this requires further exploration. There remains a lack of improvement in the outcome of patients older than 60 years, who make up a quarter of BL diagnoses and experience a higher rate of adverse events and for which the standard dose-intense regimens may be unsuitable and alternative approaches are warranted. Newer molecularly-targeted therapies may be beneficial in this cohort of patients, as well as in patients with relapsed/refractory disease who historically have an extremely poor prognosis.

Burkitt lymphoma in HIV-positive patients

A number of studies have demonstrated the feasibility of administering intensive chemotherapy regimens, such as CODOX-M/IVAC, with or without Rituximab, to HIV-positive patients with BL. These studies report a 2-year EFS of approximately 60%, similar to that observed in HIV-negative patients treated with the same regimen, with no increase in toxicity and prompt immune recovery suggesting that a uniform approach to treatment of BL should be used, regardless of HIV status. The DA-EPOCH-R regimen has also been shown to be effective in this cohort, but the lack of CNS penetrating agents included is a concern with this therapy. A recent large retrospective analysis of 249 patients with HIV-related BL found that the incidence of CNS relapse was higher with DA-EPOCH compared to other regimens, and the most effective regimen with regards to PFS

appeared to be CODOX-M/IVAC. The same study demonstrated for the first time that prognostic factors for patient outcome were associated with lymphoma characteristics, rather than HIV-related features.

Post-transplant lymphoproliferative disorder

Post-transplant lymphoproliferative disorder (PTLD) represents a spectrum of disorders resulting from lymphoid proliferations occurring as a result of immunosuppression following allogeneic solid organ or haematopoietic stem cell transplantation. The WHO 2016 classification categorises PTLD into non-destructive PTLDs (plasmacytic hyperplasia, infectious mononucleosis, florid follicular hyperplasia), polymorphic PTLD, classical Hodgkin lymphoma PTLD and monomorphic PTLDs. Monomorphic PTLDs cannot be distinguished from lymphomas with a similar lineage and cell-of- origin in immunocompetent patients, therefore subclassification of these types should be the same (i.e. DLBCL, Burkitt lymphoma, plasma cell myeloma, plasmacytoma, T-cell neoplasms). EBV causes the majority of these disorders: impaired T-cell function leads to proliferation of latently EBV-infected polyclonal B-cells, whereas subsequent genomic mutations result in monoclonal/monomorphic PTLD. Of note, EBV-negative PTLD can occur and has been documented in up to 30% of PTLD in some series.

The optimal treatment of PTLD is still not clearly defined with most published data in the form of case series. Therapeutic options in PTLD include immunosuppression reduction, chemotherapy and immunotherapy. Management should be undertaken in conjunction with a transplant physician, particularly with respect to immunosuppression reduction and surveillance of graft function. Patients may respond to reduction in immunosuppression, especially those who develop PTLD within 1 year from transplant (ORR 80 versus 10% in patients who developed PTLD beyond 1 year). Case series and Phase II studies of rituximab monotherapy following failure of reduction of immunosuppression have confirmed efficacy in inducing remission in a proportion of patients (44–65%) with PTLD. Toxicity appears to be low, but significant numbers of patients progressed on therapy or relapsed after rituximab, some died of lymphoma and many required intensification to chemotherapy.

The prospective phase 2 PTLD-1 trial previously demonstrated the efficacy and safety of sequential therapy (rituximab followed by CHOP chemotherapy) for solid organ transplant recipients with CD20-positive PTLD unresponsive to reduction of immunosuppression. Despite supportive treatment including mandatory G-CSF support and antibiotic prophylaxis, infective toxicity was still significant with a TRM of 13%. The subsequent PTLD-1/3 trial introduced a response-adapted schema whereby patients were assessed following 4 weekly rituximab doses with interim CT. Those obtaining a CR were considered 'low risk' and received four further doses of weekly rituximab only, while those not obtaining CR were deemed 'high risk' and switched to four cycles of R-CHOP-21. The median OS was identical to the PTLD-1 trial but TRM was reduced to 8%. The treatment algorithm used in PTLD-1/3 is now widely employed; however, patients with clinically aggressive lymphoma and critical organ compromise are often treated with R-CHOP-21 upfront. Prospective trials are ongoing investigating incorporation of novel agents, e.g. ibrutinib, to front-line therapy.

Patients with relapsed/refractory PTLD post-R-CHOP therapy have poor long-term survival. There is data to support use of intensive second-line chemotherapy and ASCT in this setting, but patients must be selected very carefully for this approach given the underlying comorbidity inherent in this group. Anti-EBV cytotoxic T lymphocytes have been used for chemorefractory disease but their availability is restricted, and their infusion is associated with regulatory challenges.

Other rare aggressive B-cell lymphoma subtypes

Intravascular large B-cell lymphoma

Intravascular large B-cell lymphoma is an extremely rare form of NHL and is characterised by an accumulation of large neoplastic B-cells within the lumen of blood vessels. These lymphomas preferentially affect the elderly and often involve the CNS (approximately 30% of patients), lungs and skin. Prognosis is generally poor. Patients presenting with only skin lesions appear to have a significantly better survival than patients with other clinical presentations (3-year OS: 56 versus 22%). Multi-agent chemotherapy using agents with higher CNS bioavailability is the preferred mode of treatment.

T-cell/histiocyte-rich large B-cell lymphoma

T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL) may arise de novo, but more commonly occurs as a high-grade transformation of underlying nodular lymphocyte predominant Hodgkin lymphoma (NLPHL). As the name suggests, THRLBCL is characterised by a limited number of scattered, large B-cells embedded in a background of abundant T cells and histiocytes. Pathologically, it can be difficult to distinguish from NLPHL, and therefore clinical correlation is key to diagnosing the high-grade transformation. It has a strong male predominance and typically occurs in middle-age, often presenting with advanced-stage disease and extranodal involvement. It should be treated identically to DLBCL-NOS, but often behaves in an aggressive manner with poor outcomes.

Primary cutaneous diffuse large B-cell lymphoma, leg type

This entity comprises 20% of all primary cutaneous B-cell lymphomas and typically occurs in older women. It classically presents with red or bluish-red rapidly growing tumours on one or both lower legs, but 10–15% of cases arise at other sites and dissemination to extracutaneous sites is common. The neoplastic B-cells have a gene expression profile of ABC subtype *DLBCL*, and *MYD88* L265P mutations are found in up to 60% of cases. Historically, outcomes have been reported as being very poor, although this may in part reflect the preponderance for older patients. Treatment is often similar to approaches for limited-stage DLBCL, involving R-CHOP for those deemed fit enough followed by involved field radiotherapy.

EBV-positive diffuse large B-cell lymphoma

This disease was formerly called EBV-positive DLBCL of the elderly as it typically occurs in patients over the age of 50, but the restriction to elderly patients has been removed from the WHO 2016 and 2022 classifications. It is a distinct entity which should be distinguished from other well-defined lymphomas that may be EBV-positive (e.g. plasmablastic lymphoma, DLBCL associated with chronic inflammation, PTLD). The increased incidence in older patients is thought to relate to immunosenescence. Advanced-stage disease and extranodal involvement are relatively common. Treatment approach is identical to that of DLBCL, NOS and prognosis varies according to age with older patients tending to have poorer outcomes.

Diffuse large B-cell lymphoma associated with chronic inflammation

This is a neoplasm occurring in the setting of longstanding chronic inflammation and is uniformly associated with EBV. It typically arises in patients with a lengthy history of pyothorax, but other reported sites of involvement include bone (especially femur), joints, and periarticular soft tissue. DLBCL associated with chronic inflammation is an aggressive disease and confers a poor prognosis. Immunochemotherapy and radiotherapy are typically employed, although there have been reports of complete tumour resection resulting in good long-term outcome.

Plasmablastic lymphoma

Plasmablastic lymphoma (PBL) is a rare, aggressive lymphoma subtype seen most commonly in immunosuppressed states, in particular with HIV infection, with cases in immunocompetent patients occurring rarely. PBL is thought to arise from post-germinal centre B-cells that are in transition towards plasma cell differentiation, as evidenced by loss of typical B-cell markers but strong expression of plasmacytic markers (e.g. CD138, MUM1 and BLIMP1). Approximately 60% of cases are associated with EBV infection, and 50% harbour *MYC* translocations.

PBL commonly arises in the oral cavity although may present with widespread, advanced-stage disease. Overall, outcomes are very poor, although early-stage disease and complete response to chemotherapy are associated with superior outcomes. There is no consensus regarding optimal treatment and many use CHOP but regimens used for other aggressive lymphomas are also employed, including CODOX-M/IVAC and DA-EPOCH. Given the plasmacytic differentiation of the tumour cells, the proteasome inhibitor bortezomib (commonly used to treat plasma cell disorders) has been added to regimens, with some small single-arm studies showing promising results.

Primary effusion lymphoma

Primary effusion lymphoma (PEL) is a rare disorder occurring almost exclusively in PLWH, characterised by a proliferation of monoclonal B-cells expressing the plasmacytic marker CD38 and often CD30. EBV co-infection is commonly found, but its role in the pathogenesis of PEL is not clear. As the name suggests, it typically presents with malignant effusions e.g. pleural, peritoneal or pericardial. Despite often presenting as limited-stage disease, PEL causes local destruction and has a dismal prognosis. There is a paucity of data to guide treatment, but intensive chemotherapy, such as DA-EPOCH is often attempted for patients deemed fit enough, with radiotherapy reserved for poorly responding patients or to provide symptomatic control.

HHV8-positive DLBCL

HHV8-positive DLBCL, NOS, most commonly arises in association with HHV8-positive multicentric Castleman disease (MCD) in the setting of immunosuppression. The disease usually manifests with rapidly enlarging lymph nodes and splenomegaly, often in patients with clinical features of MCD, and is associated with an extremely aggressive clinical course and refractoriness to chemotherapy.

Future directions

Over the last decade, we have seen huge advances in the field of aggressive B-cell NHL, from the application of sophisticated genetic and molecular analysis to improve subclassification of DLBCL, through to the application of novel cellular therapies for patients with relapsed/refractory disease. Although there continues to be no therapy proven to improve overall survival over R-CHOP for DLBCL, this is surely imminent as clinical trial design becomes more sophisticated and incorporates novel agents targeted to specific molecular subtypes. Response assessment using PET-CT in combination with circulating tumour DNA monitoring also has the potential to earlier identify patients

destined to do poorly with traditional immunochemotherapy. CAR T-cell therapy and bispecific antibodies are a hugely exciting advance and provide therapeutic options for patients who previously had no prospect of cure. It is likely that these therapies will move earlier in the treatment algorithm with time, although there is still much work to be done to improve response rates and reduce the substantial associated toxicity and cost of these treatments.

Epidemiology and aetiology

The annual age standardised incidence of MM is around 10 per 100,000. It represents approximately 1% of all malignant diseases and 15% of all haematological malignancies. The incidence of MM is lower in Asian populations and higher in blacks, almost twice that in whites; MM is slightly more frequent in men than in women. The median age at diagnosis is 65–70 years. Only 15 and 2% of the patients are younger than 50 and 40 years, respectively. The 5-year prevalence estimates according to the International Agency for Research on Cancer (IARC) are approximately 100,000 in North America and 138,000 in Europe.

The cause of MM is unknown although a number of risk factors have been explored. Radiation may play a role in some cases. An increased risk has been reported in farmers, particularly those who use herbicides and insecticides, and in people exposed to benzene and other organic solvents. However, the number of cases is small and more epidemiological data are needed to establish a significant relationship. MM and monoclonal gammopathy of undetermined significance (MGUS) a precursor state have been reported in familial clusters. A higher incidence is associated with older age, obesity, African or African–American ethnicity. Several studies have shown that patients with a first-degree relative with MM or the precancerous condition monoclonal gammopathy of undetermined significance are more likely to develop MGUS or MM than those without a family history. To date, many family linkage studies have been performed, providing strong evidence for an inherited component to the development of MM. The basis of this genetic contribution remains to be fully established, although studies have reported possible associations between certain genetic variations and myeloma risk. There is now clear evidence that most, if not all, myeloma cases are preceded by a previous MGUS.

Pathogenesis

MM is a B-cell malignancy characterised by the accumulation of terminally differentiated clonal plasma cells in the bone marrow, the production of a monoclonal immunoglobulin detectable in serum and/or urine and the presence of lytic bone lesions. In order to understand the pathogenesis of MM, it is important to review not only the molecular changes within the plasma cells involved in the development and behaviour of the malignant clone but also the mechanisms responsible for the interaction between the malignant plasma cells and their resident microenvironment, since they play a relevant role in bone destruction, tumour cell growth, survival, migration and drug resistance.

Cellular origin of myeloma cells

Normal differentiation from early B cells to plasma cells is characterised by three B-cell-specific DNA remodelling mechanisms that modify immunoglobulin genes: VDJ rearrangement, somatic mutation and class switch recombination. Rearrangements of the *immunoglobulin* genes of B-cell precursors to form a B-cell receptor (*BCR*) occur in the bone marrow, while antigen recognition, selection, somatic hypermutation and class switch recombination take place in germinal centres

within the lymph node, spleen or Peyer's patches. Sequence analysis of the immunoglobulin VH gene support the post-germinal centre origin of myeloma cells, which have successfully completed somatic hypermutation (without intraclonal variation) and IgH switching, before migrating to the bone marrow, where they will interact with stromal cells before finally differentiating into long-lived plasma cells.

Genomic abnormalities

Genome instability is a prominent feature of myeloma cells and in fact, almost all cases of MM are cytogenetically abnormal. Genomic abnormalities can be categorised as chromosomal translocations, mainly involving the IGH locus on chromosome 14q32, copy number abnormalities, mutations and epigenetic modifications.

IGH translocations

A primary event in many kinds of B-cell malignancy is dysregulation of an oncogene that, as a result of translocation to the *IGH* locus (14q32) or, somewhat less often, the *IGL* locus (κ 2p11 or λ 22q11), is juxtaposed near one of the potent immunoglobulin enhancers. In MM, *IGH* translocation may be classified into primary or secondary. Primary *IGH* translocations occur as initiating events during the pathogenesis of MM, whereas secondary translocations are involved in progression. Most primary *IGH* translocations result from errors in B-cell-specific DNA modification processes, mostly *IGH* switch recombination or, less often, somatic hypermutation. The breakpoints occur mainly within or immediately adjacent to *IGH* switch regions or JH regions. In contrast, secondary translocations are mediated by other kinds of recombination mechanism that do not specifically target B-cell-specific DNA modification processes. Unlike other B-cell malignancies, in MM there is a marked diversity of chromosomal loci involved in *IGH* translocations. About 40% of MM tumours have *IGH* translocations involving five recurrent chromosomal patterns (Figure 28.1): 11q13 (*CCND1*), 4p16 (*FGFR/MMSET*), 16q23 (*MAF*), 6p21 (*CCND3*) and 20q11 (*MAFB*).

The prevalence of t(11;14) according to interphase fluorescence *in situ* hybridisation (FISH) analysis is 15–20% and is readily detectable by karyotyping. As a result of the translocation, *CCND1* is juxtaposed to the powerful *IGH* 3′ enhancer(s) on der(14), and its expression is dysregulated, as indicated by gene expression profiling and reverse transcriptase polymerase chain reaction (RT-PCR) in 100% of MM cases with t(11;14).

The t(4;14) translocation is identified in approximately 15% of MM cases using FISH analysis but cannot be detected by karyotyping techniques. This translocation results in the simultaneous deregulation of the fibroblast growth factor receptor 3 (*FGFR3*) gene on der(14) and the multiple myeloma SET domain (*MMSET*) gene on der(4). FGFR3 is one of the high-affinity tyrosine kinase receptors for the FGF family of ligands. Both *FGFR3* and *MMSET* genes are not normally expressed in plasma cells but are over-expressed as a result of t(4;14). However, gene expression profiling and RT-PCR analysis have shown that only 75% of MM cases with t(4;14) display simultaneous over-expression of MMSET and FGFR3. In the remaining 25% of cases, only MMSET is upregulated and the lack of FGFR3 expression is linked in most cases to loss of the *FGFR3* gene on der(14). These data suggest that *MMSET* may be the critical transforming event in MM harbouring t(4;14), whereas *FGFR3* could be dispensable. In some cases, (10%) the translocated *FGFR3* contains activating mutations that may be involved in MM progression.

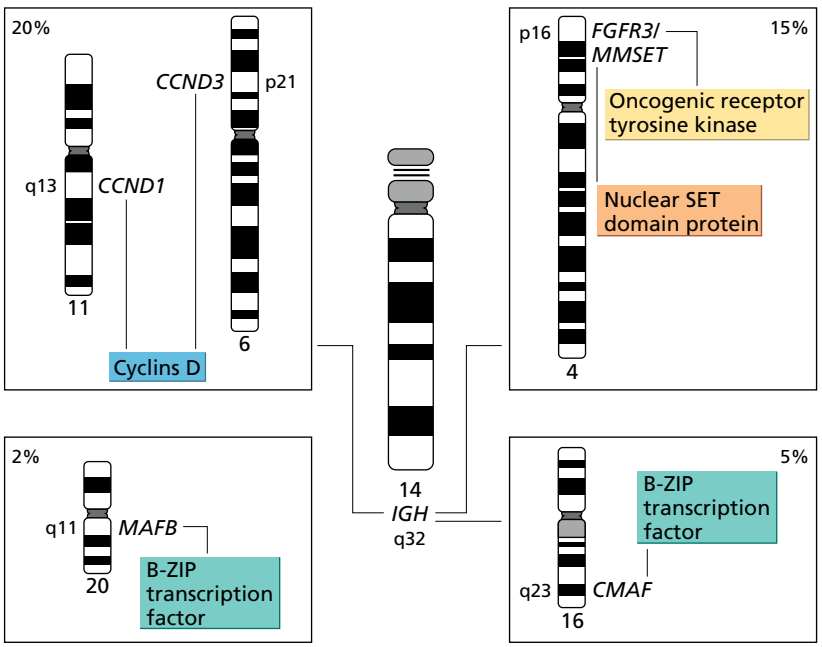

Figure 28.1 *IGH* translocations in multiple myeloma.

The incidence of t(14;16) is 5–10%. The breakpoints on 16q23 occur over a region 550–1350 kb centromeric to *MAF*. Taking into account such a long distance, it is still an open question whether or not *IGH* may act as enhancer for *MAF* in this translocation. Moreover, over-expression of MAF is observed in half of myeloma cases, while the prevalence of t(14;16) is low. The t(6;14) translocation has been found in a low proportion (3%) of MM cases. Using microarray analyses, high levels of cyclin D3 mRNA have been shown in cases with t(6;14) detected by FISH. The t(14;20) translocation leads to deregulation of *MAFB* (20q23), which, like *MAF*, encodes a B-ZIP transcription factor, but in contrast to t(14;16), *MAFB* translocations have structural features that indicate they are secondary translocations.

Gains and losses of chromosomal material

Almost all MM cases are aneuploid, as evidenced by the measurement of DNA content by flow cytometry and cytogenetic techniques. Patients with MM may be grouped into two major categories, according to ploidy status assessed by karyotyping: the hyperdiploid group (more than 46/47 chromosomes) and the non-hyperdiploid group, composed of hypodiploid (up to 44/45 chromosomes), pseudodiploid (44/45 to 46/47) and near tetraploid (more than 74) cases. Non-hyperdiploid MM is characterised by a very high prevalence of *IGH* translocations involving the five recurrent partners. Likewise, monosomy/deletion 13 and gains on 1q occur predominantly in non-hyperdiploid MM. In contrast, the hyperdiploid group is associated with recurrent trisomies involving odd chromosomes (3, 5, 7, 9, 11, 15 and 19) and with a low incidence of structural chromosomal abnormalities. Similar associations have been observed in analysing DNA content by flow cytometry.

The loss of chromosome 13 is the most common monosomy in MM (40–50% of newly diagnosed patients). This abnormality shows a strong association with t(4;14) and t(14;16), deletion of 17p and gains on 1q. Chromosome 17p deletion, which includes loss of *TP53*, occurs at a lower frequency in newly diagnosed MM (up to 10%), although the proportion is higher in advanced stages of the disease. Furthermore, 17p deletion is associated with extramedullary MM. Conventional cytogenetics, FISH and comparative genomic hybridisation analysis have all demonstrated that lesions of chromosome 1 are the most common abnormalities in MM; mostly they are 1q gains, as the result of tandem duplications and jumping segmental duplications of the chromosome 1q band. Large cooperative group studies have demonstrated that 1p losses (especially 1p22 and 1p32 deletions) are also frequent in MM patients.

Mutations detected by whole-genome sequencing

Whole-genome sequencing (WGS) strategies have shown that there are approximately 35 non-synonymous mutations per myeloma sample. However, only a few recurrently mutated genes have been detected, apart from the well-known mutations in the MAPK pathway. This is in agreement with other haematological malignancies, such as acute myeloid leukaemia, but is in contrast to hairy cell leukaemia and Waldenstrom's macroglobulinaemia, in which single unifying mutations are seen, *BRAF* and *MYD88*, respectively. Frequently mutated genes are *KRAS* and *NRAS* (20%) followed by *TP53*, *DIS3*, *FAM46C* and *BRAF*, which are all mutated in up to 10% of patients. All other mutations were observed in about 5% of patients with two or more mutations in genes involved in the MAPK pathway noted in some patients. The impact of all mutations apart from *TP53* mutation on survival and response to therapy remains unclear.

Epigenetic modifications

Compared to the considerable data available on genomic changes in myeloma patients, there is limited evidence about the epigenetic changes involved in MM pathogenesis. The most relevant epigenetic change revealed so far is aberrant methylation and up to 5% of genes relevant in DNA and histone methylation mutated in myeloma patients. Enhancer of Zeste homologue 2-*EZH2* encodes part of PRC2 complex catalytic component overexpression has been described within the context of MM, demonstrating its negative prognostic value: and increased EZH2 during disease progression, from MGUS, to myeloma has been reported. MMSET/NSD2 acts as a histone-modifying enzyme, and its abnormal expression in MM is driven by the t(4;14). *NSD2* interacts with both histone-H3 and -H4, thus leading to H3K36-dimethylation and H4K20-trimethylation; of note, it also favours the function of histone deacetylase-1, -2, and histone demethylase LSD1. These changes lead to myeloma progression. The histone deacetylase inhibitor (HDAC), Panobinostat, is approved for treatment of relapsed myeloma patients in combination with proteasome inhibitors.

Late genetic events

Some genetic changes in MM, such as secondary translocations, mutations, deletions and epigenetic abnormalities, are considered late oncogenic events and are associated with disease progression. Gain of 1q21 noted in up to 40% of patients has been observed to be amplified with additional copies of 1q at disease progression, in a proportion of patients. Dysregulation of *MYC* is a paradigm for secondary translocations in MM. Most karyotypic abnormalities involving *MYC* correspond to complex translocations and insertions that often are non-reciprocal and frequently involve three different chromosomes. Activating *RAS* mutations are considered molecular markers of disease progression. Thus, the prevalence of activating *KRAS* and *NRAS* mutations is over 75% in MM cases at relapse. *TP53* inactivation, via either deletion or mutation, seems to be more frequently associated with disease progression. Methylation is an epigenetic change that has been described in MM and acts as an inactivating mechanism of the tumour-suppressor genes *CDKN2B*

Table 28.1 Prognostic value of the main chromosomal abnormalities of multiple myeloma.

Abnormality	Prognostic value
t(4;14)	Worse prognosis
Del(17p)	Worse prognosis
Del(1p32)	Worse prognosis
1q gains	Worse prognosis
t(14;16)	Worse prognosis
Hyperdiploidy	Better prognosis
t(11;14)	Neutral prognostically

and *CDKN2A*. Although it has also been detected in MGUS, its prevalence is much higher in advanced MM and extramedullary forms of the disease.

Prognostic significance of chromosomal aberrations in myeloma

Gene expression analysis of MM has confirmed the huge genetic diversity of this malignancy. Recently, the classification of MM into seven different groups has been proposed. Each group displays a specific genetic signature and some of them are associated with a particular *IGH* translocation or ploidy status and with a characteristic clinical behaviour. Table 28.1 summarises this classification, which connects genetic abnormalities, cell transcriptome and clinical features of patients.

Dysregulation of cyclin D genes as a potential unifying event in MM pathogenesis

There is no common genetic mechanism to explain the pathogenesis of MM. However, it can be speculated that although *IGH* translocations induce upregulation of different oncogenes, it is possible that all *IGH* translocations involved in MM converge on a common pathway resulting in inhibition of differentiation and an increase in cell survival and proliferation. Gene expression profiling analysis has demonstrated that expression of *CCND1*, *CCND2* and *CCND3* is increased in virtually all MM patients, supporting the recent hypothesis of a potential unifying event in pathogenesis. Approximately 25% of MM cases display over-expression of one of these cyclins, which may be triggered directly by an *IGH* translocation such as t(11;14) and t(6;14) that dysregulates *CCND1* and *CCND3* respectively, or indirectly by an *IGH* translocation involving *MAF* and *MAFB* genes, which encode a transcription factor that targets cyclin D2. Nearly 40% of MM cases express increased cyclin D1 through biallelic dysregulation of *CCND1* and without apparent t(11;14); most of the remaining cases of MM, including those with t(4;14), have increased expression of cyclin D2.

MicroRNA expression

MicroRNAs (miRNAs) are small non-coding RNAs that regulate gene expression at the post-transcriptional level and are involved in critical biological processes, including cellular growth and differentiation. Different studies have shown that miRNA expression is deregulated in myeloma cells as compared to normal plasma cells and that their expression profile is associated with genetic abnormalities. Moreover, several miRNAs have been involved in MM pathogenesis. In this sense, it has shown a mechanism of p53 regulation through miRNAs acting on *MDM2* expression; thus, miR-192, 194 and 215 re-expression in myeloma cell lines induce degradation of *MDM2* with the subsequent p53 upregulation and cell growth inhibition.

Multistep pathogenesis of multiple myeloma

The current pathogenic models assume that MM develops through a multistep transformation from normal plasma cells (PCs) to MGUS, which implies PC immortalisation and, subsequently, the transformation to active MM, where clonal PCs cause end-organ damage. Cytogenetic studies using FISH have demonstrated that most genetic lesions typical of MM are already present at MGUS stage. Recent studies show that a major difference between these three entities is the number of PCs with genetic abnormalities, which increases from MGUS to SMM (smouldering multiple myeloma) and to MM, thus the progression from MGUS to SMM, and eventually to MM, involves a clonal expansion of genetically abnormal PCs. These findings have also been confirmed WGS. WGS in longitudinal samples has shown evidence for Darwinian evolution with both linear and branching sub clonal changes in patients with some additional spatio temporal variation. In addition, contribution from parallel changes in the immune microenvironment during this process is an active area of investigation. Ability of clonal plasma cells to evade immune surveillance and enrichment of the marrow with pro-tumoural immune microenvironment (Higher T regulatory cell numbers, T cell exhaustion, increased in myeloid-derived suppressor cells) support progression from MGUS to myeloma.

Interaction between plasma cells and their microenvironment

As far as the pathogenesis of MM is concerned, interactions between the myelomatous plasma cells and their resident marrow microenvironment have been studied in detail. In the bone marrow, MM cells adhere to extracellular matrix proteins and bone marrow stromal cells through a series of adhesion molecules, for example the β_1 integrin family (VLA-4, VLA-5, VLA-6; also called CD49d, CD49e and CD49f) (present in myeloma cells), and vascular cell adhesion molecule (VCAM)-1 and intercellular adhesion molecule (ICAM)-1 (present in stromal cells) (Figure 28.2). In addition, bone

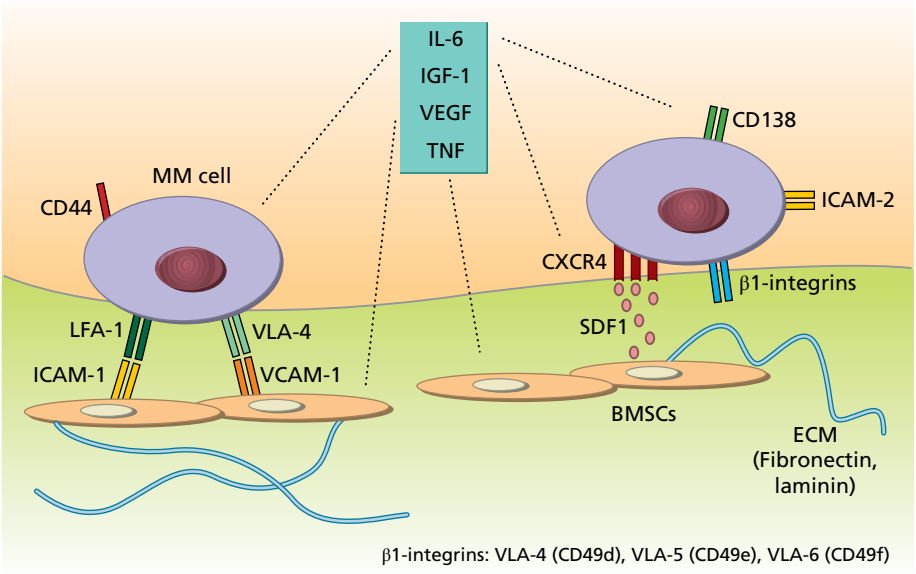

Figure 28.2 Interactions between plasma cells and the microenvironment. See text for definition of abbreviations.

marrow stromal cells produce a stromal-cell-derived factor (SDF)-1 that binds to CXCR4 on the surface of myeloma cells, inducing both chemotaxis of plasma cells and upregulation of surface adhesion molecules such as VLA-4. Bone marrow homing of plasma cells is likely further facilitated through other adhesion molecules expressed by myeloma cells, such as CD138, CD38, CD44 and CD106. Interaction of CD147 receptor on myeloma cells with cyclophilin-A secreted by bone marrow endothelial cells also promotes plasma cell homing. The binding of MM cells to the bone marrow stromal cells induces the transcription and secretion of cytokines, such as tumour necrosis factor (TNF)-α, interleukin (IL)-6, insulin-like growth factor (IGF)-1, IL-21, SDF-1α and vascular endothelial growth factor (VEGF), by plasma cells and/or bone marrow stromal cells; this trigger signalling pathways (e.g. RAF/MEK/MAPK, PI3K/AKT, NF-κB and JAK/STAT) that promote plasma cell proliferation and prevent apoptosis. These pathways are also potential targets for therapeutic intervention (Figure 28.3). In addition, cytokines modulate the production of additional adhesion molecules, which, in a vicious circle, enhances cell adhesion.

Adhesion of myeloma cells to the bone marrow microenvironment induces a cell adhesion-mediated drug resistance phenotype via three mechanisms: (i) cell cycle arrest at G_1 (associated with upregulation of p27, an inhibitor of cyclin-dependent kinases), (ii) apoptosis inhibition via over-expression of FLIP-L, an endogenous inhibitor of FAS (CD95) and (iii) protection of tumour cells from initial drug-induced DNA damage (double-strand breaks) by reducing topoisomerase II activity(iV) enhancing Nfkb activity.

In summary, it appears that the bone marrow microenvironment provides a sanctuary for myeloma cells by both promoting proliferation and blocking apoptosis, thereby allowing tumour

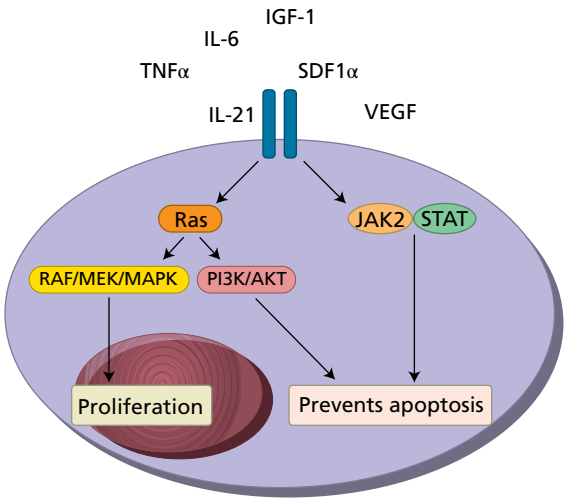

Figure 28.3 Signalling pathways involved in myeloma pathogenesis. See text for definition of abbreviations.

survival/progression and eventual emergence of drug resistance. Interruption by downregulating the interactions between the tumour cell and its marrow microenvironment can potentially halt cell growth and proliferation and be therapeutically value.

Influence of pathogenesis on the clinical features of MM and the development of bone lesions

The interaction between MM cells and bone marrow microenvironment not only favours tumour growth but is also responsible for the dominant clinical feature of myeloma bone disease (see below and Figure 28.4). This interaction stimulates other

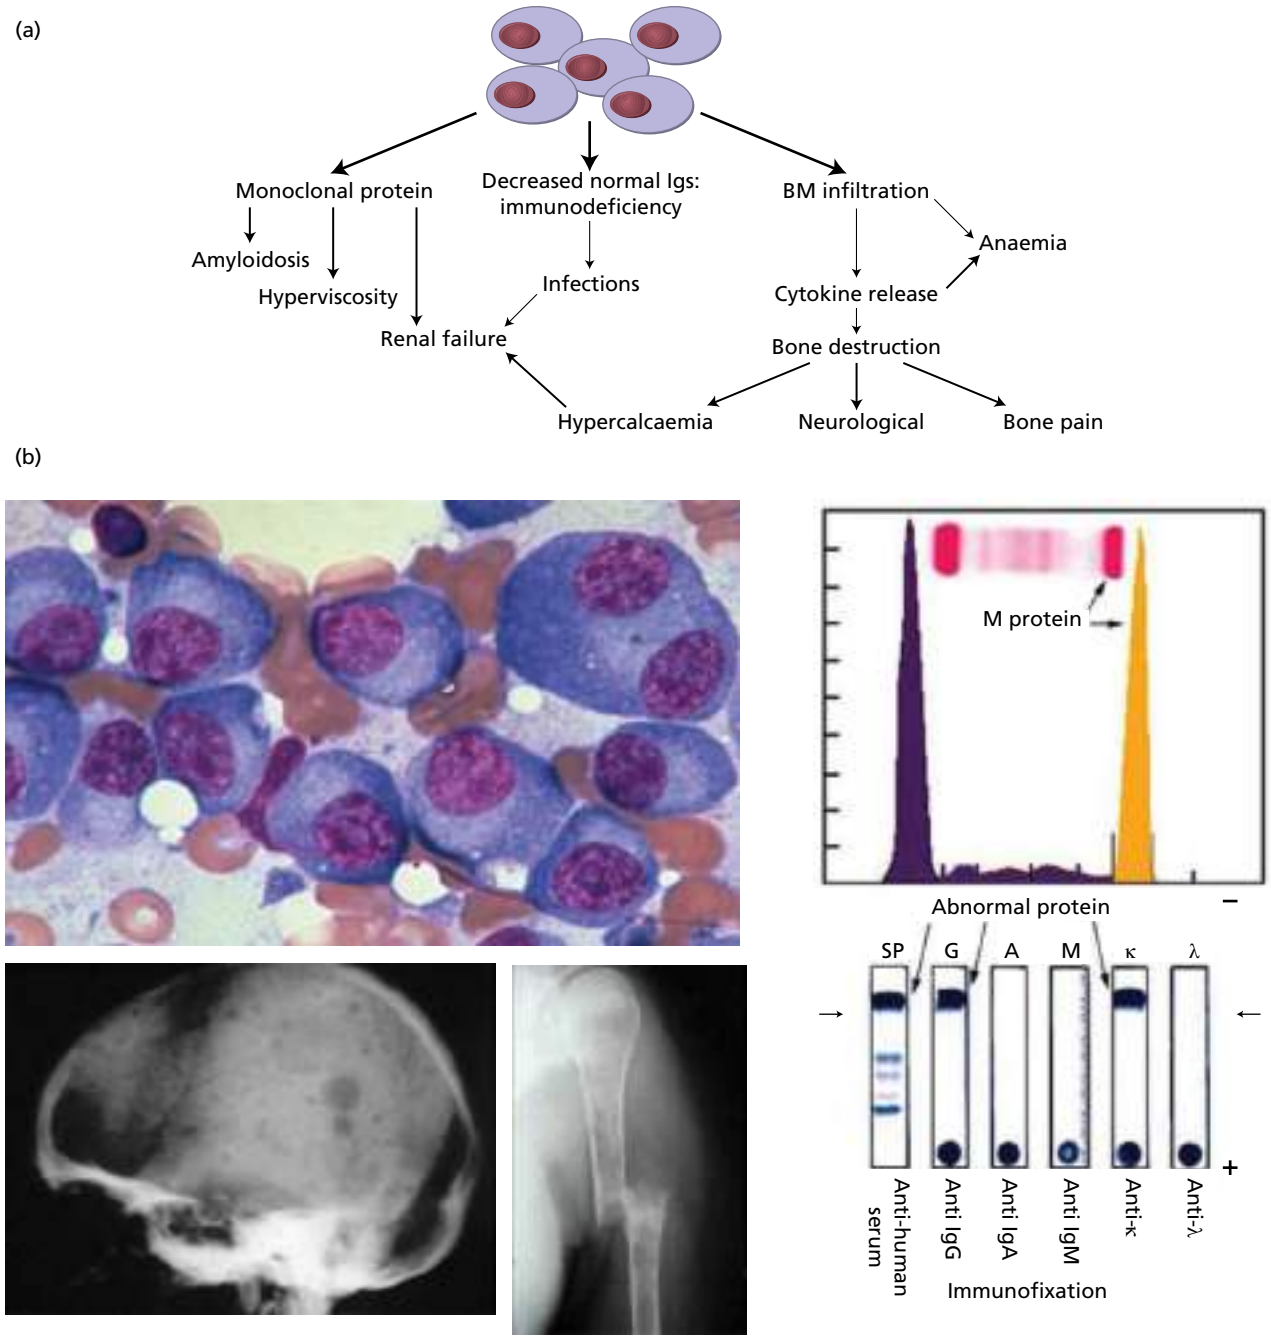

Figure 28.4 (a) Clinical manifestations in myeloma and (b) bone marrow infiltration, monoclonal band (IgGK by immunofixation) in serum, osteolytic lesions resulting in a pathological fracture.

cytokine cascades responsible for osteolytic lesions, which can result in bone pain, hypercalcaemia and neurological compression syndromes. Bone marrow infiltration with MM cells also impairs normal haematopoiesis, leading to anaemia. MM cells secrete monoclonal protein (M-protein) that increases plasma viscosity. In addition, M-protein, and particularly light chains, are responsible for the impairment of renal function, leading ultimately to renal failure. Hypercalcaemia due to osteolytic disease may also contribute to renal failure. Patients are also at increased risk of developing potentially life-threatening infections due to the lack of functional immunoglobulins.

Bone disease is one of the hallmarks of MM (see below). Osteolysis is mediated by an imbalance between osteoclast

activity (increased) and osteoblast activity (decreased). Interaction of MM cells with stromal cells and other cells (including T cells) in the microenvironment induces the secretion of numerous osteoclast-activating factors such as RANK-L, macrophage inflammatory protein (MIP)-1α (also known as CCL3), activin A, VEGF, hepatocyte growth factor (HGF), IL-3, IL-7, TNF-α, IL-6, IL-1β and MIP-3α. Two of the most important are RANK-L (receptor activator of NF-κB ligand) and MIP-1α.

RANK-L is a transmembrane molecule in stromal cells/osteoprogenitors, which is also called TRANCE (TNF-related activation-induced cytokine) or OPG-L (osteoprotegerin ligand). RANK-L binds to its functional receptor RANK (TNF receptor superfamily) on osteoclasts, stimulating osteoclastogenesis by inducing differentiation of osteoclast precursors and stimulating resorption. RANKL activity can be blocked by osteoprotegerin (OPG), a soluble-decoy receptor for RANK-L also produced by stromal/osteoprogenitor cells. Therefore, osteoclastic activity is regulated by a delicate balance between RANK-L and OPG. In fact, under normal physiological conditions, the levels of OPG are significantly higher than those of RANK-L. In contrast, in MM this balance is disrupted by increased expression of RANK-L and decreased expression of OPG on stromal cells after interaction with myeloma cells. It has been suggested that the decline in OPG is also mediated by myeloma cell uptake by binding to CD138 and subsequent degradation. MIP-1α is a potent stimulator of osteoclast formation through a dual mechanism: (i) it enhances the activity of RANK-L and (ii) it directly stimulates osteoclast precursors to differentiate into mature forms. MIP-1α gene expression is abnormally regulated in MM due to unbalanced expression of the acute myeloid leukaemia (AML)-1A and AML-1B transcription factors in myeloma cells. This imbalance also induces IL-3, which stimulates osteoclast formation and resorption directly or by further augmenting that of RANKL and MIP-1α; in addition, as mentioned below, IL-3 inhibits osteoblast formation. Other chemokines such as IL-7, TNFα and IL1β indirectly stimulate osteolytic processes, inducing RANK-L expression. Other OAFs secreted by myeloma cells and/or stromal/or osteoclast cells (e.g. HGF, IL-6, VEGF, activin A), further increase the gradient of osteoclastogenic factors in focal lesions and contribute to osteoclast production and activity.

In MM, in addition to the marked osteoclast activation, there is inhibition of osteoblast formation and function, which is mediated by both soluble factors and direct cellular interactions of myeloma and stromal cells. The WNT/bone morphogenetic protein (BMP) signalling pathways are critical for the osteogenic differentiation of mesenchymal stem cells to mature bone-forming osteoblasts. Myeloma cells (and other BM microenvironmental cells) produce numerous soluble factors that inhibit osteoblast differentiation and/or function, such as WNT signalling antagonists (e.g. DKK1, sclerostin, soluble frizzled related proteins (sFRP-2/3)), BMP inhibitors (e.g. activin A, TGF-β and HGF), and other cytokines and chemokines (e.g. IL-7, TNF-α and IL-3 (which indirectly inhibits osteoblast differentiation involving CD45+ cells in the BM)). In addition, osteoblastic cells from myeloma patients with lytic lesions show reduced Runx2 activity, Runx2 being the major transcription factor regulating osteoblast differentiation. Suppression of Runx2 activity is mediated, at least in part, by cell-to-cell contact of myeloma and mesenchymal osteoprogenitors, since blocking of VLA4-VCAM1 interactions with a neutralising anti-VLA4 antibody partially restored Runx2 function in mesenchymal cells.

Differential diagnosis

The diagnostic criteria for the monoclonal gammopathies have been reviewed by the International Myeloma Working Group (IMWG). The main clinical entities are MGUS, primary systemic amyloidosis (see also Chapter 29), smouldering multiple myeloma and symptomatic multiple myeloma.

Monoclonal gammopathy of undetermined significance

MGUS has a high prevalence (3.2 and 5.8% in individuals over 50 and 70 years of age, respectively). It is characterised by the presence of a serum M-protein (<30 g/L) and less than 10% plasma cells in the bone marrow with no evidence of other B-cell lymphoproliferative disorder and no symptoms or organ or tissue impairment due to the monoclonal gammopathy. There are three distinct clinical types of MGUS based on the secreted monoclonal protein. They are seen distinctly as the progressed malignant phenotype can be different (myeloma or Waldenstroms macroglobulinaemia) and rates of progression also differ (Table 28.2). The transformation rate to a malignant plasma cell disorder is about 1% per year, with an actuarial probability of malignant evolution of 30% at 25 years of follow-up. When the different causes of death are considered, the actuarial probability of malignant transformation at 25 years of follow-up is only 11%, much lower than the actuarial prediction. The main factors associated with MGUS progression include M-protein size, IgA isotype, abnormal free light-chain ratio and the 'evolving type' (rising M-protein during the first years of follow-up), and the presence of more than 95% phenotypically aberrant plasma cells within the bone marrow compartment. Utilising blood-based risk factors, M protein size >15 g/L; non-immunoglobulin G isotype; abnormal free light chain ration <0.26 or > 1.65, the risk of progression to malignant disease at 20 years (adjusted for competing causes of death) is 2, 10, 18 and 27% based on presence of 0, 1, 2 or 3 risk factors.

Table 28.2 Types of monoclonal gammopathy of undetermined significance.

	IgM MGUS	Non-IgM MGUS	Light-chain MGUS
M protein	Presence of serum IgM (<30.0 g/L)	Presence of serum IgA or IgG (<30.0 g/L)	No heavy-chain Ig Abnormal FLC ratio (<0.26 or > 1.65)*
BM involvement	Lymphoplasmacytic infiltration <10%	Clonal BM plasma cells <10%	Clonal BM plasma cells <10%
End organ damage	None†	None‡	None‡
Potential to progress to (lifetime risk/year)	Waldenstorms's macroglobulinaemia, NHL, or AL amyloidosis (1.4%) IgM myeloma (very rare)	Myeloma or a lymphoproliferative disorder (1%)	Light-chain myeloma (0.4%)

AL, amyloid light-chain [amyloidosis]; BM, bone marrow, FLC, free light chain; Ig, immunoglobulin; MGUS, monoclonal gammopathy of undermined significance; NHL, non-Hodgkin lymphoma.
* sFLC ratios increase with declining renal function. Renal reference range ratio of 0.26–3.1 applies here for patients with chronic kidney disease stages 3–5.
† No evidence of anaemia, constitutional symptoms, hyperviscosity, lymphadenopathy, hepatosplenomegaly, or other end organ damage that can be attributed to the underlying lymphoproliferative disorder.
‡ Absence of end organ damage based on CRAB criteria ([hyper] Calcemia, Renal insufficiency, Anaemia, Bone lesions) or amyloidosis that can be attributed to the plasma cell proliferative disorder.

Monoclonal gammopathy of clinical significance (MGCS)

Although MGUS may not transform to myeloma in vast majority of patients, the monoclonal protein secreted can cause organ damage directly or through other mechanisms. This has now been increasingly recognised in clinical practice, although the prevalence of these pathologies remains unclear. A well characterised Monoclonal gammopathy of clinical significance (MGCS) condition is Amyloidosis discussed in Chapter 29. Another group of disorders affecting renal parenchyma are grouped under monoclonal gammopathy of renal significance (MGRS). The monoclonal protein can directly injure renal tissue or mediate damage through autoantibody activity. Skin disorders, neuropathy, systemic disorders such as cryoglobulinaemia, C1 inhibitor deficiency, late-onset nemaline myopathy and capillary leak syndrome are other distinct clinical presentations aetiologically related to the presence of monoclonal protein. Treatment is targeted to underlying abnormal clone of either abnormal B cells or plasma cells.

Smouldering multiple myeloma

The term 'smouldering multiple myeloma' (SMM) was first defined by Kyle and Greipp as the presence of a serum M-protein (>30 g/L) and 10% or more plasma cells in the bone marrow in the absence of lytic bone lesions or clinical manifestations due to the monoclonal gammopathy. More recently, the IMWG considered that the term 'asymptomatic myeloma' could be more appropriate. This condition was defined as the presence of an M-protein (≥30 g/L) and/or 10% or greater bone marrow plasma cells in the absence of symptoms or organ or tissue impairment due to the monoclonal gammopathy. About 10% of patients diagnosed with MM have smouldering disease. This situation is clinically and biologically very close to that observed in MGUS. However, the plasma cell mass is much higher, and most cases will eventually evolve into symptomatic MM.

The annual risk of progression to symptomatic disease is 10% per year for the first 5 years, and it significantly decreases thereafter, 5% per year during the following 5 years and only 1% per year from the 10th year. SMM is not a uniform entity, since it ranges from indolent, low-risk forms (that behave as MGUS) to 'early myelomas' at high risk of developing symptomatic disease. This heterogeneous outcome is supported by the identification of risk factors predicting progression to symptomatic MM. The Old Mayo Clinic Risk Classification proposed three different subgroups of SMM: group 1 with ≥3 g/dL of monoclonal protein and ≥10% of plasma cells in bone marrow, in which the median time to progression (TTP) to symptomatic MM is 2 years; group 2 with <3 g/dL of monoclonal protein and ≥10% bone marrow plasma cells M-protein with a median TTP of 8 years and group 3 with ≥3 g/dL of monoclonal protein, but with <10% plasma cells bone marrow infiltration, translating into a median TTP of 19 years. The Spanish group has proposed a risk classification based on the percentage of PCs with aberrant phenotype (high risk if ≥95% of the total PCs are clonal) plus immunoparesis (decrease in one or two of the uninvolved immunoglobulins), with a median TTP of 23 months when the two risk factors were present, as compared with 73 months when only one risk factor was present and not reached when

none of the risk factors was present. Other adverse risk factors include an abnormal serum free light chain (sFLC), evolving levels of paraprotein and cytogenetic abnormalities such as t(4;14), gain of 1q21 or hypodiploidy. Revised Mayo clinic risk classification has proposed 3 different groups based on 3 variables; bone marrow plasma cells >20%, involved to uninvolved sFLC ratio > 20, >2 g/dL of monoclonal protein. The 2 year progression risk: 6% for low risk (no risk factors), 18% for intermediate risk (1 factor) and 44% for high risk (2–3 factors). These patients should be considered for early intervention in the context of clinical trials. These risk stratification classifications may allow a more individualised disease management.

Multiple myeloma

The diagnosis of MM requires the presence of an M-protein in serum and/or urine, increased plasma cells in the bone marrow or plasmacytoma and related organ or tissue impairment (including bone lesions). The more common symptoms are fatigue from anaemia and bone pain due to the skeletal involvement. Some patients may have no symptoms, but they can have related organ or tissue impairment. Clinical and laboratory features may include anaemia, skeletal involvement (lytic lesions and/or severe osteoporosis, with or without compression fractures), renal failure, hypercalcaemia, recurrent bacterial infections, extramedullary plasmacytomas or associated amyloidosis (Table 28.3). The criteria revised by the IMWG for the diagnosis of MM now includes biomarkers of malignancy which are: more than 60% plasma cells, involved: uninvolved sFLC ratio of over 100 and more than one focal lesion on MRI studies of 5 mm of more in size, shown in Table 28.4. Of note, no serum or urine M-protein values were included, since about 40% of patients with symptomatic MM have a serum M-protein level lower than 30 g/L and 3% have non-secretory myeloma. In the same sense, no minimal proportion of bone marrow plasma cells was required because about 5% of patients with well-documented symptomatic MM have less than 10% plasma cells in their bone marrow. Table 28.5 illustrates the work-up for patients with monoclonal gammopathies.

Table 28.3 Myeloma-related organ or tissue impairment (end-organ damage) due to the plasma cell proliferative process.

- Increased serum calcium
- Renal insufficiency
- Anaemia: haemoglobin 20 g/L below the lowest normal limit
- Bone lesions: lytic lesions or osteoporosis with compression fractures (possibly confirmed by MRI or CT)
- Other: symptomatic hyperviscosity (rare), amyloidosis, recurrent bacterial infections (more than two episodes in 12 months), extramedullary plasmacytomas

Table 28.4 Diagnostic criteria for Multiple myeloma. Clonal bone marrow plasma cells ≥10%, or biopsy proven plasmacytoma and any one of myeloma defining events or biomarkers of malignancy.

- Hypercalcaemia >2.75 mmol/L
- Renal insufficiency creatinine clearance <40 mL/min
- Anaemia, haemoglobin <100 g/L
- Bone lesions one or more osteolytic lesions on imaging
- Clonal bone marrow plasma cells ≥60%
- Involved: uninvolved serum free light chain ratio ≥100
- >1 focal lesions on MRI studies

Table 28.5 Work-up for a patient with monoclonal gammopathy.

- History and physical examination
- Complete blood count and differential peripheral blood film
- Chemistry including calcium and creatinine
- Serum protein electrophoresis and immunofixation
- Nephelometric quantification of immunoglobulins
- 24-hour urine collection for electrophoresis and immunofixation
- Bone marrow aspirate (Morphology, Myeloma FISH in CD138 selected cells and immunophenotyping)
- Radiological skeletal bone survey: whole body CT, whole body MRI or PET.CT
- β_2-Microglobulin, C-reactive protein and lactate dehydrogenase
- Serum free monoclonal light chains

Other special forms of plasma cell dyscrasia

Plasma cell leukaemia

Plasma cell leukaemia was initially described by Kyle in 1974 as a plasma cell disorder characterised by a relative peripheral blood plasmacytosis of more than 20% of total nucleated cells, or an absolute number of plasma cells greater than 2×10^9/L. It is likely that lower levels of circulating plasma cells (i.e. ≥5% and/or $\geq 500 \times 10^9$/L has a similar prognostic meaning. There are two forms of plasma cell leukaemia: the *de novo* presentation in leukaemic phase, and secondary cases corresponding to already diagnosed MM that evolve into a leukaemic phase. The clinical course of plasma cell leukaemia is usually very aggressive and resistant to conventional treatment and therefore new agents should be urgently investigated in these patients.

Solitary plasmacytoma of bone

The existence of a solitary plasmacytoma has been recognised in up to 3% of patients with a plasma cell dyscrasia, usually on the vertebral column. The diagnostic criteria require the existence

of a solitary plasma cell tumour in which the biopsy confirms plasma cell histology, a negative skeletal survey and absence of plasma cell infiltration in a random bone sample (<10%), as well as no evidence of anaemia, hypercalcaemia or renal impairment. Some groups suggest that patients in whom a paraprotein persists after the eradication of plasmacytoma with local treatment should undergo a review of the diagnosis. The treatment of choice is local radical curative radiotherapy, but about two-thirds of patients with solitary bone plasmacytoma develop MM at 10 years' follow-up, with a median time to progression of 2 years.

Extramedullary plasmacytoma

Extramedullary plasmacytoma is a plasma cell tumour that arises outside the bone marrow, most frequently in the upper respiratory tract (nose, paranasal sinuses, nasopharynx and tonsils). Other sites include parathyroid gland, orbit, lung, spleen, gastrointestinal tract, testes and skin. In most cases the lesion is unique, although the presence of more lesions (multiple plasmacytomas) has also been reported. Diagnosis is based on the detection of the plasma cell tumour in an extramedullary site, in the absence of bone marrow plasma cell infiltration, bone lytic lesions and other signs of MM (end-organ damage) Treatment involves, plasmacytoma resection and/or radiotherapy. Large or resistant plasmacytomas may require systemic therapy.

Non-secretory multiple myeloma

This specific type of MM requires particular attention, since it is very difficult to diagnose. The only way to make a definitive diagnosis is to demonstrate the presence of tissue infiltration (usually bone marrow) by cells with plasma cell morphology. However, plasma cell infiltration must be greater than 10% and clonality must be assessed by immunophenotyping (demonstration of cytoplasmic immunoglobulins with restricted light chain: positive production without excretion). In addition, the serum free light chains are abnormal often with positive imaging findings (FDG avidity) and these are useful parameter for the follow-up. However, exceptional cases exist in which no monoclonal protein can be observed within the plasma cells. In these cases, it is mandatory to demonstrate clonality by the study of the rearrangement status of the immunoglobulin genes.

IgM multiple myeloma

This exceptional form of myeloma has been reported very rarely and must be distinguished from Waldenström macroglobulinaemia. The morphology and immunophenotype of the infiltrating cells will give the definitive diagnosis, as well as the existence of osteolytic lesions on imaging, which are typically absent in Waldenström macroglobulinaemia. Recent studies have shown IgM myeloma developing from pre germinal centre B cells; up to 60% of patients have t(11;14) and proportion of patients with chromosome 6 and 13 deletion. Cells have a high expression of CD20 and bcl2.

Osteosclerotic myeloma (POEMS syndrome)

POEMS syndrome is characterised by polyneuropathy, organomegaly, endocrinopathy, M-protein and skin changes. The clinical picture consists of a chronic inflammatory demyelinating polyneuropathy, more motor than sensory, and osteosclerotic lesions. Hepatomegaly, hyperpigmentation, hypertrichosis, angiomatous lesions on the trunk, gynaecomastia, testicular atrophy and papilloedema or thrombocytosis may occur. The M-protein is commonly of IgA λ type and the bone marrow contains less than 5% plasma cells. Castleman disease can be associated and VEGF is universally increased. Biopsy of an osteosclerotic lesion may be necessary to confirm the diagnosis. Mandatory diagnostic criteria are the presence of an M-protein and polyneuropathy, and major criteria are the presence of osteosclerotic lesions, Castleman disease and elevated VEGF. At least, the two major criteria plus one major finding and a minor clinical criteria (above mentioned) are necessary for diagnosis.

Amyloid disease is dealt with in Chapter 29.

Disease complications and their management

Figure 28.4 illustrates the clinical manifestations of multiple myeloma.

Bone involvement: assessment and treatment

Bone involvement is the most frequent clinical complication in patients with MM. About 70% of patients have lytic bone lesions, with or without osteoporosis, and another 20% have severe osteoporosis without lytic lesions. This frequency corresponds to conventional skeletal radiography assessment, a technique that is associated with low sensitivity (only demonstrating lytic disease when at least 30% of bone substance has been lost), particularly in some areas (ribs, sternum), low specificity (gas in colon) and long examination time. Newer imaging techniques have greater sensitivity compared with radiographic bone survey for detection of MM bone lesions (Figure 28.5). Computed tomography (CT) has the highest sensitivity for the detection of bone defects and with the whole-body low-dose modality the radiation exposure is much lower than with conventional CT, the scanning time is short and it may replace conventional X-ray in the near future. Magnetic resonance imaging has the highest resolution for soft tissue and bone marrow infiltration; it is particularly valuable for differentiation between benign and malignant fractures, but is inferior to CT for assessment of bone disease. Finally, positron emission tomography (PET) allows

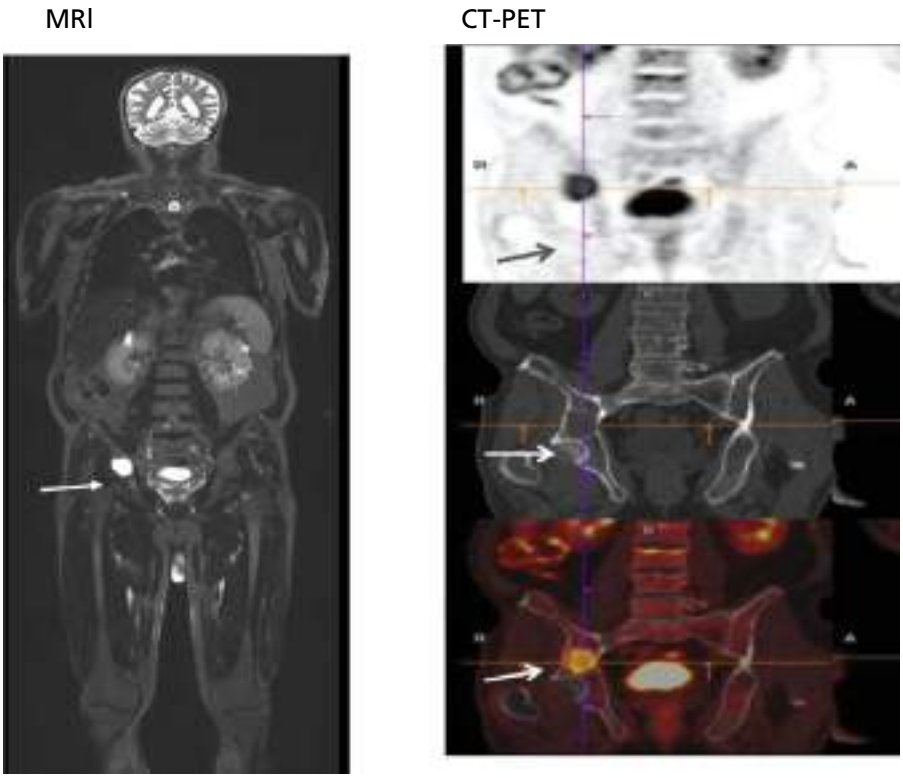

Figure 28.5 MRI and PET/CT in a myeloma patient. The arrows show a myeloma lesion in the lower part of the right iliac bone. The T2 weighted MRI shows a hyperintense image (left) and an active lesion at FDG PET/CT is confirmed (right).

assessment of tumour metabolism and disease activity (versus inactive or necrosis), and may be of prognostic significance; however, it still requires work on standardisation.

These new techniques are already recommended to evaluate patients with SMM and solitary plasmacytoma, and although up until now the presence of one or more clear sites of osteolytic bone destruction seen on CT and/or PET-CT does fulfil the diagnostic criteria, the situation will probably change soon. Nevertheless, great caution should be paid to avoid over-interpretation of equivocal or tiny lucencies seen only on CT or PET-CT.

From the clinical point of view, skeletal involvement leads to bone pain and can result in pathological fractures. The pathophysiology of bone disease has been described above and is summarised in Figure 28.6. Some patients develop pathological fractures of long bones and require orthopaedic surgery. In the event of extensive lesions, surgery can be followed by radiation therapy. On the other hand, prophylactic orthopaedic intervention must be considered in patients with large lytic lesions at high risk of fracture. It is important to consider that patients with severe back pain due to vertebral compression fractures can benefit from vertebroplasty or kyphoplasty. Spinal cord compression caused by a vertebral fracture is very rare in patients with MM. This complication is usually caused by a plasmacytoma arising from a vertebral body.

Between 15 and 20% of patients with MM have hypercalcaemia at the time of diagnosis. A common complication of hypercalcaemia is renal impairment caused by interstitial nephritis. Treatment of hypercalcaemia with hydration and bisphosphonates is a medical emergency. Zoledronic acid is the bisphosphonate of choice (quicker response and significantly longer time to recurrence compared with pamidronate).

The intravenous agents pamidronate and zoledronic acid are of clinical benefit in the treatment of bone disease in patients with MM. Pamidronate is administered at a monthly dose of 90 mg via a 2-hour intravenous infusion. Zoledronic acid, at a monthly dose of 4 mg, is at least as effective as pamidronate and has the advantage that it can be administered via a 15-min infusion. In patients with renal function impairment, the dose of zoledronic acid must be reduced to a maximum of 3 mg. It was suggested that bisphosphonates should be used indefinitely, once initiated. However, the appearance of severe late complications, such as osteonecrosis of the jaw, related to the duration of bisphosphonate exposure has resulted in a reconsideration of the initial recommendations. Osteonecrosis of the jaw is associated with the duration of bisphosphonate exposure, type of bisphosphonate (higher with zoledronic acid than with pamidronate) and history of recent dental procedure. The current recommendations for treatment with bisphosphonates in MM patients, based on consensus panels from both the IMWG and the ASCO, do not recommend the initial use of bisphosphonates for more than 2 years. Finally, in renal impaired patients, the recently

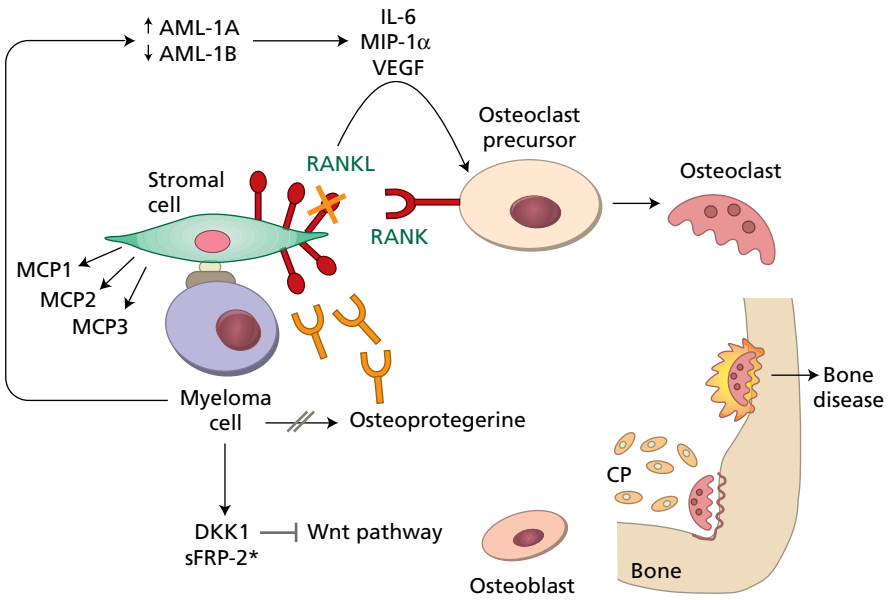

Figure 28.6 Pathogenesis of bone disease. See text for definition of abbreviations.

approved agent denosumab might be of benefit. Denosumab was shown to be non-inferior to Zoledronic acid. In relapsed patients, treatment with bisphosphonates or Denosumab can be re-started and administered concomitantly with active therapy.

Renal failure

About 20% of patients with MM have a serum creatinine higher than 177 µmol/L (2 mg/dL) at diagnosis. The degree of renal failure is usually moderate, with a serum creatinine lower than 354 µmol/L (4 mg/dL). However, in some series up to 10% of patients with newly diagnosed MM have renal failure severe enough to require dialysis from the time of diagnosis. The main causes of renal failure in MM are: (i) light-chain excretion resulting in cast nephropathy (myeloma kidney) and (ii) glomerular deposition of immunoglobulin (light-chain amyloidosis or immunoglobulin deposition disease). In myeloma kidney, the typical feature consists of the presence of myeloma casts, mainly composed of light chains, in the distal tubules and collecting ducts. There is a correlation between the degree of cast formation and the severity of renal failure. Light-chain tissue deposition usually consists of glomerular deposits of immunoglobulins, resulting in nephrotic syndrome. The amyloid deposits are fibrillar structures of light chains showing positive Congo red staining. In light-chain deposition disease, the deposit of light-chain immunoglobulins is non-fibrillar (Congo red negative). In contrast with amyloidosis, the light chain is usually of the κ type. The characteristic clinical feature is a nephrotic syndrome, but renal function can rapidly deteriorate, resembling glomerulonephritis (see also Chapter 29).

The median survival of patients with MM and renal insufficiency is significantly lower than patients with normal renal function. However, the prognosis mainly depends on the reversibility of renal function. Thus, the median survival of patients with reversible renal failure is similar to that of patients with normal renal function, whereas patients with non-reversible renal failure have a median survival of a few years. The factors associated with renal function recovery include serum creatinine lower than 354 µmol/L (4 mg/dL), 24-hour urinary protein excretion lower than 1 g, and serum calcium higher than 2.875 mmol/L (11.5 mg/dL).

The mechanism of action of bortezomib is rapid, and it is probably an ideal agent for rapidly decreasing light chains in order to prevent the development of irreversible renal failure by avoiding further tubular light-chain damage. In a retrospective series of 24 patients with relapsed/refractory MM and dialysis-dependent renal failure, the overall response rate (RR) was 75% with 30% complete remissions (CR) or near-CR. Recent studies have confirmed the benefit of bortezomib-based therapies in patients with newly diagnosed myeloma and renal failure. Bortezomib based combinations should be considered to deepen remissions and induce renal reversibility.

With regard to the use of high-dose therapy/autologous stem cell transplantation (SCT) in patients with MM and renal failure, the largest experience comes from the Arkansas group, with a reversibility of renal failure of 43%, but higher morbidity and mortality (6 and 13% after a single or tandem transplant, respectively) than in patients with normal renal function. Chemo resistant disease, low serum albumin and older age were associated with a poorer outcome. In any event, the dose of melphalan must be reduced to 140 mg/m^2. In patients with no overt myeloma and low plasma cell mass

in whom renal function impairment is due to glomerular light-chain deposition (light-chain deposition disease), the likelihood of response is higher than that in MM because of the low plasma cell mass at the time of transplantation. In this situation there is no need for tumour reduction with induction chemotherapy before stem cell mobilisation and high-dose therapy.

Theoretically, the removal of nephrotoxic light chains with plasma exchange could avoid further renal failure and hopefully prevent irreversible renal failure. MYRE and Eulite randomised trials failed to conclusively demonstrate that use of high cut-off dialysis results in higher proportion of patients recovering kidney function. Therefore, early diagnosis, preventing nephrotoxic agents, hydration and use of effective antimyeloma therapies are the measures to improve renal function in these patients

Anaemia and bone marrow failure

Approximately 35% of patients with newly diagnosed MM have a haemoglobin level lower than 90 g/L. In addition, severe anaemia is a frequent complication later in the course of the disease due to disease progression. Anaemia is associated with a significant loss in quality of life and poor prognosis. The main causes of anaemia in MM are bone marrow replacement by plasma cells, relative erythropoietin deficiency, renal insufficiency and chemotherapy with cytotoxic agents.

Severe granulocytopenia and thrombocytopenia at the time of diagnosis are unusual. About 10% of patients have a platelet count of less than 100×10^9/L, but platelet counts lower than 20×10^9/L with risk of severe bleeding are very unusual. The development of an unexplained pancytopenia in patients previously treated with alkylating agents, particularly melphalan, is suspicious of myelodysplasia.

A number of trials have shown the beneficial effect of recombinant human erythropoietins and darbepoetin-α in the treatment of myeloma-associated anaemia. The response to erythropoietin is associated with a significant improvement in quality of life. An important aspect is that the most significant improvement in quality of life is reached when the haemoglobin increases from 110 to 120 g/L, but levels above 140 g/L should be avoided due to its association with a higher risk of thrombosis. Thus, the goal should be maintenance of the haemoglobin around 120 g/L, with careful dose titration in order to achieve a good quality of life, while minimising severe complications such as thrombotic events. The major cause of erythropoietin failure is iron deficiency. Iron repletion should be indicated when there is evidence of functional iron deficiency measured by an increased soluble transferrin receptor. It seems that the best iron supplemental therapy is the administration of iron saccharate. Treatment with granulocyte colony-stimulating factor (G-CSF) may be required to treat chemotherapy-induced severe granulocytopenia.

Infection

Infectious complications are the major cause of morbidity and mortality in patients with MM. The highest risk of infection is observed during the first 2 months of starting therapy, in patients with severe chemotherapy-induced granulocytopenia and in those with relapsed and refractory disease. The main cause of infection in MM is the impaired antibody production, leading to a decrease in the uninvolved immunoglobulins. Other important causes include chemotherapy-induced granulocytopenia, renal function impairment and glucocorticoid treatment, particularly high-dose dexamethasone. Most infections in newly diagnosed patients and during the first cycles of chemotherapy are caused by *Streptococcus pneumoniae*, *Staphylococcus aureus* and *Haemophilus influenzae*, while in patients with renal failure, as well as in those with relapsed and/or refractory advanced disease, more than 90% of the infectious episodes are caused by Gram-negative bacilli or *Staph. aureus*. The TEAMM trial tested use of fluroquinolones for a 3-month period for newly diagnosed myeloma patients. Use of fluroquinolones reduced the number of febrile episodes and deaths without inducing increase in healthcare associated infections.

An infectious episode in a patient with MM should be managed as a potentially serious complication requiring immediate therapy. In case of suspected severe infection and before the identification of the causal agent, treatment against encapsulated bacteria and Gram-negative microorganisms should be initiated. Routine use of immunoglobulin prophylaxis is not usually recommended. But select patients may benefit from this approach. Pneumococcal vaccination is recommended, particularly in patients with IgG myeloma with high-serum M-protein levels, which are usually associated with very low levels of uninvolved immunoglobulins. Patients should receive prophylaxis against varicella-zoster infections and should be vaccinated against shingles using Shingrix recombinant vaccination. Annual flu vaccination is also recommended. During the COVID-19 pandemic a significantly high mortality rate was noted in myeloma patients. Therefore, regular covid-19 vaccination is recommended to reduce severity of COVID-19 infection.

Nervous system involvement

Spinal cord compression from a plasmacytoma, which occurs in about 10% of patients, is the most frequent and serious neurological complication in MM. The thoracic spine is the most common site of involvement, followed by the lumbar region. The clinical picture of spinal cord compression consists of back pain and paraparesis. Although it can evolve for several days or even a few weeks, the onset can be abrupt, resulting in severe paraparesis or paraplegia in a few hours. The picture is usually accompanied by a high sensory level. Lumbar involvement can cause a cauda equina syndrome (low back pain with radicular distribution and leg weakness).

Spinal cord compression is an emergency requiring immediate medical action. When suspected, urgent magnetic resonance imaging (MRI) should be performed. If confirmed, treatment with high-dose dexamethasone must be started immediately, followed by progressive tapering. Simultaneous local radiation therapy should be started as soon as possible. If the spinal cord compression is caused by a vertebral collapse or by spinal instability rather than a plasmacytoma (which is very rare), urgent surgical decompression followed by fixation of a prothesis of bone graft or methacrylate is required.

Nerve root compression can cause back pain that follows a radicular distribution with or without radicular sensory involvement. Treatment with radiation therapy is helpful, alongside use of Gabapentinoids allowing time for the action of systemic chemotherapy. Clinically significant peripheral neuropathy (PN) is very uncommon in newly diagnosed patients with MM. Leptomeningeal involvement in the central nervous system (CNS) with detection of plasma cells in the cerebrospinal fluid (CSF) is exceedingly rare. The frequency of CNS involvement is roughly 1%, the most frequent presenting features being paraparesis, symptoms from increased intracranial pressure, cranial nerves palsies and confusion. The CSF examination frequently shows plasma cells of plasmablastic morphology, as well as an increased protein concentration with positive immunofixation for the myeloma protein. Unfortunately, despite active treatment measures such as intrathecal therapy (methotrexate, cytarabine, glucocorticoids), cranial or even craniospinal irradiation, the prognosis is extremely poor with a median survival of months to a few years from the diagnosis of CNS involvement.

Prognostic factors

The outcome for patients with MM is highly heterogeneous, with survival duration ranging from a few months to more than 10 years. This heterogeneity relates to: (i) specific characteristics of the tumour itself, (ii) host factors and (iii) a series of factors resulting from the interaction between the tumour clone and the host, which mainly reflect tumour burden and disease complications (Table 28.6).

Host factors

The favourable influence of a good performance status (ECOG ≤2) and young age (<65–70 years) is well established. In contrast, neither sex nor race has prognostic influence. Immune surveillance, by T and natural killer (NK) cells, plays a relevant role in most malignancies, and low numbers of mature NK and CD4 cells have been reported in advanced-stage MM. In addition, patients who develop expanded T-cell clones (CD8+CD57+CD28−), which can recognise autologous idiotypic immunoglobulin structures, display favourable outcomes. Poor renal function due to disease or general health limits ability to give combination antimyeloma therapy and patients often have higher rates of side effects. Frailty measured by specific indices appear to be a better predictor of survival in older myeloma patients as this correlates with ability to receive therapy and toxicities from therapy.

Malignant clone factors

The second cohort of prognostic factors are those that reflect specific characteristics of myelomatous plasma cells and include morphology, immunophenotyping, cytogenetics, oncogenes, multidrug resistance and proliferative activity of plasma cells. Immature/plasmablastic morphology is associated with poor outcome. With regard to antigen expression, it has been observed that downregulation of CD117 (c-Kit) and CD56, and expression of CD28 and CD19, are associated with poor prognosis. As occurs with acute leukaemia, cytogenetic abnormalities are the most important prognostic markers for MM. Nowadays, cytogenetic evaluation is mandatory in all patients with newly diagnosed MM and should always include FISH in purified PCs or in combination with immunofluorescent detection of light-chain-restricted PCs (cIg-FISH). Amongst *IGH* translocations, patients with t(4;14) treated with either conventional or intensive chemotherapy display shorter event-free survival and overall survival. However, recent analysis supports the notion that patients with t(4;14) make up a heterogeneous group. Thus, the French group has discriminated a subgroup of these patients (approximately 45%) with both low β2-microglobulin and high haemoglobin levels at diagnosis, which displays prolonged survival after tandem transplant and

Table 28.6 Prognostic factors in MM.

Prognostic factors	Tumour related	Host related	Tumour burden
Essential	Cytogenetics/FISH: t(4;14), t(14;16), t(14;20), *17p deletions, 1q gain/ amplification, 1p deletions*	Age, performance status	International staging system (β_2-microglobulin/albumin)
Additional	Hypodiploidy LDH Plasma cell proliferation	Frailty Renal function	
New and promising	More than 1 high risk abnormality, myc aberrations	Immune status	Circulating clonotypic plasma cells

benefits from high-dose therapy. The association of t(14;16) with prognosis has not been well supported because of its low frequency. According to Mayo Clinic data, t(14;16) was linked to poor outcome in the context of conventional chemotherapy. However, controversial results have been reported using autologous transplant: the IFM group did not confirm the poor prognostic value of t(14;16) in patients receiving a tandem-autologous transplantation approach, whereas a recent study from the MRC showed a significantly shorter survival amongst patients with t(14;16) treated with autologous transplant. In contrast to t(4;14) and t(14;16), the presence of t(11;14) was shown to have either a favourable or an irrelevant influence on prognosis. Initial studies indicated that monosomy 13/del(13) was associated with poor outcome; however, analyses based on large series of MM patients have revealed that the presence of monosomy 13/del(13) as a unique abnormality, without concomitant *IGH* abnormalities, is not indicative of unfavourable prognosis. In contrast, del(17p) (with deletion of the *TP53* gene) is one of the most, if not the most, adverse prognostic factor in MM. It seems that the higher the proportion of PCs bearing 17p deletions (55% or more), the shorter the survival. Several studies have shown that 1q gains have a significant and independent poor prognostic factor; in addition, the IFM group has reported that 1p deletions are a major independent prognostic factor. A combination of ISS3 and chromosome 1q amplification has been described as a 'double hit' feature associated with poor survival. Moreover, the presence of complex, as well as non-hyperdiploid karyotypes also predict treatment failure. In contrast, hyperdiploid tumours with multiple trisomies involving chromosomes 3, 5, 7, 9, 11, 15, 19 tend to have a favourable prognosis. Finally, the proliferative activity of the malignant plasma cells, as assessed either by the labelling index with bromodeoxyuridine or by flow cytometry, is an important prognostic markers but not routinely analysed.

One of the aims of cytogenetic classification is to define a high-risk group that should be managed differently from standard-risk patients. According to IMWG recommendation, the term 'high-risk MM' should include those patients with at least one of the following features: deletion of 17p, t(4;14) or t(14;16), detected by FISH analysis. Hypodiploidy defined by karyotyping is also used by the Mayo Clinic to define high-risk patients. Recently, a prognostic model in MM based on the frequently associated genetic lesions has been proposed. Accordingly, three genetic risk groups were defined: a favourable risk group with no adverse FISH lesions, an intermediate group with one adverse genetic lesion – t(4;14), t(14;16) or t(14;20); 17p deletion or 1q gain/amplification – and a high-risk group with more than one adverse genetic lesion.

Tumour burden and disease complications

A high proportion of plasma cells in the bone marrow, diffuse bone marrow infiltration and the presence of circulating plasma cells reflect a high tumour burden, but their prognostic influence is modest. Similarly, the impact of skeletal lesions, evaluated by radiography or bone resorption markers, is not clear. In contrast, disease complications such as anaemia, thrombocytopenia and particularly renal insufficiency have a major influence. Nevertheless, the most important factor is the concentration of β2-microglobulin, which increases as a result of both growth of tumour burden and deterioration in renal function. The higher the value, the worse the prognosis. Nevertheless, β2-microglobulin is not helpful for disease monitoring. C-reactive protein is a surrogate marker for IL-6 (a major plasma cell growth factor), which also correlates with outcome. In contrast to hypoalbuminaemia, neither the amount of paraprotein nor its isotype influences prognosis.

Only a few of the prognostic factors have real independent value. A summary of the most important is shown below:

1 Two host factors (*age* and *performance status*) reflect the ability of the patient to tolerate chemotherapy

2 Two intrinsic characteristics of the malignant clone (*cytogenetics* and *plasma cell proliferative activity*)

3 One biochemical marker that reflects tumour burden (β_2*-microglobulin*).

The International Staging System (ISS), derived from more than 11,000 patients, has shown that β2-microglobulin and albumin are the best combination of easily available markers for discriminating prognostic subgroups: stage I (β2-microglobulin <3.5 mg/L, albumin >3.5 g/dL); stage III (β2-microglobulin >5.5 mg/L); stage II (the rest). This substitutes for the Durie and Salmon classification, which affords little prognostic information. The International Staging System incorporates both ISS and LDH levels and/or genetic features. They defined the following three groups: revised ISS (R-ISS) I including ISS stage I (serum β2-microglobulin level <3.5 mg/L and serum albumin level ≥3.5 g/dL), no high-risk Cytogenetic abnormalities [del(17p) and/or t(4;14) and/or t(14;16)], and normal LDH level (less than the upper limit of normal range); R-ISS III, including ISS stage III (serum β2-microglobulin level >5.5 mg/L) and high-risk Cytogenetic abnormality or high LDH level; and R-ISS II, including all the other possible combinations. At a median follow-up of 46 months, the 5-year OS rate was 82% in the R-ISS I, 62% in the R-ISS II, and 40% in the R-ISS III groups. This is now routinely used in both clinics and myeloma trials.

Response to therapy as a prognostic factor

In addition to all the variables that can be measured at diagnosis and which have already been mentioned, response to front-line therapy represents one of the most important prognostic factors in most haematological malignancies. In the case of MM, there is still open debate about the importance of the depth of response on patient outcome. The reason for this controversy is probably that, historically, until the introduction of high-dose

chemotherapy, CR was extremely rare and the only available comparison was between responding patients (achieving partial or minor responses) and non-responding patients, with the former having a better outcome. Now patients have very high CR rates and up to a third of patients at minimal residual disease negative by flow or next-generation sequencing of VDJ clonotypes. A recently published meta-analysis, using cooperative trials for which outcome data were reported, has shown a very significant association between the minimal residual disease (MRD) negativity after treatment and the two main long-term-outcome parameters, i.e. overall survival (OS) and time to progression-related events. However, it is clear that more sensitive techniques applied regularly (e.g. multiparametric immunophenotyping [MRD flow], molecular analysis of bone marrow plasma cells by NGS, serum free light-chain test and imaging techniques such as MRI or PET to detect myeloma activity outside the bone marrow) are needed to evaluate sustained response in MM and these may contribute to a better assessment of the impact of response resulting in durable outcome such as operational cure. Both the Spanish and UK groups have shown that when transplanted and elderly MM patients show undetectable residual myelomatous plasma cells by immunophenotyping, progression-free survival (PFS) and OS are significantly longer, and this parameter is significantly more powerful than negative immunofixation.

Criteria of response

Response criteria were initially developed by the Chronic Leukaemia and Myeloma Task Force (CLMTF) in 1968. The main response parameter was a minimum 50% reduction in the M-protein. In 1972 the Southwest Oncology Group (SWOG) defined partial response (PR) as a reduction of at least 75% in the calculated serum paraprotein synthetic rate and/or a decrease of at least 90% in urinary light-chain urine protein excretion sustained for at least 2 months. The Medical Research Council (MRC) introduced the concept of plateau phase, defined as a period of stability after chemotherapy in which tumour progression does not occur, despite the presence of measurable disease. The minimum period of stability required for definition of plateau phase was 3 months. Since CRs were rarely observed with the classical conventional dose chemotherapy, neither the CLMTF nor the SWOG response criteria included a definition of CR. In addition, there were no definitions for relapse and progression.

EBMT criteria for response, relapse and progression

With the introduction of high-dose therapy/SCT, the M-protein disappears in a significant number of patients, a fact that is associated with a significant prolongation of survival. In this context, the European Group for Blood and Marrow Transplantation (EBMT) developed new criteria defining CR (negative immunofixation in serum and urine and less than 5% bone marrow plasma cells), PR (≥50% reduction in serum M-component and ≥90% in 24-hour urine Bence–Jones proteinuria) and minimal response (MR) (25–49% decrease in M-component), as well as criteria for relapse (reappearance of M-protein by immunofixation in patient who had achieved CR, and progression from PR or MR). Any type of response should be maintained for a minimum of 6 weeks. These criteria have been shown to be useful and reproducible in both transplant and non-transplant series as well as in prospective clinical trials.

IMWG response criteria

The IMWG has expanded the EBMT criteria by adding the categories of stringent CR (sCR) and very good partial response (VGPR) (Table 28.7). Patients with negative immunofixation in serum and urine and with a normal free light-chain ratio are considered in sCR. The free light-chain measurement has also been included for the evaluation of response in patients with non-secretory and oligosecretory disease. VGPR requires a decrease in the M-protein size of at least 90%. In addition, time to event, duration of response, clinical relapse and time to alternative therapy are emphasised as critical endpoints. More recently, the IMWG has revised the criteria in order to account not only biochemical assessment of response, but to now include criteria for MRD assessment (minimal residual disease) of CR using one of 2 different methods. While it is clear that PFS and OS are superior for patients who achieve MRD negativity, the depth required for long-term disease control (or cure) remains unclear. Sensitivity at a level of 10^{-5} may be useful for regulatory endpoints such as drug approvals or for comparison between two different treatment approaches, but as we seek to eliminate the residual clone and discontinue therapy, using deeper measures such as 10^{-6} or greater and sustained MRD negativity as benchmarks will be increasingly important.

Treatment

In this section, we focus on the treatment of the malignant clone, since the management of disease complications (anaemia, renal insufficiency, bone disease) has been discussed above.

Melphalan–prednisone (MP) was introduced for the treatment of MM in the late 1960s. In the subsequent 30 years, treatment improvements remained stagnant, since more complex chemotherapy combinations (e.g. VCMP, VBAD, VAD) only led to small increases in the overall RR, but without differences in survival, as assessed in a large meta-analysis that included over 6000 patients. The next step forward was the use of high-dose

Table 28.7 IMWG Standard and MRD response criteria.

IMWG standard response category*	Criteria	IMWG MRD category	Criteria – requires patient is in a CR standard CR
Stringent CR	As above, *plus* Normal free light-chain ratio Absence of clonal plasma cells†	Sustained MRD Negative	MRD negativity in the marrow (Flow or Sequencing) and by imaging confirmed at a minimum of 12 months apart
Complete remission (CR)	Negative immunofixation (serum and urine) <5% bone marrow plasma cells No soft tissue plasmacytomas	Flow MRD-negative	Absence of phenotypically aberrant clonal plasma cells by NGF on bone marrow aspirate using EuroFlow procedure (or validated equivalent method) with a minimum sensitivity of 10^{-5}
Very good partial response	≥90% decrease in serum M-protein Urine M-protein <100 mg per 24 hours	Sequencing MRD-negative	Absence of clonal plasma cells by NGS on bone marrow aspirate in which presence of a clone is defined as less than 2 identical reads obtained after DNA sequencing of bone marrow aspirates using the LymphoSIGHT platform (or validated equivalent method) with a minimum sensitivity of 10^{-5}
Partial response	≥50% decrease in serum M-protein ≥90% decrease in urine M-protein or <200 mg per 24 hours ≥50% decrease in soft tissue plasmacytomas	Imaging plus MRD-negative	MRD negative as defined by NGF or NGS plus disappearance of every area of increased tracer uptake found at baseline or preceding PET/CT or decrease to less than mediastinal blood pool SUV or decrease to less than that of surrounding normal tissue.
Minimal response	≥25% but ≤49% reduction in serum M protein and reduction in 24-hour urine protein by 50–89% If present at baseline, ≥50% reduction in size of soft tissue plasmacytoma		
Stable disease	Not meeting the above response criteria or progression criteria		

* All response categories require two consecutive measurements made at any time.

melphalan followed by stem cell support (autologous SCT) for fit myeloma patients, which resulted in a significant improvement in disease-free survival and OS. However, for elderly patients, MP remained the standard of care until it was replaced by the use of lenalidomide/dexamethasone in several randomised trials. Now the major questions in the field revolve around the use of combinations with len/dex for frail patients, and the use of three or four drug combinations as part of induction and risk-adapted maintenance for fitter patients with newly diagnosed myeloma.

In this section, we first discuss the treatment of newly diagnosed patients stratified according to fitness status with age as a variable but not the sole determinant of treatment decisions, and then analyse the options for relapse/refractory patients, as well as emerging novel agents.

Should all myeloma patients be treated?

Currently, only myeloma patients with symptomatic disease (defined by CRAB criteria) should be treated, patients with

smouldering myeloma are not treated until they develop symptomatic disease. Attempts at early intervention in SMM patients with alkylating agents, bisphosphonates and antagonists of the receptor of interleukin 1β or thalidomide failed to show a significant benefit. However, none of these studies discriminated between high-, standard- or low-risk SMM patients, and all used agents that carried modest single-agent activity, and toxicity. By contrast, the Spanish group conducted a Phase III randomised trial focusing only on high-risk smouldering myeloma patients, comparing early treatment with lenalidomide–dexamethasone induction therapy followed by lenalidomide maintenance therapy versus observation for a 2-year defined period of treatment. The results showed that the experimental arm was associated with a significant delay in progression to symptomatic myeloma (3 years after study entry, 77% of patients in Group A and 30% in Group B were progression-free; hazard ratio, 5.59; $P < 0.001$). This delay translated into a significant overall survival benefit (the proportions of patients alive at 3 years was 94 and 80%, respectively; hazard ratio, 3.24; $P = 0.03$). Newer updates of this data suggest that the difference in PFS and OS remains at 7 and 10 years follow-up, and more importantly, the use of lenalidomide did not shorten second remission duration (PFS2) refuting a concern that patients would develop drug resistance and then be less responsive to additional therapy. More recently the ECOG group in the US published results from another phase 3 randomised trial also evaluating patients with intermediate and high-risk SMM who were randomised to receive either lenalidomide alone or observation. In this trial, it was also demonstrated that there was a significant delay in time to developing MM with a similar hazard ratio to the Spanish trial. OS analysis was too soon to evaluate but was not worse for patients who received lenalidomide alone. On the heels of these 2 trials, there are now several trials ongoing evaluating new antibodies targeting CD38 with lenalidomide, as well as more intensive 'myeloma like' treatments that are currently ongoing and are seeking to challenge the notion that patients with high-risk SMM should only be observed. In the context of these small phase 2 studies, as well as now 2 large phase 3 trials demonstrating benefit for early intervention, it is reasonable to discuss with patients about the pros and cons of limited duration therapy with either lenalidomide or len/dex as an attempt to delay progression to MM. Whether more intensive approaches are more successful than the prevention approaches described above will need to wait for longer follow-up and phase 3 trials before they become more widely used.

Treatment of newly diagnosed transplant candidate patients

Currently, treatment in this setting usually includes four to six cycles of induction therapy, followed by autologous SCT and maintenance.

Induction therapy

The history of induction therapy and myeloma was focused on changing the recipe of akylators and steroids used in combinations to debulk the disease prior to stem cell collection and transplant. This included combinations such as VAD, VBMCP and others that used cyclophosphamide as part of the initial induction therapy. With the observation that thalidomide had activity in refractory MM, it too was used with steroids and alkylators, but these regimens were limited by toxicity and lacked the real efficacy that we have now come to expect from induction regimens using modern agents. The current standard of care for a fit MM patient undergoing induction therapy is at a minimum a combination of an immunomodulatory agent such as lenalidomide (or thalidomide) with a proteasome inhibitor such as bortezomib (or carfilzomib). The regimen with the largest data set supporting its use in phase 2 and 3 trials is the RVD regimen combining bortezomib and lenalidomide with dexamethasone, and in the initial phase 2 study had an overall response rate of 100% with a very high VGPR or better rate. The advantage of RVD over its European counterpart of VTD (substituting the lenalidomide with thalidomide) is less neurotoxicity and higher efficacy as manifested by deeper responses. Based on data from the SWOG 0777 trial and others, RVD was demonstrated to be superior to the doublet of len/dex in terms of both PFS and OS. Since the establishment of a non-chemotherapy-based triplet as a standard induction regimen, variations on the agents used have also occurred and led to the creation of the KRD regimen, a combination that substitutes the bortezomib with carfilzomib. Several phase 2 studies demonstrated better depth and overall responses with less neuropathy when KRD was used compared to historical data using RVD. The ECOG cooperative group led a randomised phase 3 trial for standard-risk patients and compared RVD with KRD to address this question and demonstrated equivalence with more neuropathy in the RVD group, and more cardiac and pulmonary toxicity in the KRD group. While the ORR and VGPR rates were higher with KRD, this did not translate into an improvement in PFS in the trial. The differences between three-drug regimens using one or the other proteasome inhibitor have now given way to a larger discussion regarding the incorporation of monoclonal antibodies targeting CD38 into the mix as part of a four-drug induction for fit myeloma patients with planned transplant. The largest of these trials, the Cassieopia trial, compared VTD +/− Daratumumab as induction followed by transplant, consolidation with VTD +/− Daratumumab and then a second randomisation between data and observation. The second randomised has clouded the ability to interpret PFS as an endpoint for this study but clearly one can see differences in response rates and depth of response favouring the use of adding Dara to the induction regimen of VTD prior to transplant. In a more US styled trial, patients were randomised to

either RVD+/− dara induction, transplant, RVD+/− dara consolidation, and then either len+/− dara maintenance. This trial confirmed the improvement in depth and overall response rate with significantly higher MRD negative rates amongst the patients in the dara arm, and after 2 years of follow-up there is now a suggestion that the PFS is beginning to separate. These trials have now established that quadruplet-based inductions will likely become adopted more broadly, at least in the induction phase of treatment.

Autologous stem cell transplantation

High-dose therapy followed by autologous SCT was demonstrated to improve OS compared with standard-dose therapy in prospective randomised trials conducted by the French (IFM) and English (MRC) groups, and has revolutionised the care of patients with myeloma. The use of age as a determining factor for eligibility is one that has predominated in Europe but has in part given way to one that is more focused on using performance status as a guideline rather than age alone. In the US, patients are considered eligible for SCT up to 79 years of age, presuming adequate organ function and performance status, though the dose of melphalan may be reduced for older patients or for patients with significant comorbidities (Mel 140 mg/m^2 versus Mel 200 mg/m^2) such a chronic renal failure.

The question at hand currently is about the benefit of HDT in the era of modern induction. The continued use of HDT initially is based on inducing a higher rate of CR, something historical induction regimens were not able to do with any significance. However, in an era where we are using IMID/PI/Dex combinations are frontline therapy and have reduced or eliminated the routine use of alkylator-based inductions, the speed and depth of response is much higher than we have seen before, and again the benefit of HDT questions have arisen. The first trial to really address this was the IFM 2009 trial, a randomised trial of RVD induction followed by either transplant, or continued RVD induction and then maintenance therapy. In each of the reported updates so far, there remains a benefit for the group that underwent early HDT in terms of PFS compared to the patients who were treated with RVD alone. In the most recent update, even amongst patients who achieved MRD negativity, those who underwent HDT had a longer PFS than those who did not. While there is no difference in overall survival between the 2 arms, given that the median OS for MM patients is now well beyond 10 years, the use of OS as a metric of success in this patient population is perhaps unrealistic, and improving PFS is the better endpoint. In the RVD 1000 series from the group at Emory, median PFS for all patients is 65 months with continuous maintenance, demonstrating that prolonging PFS in this group really should be a major goal, presuming OS for the transplanted group is not worse, which has not been demonstrated in modern series.

A second trial asked a similar question but with a different induction regimen, In the FORTE trial, the use of KRD was tested in 2 arms, with a 3rd arm using KCD as induction. In one of the KRD arms, patients were transplanted, in the other, they were not. In the KCD arm, all patients underwent transplant. While the overall response rate for the KRD arms were similar (with or without transplant) the group that did not have a transplant again had a shorter PFS and sustained MRD negativity again supporting the use of HDT even with highly active induction regimens. The KCD arm was inferior in every analysis, though in some settings it was similar to the KRD with no transplant arm. While these trials do not reflect all the new and different induction regimens currently available and do not address the addition of daratumumab or other CD38 targeting antibodies, to date there is no randomised trial suggesting that transplant does NOT offer benefit even in the context of highly effective induction therapy, and thus, should be considered for all patients seeking to prolong their first remission and maximise the initial depth of response to treatment.

With regard to tandem autologous SCT, there has been a resurgence, particularly in Europe, for its use in high-risk MM. This will be discussed in greater detail below, however at this time, unless patients have not responded to standard novel agent-based treatments, or do not have access to triplet maintenance in the context of high-risk disease, the routine use of tandem autologous transplant is to be discouraged.

Consolidation and maintenance

Consolidation and maintenance are areas of treatment that have rapidly advanced in the past decade based on small phase 2 studies as well as larger phase 3 experiences. In the context of consolidation, we are classically referring to treatment given after 1 cycle of HDT and transplant, but before maintenance starts. A large BMT CTN trial compared the use of RVD consolidation vs a second autologous transplant (tandem) versus no consolidation and proceeding directly to maintenance therapy. The maintenance in each arm was the same, lenalidomide, and following the first 2 arms of treatment, patients also received lenalidomide maintenance. In this trial, there was no difference in progression free survival or overall survival suggesting that there was no real benefit for consolidation, and this has become the standard approach in the US.

At the same time, the EMN was also doing a trial of tandem autologous transplant vs single transplant as consolidation, with all patients receiving some form three drug consolidation after transplant. In their analysis, there was a benefit for tandem autologous transplant, most noted in the high-risk patient population, however this must be put into context. In the EMN trial, most patients received VCD induction, which we know from randomised trials is inferior to VTD or VRD, and thus they received suboptimal induction. In the BMTCTN study, most patients received VRD induction, and many received more than four cycles of induction suggesting they were in a lower disease

burden state prior to undergoing HDT and transplant. Given very strong OS benefit associated with lenalidomide maintenance, and emerging data supporting the use of PI/IMID +/− dex as maintenance for high-risk patients, the absolute benefit of consolidation with a second transplant remains unclear. At this time, if a patient is not able to receive three drug maintenance with high-risk disease, a second autologous transplant could be considered, but if they are able to receive either VRD or KRD as consolidation post-transplant, this too may be sufficient to reduce the risk of relapse in a high-risk patient population.

Allogeneic stem cell transplantation

Allogeneic SCT, in the context of so many novel agents have clearly fallen to the side as a routine approach for patients with myeloma. Even amongst younger patients with high-risk disease, their relative benefit from an allogeneic transplant is limited by a remaining high risk of relapse, GvHD, and death as a treatment related event when compared with standard and new treatment approaches. The benefit of allogeneic transplant appears to be minimal in the setting of highly proliferative myeloma, often the worst amongst the high- risk groups, and in the era of novel bispecific, CAR T-cells, and other new precision and immune based treatments that are currently in the armamentarium for myeloma patients, the indications for the routine use of allogeneic transplant are non existent outside the context of a well-designed and hypothesis driven clinical trial.

Treatment of newly diagnosed elderly and non-transplant candidate patients

Melphalan + prednisone (MP) has been the gold standard for over 40 years; however, the scenario has completely changed with the introduction of novel agents such as thalidomide or bortezomib, lenalidomide and now daratumumab.

While many trials over the past decade added in novel agents with the MP backbone (MP + bortezomib, MP + thalidomide, MP + lenalidomide, MP + carfilzomib), each demonstrating superiority over the use of MP alone, there was a movement to eliminate the use of MP in total from regimens for older/frailer patients. This was initiated in the E4A03 which took all newly diagnosed MM patients regardless of performance status, and randomised them to receive lenalidomide with either high dose or low dose dexamethasone. This trial alone ushered in a new era of non-aklylator based treatments for older patients. Subsequent to this trial, the FIRST trial was completed that compared 3 arms:MPT, RD for 18 months(RD18) 18 or RD continuous therapy. This demonstrated that both RD arms was superior to MPT in terms of PFS, and that PFS appeared to be longer with the use of continuous therapy with RD. These 2 trials combined with the SWOG 0777 trial that also evaluated both older and younger patients with either RVD or RD without transplant further cemented in the notion that MP based regimens are no longer needed in order to gain long remissions, and by avoiding the use of alkylators, patients are able to enjoy even longer remissions and stay on continuous therapy. In an effort to incorporate the CD38 targeting antibody daratumumab into treatment for older/frail patients, the ALCYONE trial was initiated that randomised patients to receive either MPV or MPV+ daratumumab. In this trial, the depth and speed of response was significantly higher with the addition of daratumumab, and this translated into a higher MRD negative rate, higher CR rate, and a longer PFS. Additionally, with longer follow-up, there is now an overall survival benefit for the use of D MPV vs MPV alone, however this regimen remains a throwback to the era of using MP based backbones, and in the US gets very little use. Most recently, RD was compared in the MAIA trial with Daratumumab + RD (DRD), and in the initial paper as well as subsequent updates, a very long PFS is being reported, more than 60 months, suggesting that not only is the use of a monoclonal antibody such as daratumumab highly effective in deepening the response, but that the safety profile when combined with RD is maintained, allowing even older patients to tolerate this treatment and stay on therapy for 5 years.

A major question that is being asked at this point is if we are ready to omit the use of proteasome inhibitors as initial therapy for older frailer patients given the very long PFS and depth of response seen with DRD. While DRD has not been compared head to head with VRD, the PFS from the SWOG trial suggests that VRD with len maintenance is around 36 months, while the MAIA trial suggests with both dara and len, the PFS is closer to 60 months. However, it is important to note that in the MAIA trial, the proportion of genetic high-risk patients was very low, and thus the efficacy for either arm in the high-risk group cannot be easily quantified. Thus, one approach may be to reserve the use of initial proteasome inhibitor for patients who have high risk genetics at presentation, while others may be safely treated with DRD. Given the large amount of data and safety on VRD for older patients, this may be the treatment of choice for the high-risk group, though there remains no data for high risk older patients in a randomised setting to confirm this approach. Alternatively, in a randomised trial of MVP vs carfilzomib + MP, it appears that MPV was superior from a safety aspect suggesting that perhaps carfilzomib in current doses and schedules or combinations is not an optimal approach for induction of the older frail patient.

Treatment at relapse

The landscape for management of relapsed myeloma varies by a number of different factors that all go into play when defining next treatment steps. There has been an explosion of several large randomised phase 2 and 3 trials in this space, that complicates choice of treatment, and thus paying specific attention to three types of factors: patient-related factors (renal function, hepatic function, comorbidity and patient preference); disease related factors (nature of relapse, genetic risk/stage, disease

burden), and treatment related factors (previous drug therapy and resistance, treatment related toxicity, duration and depth of previous response). Each of these are weighed in the context of relapse and balanced with the weight of available evidence that may support how to best move forward for any given patient.

In the setting of current myeloma therapy, where an immunomodulatory agent is combined with a proteasome inhibitor for induction therapy, there are three options for the 'backbone' of salvage therapy. These can include a proteasome inhibitor (bortezomib, ixazomib, or carfilzomib), an immunomodulatory agent (lenalidomide or pomalidomide) or a CD38 directed monoclonal antibody (daratumumab or isatuximab). Amongst these 3, if a patient is not resistant to an anti-CD38 Moab, then this becomes the backbone and either an IMID or PI is added to it, and each of these scenarios has phase 3 randomised data supporting its use. If a patient is sensitive to lenalidomide, the longest PFS in early relapse is the combination of daratumumab with len/dex, but since most patients who are relapsing are progressing on continuous len maintenance, the options that are often considered are carfilzomib/CD38/dex or pomalidomide/CD38/dex. There are other non-CD38 based triplet combinations that have demonstrated benefit in randomised phase 3 trials over doublet regimens but given the very high activity and PFS favouring CD38-directed salvage therapy, it would seem that amongst 3 highly active classes, using a CD38 as the central part of a regimen and partnering with either an IMID or PI makes the most sense.

In the context of progressive relapse, again going to the three factors that help define how to approach a patient is the standard, but in this setting, the list of agents that a patient with myeloma is resistant to is a much larger list, and so using remaining sensitive agents in combinations makes the most sense. If a patient received IMID/PI induction, then at salvage received PI/CD38, that leaves an IMID backbone for salvage 2 with other available agents, or if IMID/CD38 was used in salvage, then PI backbone becomes the next step. Once a patient develops myeloma that is triple class refractory (resistant to PI, IMID and CD38 antibody, the choices of options are much more limited. In the US options at this point that are approved are 2 BCMA directed approaches, an antibody drug conjugate (ADC) and a chimeric antigen receptor T-Cell (CART), and the other is a new agent Selinexor, which targets expo1. All three of these agents approved in refractory myeloma were approved in the context of five or more prior lines of treatment and have different pro's and con's for their use.

Belantamab mafadotin is a BCMA directed ADC that has activity in refractory myeloma, and while it does have deep and durable responses in many patients, does have a new side effect that impacts visual acuity through corneal microcysts. Fortunately, this adverse event is reversible and can be managed in partnership with an ophthalmologist along withdose holds and dose modifications.

Selinexor is an oral agent that also has activity when combined with dexamethasone in the context of refractory disease, and also has significant activity when combined both with proteasome inhibitors (bortezomib and carfilzomib) as well as with pomalidomide. The advantage of the combinations is that it allows one to use once a week dosing, which seems to improve the adverse event profile and is synergistic with agents in myeloma. Adverse events with Selinexor include nausea, diarrhoea, anorexia, weight loss and fatigue. These can be mitigated with aggressive supportive care measures that are to be used preemptively for the management of patients. With lower doses, combination therapy and aggressive supportive care many patients can gain the benefit of this new target and treatment even with refractory myeloma.

Idecabtagene vicleucel (ide-cel) is a CART directed at BCMA and is now FDA-approved for the management of patients with triple class refractory myeloma. The efficacy of ide-cel is quite impressive with a very high overall response rate, and the added advantage of not requiring additional therapy once the cells are delivered as part of a 'one and done' treatment approach. While there is lymphodepletion therapy (LD) this typically uses low doses of cyclophosphamide and fludarabine that can be administered as an outpatient. The most common adverse events related to CART therapy are cytopenias, cytokine release syndrome (CRS) and neurotoxicity (ICANS). There are specific grading criteria for CRS and ICANS, but overall, the severity of both of those are lower than is seen with CARTs used targeting CD19 in ALL or NHL.

Side-effects associated with novel agents

Because of the previous history of thalidomide, a major concern was its toxicity profile. The side-effects are dose related and the most common include constipation, weakness, somnolence and neuropathy. Peripheral neuropathy is a common adverse event with thalidomide therapy and often limits the dose and duration of treatment. The use of combination therapy has raised concerns about an increased risk of DVT. Apparently, the major risk of DVT occurs when tumour load is high and thalidomide is combined with chemotherapy, especially adriamycin. Accordingly, in this setting, anticoagulant prophylaxis with low-molecular-weight heparin (LMWH) or aspirin is mandatory. Current data suggest that lenalidomide is better tolerated than thalidomide in several aspects: it does not usually produce clinically significant somnolence, constipation or neuropathy, although the incidence of myelosuppression is higher, mainly neutropenia (grade 3 in 17–30%) and thrombocytopenia, which are manageable with dose reduction and growth factor support. Similarly to thalidomide, lenalidomide is associated with a higher risk of DVT (5–25%) and the risk increases in patients with comorbidities, previous history of DVT, concomitant use of erythropoietin, high-dose dexamethasone, anthracyclines or high tumour mass. For these reasons, anticoagulant prophylaxis with LMWH or aspirin is mandatory. The most frequent toxicities of bortezomib include fatigue, gastrointestinal symptoms, cyclical thrombocytopenia

and, particularly, peripheral neuropathy. This latter side-effect, classified as grade 3 in 9–20% of patients, is the main reason for treatment discontinuation, and the early detection of peripheral neuropathy is most important in order to reduce the dose or frequency of injections. The use of a weekly schedule of bortezomib and particularly the subcutaneous administration has resulted in a significant decrease in peripheral neuropathy. Concerning panobinostat, thrombocytopenic and gastrointestinal effects are the most relevant toxicities. Elotuzumab and daratumumab can produce infusion reaction.

Promising new drugs

The field of new drugs is one that is rapidly expanding in the past few years on top of an already rapidly growing list of treatment options for patients. Most notable has been the explosion of immune-based treatments that first started with the unconjugated monoclonal antibodies targeting CD38 and SLAMF7, but has more recently grown to include agents that target BCMA, GPRC5D and FCRH5. Additionally, there are several signalling or newer generation versions of older agents that also have shown promise (non-immune) and are worth discussing in this section as well

Immune-based treatments

Chimeric antigen receptor T-Cells

In the area of BCMA-directed CART, there are a number of autologous and allogeneic CART products that are currently being developed. The field was rapidly advanced with the development and approval of CD19-directed CART in ALL and NHL, and with that initial experience, BCMA was the first target used in the context of myeloma. In the autologous setting, the advantages include lack of GvHD or rejection, which results in a longer half-life for the product when compared with allogeneic sources for CART, which have the advantage of a higher quality T-cells (fewer exhaustion phenotype T-cells) and more rapid availabilty (off the shelf). In the context of refractory disease, overall response rate is typically what is used to assess efficacy, but in the area of CART therapy, the overall response rate is usually >70% for most products, making that assessment less useful for identifying differences between products. The Karmma trial enrolled a group of refractory myeloma patients to receive one of three different CART doses following standard lymphodepletion therapy. The overall response rate for all doses and patients was 70% with a median duration of response (DOR) of 11 months. In the Cartitude 1 trial using cilta cel, the overall response rate was 97% and a high fraction of those patients became MRD negative over the next few months. The median PFS is expected to be >24 months with longer follow-up. There are several other CART products in development all with high overall response rates and variable durations of response and remission. How these will compare with cilta-cel and ide-cel remains unknown as does the response to CART in earlier lines of therapy. In terms of toxicity, the most common adverse events include haematologic toxicity, cytokine release syndrome (CRS) as well as neurologic toxicity. In general, the severity of grade 3/4 CRS and neurologic toxicity is lower for BCMA-directed CART than we see with CD19-directed CART, and most patients can be managed with steroids and tociluzumab. The time to develop CRS does vary by product used with ide-cel being relatively early after infusion, while with cilta-cel occurring around 7 days after infusion. The other major adverse event that is noted is a higher incidence of infections following CART so aggressive prophylaxis for the period of time when the plasma cell suppression is most intense is recommended for all patients

Bispecific antibodies

The use of bispecific antibodies or T-cell engagers (TCE) is a treatment approach that has had significant activity in the area of ALL or DLBCL. In myeloma, there were concerns early on that in the setting of refractory MM that T-cell function may be an issue, yet in early phase 1 studies using TCEs in MM, it was identified that response rates that range from 55 to 80% even in the context of refractory MM. There are now 6 different TCEs that are directed against BCMA that are in phase 1 and phase 2 studies, and the responses and depth of response are all very encouraging with some patients achieving MRD negativity. In addition to TCEs targeting BCMA, there are two additional immune targets in development, GPRC5D and FCRH5. These targets are expressed on nearly all plasma cells, and early data with talquetamab (GPRC5D) and cevostamab (FCRH5) suggest high response rates and similar adverse events with BCMA-directed TCEs. One new toxicity noted with targeting GPRC5D is dysgusia and skin/nail issues, both of which are reported in phase 1 studies as mostly occurring as grade 1/2.

Other targets in development

Venetoclax

Venetoclax is a bcl-2 inhibitor that is approved for patients with B-cell malignancies such as CLL and indolent NHL. Unlike most lymphomas, most myeloma cells are mcl-1 dependent, limiting the activity of venetoclax for all myeloma patients. However, preclinically there are subsets of myeloma patients who are bcl-2 dependent and thus are sensitive to this treatment approach. In early phase1 development, it was clear that patients whose myeloma carried the t(11;14) translocation had a much higher overall response rate than those who did not (40 versus 5%), and this improved with the addition of dexamethasone. These early phase trials held signficant promise for Ven in a subset of myeloma patients and led to larger combination trials with daratumumab, bortezomib and carfilzomib. These early combination trials demonstrated significant activity and did so in both sensitive and resistant patients. The randomised phase 3 Bellini trial tested the hypothesis that bortezomib and dex were a synergistic partner for Ven and compared borteomib/Ven/Dex with

borteomib/dex in an unselected early relapse population. While the early phase studies suggested benefit for Ven even amongst non-t(11;14) patients, in hind site much of that activity may have been related to the partner agent (bortezomib or carfilzomib) as results from the phase 3 trial demonstrated a big difference in PFS favouring the addition of Ven, but a survival decrement for Ven treated patients. On further analysis, Bellini demonstrated significant benefit in PFS and OS for t(11;14) patients, but the survival decrement was noted in the non-t(11;14) population, which was enriched for high-risk patients. Ongoing confirmatory trials continue in the biomarker-specified population, and hopefully will result in the first precision medicine approach being approved in myeloma using venetoclax.

CelMods

Celmods represent the next generation of immunomodulatory agents (ImiDs) that come in the line of thalidomide, lenalidomide and pomalidomide. The two agents with the most clinical data in myeloma are CC-220 (iberdomide) and CC-92480. Both agents have completed phase 2 evaluation alone and with dexamethasone and have impressive overall response rates of 30% or greater in triple-class refractory myeloma. Iberdomide is currently being evaluated in combination with bortezomib, carfilzomib and daratumumab, and currently, it appears that they can be combined with full doses of both agents in refractory myeloma. Both agents are able to overcome pomalidomide resistance in some patients, and there are no new adverse events noted from these early phase trials different from other agents in this class, and neither agent has neuropathy as a significant side effect. Future trials setting up regulatory approval are in the planning for both, and not only are the exciting from the aspect of new agents that can overcome ImiD resistance but also from the immune stimulating aspect, where it appears that the ability to partner with immune targeted agents is even better than previous agents in this class setting up important combination trials in the future.

CHAPTER 29

Amyloidosis

29

Ashutosh D Wechalekar

National Amyloidosis Centre, University College London (Royal Free Campus) and Department of Haematology, University College London Hospitals, London, UK

Introduction

Amyloidosis is a disorder of protein folding in which normally soluble proteins are deposited in the extracellular space as insoluble fibrils that progressively disrupt tissue structure and function. Over 30 unrelated proteins can form amyloid *in vivo*, the clinical amyloidosis syndromes are classified according to the fibril protein (Table 29.1).

Amyloid deposition is remarkable in its diversity; it can be systemic or localised, acquired or hereditary, life-threatening or merely incidental. Clinical consequences occur when accumulation of amyloid fibrils is sufficiently substantial to interfere with normal function. However, it is apparent that the disease caused by amyloidosis is not just because of the physical deposition of the protein fibrils but also due to direct proteotoxicity of the pre-fibrillary oligomers. The pattern of organ involvement varies within and between fibril types and clinical phenotypes overlap greatly. In systemic amyloidosis where virtually, any tissue may be involved, the fibrils target certain organs with greater frequency (heart, kidneys, nerves and liver). Untreated, the disease is often fatal, although prognosis has improved with increasingly effective treatments of many underlying conditions. Greater understanding of the pathogenesis of the disease, allowing improved subtyping and appropriate targeted therapies, with improved supportive care, including haemodialysis and solid organ transplantation in selected patients have also influenced the prognosis of this disorder. In localised amyloidosis, deposits are confined to a particular organ or tissue, but may have serious consequences such as haemorrhage. Localised amyloid deposition is also a pathological hallmark of uncertain significance in some important common diseases including Alzheimer's disease and type 2 diabetes mellitus.

This chapter describes the clinical features, differential diagnosis and management of systemic AL (monoclonal immunoglobulin light chain) amyloidosis, which is the most common and serious form of the disease.

Pathogenesis of amyloid

Proteins that can form amyloid can exist in two completely different three-dimensional conformations, the transformation involving massive refolding of the normal form into one that can autoaggregate in a highly ordered manner to produce the characteristic predominantly β-sheet, rigid, non-branching fibrils of 10–15 nm in diameter and indeterminate length. Acquired biophysical properties common to all amyloid fibrils include insolubility in physiological solutions, relative resistance to proteolysis, and ability to bind Congo red dye in an ordered manner that gives the diagnostic green birefringence under cross-polarised light.

Amyloid deposition can occur in three circumstances:

1 When there is a sustained abnormally high concentration of certain normal proteins, such as serum amyloid A protein (SAA) in chronic inflammation or β_2-microglobulin in renal failure, which underlie susceptibility to AA and β_2-microglobulin amyloidosis, respectively.

2 When there is a normal concentration of a normal, but inherently amyloidogenic, protein over a prolonged period, such as transthyretin (TTR) in wild-type transthyretin (previously also known as senile systemic) amyloidosis.

Table 29.1 Classification of amyloidosis (by clinical frequency).*

Type	Fibril precursor protein	Clinical syndrome	Organs involved
ATTR	Normal plasma transthyretin	Senile systemic amyloidosis with predominant cardiac involvement	Heart, Carpal tunnel and lower spine
	Genetic variants of transthyretin (e.g. ATTR Met30, Ala60, Ile122)	Familial amyloid polyneuropathy (FAP), with systemic amyloidosis and often prominent amyloid cardiomyopathy	Nerves and heart
AL	Monoclonal immunoglobulin light chains	Systemic amyloidosis associated with myeloma, monoclonal gammopathy, occult B-cell dyscrasia. Formerly known as primary amyloidosis	Kidneys, heart, nerves, liver and soft tissues
ALECT2	Leucocyte chemotactic factor II	Systemic amyloidosis with predominant renal involvement	Kidney and liver
AA	Serum amyloid A protein	Systemic amyloidosis associated with acquired or hereditary chronic inflammatory diseases. Formerly known as secondary or reactive amyloidosis	Kidney (may involve other organs in very advanced stages)
$A\beta_2M$	β_2-Microglobulin	Dialysis-related amyloidosis (DRA) associated with renal failure and long-term dialysis. Predominantly musculoskeletal symptoms	Joints
AFib	Genetic variants of fibrinogen α chain (e.g. Afib Val526)	Autosomal dominant systemic amyloidosis. Non-neuropathic usually with prominent nephropathy	Kidneys
AapoAI	Genetic variants of apolipoprotein A-I (e.g. AapoAI Arg26 and Arg60)	Autosomal dominant systemic amyloidosis. Predominantly non-neuropathic with prominent visceral involvement, especially nephropathy. Minor wild-type ApoAI amyloid deposits may occur in the aorta	Kidneys, liver and heart (nerves in some mutations)
ALys	Genetic variants of lysozyme (e.g. ALys His67)	Autosomal dominant systemic amyloidosis. Non-neuropathic with prominent renal and gastrointestinal involvement	Gut, skin, liver and kidneys
AApoAII	Genetic variants of apolipoprotein A-II	Autosomal dominant systemic amyloidosis with predominant renal involvement	Kidneys
AGel	Genetic variants of gelsolin (e.g. Asn187)	Autosomal dominant systemic amyloidosis. Predominant cranial nerve involvement with lattice corneal dystrophy	Cranial nerves, cornea and skin
ACys	Genetic variant of cystatin C (Gln68)	Hereditary cerebral haemorrhage with cerebral and systemic amyloidosis	Cerebral blood vessels
AIAPP	Islet amyloid polypeptide	Amyloid in islets of Langerhans in type 2 diabetes mellitus and insulinoma	Pathogenic impact unclear

* Amyloid composed of peptide hormones, prion protein and unknown proteins not included.

3 When there is production of an acquired or inherited variant protein with an abnormal amyloidogenic structure, such as monoclonal immunoglobulin light chains in AL amyloidosis or some hereditary variants of TTR, lysozyme, apolipoprotein A-I and fibrinogen Aα chain.

Genetic and environmental factors that may influence susceptibility and timing of as well as the tissue target of amyloid deposition are unclear, but once underway, amyloid deposition is unremitting and exponentially progressive in face of ongoing supply of the precursor protein.

Amyloid deposits not only consist mainly of amyloid fibrils, but also contain some common minor constituents, including certain glycosaminoglycans (GAGs) and the normal circulating plasma protein serum amyloid P component (SAP), as well as various other trace proteins. SAP binds in a specific calcium-dependent manner to all amyloid fibrils, but not their precursor

proteins, which is the basis for the use of radiolabelled SAP for scintigraphy to image and monitor amyloid deposits. Amyloid fibril-associated GAGs mainly comprise heparan and dermatan sulfates; their universal presence, restricted heterogeneity and intimate relationship with the fibrils suggest a contribution to the development or stability of amyloid deposits.

Many of the pathological effects of amyloid can reasonably be attributed to its substantial physical presence or precise location, for example within glomeruli or nerves. The relationship between amyloid load and associated organ dysfunction differs greatly between locations and individuals, and the rate of new amyloid deposition may be an important factor. Aggregated amyloid proteins may also be directly cytotoxic, but they appear to evoke little or no local reaction in the tissues. However, clearance of amyloid deposits from tissue sites is mediated by complement-dependent macrophage activation and giant cell formation – a potential for therapeutic exploitation to accelerate amyloid clearance.

Treatments that substantially reduce the supply of amyloidogenic precursor protein frequently result in stabilisation or regression of existing amyloid deposits and are often associated with preservation or improvement in the function of amyloidotic organs.

Systemic AL amyloidosis

Systemic AL ('primary') amyloidosis is an uncommon complication of monoclonal gammopathy or multiple myeloma. With an incidence of approximately 8–10 cases per million population, it is about a fifth as common as myeloma. As a rule of thumb, for every five myeloma patients, there is one amyloid patient (often undiagnosed). AL fibrils are derived from monoclonal immunoglobulin light chains, which are unique in each patient. The uniqueness of an individual's light chain may explain the considerable heterogeneity in organ involvement and outcome in AL amyloidosis. Virtually any organ other than the brain may be directly affected, most commonly the kidneys, heart, liver and peripheral nerves. Early symptoms are non-specific, and lack of a single diagnostic test is seriously limiting for easy early diagnosis. Routine screening techniques often fail to detect the subtle underlying monoclonal gammopathy, causing delay in diagnosis and detrimental disease progression. Awareness of AL amyloidosis is thus essential, with early recourse to more informative investigations such as serum-free light chain (SFLC) analysis and target organ or screening tissue biopsies.

AL fibrils and monoclonal light chains

AL amyloid fibrils are derived from monoclonal immunoglobulin light chains and consist of the whole or part of the variable (V_L) domain with molecular mass between about 8 and 30 kDa. Monoclonal light chains are unique in structure in each individual and in their inherent propensity to form amyloid fibrils. Overall, about 1–2% of patients with monoclonal gammopathies eventually develop AL amyloidosis, but this is not possible to predict. The inherent 'amyloidogenicity' of certain monoclonal light chains has been demonstrated in an *in vivo* model in which purified Bence–Jones proteins were injected into mice. Light chains from patients with AL amyloidosis formed amyloid, whereas those from myeloma patients did not. AL fibrils are more commonly derived from λ than κ light chains, despite κ isotypes predominating amongst both normal immunoglobulins and monoclonal gammopathies. Some amyloidogenic light chains have distinctive amino acid replacements or insertions compared with non-amyloid monoclonal light chains, including replacement of hydrophilic framework residues by hydrophobic ones, changes that can promote aggregation and insolubility. Certain light-chain isotypes, notably $V_{\lambda VI}$, are especially amyloidogenic, and there is a degree of concordance between some isotypes and their tropism for being deposited as amyloid in particular organ systems. For example, the $V_{\lambda VI}$ isotype often presents with dominant renal involvement, whereas the $V_{\lambda II}$ isotype frequently involves the heart.

The plasma cell dyscrasia

Any B-cell dyscrasia, including multiple myeloma, Waldenström macroglobulinaemia and other malignant lymphomas/leukaemias, producing a monoclonal immunoglobulin may be complicated by AL amyloid deposition. Ninety percent of patients with AL amyloidosis have clonal plasma cells in the bone marrow (median plasma cell percentage ~9%) and 6% have an IgM-producing monoclonal B cell clone (typically a lymphoplasmacytic lymphoma/ Waldenström's macroglobulinaemia). Amyloid deposits can be found histologically in up to 15–20% of patients with myeloma and are generally asymptomatic but with marked improvement in the longevity of patients with myeloma, there is a potential that amyloidosis may become symptomatic later in the disease course. Molecular transcriptomic profiling reveals interesting differences between plasma cells in AL vs. those in other MGUS or myeloma (such as fourfold upregulation of glycosylation genes and downregulation of genes encoding for oxidative phosphorylation, MYC or ribosome biogenesis). Translocation t(11;14) is disproportionally common in AL (seen in ~50% of all cases). The presence of t(11;14) or hyperdiploidy is associated with a poorer prognosis in AL (opposed to favourable or neutral impact in myeloma).

Clinical features

AL amyloidosis accounts for 1 in 1500 deaths in the UK and occurs equally in men and women, equating to an incidence of about 8 per million persons per year. The median age at presentation is about 65 years, but it can occur in young adults and most likely remains underdiagnosed in the elderly.

Commonly, presenting features are non-specific, such as decreased exercise tolerance, fatigue, anorexia, weight loss and malaise. Proteinuric renal dysfunction and cardiac failure are common, and the combination is strongly suggestive of amyloidosis. The heart is affected in more than 70% of patients and in 30% restrictive cardiomyopathy is a presenting feature. Rarer cardiac presentations include arrhythmias and angina, the latter sometimes due to coronary amyloid angiopathy. Dominant renal amyloid is the presenting feature in one-third of patients, typically presenting with nephrotic syndrome and/or renal impairment. Gut involvement (either direct or more commonly due to autonomic neuropathy) causes motility disturbances, malabsorption, and less commonly, perforation, haemorrhage or obstruction. Macroglossia occurs in 5–10%, but is almost pathognomonic of AL amyloidosis (Figure 29.1). Other soft-tissue infiltration may occur, characteristically involving the submandibular region or the glenohumeral joints and surrounding tissues to produce the 'shoulder pad' sign, or lymph nodes themselves can be infiltrated. Hyposplenism is not infrequent but is rarely documented. Painful sensory polyneuropathy with changes in pain and temperature sensation followed later by motor deficits occur in 10–20% of cases and carpal tunnel syndrome occurs in 20%. Autonomic neuropathy leading to impotence, orthostatic hypotension and gastrointestinal disturbances may occur alone or together with peripheral neuropathy – a combination that should strongly raise suspicion for amyloidosis in absence of long-standing uncontrolled diabetes.

Figure 29.1 Macroglossia in AL amyloidosis.

Involvement of dermal blood vessels is common and may cause purpura, most distinctively in a periorbital distribution ('raccoon eyes'). Direct skin involvement is uncommon in systemic AL and is more frequent in localised AL. It presents as papules, nodules and plaques, usually on the face and upper trunk. Articular amyloid is rare, but the symptoms can be severe and superficially mimic an inflammatory polyarthritis. Thyroid infiltration with amyloid, occasionally resulting in hypothyroidism, has been reported. An uncommon, but serious manifestation peculiar to AL amyloidosis is an acquired bleeding diathesis that may be associated with deficiency of factor X and sometimes also factor IX.

Diagnosis and investigation of AL amyloidosis

Amyloidosis should be considered in the differential diagnosis of patients with a multisystem disease and combination such as nephrotic syndrome + restrictive cardiomyopathy, peripheral and autonomic neuropathy; acquired factor X deficiency; thick-walled heart failure with low voltage electrocardiogram and typical periorbital purpura or macroglossia in patients known to have clonal B-cell dyscrasias. In practice, the diagnosis of amyloidosis is usually an unexpected finding following biopsy of an organ with disturbed function. An approach to diagnosis is outlined in Figure 29.2, and comprising confirmation of amyloid, determination of fibril type, characterisation of the underlying plasma cell dyscrasia, and evaluation of the extent, distribution and function of involved organs.

Confirming the presence of amyloid

Histology

Histological confirmation of amyloidosis is almost always required. Critically, lack of amyloid deposits on a biopsy (any biopsy) does not categorically rule out amyloidosis due to the patch nature of the disease. Amyloid deposits occur in blood vessels and small interstitial foci throughout the body, providing the basis for 'screening' biopsies of the GI tract and abdominal fat aspiration, which are both diagnostic in 50–80% of cases. The combination of abdominal fat and bone marrow biopsy will identify amyloid deposits in 80% of cases with AL amyloidosis. Biopsy of a clinically affected organ is diagnostic in 95% of cases but can be avoided in many cases. Pink amorphous material on haematoxylin and eosin-stained tissue should raise suspicion of amyloid and prompt Congo red staining, which produces green birefringence under cross-polarised light and is the diagnostic gold standard (Figure 29.3). False-positive and false-negative interpretation of the Congo red stain is not rare but can be minimised by using the alkaline-alcohol method (described by Puchtler and colleagues), fresh reagents, tissue sections of optimal 5–10 μm thickness, inclusion of positive control tissue and high-quality polarising filters. Some Congo red techniques stain connective tissues quite strongly and produce white or very

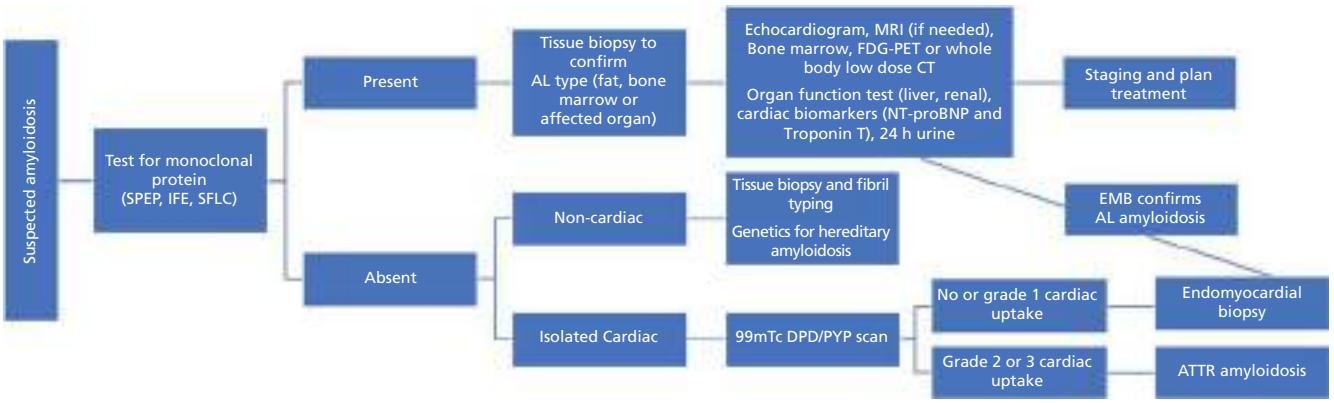

Figure 29.2 Suggested approach to the investigation of suspected amyloidosis. EMB, endomyocardial biopsy; IFE immunofixation electrophoresis; NT-proBNP N-terminal pro-brain natriuretic peptide; sFLC, serum free light chains; SPEP, serum protein electrophoresis.

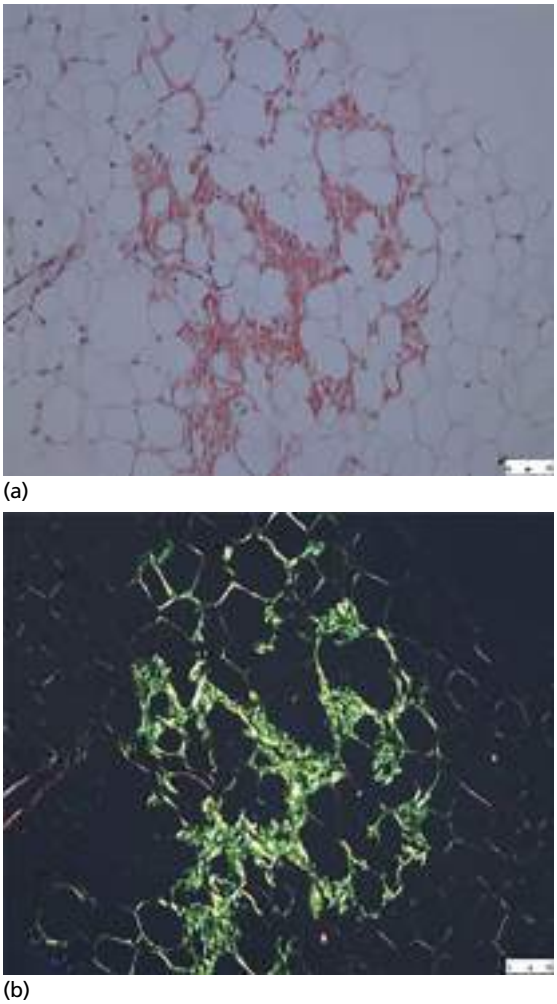

Figure 29.3 Appearance of amyloid in a bone marrow biopsy (×40, 6-μm section). (a) Congo red stain showing amorphous pink material in the interstitium and small blood vessel (arrow). (b) The same section under high-intensity cross-polarised light showing diagnostic apple-green birefringence.

pale-green birefringence that causes diagnostic errors. The differential diagnosis includes light chain deposition disease (LCDD), but these non-fibrillar deposits do not stain with Congo red.

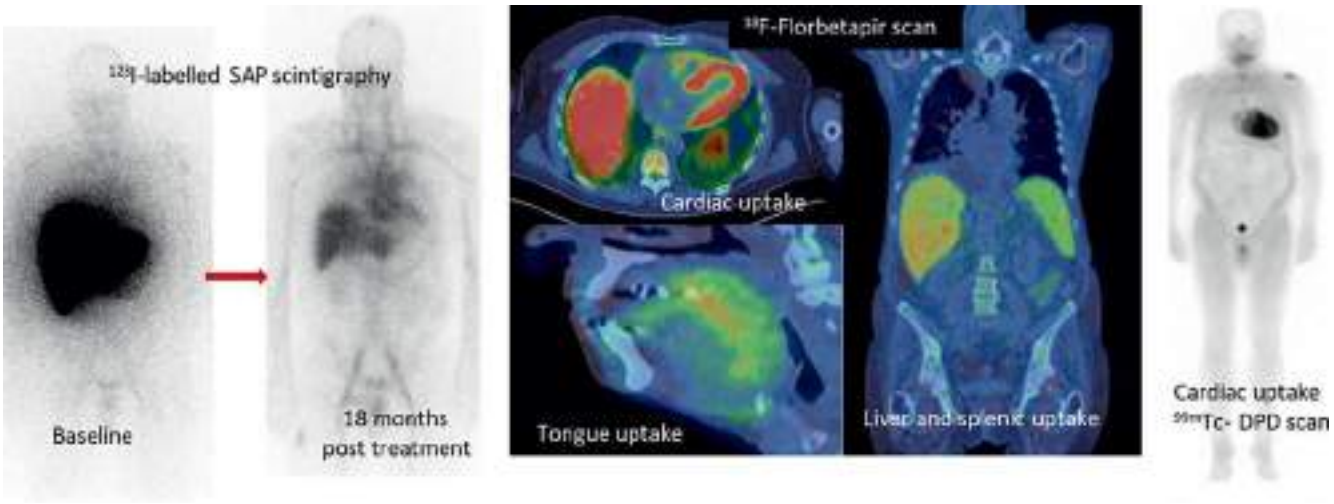
Electron microscopy is helpful in confirming the presence of amyloid and excluding LCDD. A diagnosis of amyloidosis made through electron microscopy alone needs additional clinical or imaging correlated to confirm amyloidosis.

Imaging in amyloidosis

Imaging of amyloid deposits is difficult but, when possible, may give important information about the extent of the disease. Imaging is also becoming important in assessing prognosis for patients with amyloidosis. Echocardiogram with measurement of global longitudinal strain is a widely available tool that can be used in routine clinical practice. Cardiac magnetic resonance imaging can give detailed structural information about amyloid heart and provide additional prognostic information. However, it has limitations as it cannot be done in patients with implanted devices or impaired renal function. Radionuclide imaging using ^{123}I-labelled serum amyloid P component scintigraphy can serially monitor changes in the total body amyloid load – and can act as a useful guide to therapy. However, this is not widely available but is routinely used in the UK National Amyloidosis Centre (Figure 29.4). PET scan using tracers such as Florbetpir or Florbetaben appear to be highly sensitive and specific for cardiac imaging in AL and may well become a new standard of care. Imaging with ^{99m}Tc-labelled DPD/PYP, bone scanning agents, is highly sensitive for imaging cardiac ATTR amyloidosis and useful non-invasive tool to differentiate between cardiac AL and ATTR amyloidosis (18).

Identifying fibril type

A monoclonal gammopathy may be incidental to the presence of amyloid and be gravely misleading. AL amyloidosis must be confirmed through immunohistochemical staining,



(a) (b) (c)

Figure 29.4 Radionuclide imaging in amyloidosis: (a) Radiolabelled^{123} I-SAP whole-body scintigraphy, anterior images, showing marked hepatic uptake at baseline with nearly complete regression of amyloid deposits from the liver 18 months after achieving a complete response (CR) to treatment. (b) 18F-Florbetapir scan showing cardiac, soft tissue (tongue) and hepato-splenic uptake – a new promising amyloid-specific tracer. (c) ^{99m}Tc-diphosphono-1,2-propanodicarboxylic acid (DPD) scan in a patient with wild-type cardiac transthyretin amyloidosis. There is marked cardiac uptake to the extent that the normal bone signal is not visualised.

proteomic analysis or by comprehensive exclusion of other types, including hereditary forms through DNA analysis. This is becoming critically important as elderly patients with wild type ATTR amyloidosis are diagnosed with increasing frequency and have a monoclonal gammopathy (also commoner with age) in nearly a quarter of all cases. The two important methods for fibril typing involved immunostaining with a panel of antibodies to the commoner amyloid fibril proteins (kappa, lambda, SAA, transthyretin, LECT2 and ApoA1) or laser capture of the amyloid deposit followed by tryptic digestion and mass spectrometry. The latter is now considered as the gold standard for fibril typing. Immunohistochemical staining of amyloid-containing tissue sections using a panel of antibodies should only be undertaken in experienced laboratories due to very high false positive and negative results with the exception of staining with antibodies to SAA and LECT2.

Ruling out hereditary amyloidosis

Sequencing of the genes associated with hereditary amyloidosis should be performed routinely to exclude hereditary amyloidosis when the AL type cannot be confirmed with absolute certainty by immunohistochemistry and/or proteomics. Of patients attending the UK National Amyloidosis Centre, 5% have hereditary amyloidosis, those with TTR mutations usually presenting with neuropathy and/or cardiac amyloidosis and those with fibrinogen Aα chain mutations presenting with renal dysfunction. It is necessary to confirm that identified mutations are indeed the cause of the amyloid with fibril typing as described above.

Assessment of the clone

All patients with suspected amyloidosis should have both serum and urine tested for monoclonal protein with electrophoresis and immunofixation as well as measurement of serum-free light chains. Using a combination of serum/urine plus serum-free light chains 98% of patients with AL amyloidosis will show a monoclonal component, although at a low level in many cases. All patients should have bone marrow biopsy with appropriate cytogenetic evaluation for presence of translocations or ploidy changes. Cross-sectional imaging with FDG positron emission tomography (PET) or low dose whole body CT or whole-body MRI is needed to exclude myeloma-defining bone lesions.

Assessment of organ involvement

International society of amyloidosis has developed criteria to define organ involvement in AL amyloidosis (Table 29.2). ECG and two-dimensional Doppler echocardiography are often the initial tools for evaluating cardiac involvement. In cardiac amyloidosis, ECG may demonstrate reduced QRS voltages in the limb lead and poor R-wave progression in the chest leads ('pseudo-infarct' pattern). Cardiac amyloidosis is a restrictive cardiomyopathy and diastolic dysfunction is easily missed and difficult to quantify. Echocardiography typically reveals concentrically thickened left ventricle with echogenic heart valves with impaired diastolic function. Global longitudinal strain shows early and marked impairment of the longitudinal systolic function of the heart – a very

Table 29.2 Non-invasive diagnostic criteria for amyloid-related major organ involvement.

Heart
Echocardiogram demonstrates mean wall thickness >12 mm, no other cardiac cause found
Kidney
Proteinuria >0.5 g per 24 hours, predominantly albumin
Liver
Total liver span >15 cm in the absence of heart failure or alkaline phosphatase >1.5 times the institutional upper limit of normal
Nerve
Peripheral: clinical; symmetric lower extremity sensorimotor peripheral neuropathy
Autonomic: gastric emptying disorder, pseudo-obstruction, voiding dysfunction not related to direct organ infiltration
Gastrointestinal tract
Direct biopsy verification with symptoms
Lung
Direct biopsy verification with symptoms
Interstitial radiographic pattern
Soft tissue
Tongue enlargement, clinical
Arthropathy
Claudication, presumed vascular amyloid
Skin
Myopathy by biopsy or psudohypertrophy
Lymph node (may be localised)
Carpal tunnel syndrome

specific feature of cardiac amyloidosis and a crucial marker for prognosis. Cardiac magnetic resonance imaging (MRI) is a very useful tool for identifying cardiac amyloidosis and distinguishing it from other restrictive cardiomyopathies and should be undertaken in all patients where the echocardiographic picture is unclear. The status of other organs can be assessed either through routine tests of organ function, such as liver function tests, serum creatinine and 24-hour urine measurements, or by specialist investigations as indicated, for example autonomic function and nerve conduction tests and high-resolution pulmonary computed tomography (CT).

Glomerular proteinuria (predominantly albuminuria) is present in about 90% of patients with renal involvement. Liver amyloidosis is often asymptomatic and presented with abnormal alkaline phosphatase and GGT as the early serological markers with other transaminases and bilirubin abnormalities seen only in very advanced disease.

Coagulation abnormalities in amyloidosis can be challenging. Nephrotic patients are often pro-thrombotic. Conversely, an abnormal clotting screen is relatively common. A prolonged thrombin time is the most frequent abnormality and may be a technical consequence of hypoalbuminaemia, and is generally of no clinical consequence. All patients with a prolonged prothrombin time or significant hepatic/splenic amyloid deposits should have formal measurement of clotting factors, particularly factor X; deficiency of which is commonest and the most likely coagulation abnormality to be associated with clinically significant bleeding.

Cardiac biomarkers (N-terminal probrain natriuretic peptide (NT-pro-BNP) and cardiac troponin) are powerful predictors of prognosis and survival after chemotherapy in cardiac amyloidosis. These have to be interpreted in context of renal function and other known cardiac disease. Significant myocardial AL amyloidosis is excluded by NT-pro-BNP concentrations below 175 ng/L. The Mayo clinic staging system incorporates NT-proBNP and troponin-T (later modification also including serum-free light chains). Stage 1, with cardiac biomarkers below threshold values (cTnT <0.035 μg/L and NT-proBNP <332 ng/L) is associated with the lowest risk of death and a median survival not reached at 5 years (90% alive at 5 years); stage 2, with either biomarker above the threshold values, has a survival 70% at 5 years; Stage 3a, with both biomarkers above the threshold values but NT-proBNP <8500 ng/L, is associated with a median survival of 36 months; and stage 3b (with NT-proBNP >8500 ng/L) has a median survival of 4 months.

Differential diagnosis

Alternative diagnoses that frequently need to be considered include amyloidosis of non-AL types (principally wild-type cardiac ATTR amyloidosis, less frequently ALECT2, AA and hereditary forms). In all cases with amyloid deposits at a single site, localised forms of AL amyloidosis become more likely. Isolated proteinuric renal involvement in presence of a monoclonal protein, raises the strong possibility of a renal lesion associated with monoclonal gammopathy of renal significance (MGRS), LCDD is the commonest. Isolated peripheral neuropathy is an uncommon presenting feature in AL amyloidosis with POEMS and other paraprotein-associated neuropathies as crucial differential diagnosis as indeed treatment-related toxicities.

Natural history

Systemic AL amyloidosis is a progressive disease with a very poor prognosis, if untreated. Median survival without treatment in historical series is only 12–15 months but has improved to over 5 years in contemporary cohorts. At diagnosis, 40% of patients have Mayo Stage III disease (elevated cardiac troponin and NT-pro-BNP) and continue to have a high early mortality

(30–40% in 12 months from diagnosis). However, amyloidosis is not, as previously believed, inexorably progressive and irreversible – it is now clear that amyloid deposits almost always gradually regress when the supply of amyloid fibril precursor protein is eliminated.

Management

Specific therapies that inhibit formation of amyloid or enhance its clearance are not yet available, although are in development. Currently, the objective of treatment in AL amyloidosis is to suppress production of amyloidogenic monoclonal light chains with the aim that progression of the disease will be slowed, halted or reversed. There has been remarkable progress in the treatment of AL amyloidosis using drugs developed for multiple myeloma with improving depth of response and decreasing mortality (Figure 29.5). In 2021, daratumumab-cyclophosphamide-bortezomib-dexamethasone (Dara-VCd) has become the first licensed treatment for AL amyloidosis.

Goals of treatment

Response in AL amyloidosis involves assessment of the direct impact of chemotherapy on the clone and, an indirect effect, of improvement in organ function on the a priori organ damage (an 'organ response') as well as depth of haematologic response achieved. Although the deeper the haematologic response, the greater is the likelihood of organ responses, there may be a discrepancy between the haematologic response and organ response. While organ response is the ultimate goal, since none of available agents can influence this directly, achieving a very good partial hematologic response (VGPR) was considered as the 'goal' of treatment in AL amyloidosis. It is clear that a CR is associated with superior outcomes and, lately, single centre studies shown that reaching very low free light chain levels after treatment (difference between involved and uninvolved light chains (dFLC) or involved free light chain [iFLC]) is also predictive of better outcomes. Thus, achieving a complete haematologic response is the goal of treatment in AL amyloidosis, ideally associated with iFLC <20 mg/L or dFLC <10 mg/L.

Haematologic response should be evaluated at least fortnightly for the initial 1–2 cycles and then monthly. Early treatment modification is imperative if the patient does not achieve progressive FLC response within the initial cycles (if the response following two cycles is ≤ partial response (PR) or following three cycles < VGPR and no organ response has occurred). An algorithm to help treatment modification based on depth of response has been published.

Certain organs affected by amyloid tend to fare better than others, following treatment. Proteinuria and liver function often improve when the clonal disease is adequately suppressed. While it was previously considered that cardiac disease would not improve, it is clear that with a CR, the majority of patients will achieve significant cardiac improvements. Improvement in macroglossia and peripheral nerve function tend to respond extremely slowly if at all. Criteria on the definitions of clonal and organ responses and progression were published by the International Society of Amyloidosis in 2012 and updated in 2020.

An approach to treatment of AL Amyloidosis

Elimination of the bone marrow clone producing the amyloidogenic light chains remains the mainstay of therapy for AL amyloidosis. Three factors determine the choice of therapy: (i) Age/performance status (ii) Extent of amyloidotic organ involvement (iii) Bone marrow plasmacytosis. Younger fit patients with limited amyloid-related end organ damage remain candidates for high-dose melphalan followed by autologous stem cell transplantation (SCT) while older/less fit patients with advanced organ involvement are treated with combination chemotherapy (but with the caveat that some may recover enough to become transplant candidates at a later date). Patients with low-level plasma cell infiltration may not need prolonged treatment courses while those with >20% plasma cells need to closely follow the paradigms established

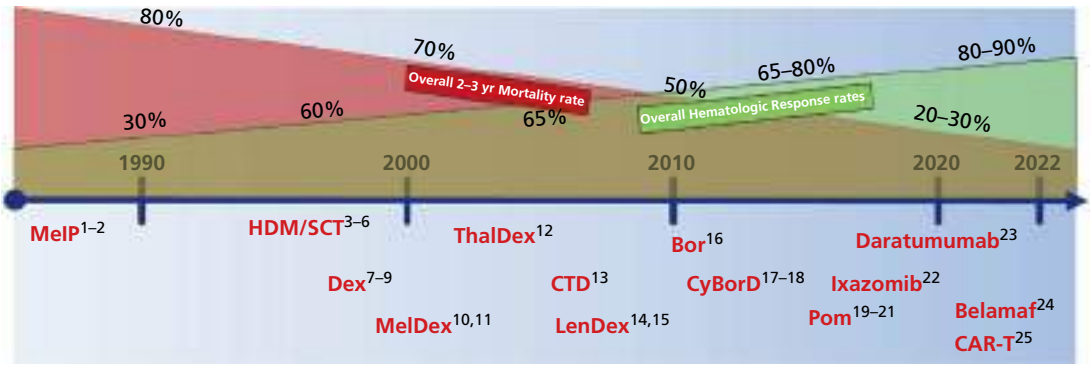

Figure 29.5 Improving response and decreasing mortality with wider access to AL treatments (*Source:* Wechalekar and Sanchorawala 2022/with permission from Elsevier).

for treatment of multiple myeloma. The International Society of Amyloidosis has published guidelines for both transplant and non-transplant chemotherapy for treatment of AL amyloidosis which should form the guiding principles for treatment choice in AL amyloidosis.

Autologous peripheral blood stem cell transplantation

Pioneered in the mid-1990's, high-dose melphalan therapy and autologous SCT was the first transformative treatment in AL amyloidosis and still the only treatment showing very durable responses lasting 10 years or more. The treatment-related mortality (TRM) in AL amyloidosis has largely been eliminated by careful and strict patient selection. Due to these criteria, only 15–20% of all patients are suitable for SCT. Advanced cardiac involvement (NT-proBNP >5000 ng/L or troponin T >0.06 ng/L), recurrent pleural effusions, poor performance status, supine systolic blood pressure <90 mm of Hg, GI bleeding and uncontrolled autonomic neuropathy are absolute contraindications for transplantation. Stem cell mobilisation has significant risks in AL amyloidosis with cardiac involvement and should be undertaken with growth factors alone. Regardless, because of its special problems in AL amyloidosis, it is recommended that such patients are treated in units with expertise in this particular disease (undertaking at least 4–5 AL transplant annually). Melphalan dose reduction in the conditioning (apart from renal impairment) leads to a significant compromise in the efficacy. Hence, dose-reduced melphalan SCT, apart from renal reasons, is not recommended in AL.

The exact role of SCT in AL amyloidosis has changed over the years. The current recommendations suggest that induction chemotherapy should be considered for the vast majority of patients with AL amyloidosis using a bortezomib-based regime. Patients with >10% bone marrow plasma cell infiltration as well as selected younger patients with even a lower plasma cell infiltrate and achieving less than a CR should proceed, as long as eligible, for SCT. There is no routine indication for SCT in patients with <10% bone marrow plasmacytosis and achieving CR with induction chemotherapy to proceed with SCT.

There is no role for allogeneic SCT in the treatment of AL amyloidosis.

Non-transplant chemotherapy for AL amyloidosis

The majority of patients with AL amyloidosis are treated with combination chemotherapy. The treatment has to be risk-adapted based on the extent of end-organ damage by amyloid deposits. Patients with advanced cardiac disease or severe autonomic neuropathy are at particular risk of treatment toxicity and may need inpatient care at the start of chemotherapy. Close and meticulous attention to supportive care is critical to success of the treatment programme.

Bortezomib has been mainstay of upfront treatment in AL for the last decade. The benefit of bortezomib-melphalan-dexamethasone was clearly demonstrated in a recent randomised phase III trial of 100 newly diagnosed patients with AL amyloidosis; improving CR/VGPR rates from 28 to 53%. The most widely used regimen is CyBorD (combination of cyclophosphamide, bortezomib and dexamethasone). A European collaborative study of 230 patients demonstrated efficacy of CyBorD, reporting haematologic, renal and cardiac response rates of 60, 25 and 17%, respectively. A study from UK National Amphoidosis Centre reported the outcomes of 915 patients with haematologic, renal and cardiac response rates of 65, 15.4 and 32.5% respectively. A rapid response with bortezomib-based therapy can significantly improve outcomes even in advanced cardiac patients (median OS improving from 5 to 26 m in patients achieving a CR/VGPR by end of 1 month).

The ANDROMEDA clinical trial compared daratumumab or placebo combined with CyBorD. In 388 patients who underwent randomisation, at a median follow-up of 11.4 months, the percentage of patients who had a haematologic CR was significantly higher in the daratumumab group than in the control group (53.3 versus 18.1%) (relative risk ratio, 2.9; 95% confidence interval [CI], 2.1–4.1; $P < 0.001$). Survival free from major organ deterioration or haematologic progression favoured the daratumumab group (hazard ratio for major organ deterioration, haematologic progression, or death, 0.58; 95% CI, 0.36–0.93; $P = 0.02$). At 6 months, more cardiac and renal responses occurred in the daratumumab group than in the control group (41.5 versus 22.2% and 53.0 versus 23.9%, respectively). The four most common grade 3 or 4 adverse events were lymphopenia (13.0% in the daratumumab group and 10.1% in the control group), pneumonia (7.8 and 4.3%, respectively), cardiac failure (6.2 and 4.8%) and diarrhoea (5.7 and 3.7%). Systemic administration-related reactions to daratumumab occurred in 7.3% of the patients. A total of 56 patients died (27 in the daratumumab group and 29 in the control group), most due to amyloidosis-related cardiomyopathy. The addition of daratumumab to bortezomib, cyclophosphamide and dexamethasone was associated with higher frequencies of haematologic CR and survival free from major organ deterioration or haematologic progression. The results of this study led to the licensing of daratumumab-CyBorD for front-line treatment of AL amyloidosis.

Alkylator-based chemotherapy regimens were the mainstay for many years but have now been superseded by combination novel agent-based chemotherapy. Oral melphalan and dexamethasone (MDex) induced a haematologic response rate of 67%, a CR rate of 33% and organ response rate of 48% in a phase II study of 45 patients. An update of this cohort with 5-year follow-up showed impressive median progression-free survival (PFS) of 3.8 years and median OS of 5.1 years. It still continues

to have a role in selected patients who are not candidates for novel agent chemotherapy.

Immunomodulatory drugs such as lenalidomide, pomalidomide and thalidomide have been used in treatment of amyloidosis for many years. Thalidomide-based treatments are no longer considered appropriate for patients with amyloidosis due to high toxicity. Lenalidomide and pomalidomide are useful for patients in treatment of relapsed disease. In phase II trials, full-dose lenalidomide had significant toxicity requiring dose reductions or discontinuation and was better tolerated at 15 mg/day in combination with weekly dexamethasone (LenDex), with haematologic response rates of 40–50%. Single-agent lenalidomide has limited efficacy and is not recommended. A retrospective study in relapsed AL treated with LenDex, there was a 49% haematologic response rate with 16% CR, median OS of about 2 years, and in those achieving CR, a PFS of over 3 years. In a preliminary report on a phase II study of pomalidomide with weekly dexamethasone, over 30% of relapsed AL patients achieved a CR, highlighting the promise of this potent immunomodulatory (IMiD) therapy. A combined retrospective analysis reported good responses (VGPR or better in 40%) with 27 months (95% confidence interval 15·7–38·1 months) and median progression-free survival (PFS) was 15 months (95% confidence interval 6·24–23·77) in multiply relapsed AL patients treated with pomalidomide.

Translocation t(11;14) is seen in 45% of patients with AL amyloidosis. This is a potential group for targeted therapy due to specific activation of cyclin D1. Venetoclax is one such agent which has been used in the treatment of multiple myeloma. We recently reported a retrospective international collaborative study showing high response rates in patients treated with Venetoclax in patients with relapsed AL amyloidosis. Amongst 43 patients reports, the haematologic response rate for all patients was 68%; 63% achieved VGPR/CR. Patients with t(11;14) had higher haematologic response (81 versus 40%) and higher VGPR/CR rate (78 versus 30%, odds ratio: 0.12, 95% CI 0.02–0.62) than non-t(11;14) patients. The toxicities appeared to be modest and the deep response rates were striking. This agent, or similar agents, needs to be investigated in prospective trials in AL (Figure 29.6).

BMPC, bone marrow plasma cells; CR, complete remission; CyBorD, cyclophosphamide-bortezomib-dexamethasone; dara, daratumumab; dFLC, difference between the involved and uninvolved free light chains; Len, lenalidomide; SCT, stem cell transplantation; VGPR, very good partial remission.

Supportive treatment

Supportive therapy remains a critical component of management of AL amyloidosis. For cardiac amyloidosis, the mainstay of treatment is diuretics. Vasodilating drugs and β-blockers are generally best avoided as they often worsen symptoms significantly. Fluid overload should be treated with fluid restriction, loop diuretics and a low-salt diet; often with addition of aldosterone antagonists (spironolactone/eplerenone). Salt-poor albumin infusions can occasionally be helpful in severely nephrotic patients. Dysrhythmias may respond to amiodarone or to pacing. Implantable cardioverter defibrillators have been used very effectively in selected patients.

In autonomic neuropathy, fludrocortisone may cause or exacerbate fluid retention. Midodrine is an effective pressor agent, starting at 2.5–15 mg thrice daily. Midodrine causes activation of the α-adrenergic receptors of the arteriolar and venous vasculature, producing an increase in vascular tone and elevation of blood pressure. Its chief adverse effect is supine hypertension, and other pressor agents must be coadministered with caution. Gastroparesis causing symptoms of early satiety and nausea can be managed with prokinetic agents such as metoclopramide, along with advice about small frequent meals that are of soft consistency. Diarrhoea due to amyloid gut involvement or autonomic neuropathy may respond to loperamide and codeine phosphate. Refractory diarrhoea can respond to octreotide. Malnutrition is not uncommon and is a poor prognostic factor. Formal and early review by an experienced dietician is important. Most patients, particularly during chemotherapy, need calorie/protein supplementation. Marked soft tissue amyloidosis involving the tongue or mouth area results in severe dysphagia and may need feeding via a percutaneous endoscopic gastrostomy. Amyloid- and treatment-related peripheral neuropathy can be disabling and difficult to treat. Amitriptyline, venlafaxine, antiepileptics, TENS and/or gabapentin/pregabalin have all been used with variable efficacy. Withdrawal or dose reduction of any neurotoxic chemotherapies, such as thalidomide or bortezomib, is needed in all such cases.

Bleeding and thrombosis are both seen in amyloidosis; and occasionally in the same patient. Patients with severe nephrotic syndrome, atrial fibrillation (or even poor atrial function) and on treatment with immunomodulatory agents need appropriate anticoagulation. Use of novel oral anticoagulants, like rivoroxaban or apixaban, appears safe in patients with good renal function. Conversely, patients with extensive gut amyloid deposits, skin amyloid deposits and those with factor X deficiency have a high risk of bleeding. Patients with factor X deficiency and clinically significant bleeding need treatment with either clotting factor concentrates (high thrombotic risk), activated factor VIIa or, if available, factor X concentrate replacement. Tranexamic acid can be useful.

Surgical resection of amyloidotic tissue is occasionally beneficial but, in general, a conservative approach to surgery, anaesthesia and other invasive procedures are advised. Should any such procedure be undertaken, meticulous attention to blood pressure and fluid balance is essential, especially in patients with renal and/or cardiac involvement. Amyloidotic tissues may heal poorly and are liable to haemorrhage.

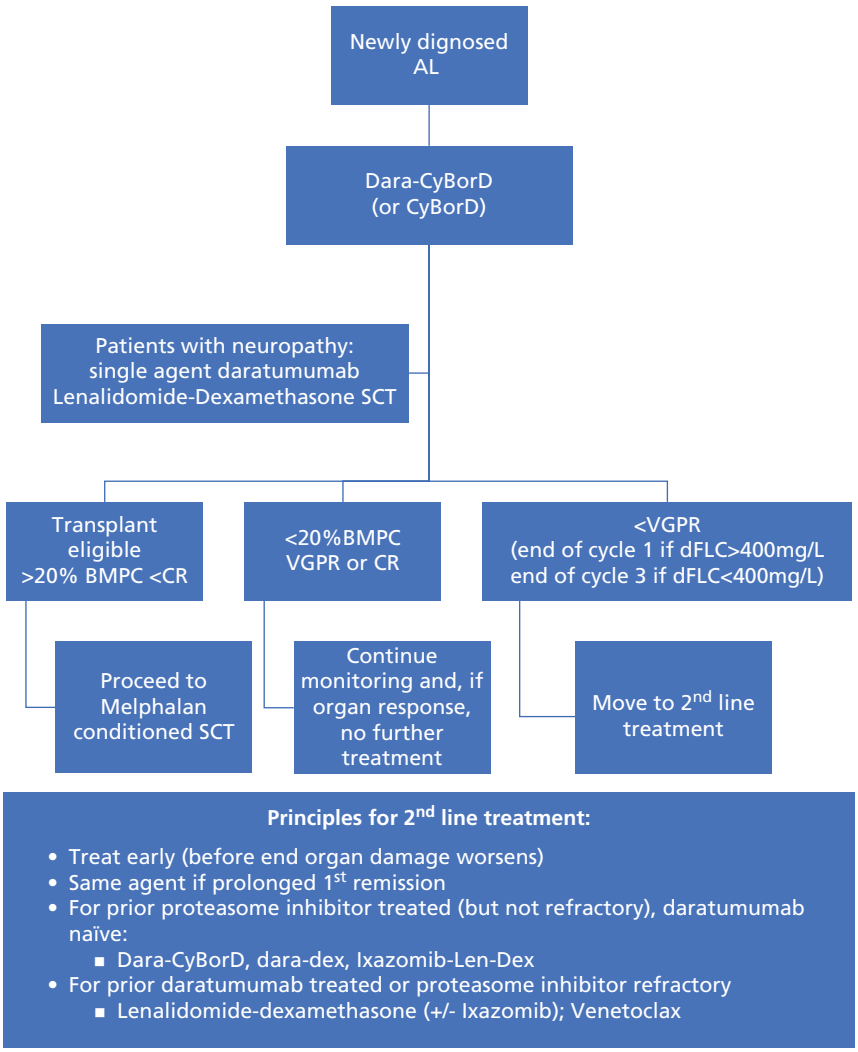

Figure 29.6 A proposed treatment algorithm for AL amyloidosis.

Solid organ transplantation

Renal and cardiac transplantation have been used in selected patients with AL amyloidosis for over 25 years. Renal transplantation should be considered in relatively young patients with otherwise well-preserved extrarenal organ function who have chemotherapy-responsive disease. Patients with renal amyloidosis transplanted when in a haematologic complete remission have good renal transplant outcomes with only rare renal grafts lost due to recurrent amyloid deposition. Cardiac transplantation can be life-saving procedure in highly selected otherwise fit patients with isolated cardiac amyloidosis but has to be followed by treatment to suppress the clone and ideally considered for SCT. Liver transplantation has been performed in only a very small number of patients, with generally disappointing results, reflecting the fact that liver failure in AL amyloidosis is always associated with substantial amyloid deposition in other vital organs.

Localised AL amyloidosis

Localised deposits of AL amyloid can occur almost anywhere in the body, with characteristic sites including the skin, airways, conjunctiva and urogenital tract. They may be nodular or confluent amyloid deposits and are associated with a usually inconspicuous focal infiltrate of clonal plasma cell producing amyloidogenic light chains. Progression of localised AL amyloid into a truly systemic disease is exceedingly rare, and conservative management is usually appropriate.

Conjunctival amyloidosis is commonest and responds to local treatment with surgical removal if symptomatic. Orbital AL amyloid presents as mass lesions that can disrupt eye movement and the structure of the orbit. These are deposits may need local or, even rarely, systemic treatment.

Airway amyloidosis may localise to larynx or involve the trachea-bronchial tree. Localised laryngeal AL amyloidosis is a well-recognised syndrome that is often amenable to direct or laser excision, but hereditary systemic apolipoprotein A-I amyloidosis can also present in this manner. Amyloidosis in the bronchial tree is virtually always of localised AL type, as are solitary or multiple amyloid nodules within the lung tissue. Patients can have significant symptoms due to airway narrowing and early bronchoscopic laser treatment of stenosing lesions can bring symptom relief. Local radiotherapy may have a role. In contrast, diffuse alveolar septal parenchymal deposition is commonly a manifestation of systemic AL amyloidosis.

Patients with Sjögren disease may present with glandular amyloid deposits – breast, salivary or lacrimal glands and lungs (either in single or multiple sites). Mucosa-associated lymphoid tissue (MALT) lymphoma should be excluded in such cases.

Lichenoid and macular forms of cutaneous amyloid are thought to be derived from keratin or related proteins. The cause is unclear and seems to be commoner in those with darker skin. Nodular cutaneous amyloid deposits are generally of AL type and can sometimes be a manifestation of systemic AL amyloidosis. Localised urogenital AL amyloid deposits are often incidental findings but may present with haematuria or, less commonly, obstruction. They can occur anywhere from the renal collecting system to the urethra, although are most usually identified within the bladder. Management is conservative or with transurethral laser resection when symptoms occur; cystectomy is rarely required.

Other forms of systemic amyloidosis

Amongst more than 5000 patients with systemic amyloidosis who have been referred for evaluation at the National Amyloidosis Centre, approximately 55% have had AL type, 15% AA (reactive systemic) type, and the remainder have had a variety of hereditary, localised and other types. Although some features of systemic AL amyloidosis are very characteristic of this particular type, such as macroglossia, periorbital purpura and certain permutations of organ involvement, the clinical phenotypes of AA, AL and hereditary systemic amyloidosis can be indistinguishable. Furthermore, the underlying chronic inflammatory disease process is clinically covert in 5–10% of patients with AA amyloidosis, and a family history is often absent in patients with hereditary ATTR and fibrinogen Aα-chain amyloidosis, which are the most common familial forms.

AA amyloidosis

Reactive systemic AA (secondary) amyloidosis occurs in 1–5% of patients with chronic inflammatory diseases that evoke a substantial acute-phase response, after a median latency of about 15–20 years. This is becoming an increasingly rare disease. AA amyloid fibrils are derived from the circulating acute-phase reactant SAA, the serum concentration of which can increase from the healthy reference range of less than 10 mg/L to over 1000 mg/L during active inflammation. The commonest associated diseases in the developed world include rheumatoid arthritis, juvenile idiopathic arthritis and Crohn's disease. Familial Mediterranean fever and other rare periodic fever syndromes can result in AA amyloidosis. Chronic infections remain important cause in some parts of the world. Castleman disease of the solitary plasma cell type should be considered amongst the underlying conditions that remain clinically covert.

Most patients present with nephropathy, particularly proteinuria, but liver and gastrointestinal involvement may occur at a late stage. Clinical involvement of the heart and nerves occurs very rarely. Treatment in AA amyloidosis should decrease the underlying inflammation so that SAA levels remain well controlled, preferably below 10 mg/L – a goal that frequently leads to the regression of existing amyloid deposits, with improvement in amyloid-related organ dysfunction, and significantly improves long-term survival. The exact nature of the treatment will depend on the underlying inflammatory disease and ranges from inhibitors of tumour necrosis factor in rheumatoid arthritis and colchicine in familial Mediterranean fever to surgical resection of Castleman disease tumours.

Leucocyte chemotactic factor II (LECT2) amyloidosis

The newly described leucocyte chemotactic factor II (LECT2) form of amyloidosis has become the second commonest acquired amyloidosis in some parts of the world. It mimics AL, AA and hereditary forms of amyloid-related kidney disease and usually manifests as isolated, stable or slowly progressive renal impairment. Asymptomatic liver involvement is not uncommon with a small proportion of patient progressing to end-stage liver failure. Diagnosis is by histological confirmation on LECT2 fibrils by immunohistochemistry or by mass spectrometry. The pathogenesis of ALECT2 amyloidosis is not known, but it is currently not thought to have a genetic aetiology. There is no known treatment for LECT2 amyloidosis apart from organ transplantation for end-stage renal disease.

Transthyretin amyloidosis (ATTR amyloidosis)

Normal *TTR* is inherently, but weakly, amyloidogenic, and minor ATTR amyloid deposits are common in elderly individuals. Clinically significant involvement is rare before the 6th decade but appears to be a relatively common occurrence in those aged over 80 years. The exact incidence remains unknown but may account for ~15% of patients with the

syndrome of heart failure with preserved ejection fraction (this estimation would suggest ~60,000 patients in the UK). Wild-type ATTR amyloidosis typically causes heart failure, carpal tunnel syndrome, spinal canal stenosis and biceps tendon rupture. Patients typically survive for several years with reasonably good quality of life managed with diuretics alone. The re-purposed use of bone tracer ^{99m}Tc-DPD or similar agents is highly sensitive for cardiac ATR amyloidosis and has greatly improved the diagnostic yield. Tafamidis is a TTR-stabilising small molecule that is licensed for this condition and has been shown to prolong survival.

Familial amyloidotic polyneuropathy (FAP) associated with mutations in the gene for *TTR* is the most common type of hereditary amyloidosis. It is characterised by progressive and disabling peripheral and autonomic neuropathy, often with cardiac involvement. Vitreous amyloid deposits may also occur and are virtually pathognomonic of the syndrome. Symptoms typically present between the third and seventh decades. More than 100 *TTR* variants are associated with FAP, the most frequent of which is the substitution of methionine for valine at residue 30 (TTR Met30). There are well-recognised foci of this in Portugal, Japan and Sweden, but FAP has been reported in most ethnic groups. *TTR* Ala60 is the most frequent cause of FAP in the British and Irish population, typically presenting after 50 years of age and usually with marked cardiac involvement. *TTR* Ile122 occurs in 3–4% of black Africans and is associated with a phenotype indistinguishable from senile (wild-type) cardiac amyloidosis. Patisiran (a small interfering RNA) and Inotersan (an antisense oligonucleotide) specifically inhibit TTR protein production and are licensed for treatment of hereditary ATTR amyloidosis with neuropathy.

Hereditary systemic amyloidoses

Hereditary systemic amyloidosis is caused by deposition of genetically variant proteins as amyloid fibrils, and is associated with mutations in the genes for *TTR*, fibrinogen Aα chain, cystatin C, gelsolin, apolipoprotein A-I, apolipoprotein A-II and lysozyme. These disorders are all inherited in an autosomal dominant manner with variable penetrance, and usually present in adult life.

The syndrome of non-neuropathic hereditary systemic amyloidosis is caused by mutations in the genes for fibrinogen Aα chain, lysozyme, apolipoprotein A-I and apolipoprotein A-II. Most such patients present with renal impairment and/or proteinuria, but substantial deposits in the liver and spleen are frequent in hereditary lysozyme and apolipoprotein A-I amyloidosis, and the heart may be involved in hereditary apolipoprotein A-I amyloidosis. Prominent neuropathy occurs in some patients with apolipoprotein A-I Arg26. Although kindreds with hereditary amyloidosis are rare, 5–10% of patients referred to the National Amyloidosis Centre with apparently sporadic amyloidosis do in fact have hereditary forms of the disease. About half of these are associated with *TTR* mutations, and most of the remainder are associated with variant fibrinogen Aα chain Val526. Penetrance of this particular mutation is extremely low in most families, thus obscuring the genetic aetiology, but the renal histology is characteristic, showing substantial accumulation of amyloid within enlarged glomeruli, but none in blood vessels or the interstitium. Renal impairment is often noted in the fourth or fifth decade, and end-stage renal failure is managed with dialysis or renal transplantation. Variant fibrinogen Aα-chain amyloidosis can recur in the transplanted graft and median survival of kidney transplants in patients attending our centre has been 7 years, though this can be much longer. Combined liver–kidney transplants have been performed in this condition though, with notable mortality. Hereditary cystatin C amyloidosis manifests in Icelandic families as cerebral amyloid angiopathy, with recurrent cerebral haemorrhage, and gelsolin variants are associated with corneal lattice dystrophy and cranial neuropathy, most often in Finnish patients.

DNA analysis should now be performed routinely on patients with systemic amyloidosis in whom AA or AL fibril type cannot be definitively verified.

Conclusion and future directions

Improved understanding of the aetiology and pathogenesis of amyloid has led to many recent advances in the characterisation and management of amyloidosis. Use of mass spectrometry has allowed for accurate amyloid typing. The clonal biology in AL shows the differences between AL and MGUS/Myeloma with potential specific targets for treatment. Imaging in amyloidosis with development of cardiac MRI and amyloid-specific tracers has been brought to the mainstream. Clinical improvement following successful treatment of the various conditions that underlie amyloidosis is always gradual, and the crucial need for multidisciplinary supportive measures is better recognised. The biggest leap has been in treatment for AL with licensing of daraCyborD as the 1st licensed treatment in 2021. The expanding therapeutic armamentarium in agents treating multiple myeloma has started making earlier inroads into amyloidosis. Active immunotherapy holds potential promise of long-term responses and may challenge the place of SCT in the treatment pathway.

Novel therapies specifically for amyloidosis now in development include small molecules, monoclonal antibodies, peptides and GAG analogues that variously interfere with amyloidogenesis. Immunotherapy approaches are in the advanced phases of clinical trials with the aim of promoting regression of amyloid now tantalisingly close. Amyloidosis, no longer a true rarity, is now a treatable condition from which patients can hope for recovery and longevity.

PART IV

Stem cell and myeloid disorders

CHAPTER 30

Inherited aplastic anaemia/bone marrow failure syndromes

30

Inderjeet S Dokal

Barts and The London School of Medicine and Dentistry, Queen Mary University of London, Barts Health NHS Trust, London, UK

Introduction

A number of inherited (constitutional/genetic) disorders are characterised by aplastic anaemia (AA)/bone marrow failure (BMF), usually in association with one or more somatic abnormalities (Table 30.1). The features of some of these are summarised in Table 30.2. The precise incidence/prevalence of these remains unclear but, collectively, they represent approximately 20–30% of patients presenting with AA and constitute a significant clinical burden, as many are associated with premature mortality. The BMF may present at birth or at a variable time thereafter, including in adulthood in some cases. The BMF may involve all lineages or a single lineage; in some cases, it may initially be associated with a single cytopenia and then progress to pancytopenia. Scientifically, they constitute an important group of diseases as advances in understanding the genetics of some of these are not only unravelling their pathophysiology, but are also providing important insights into normal haemopoiesis.

The two syndromes that are frequently associated with generalised BMF/AA are Fanconi anaemia (FA) and dyskeratosis congenita (DC). These two syndromes are also two of the best characterised and are discussed in some detail in this chapter (followed by sections on Shwachman–Diamond syndrome, Diamond–Blackfan anaemia, congenital dyserythropoietic anaemia, congenital neutropenia, thrombocytopenia with absent radii, congenital amegakaryocytic thrombocytopenia and newly identified subtypes). This chapter discusses the clinical and genetic heterogeneity of these BMF syndromes, their management and their impact on our understanding of the pathophysiology of more common forms of 'idiopathic aplastic anaemia'. Indeed, patients with FA, DC and other inherited BMF subtypes can sometimes present with AA/BMF alone as their initial manifestation and pose a diagnostic/management challenge.

Fanconi anaemia

Clinical features

Since the first description by Guido Fanconi in 1927, FA has come to be recognised as an autosomal recessive (AR) disorder (X-linked in a rare subset) in which there is progressive BMF and an increased predisposition to malignancy, especially acute myeloid leukaemia (AML). Most, but not all, affected individuals also have one or more somatic abnormalities, including skin (café-au-lait spots), skeletal (absent thumbs, radial hypoplasia, scoliosis), genitourinary (underdeveloped gonads, horseshoe kidneys), gastrointestinal, cardiac and neurological anomalies (Table 30.3). Some of these somatic abnormalities are shown in Figure 30.1. The course of the disease and the pattern of somatic abnormalities show considerable variation, with approximately one-third of patients having no physical abnormalities. This makes diagnosis based on clinical criteria alone difficult and unreliable.

The cumulative incidence of BMF by the age of 40 years in patients with FA is ~90%. At birth, the blood count is usually normal. Pancytopenia develops insidiously and presents in most cases between the ages of 5 and 10 years (median age 7 years).

However, in some cases, the pancytopenia develops in adolescence or even in adult life. The haemoglobin and platelet count are usually first to fall; the granulocytes are usually well-preserved in the early stages. As the pancytopenia develops, the bone marrow (BM) becomes progressively hypocellular. There is often a marked increase in macrophage activity with evidence of haemophagocytosis. BMF, leading to fatal haemorrhage or infection, is the main cause of death. In an analysis of the International Fanconi Anaemia Registry (IFAR), the median survival time was 24 years; this is changing with improvements in clinical care.

Table 30.2 Characteristics of the BMF syndromes.

(b) Abnormalities of pigmentation (hyper- and hypopigmentation) on the abdomen (B1) with a close-up (B2) of a café-au-lait spot and a hypopigmented patch. The bottom photograph (B3) shows the back of an FA patient demonstrating lumbar scoliosis. (c) Hands/forearms of FA children showing hypoplastic thumbs (C1), rudimentary ('dangling') thumbs (C2) and a radiograph (C3) showing rudimentary thumb (skeletal) development.

FA is associated with an increased risk of leukaemia and other malignancies. The leukaemias are usually of the acute myeloid type, particularly FAB types M4 and M5 (see Chapter 32). In some rare cases, leukaemia may be the initial event leading to the diagnosis of FA. The cumulative incidence of haematological malignancy by the age of 40 years is 33%. Recent studies suggest leukaemia development is frequently associated with chromosome 1q/MDM4 trisomy which leads to downregulation of p53 signalling. Besides haematological malignancies, there is a significant risk of hepatic tumours and squamous cell carcinoma of the vulva, oesophagus, head and neck. The cumulative incidence of solid tumours is calculated to be 28% by the age of 40 years. Malignancies occur mainly in patients with late-onset BMF and longer survival, with a median age of 13 years for leukaemia and 25 years for solid tumours. Analysis from the German FA registry largely concurs with these earlier observations. Furthermore, long-term follow-up in FA patients who have been treated by haemopoietic stem cell transplantation (HSCT) is showing a higher incidence of non-haematological malignancies in patients with FA than patients with other types of BMF who underwent HSCT.

Cell and molecular biology

Over the last four decades, many advances have been made in our understanding of the pathophysiology of FA. FA cells characteristically display a high frequency of spontaneous chromosomal breakage and hypersensitivity to DNA cross-linking agents such as diepoxybutane (DEB) and mitomycin C (MMC). This genomic instability (Figure 30.2) led to the development of a diagnostic test (i.e. increased chromosomal breakage in FA cells compared with normal controls after exposure to DEB/MMC) over four decades ago and this remains a useful FA screening test today. This 'FA cell phenotype' has also facilitated many advances in our understanding of FA, including elucidation of the complex genetics of this disease, with 22 subtypes/complementation groups currently characterised. The genes responsible for these subtypes are designated *FANCA*, *FANCB*, *FANCC*, *FANCD1*, *FANCD2*, *FANCE*, *FANCF*, *FANCG*, *FANCI*, *FANCJ*, *FANCL*, *FANCM, FANCN, FANCO*, *FANCP*, *FANCQ, FANCR, FANCS, FANCT, FANCU, FANCV* and *FANCW*. (Table 30.4).

Studies from several groups have demonstrated that the proteins encoded by the FA genes participate in a complicated network important in DNA repair. Eight of the FA proteins (FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL and FANCM) interact with each other and form the FA core complex (Figure 30.3). The FA core complex is required for the activation of the FANCI-FANCD2 protein complex to a monoubiquitinated form (FANCI-FANCD2-Ub). FANCI-FANCD2-Ub then interacts with DNA repair proteins (including BRCA2, BRCA1 and RAD51) leading to repair of the DNA damage. FA-D1 patients have biallelic variants in BRCA2. These observations have linked the FA proteins with BRCA1 and BRCA2 (FANCD1) in a DNA damage response pathway 'The FA/BRCA pathway'. The BRCA2 protein is important in the repair of DNA damage by homologous recombination. Cells lacking BRCA2 inaccurately repair damaged DNA and are hypersensitive to DNA cross-linking agents. It has been established that FANCJ is BRIP1 (partner of BRCA1), FANCN is PALB2 (partner of BRCA2), and that SLX4 is also an FA protein. These findings further strengthen the connection between FA and DNA repair; specifically, it appears that the FA pathway orchestrates incisions at sites of cross-linked DNA. Recent studies suggest the FA proteins may be important in counteracting aldehyde-induced genotoxicity in haemopoietic stem cells.

The FA–BRCA pathway is activated in response to DNA damage (e.g. replication fork arrest) and involves ATR (ataxia telangiectasia and RAD3-related protein) (Figure 30.3). The pathway is inactivated by the de-ubiquitinating enzyme USP1. ATR appears to directly regulate the FA pathway as it is required for the monoubiquitination of FANCD2 and FANCI. ATR is

FA subtypes (complementation groups) A, C and G account for the majority of FA patients. As can be noted from the table, many FA genes encode proteins that had previously been known by other names and have important roles in DNA repair.
* Biallelic variants in *FANCM*, *FANCO* and *FANCS* and heterozygous variants in *FANCR/RAD51* produce FA-like disease.

mutated in a subset of patients with Seckel syndrome, a disease exhibiting some clinical similarity to FA. ATR and ATM (ataxia telangiectasia mutated) are known to phosphorylate FANCD2 and FANCI. Interestingly, ATR-Seckel cells also exhibit defects in FANCD2 monoubiquitination. Furthermore, Nijmegen breakage syndrome (NBS) cells (mutated in *NBN*) show defects in FANCD2 monoubiquitination. This suggests that as well as clinical overlap between patients with FA, NBS and Seckel syndrome, there is also overlap in the biological defects observed in cells from these patients. This highlights the complexity of physical interactions between the different molecules involved in this matrix of pathways. Equally, it is clear that FA cells also display other abnormalities in addition to DNA repair (Figure 30.3). This includes hypersensitivity to oxygen, accelerated telomere shortening, abnormal cell cycle kinetics, upregulation of p53 and over-activation of the mitogen-activated protein kinase (MAPK) pathways leading to over-production of tumour necrosis factor (TNF)-α. These observations highlight the multiple biological functions of the FA proteins.

It is noteworthy that the phenotypes associated with biallelic *BRCA2* (FA-D1) and *PALB2* (FA-N) variants are markedly similar to each other, but different from the other FA genes. Specifically, FA-D1 and FA-N are associated with high risks of solid childhood malignancies (e.g. Wilm tumour and medulloblastoma), which are not usually seen in the other FA subtypes. Furthermore, heterozygous variants in *BRCA2* (FA-D1), *PALB2* (FA-N) and *BRIP1* (FA-J) confer an elevated risk of breast cancer yet this is not the case for the other FA genes. These differences highlight that the relationship between the FA proteins and their interactions with other molecules is complex at both the clinical and molecular level.

In vitro gene transfer studies have demonstrated that introduction of the appropriate wild-type FA gene into FA human lymphoid and haemopoietic cells markedly enhances their growth and normalises their response to MMC; in lymphoid lines, cell kinetics (G_2 phase) and chromosomal breakage are normalised. Thus, the transfer of the wild-type FA genes corrects the extreme sensitivity to DNA cross-linking agents, the hallmark of the FA cell phenotype. These studies provide the rationale for haemopoietic gene therapy (discussed below).

Murine models of FA have shown that haemopoietic progenitors are hypersensitive to TNF-α and interferon (IFN)-γ. This differential hypersensitivity to IFN-γ is thought to be mediated by *fas*-induced apoptosis and may

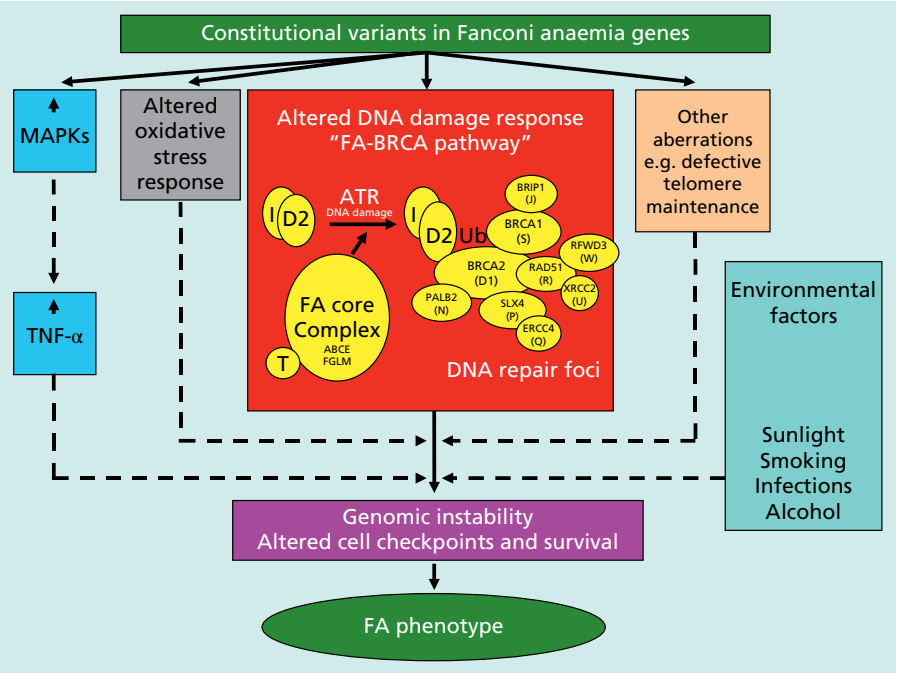

Figure 30.3 Schematic representation of the FA–BRCA pathway and related networks. The diagram shows that the constitutional variants in FA genes lead to aberration of the FA–BRCA pathway, abnormal handling of oxidative stress, aberrant activation of mitogen-activated protein kinases (MAPKs) and defective telomere maintenance, as well as other biological aberrations. The net impact of these is increased genomic instability and altered cell survival/checkpoints. The diagram also highlights the potential role of environmental factors such as smoking in adding to the effect of the constitutional FA gene variants. Within the FA–BRCA pathway, the proteins shown in yellow are those mutated in different FA patients. The FA core complex consists of eight FA-proteins (A, B, C, E, F, G, L and M), and this, together with ATR (ataxia telangiectasia and RAD3-related protein), is essential for activation (ubiquitination) of the I–D2 complex after DNA damage. Activated I–D2-Ub translocates to DNA repair foci where it associates with other DNA damage response proteins including BRCA2, RAD51 and SLX4 and participates in DNA repair. TNF, tumour necrosis factor; Ub, ubiquitination.

turn out to be an important mechanism in the development of progressive BMF in FA. It is noteworthy that patients with idiopathic AA usually have raised IFN-γ levels, thus providing a possible link in the pathophysiology of BMF in both idiopathic and FA-associated AA. The presence of short telomeres in cells from patients with both FA and idiopathic AA can also be expected to be important in the pathophysiology of BMF in both diseases. This feature is discussed further in relation to DC.

Treatment

The major cause of mortality in FA is the development of BMF. Anabolic steroids such as oxymetholone and danazol can produce useful trilineage haematological responses in 50–70% of patients but many will become refractory after a variable time. These can be associated with side-effects such as liver dysfunction; patients therefore need close monitoring. HSCT is the only curative treatment for BMF. From the *in vitro* and *in vivo* studies, it has become clear that cells from FA patients are hypersensitive to agents such as cyclophosphamide and irradiation compared with non-FA patients. Therefore, HSCT conditioning regimens have been modified by reducing the dose of cyclophosphamide and radiation. Initially, using low-dose cyclophosphamide (20 mg/kg) and 4.5–6 Gy of thoracoabdominal irradiation, the actuarial survival for patients transplanted using HLA-identical sibling donors was ~70% at 2 years. The results using unrelated donors were less good, with 2-year survival between 20 and 40%. Long-term follow-up of patients who have survived after HSCT shows a much higher incidence of malignancies (compared to idiopathic BMF), particularly of the head and neck, usually 8–10 years after the transplant. This partly relates to the inherent predisposition of FA patients to malignancy (which can perhaps now be explained given the link to defects in DNA repair) and partly to factors such as the use of radiotherapy in the conditioning. Transplant groups are therefore exploring low-dose cyclophosphamide (20–40 mg/kg) HSCT

protocols that avoid the use of radiotherapy. Results using fludarabine (120–150 mg/m^2) in association with low-dose cyclophosphamide are very encouraging for both sibling and unrelated HSCT. Longer follow-up is necessary to determine if such protocols will be associated with a lower risk of malignancy.

In addition to HSCT, alternative treatment strategies are being explored. The identification of the FA genes, combined with the *in vitro* gene transfer data, which show that FA haemopoietic stem cells rescued by gene therapy should have a selective growth advantage within the hypoplastic BM environment, has resulted in studies aimed at developing gene therapy for FA patients. Recently there has been some success in using this approach in FA-A patients.

The identification of FA *mosaic* patients strengthens the case for future trials of gene therapy. In such cases, the DEB/MMC test may be negative or only demonstrate chromosomal instability in a subgroup of cells. Somatic mosaicism is due to reversion of a pathogenic allele to 'wild' type in a single haemopoietic (somatic) cell. The mechanism of how this occurs can vary, but in each case, it generates one 'normal' FA allele and the resulting cell effectively becomes a 'heterozygous cell', which would be expected to have a growth/survival advantage in the background of FA cells. These mosaic patients can have an improvement in their haematological profile, suggesting that a single pluripotent stem cell may be sufficient to restore adequate haemopoiesis. FA patients with somatic mosaicism can thus be regarded as having undergone natural haemopoietic gene therapy.

Over the last 20 years, there has been significant progress in treating the BMF associated with FA. In future, the major challenge in Fanconi anaemia may relate to the treatment of the associated malignancies and the management of complications (e.g. pulmonary disease) in adulthood.

Dyskeratosis congenita

Clinical features

Classical DC is characterised by the mucocutaneous triad of abnormal skin pigmentation, nail dystrophy and mucosal leucoplakia (Figure 30.4). Since its first description by Jacobi in 1906 and Zinsser in 1910, a variety of non-cutaneous (dental, gastrointestinal, genitourinary, haematological, neurological, ophthalmic, pulmonary and skeletal) abnormalities have also been reported (Table 30.5). BMF is the principal cause of early mortality, with an additional predisposition to malignancy (haematological and non-haematological) and fatal pulmonary complications. X-linked recessive, AD and AR forms of the disease are recognised. DC is a very heterogeneous disorder, both clinically and genetically.

Clinical manifestations in DC often appear during childhood. The skin pigmentation and nail changes typically appear first, usually by the age of 10 years. BMF usually develops below the age of 20 years; 80–90% of patients will have developed BM abnormalities by the age of 30 years. In some cases, the BM abnormalities may appear before the mucocutaneous

Figure 30.4 Photographs of patients with DC showing abnormal skin pigmentation (a, b, c), nail dystrophy (d, e) and leucoplakia of the tongue (f).

Table 30.5 Somatic abnormalities in dyskeratosis congenita.

Abnormality	Percentage of patients
Abnormal skin pigmentation	89
Nail dystrophy	88

Osteoporosis/aseptic necrosis/scoliosis	5.1
Deafness	0.8

manifestations and the patients may be categorised as having 'idiopathic aplastic anaemia'. The main causes of death are BMF/immunodeficiency (~60–70%), pulmonary complications (~10–15%) and malignancy (~10%).

The minimal clinical criteria for diagnosis of DC includes the presence of at least two out of the four major features (abnormal skin pigmentation, nail dystrophy, leucoplakia and BMF) and two or more of the other somatic features known to occur in DC.

Cell biology and link to other diseases

Since 1998, 20 DC genes have been identified and these account for ~80% of DC (Table 30.6).

X-linked DC and the Hoyeraal-Hreidarsson (HH) syndrome

The gene (*DKC1*) responsible for X-linked DC was mapped to Xq28 in 1986 and identified through positional cloning in 1998. The *DKC1* gene is highly conserved and encodes the protein dyskerin. With the identification of variants in *DKC1* the first diagnostic tests became available. It also provided the first firm evidence that DC was not a homogeneous disorder and that other syndromes with overlapping presentation can share the same genetic mutations. The first such example was the HH syndrome, a severe multisystem disorder that is characterised by intrauterine growth restriction, microcephaly, cerebellar hypoplasia, AA and immunedeficiency. Due to the overlap in features it was suggested and subsequently proven that HH is a severe variant of DC due to the presence of *DKC1* variants in males with the classical presentation of HH. However, *DKC1* variants are not the only cause of HH; variants in other genes can also lead to a phenotype of HH (see below).

Autosomal dominant (AD)-DC and its link to telomeres and other diseases

AD-DC is heterogeneous; heterozygous variants in several genes (including *TERC*, *TERT* and *TINF2*) have been characterised. The identification of heterozygous variants in *TERC* (telomerase RNA component) in 2001 was a major advance in the DC field, as it provided a direct link between DC and telomerase. Telomerase is a ribonucleoprotein composed of two core components: a catalytic component that adds the repeats, telomerase reverse transcriptase (*TERT*) and *TERC*, which acts as the template. It functions as a specialised polymerase that adds the telomeric repeat (TTAGGG) to the end of the 3′ lagging strand of DNA after replication. Due to the semi-conservative nature of DNA replication, telomerase is essential to maintain telomere length in rapidly dividing cells, as found in the haemopoietic system. Without telomerase the telomeres shorten with each successive round of replication, when they reach a critical length, the cells enter senescence. Telomerase is mainly restricted to cells such as germ cells, stem cells and their immediate progeny, activated T cells and monocytes, but in cells where telomerase is not present telomere shortening is part of the normal process of cellular ageing.

In patients with AD-DC variants were identified in *TERC* initially and it was through the identification of variants within this molecule that led to significant expansion of the DC phenotype to include other haematological and non-haematological disorders. Firstly, heterozygous *TERC* variants were identified in patients with AA and soon after in patients with myelodysplastic syndrome (MDS).

The identification of constitutional variants in *DKC1* and *TERC* established the pathology of defective telomere maintenance (Figure 30.5) as being the principal underlying cause of DC; both dyskerin (encoded by *DKC1*) and *TERC* are now recognised to be core components of telomerase and patients with *DKC1* and *TERC* variants have very short telomeres compared to age-matched controls. This led to further study of the telomerase complex to determine the genetic basis of the remaining uncharacterised patients. The next gene to have variants identified was *TERT*, which encodes the enzymatic component of the telomerase complex. The clinical presentation in patients with *TERT* variants is highly variable, ranging from near DC phenotype to just AA. Heterozygous variants in *TERT* and *TERC* have

Table 30.6 Genetic subtypes of dyskeratosis congenita.

*Heterozygous variants in these genes have been associated with pulmonary disease in late adulthood. The majority of the DC genes encode products that have a principal role in telomere maintenance; however, this is not the case for USB1 and NPM1.

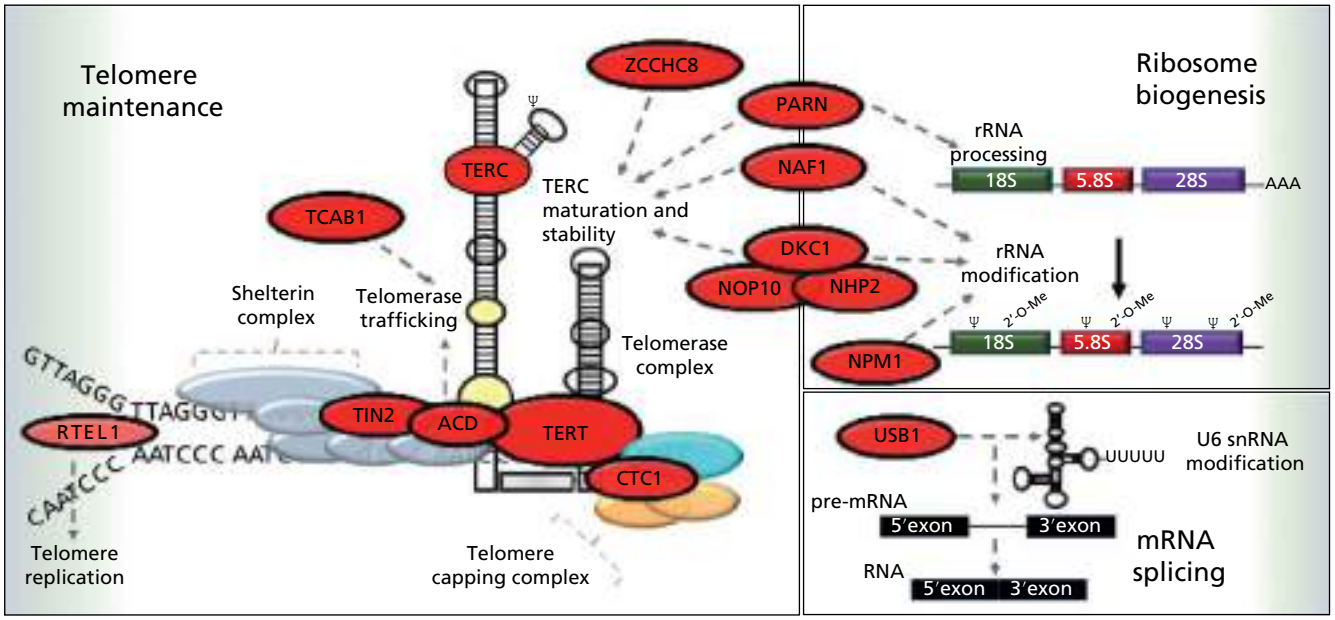

Figure 30.5 Functional overlap of DC genes involved in telomere maintenance and ribosome biogenesis. Proteins mutated in DC are indicated by red capsules and affect molecular functions such as telomere replication (RTEL1), telomere protection (TIN2, ACD) telomerase (TERC and TERT and DKC1), telomerase maturation and stability (ZCCHC8, NAF1, PARN, DKC1, NOP10 and NHP2). Pseudouridylation of TERC and ribosomal RNA (rRNA) is performed by DKC1. The deadenylation function of PARN also regulates the maturation and processing of both TERC and rRNA. Recently, variants in NPM1 that regulate 2′O methylation of rRNA have been reported in patients with DC. USB1 is an outlier, in that it is involved in the processing of the U6 spliceosomal RNA. Dashed arrows link the different proteins to the specific functions in which they are involved. Some of the DC disease genes (such as *DCLRE1B* and *TYMS::ENOSF1)* are not included in this Figure as they do not easily fit into the cartoon scheme.

also been identified in some patients with idiopathic pulmonary fibrosis, liver disease and leukaemia.

In 2008, variants in a component (TIN2) of the shelterin complex were identified in one subtype of AD-DC. The shelterin complex (comprised of six proteins) has at least three effects on telomeres. It determines the structure of the telomeric terminus, it has been implicated in the generation of t-loops and it controls the synthesis of telomeric DNA by telomerase. The composition and protein interaction of the components of shelterin complex appears to be highly ordered, with TIN2 playing a pivotal role. In a subset of patients with DC, HH, AA and Revesz syndrome, heterozygous TIN2 variants have been identified. This discovery extends the range of the DC spectrum of diseases even further. Revesz syndrome is characterised by bilateral exudative retinopathy, BMF, nail dystrophy, fine hair, cerebellar hypoplasia and growth restriction. Patients with TIN2 variants tend to have severe disease and this is associated with very short telomeres. Interestingly, nearly all the patients have *de novo* TIN2 variants, which give rise to a different mechanism causing the disease. In patients with heterozygous *TERC* and *TERT* variants, studies have shown that the phenomenon of genetic anticipation is frequently involved; a parent of an affected child has the same telomerase variant, but usually no overt signs of disease. However, in a child with the same heterozygous telomerase variant the disease manifests itself at a much younger age and is usually more severe.

In recent years heterozygous variants in other genes have been identified that are associated with AD DC or DC-like phenotypes. This includes heterozygous variants in *ACD*, *RTEL1*, *PARN, NAF1*, *ZCCHC8*, *NPM1, MDM4, POT1* and *RPA1*). All these patients usually have short telomeres except those with *NPM1* variants. It is also notable that there is considerable heterogeneity in the age of onset and the number of clinical features seen in the different genetic subtypes.

Autosomal recessive DC

Since 2007 progress has been made in the genetic basis of AR-DC. A large linkage study of 16 consanguineous families comprising 25 affected individuals did not identify a single common locus, suggesting there is genetic heterogeneity within AR-DC. Since this observation, variants in 11 genes have been identified as causing AR-DC. The first AR-DC gene to be identified was *NOP10*. The homozygous *NOP10* variant identified in a large family affected a highly conserved residue. As a result of this variant, all the affected individuals had reduced telomere length and reduced TERC levels. In a subset of AR-DC biallelic variants have been identified in *TERT*. These variants give very different profiles regarding telomerase activity and telomere length, with both being greatly reduced compared with heterozygous *TERT* variants. Biallelic variants in *NHP2* have been identified in a third subset of AR-DC patients. Again, telomere lengths and TERC levels are reduced in patients compared to normal controls. Both NOP10 and NHP2 are components of H/ACA ribonucleoprotein complex (H/ACA RNP). This complex is comprised of a RNA molecule and four proteins, dyskerin, GAR1 as well as NOP10 and NHP2. These four proteins are highly conserved and have been shown to be involved in ribosome biogenesis, pre mRNA splicing and telomere maintenance. Variants have been identified in all components of this H/ACA RNP complex in patients with DC except for GAR1.

In 2011, biallelic variants in *TCAB1* were identified in two patients with AR-DC. TCAB1 is a telomerase holoenzyme protein that facilitates trafficking of telomerase to Cajal bodies, the nuclear sites of nucleoprotein complex modification and assembly. Compound heterozygous variants in TCAB1 disrupt telomere localisation to Cajal bodies, resulting in misdirection of telomerase RNA to nucleoli. This in turn prevents telomerase from elongating telomeres, thereby resulting in short telomeres.

In another subgroup of AR-DC, biallelic variants have been found in *USB1*. It is noteworthy that variants in this gene have unified this subgroup of DC with patients classified as having poikiloderma with neutropenia and Rothmund–Thomson syndrome. This subgroup of AR-DC patients appear to have normal-length telomeres and therefore represents a biologically different subtype.

In 2012, biallelic variants in *CTC1*, encoding conserved telomere maintenance component 1, were identified in a rare subgroup of DC patients. As *CTC1* variants were initially identified in the pleotropic syndrome, Coats plus (characterised by retinopathy, intracranial calcifications and cysts, osteopenia and gastrointestinal abnormalities), this observation expands further the complexity of phenotypes associated with the 'telomeropathies'.

In 2013, biallelic variants in *RTEL1* (regulator of telomere length 1) were identified in some patients with severe DC (close to HH) and these patients have very short telomeres as well as qualitative defects in telomeres. RTEL1 is a helicase with an important role in homologous recombination and telomere maintenance (dismantles telomere t-loops during DNA replication).

More recently, biallelic variants in *PARN* (poly(A)-specific ribonuclease, 2015), *ACD* (adrenocortical dysplasia, 2018), *DCLRE1B* (DNA Cross-Link Repair 1B, 2022) and *TYMS-ENOSF1* (Thymidylate Synthetase and Enolase Superfamily Member 1, 2022) have been identified in patients with DC or DC-like phenotypes, further highlighting the genetic heterogeneity of AR-DC. These patients also have very short/abnormal telomeres.

Treatment

BMF is the main cause of mortality in DC. Use of the anabolic steroids (oxymetholone and danazol) can produce improvement in the haemopoietic function. Approximately two-thirds

of patients with DC will respond to oxymetholone; in some cases, the response can last several years and involve all lineages. Patients with DC can respond to a dose as low as 0.25 mg oxymetholone/kg/day and this can be increased, if necessary, to 2–5 mg/kg/day. It is important to monitor for side-effects (e.g. liver toxicity). It is possible to maintain reasonable blood counts by this approach in many patients. More recently danazol has become to be recognised as a very useful drug in DC patients and is now used as a first-line drug.

The only long-term cure for the haemopoietic abnormalities is allogeneic HSCT. There is significant mortality associated with BM transplants for DC patients than with other BMF syndromes. One of the main reasons for this is the high level of pulmonary/vascular complications that present in these patients, probably as a result of the underlying telomere defect. The conditioning regimen appears to have an impact on patient survival. The standard myeloablative conditioning regimes are associated with frequent and severe adverse effects, such as pulmonary complications and veno-occlusive disease. Recently, the adoption of non-myeloablative fludarabine-based protocols has allowed for successful engraftment in some patients with fewer complications and lower toxicity. The long-term survival, however, is unknown at present, but the initial response is encouraging as a more effective treatment for DC.

New agents (e.g. PAPD5 inhibitors) that can correct the telomere defect *in vitro* represent potentially new treatments for the future.

Shwachman–Diamond syndrome

Clinical features

Shwachman and Bodian and their colleagues first reported this disease independently in 1964. SDS is now recognised as a genetic disorder characterised by exocrine pancreatic insufficiency (100%), BMF (100%) and other somatic abnormalities (particularly involving the skeletal system). Signs of pancreatic insufficiency (malabsorption, failure to thrive) are apparent early in infancy (NB: pancreatic function can improve in a subset of SDS patients). Other somatic abnormalities include short stature (~70%), protuberant abdomen and an ichthyotic skin rash (~60%). Metaphyseal dysostosis is seen on radiographs in about 75% of patients. Other abnormalities include hepatomegaly, rib/thoracic cage abnormalities, hypertelorism, syndactyly, cleft palate, dental dysplasia, ptosis and skin pigmentation.

The spectrum of haematological abnormalities includes neutropenia (~60%), other cytopenias (~20% have pancytopenia), MDS and AML (~25%). The age at which leukaemia develops varies widely, from 1 to 43 years. AML is the commonest category and there is an unexplained preponderance of cases of leukaemia in males.

Exocrine pancreatic insufficiency and haematological abnormalities are also seen in Pearson syndrome (PS), and this is, therefore, an important differential diagnosis. In PS, the anaemia is usually more prominent than neutropenia and the marrow usually shows ringed sideroblasts along with vacuolation of myeloid and erythroid precursors. In addition, acidosis, abnormalities of liver function and mitochondrial DNA rearrangements are seen in PS. PS has a worse prognosis than SDS, with many patients dying before the age of 5 years from liver or BMF. Other differential diagnoses to be excluded are cartilage hair syndrome and cystic fibrosis.

Cell and molecular biology

The SDS gene (*SBDS*) on 7q11.21 was identified in 2003. The majority (>90%) of SDS patients have biallelic variants in this gene (Table 30.7). Data from yeast and human studies suggest that the SBDS protein has an important role in the maturation of the 60S ribosomal subunit (Figure 30.6). These observations suggest that SDS is principally a disorder of ribosome biogenesis. Recently, it has been observed that biallelic variants in *EFL1* and *DNAJC21,* and heterozygous variants in *SRP54* can produce SDS-like disease. Like *SBDS*, *EFL1* and *DNAJC21* also have a role in ribosome biogenesis.

Treatment

The malabsorption in SDS responds to treatment with oral pancreatic enzymes. For those with neutropenia, G-CSF may produce an improvement in the neutrophil count. Some patients

Table 30.7 Genetic subtypes of Shwachman–Diamond syndrome.

SDS subtype	Approximate percentage of patients	Chromosome location	Protein product	Exons
Classical Autosomal recessive	>90	7q11.21	SBDS	5
SDS-like Autosomal recessive	<2	5p13.2	DNAJC21	14
	<2	15q25.2	EFL1	22
Autosomal dominant	<2	14q13.2	SRP54	17

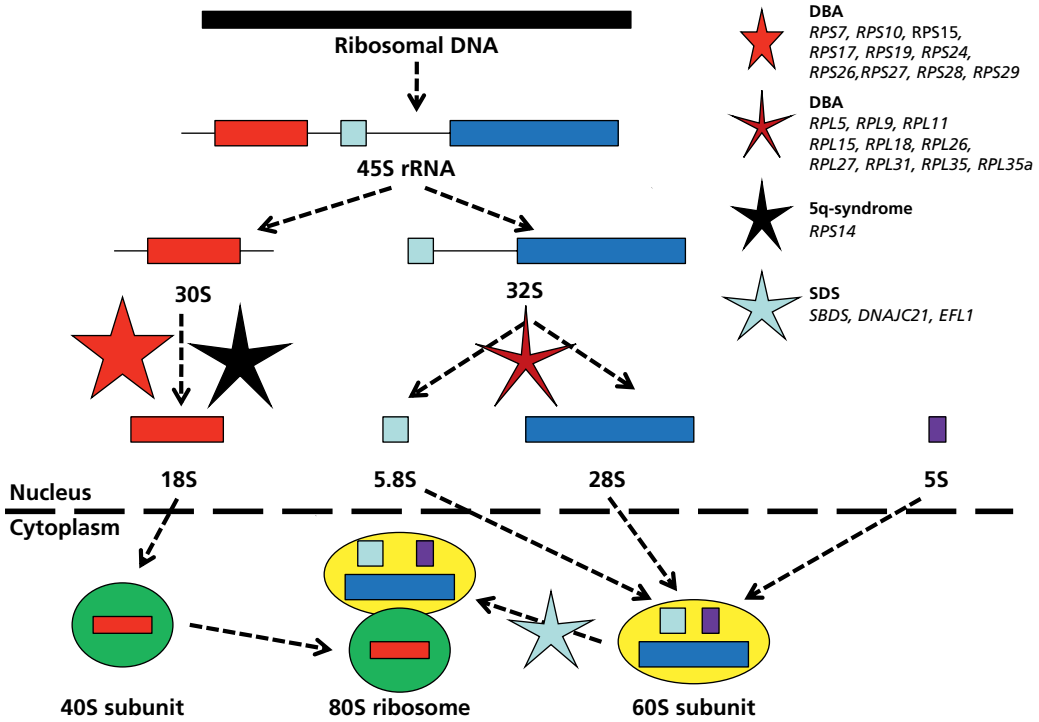

Figure 30.6 Schematic diagram showing scheme of ribosomal (r) RNA processing in human cells and the points at which this is possibly disrupted in the different BMF syndromes. The rRNAs are transcribed by RNA polymerase I as a single precursor transcript (45S rRNA). The 45S rRNA is then processed to 18S, 5.8S and 28S rRNAs. The 18S is a component of the 40S ribosomal subunit. The 5.8S and 28S together with 5S (synthesised independently) are components of the 60S ribosomal subunit. The 40S and 60S subunits are assembled to form the 80S ribosome. The processing steps affected in DBA (heterozygous variants in *RPS7*, *RPS10*, *RPS17*, *RPS19*, *RPS24*, *RPS26*, *RPS27*, *RPS28*, *RPS29*, *RPL5*, *RPL9*, *RPL11, RPL15, RPL18, RPL26, RPL27, RPL31, RPL35* and *RPL35a*), 5q– syndrome (haploinsufficiency of *RPS14*) and SDS (biallelic variants in *SBDS, DNAJC21* and *EFL1*) are indicated by the different coloured stars.

with anaemia and/or thrombocytopenia may achieve haematological responses with oxymetholone treatment. As in other types of BMF, supportive treatment with blood products and antibiotics is very important.

The development of leukaemia, often with features of myelodysplasia and *TP53* mutations, usually has a poor prognosis. SDS patients with leukaemia treated with conventional courses of chemotherapy usually fail to regenerate normal haemopoiesis. As this is a constitutional disorder, all somatic cells, including haemopoietic stem cells, are abnormal. In addition, the haemopoietic stem cells may have accumulated secondary abnormalities, as suggested by complex karyotypes (especially involving chromosome 7) often observed in the BM from these patients. Therefore, for those who develop leukaemia, the only approach likely to be successful is allogeneic HSCT, using conditioning regimens that include fludarabine. It is noteworthy that non-haematological malignancies have not been observed in SDS patients.

Diamond–Blackfan anaemia (DBA)

Clinical features

Red cell aplasia was first reported in 1936 by Josephs. In 1938, Diamond reported on four children with hypoplastic anaemia and this has now come to be recognised as DBA or congenital pure red cell aplasia. DBA usually presents in early infancy, with features of anaemia such as pallor or failure to thrive. The hallmark of classical DBA is a selective decrease in erythroid precursors and normochromic macrocytic anaemia associated with a variable number of somatic abnormalities such as craniofacial, thumb, cardiac and urogenital malformations. Hitherto the diagnostic criteria for DBA have comprised: (i) normochromic, usually macrocytic, but occasionally normocytic anaemia developing in early childhood; (ii) reticulocytopenia; (iii) normocellular BM with selective deficiency of erythroid precursors (erythroblasts <5%); (iv) normal or slightly decreased leucocyte

counts and (v) normal or often increased platelet counts. More recently, elevated erythrocyte deaminase activity, macrocytosis and elevated fetal haemoglobin levels have been added to the list of supportive features of DBA. It has also been recognised that in a subset of cases, the presentation may be in adulthood.

There is considerable heterogeneity in the associated somatic abnormalities and response to therapy. Analysis of cases recruited to the DBA Registry of North America (DBAR) has shown that the annual incidence of DBA is about 5 per million live births. The median age at presentation was 8 weeks and 93% of patients presented in the first year of life. In total, 79% were initially responsive to steroids, 17% were non-responsive and 4% were never treated with steroids; 31% of patients were receiving transfusions at analysis. The actuarial survival rates older than 40 years were 100% for those in sustained remission, 87% for steroid-maintained patients and 57% for transfusion-dependent patients. Of the 36 deaths reported, 25 were treatment-related: 5 from infections, 5 from complications of iron overload, 1 related to vascular access and 14 from transplant-related complications.

In the DBAR, 8.8% of families had more than one affected individual. Most of the familial cases displayed AD inheritance. Somatic anomalies, excluding short stature, were found in 47% of patients. Of these, 50% were craniofacial (high-arched palate, cleft lip, hypertelorism and flat nasal bridge), 38% were upper limb and hand (flat thenar eminence, triphalangeal thumb), 39% genitourinary and 30% cardiac. Height was below the third centile for age in about 30%.

MDS and AML have been reported in a few patients with DBA. There are also cases that have evolved into AA; neutropenia and thrombocytopenia are relatively common after the first decade. Giri and colleagues reported on moderate to severe BM hypocellularity in 21 of 28 (75%) patients with steroid-refractory DBA; marrow hypoplasia correlated with the development of neutropenia (9/21, 43%) and/or thrombocytopenia (6/21, 29%). Furthermore, using *in vitro* long-term culture-initiating cell assay, they provided evidence for a trilineage haemopoietic defect in patients with refractory DBA. Thus, although DBA has been regarded classically as a pure red cell aplasia, a more global haemopoietic defect is likely to be present, and this may be seen more frequently in the future as patients survive longer due to improved medical care.

Cell and molecular biology

A number of different defects of *in vitro* erythroid progenitor proliferation, differentiation and cytokine responsiveness have been reported. The establishment of DBA registries and advances in genetics have led to genetic categorisation of many DBA cases. The first gene to be identified was *RPS19* (1999). Subsequently, heterozygous variants in other genes encoding proteins of the small (RPS7, RPS10, RPS15, RPS17, RPS24, RPS26, RPS27, RPS28 and RPS29) and large (RPL5, RPL9, RPL11, RPL15, RPL18, RPL26, RPL27, RPL31 and RPL35A) ribosomal subunits have also been reported (Table 30.8); collectively the genetic basis of approximately 75% of DBA patients can now be substantiated at the genetic level. These findings suggest that the primary defect in DBA is defective ribosome biogenesis, which then leads to other biological defects, including increased apoptosis and upregulation of p53. It will now be important to establish how precisely variants in these ribosomal protein genes lead to altered cell growth (and anaemia), developmental anomalies and increased susceptibility to cancer. A subgroup of patients with DBA/DBA-like disease have been found to be associated with variants in *GATA1*, *CECR1*, *TSR2* and *EPO*.

Review of clinical and genetic data has shown that patients with *RPL5* variants tend to have multiple physical abnormalities, including craniofacial, thumb and heart anomalies, whereas isolated thumb malformations are predominantly seen in patients with heterozygous *RPL11* variants. Some genotype–phenotype correlations are therefore beginning to emerge.

It is noteworthy that recent advances have provided a very interesting connection between DBA, SDS, MDS and defective ribosome biogenesis (see Figure 30.6). Specifically: (i) DBA (as highlighted here) is caused by variants in genes important in the biogenesis of the small and large ribosomal units; (ii) the SDS genes (see above) are required for the maturation of the large ribosomal unit; and (iii) the 5q – syndrome (a recognised subtype of acquired myelodysplasia) is associated with haploinsufficiency of the gene encoding the ribosomal protein RPS14. These advances highlight the importance of studies on rare syndromes, as often they can provide significant insights into the pathology of more common diseases.

Treatment

The first line of treatment for DBA remains corticosteroids. Once a maximal haemoglobin response has been achieved, the dose of prednisolone should be tapered slowly until the patient is on the lowest dose possible on an alternate-day regimen. For those patients who fail to respond or become refractory to steroids, blood transfusion is the mainstay of treatment. The major complication from transfusions is iron overload, and chelation of iron (avoiding deferiprone) should therefore be commenced as soon as patients have increased iron stores (Chapter 12). Splenectomy may be indicated in the event of an increased transfusion requirement secondary to hypersplenism. For patients who are transfusion-dependent and who have a HLA-compatible donor, HSCT may be appropriate.

Congenital dyserythropoietic anaemia

CDA comprises a heterogeneous group of disorders of erythropoiesis characterised by anaemia, ineffective erythropoiesis and frequently morphological evidence of dyserythropoiesis.

Table 30.8 Genetic subtypes of Diamond–Blackfan anaemia.

DBA subtype	Approximate percentage of patients	Chromosome location	Protein product	Exons
Autosomal dominant	25	19q13.2	RPS19	6
	10–20	Various*		
	7	1p22.1	RPL5	8
	7	12q13.2	RPS26	4

	<1	Xp11.22	TSR2	5
Uncharacterised	~25	?	?	?

* This refers to large deletions in different DBA genes. Variants in *EPO* and *CECR1/DADA2* can also produce DBA-like disease.

The first description of these disorders was in 1966 by Crookston and colleagues. In 1968 Wendt and Heimpel classified CDA into three types (I, II and III) (Table 30.9). Over the years many additional subtypes (IV, V, VI and VII) have been added to the list, often based on case reports.

CDA type I

The majority of patients present with splenomegaly and mild to moderate anaemia (~66–116 g/L); approximately 70% have macrocytosis. In some cases, non-haematological features (e.g. skeletal abnormalities and abnormal skin pigmentation) have been observed. Ineffective erythropoiesis is evidenced by morphological abnormalities in the peripheral blood (anisocytosis) and in the marrow (megaloblastic erythroid precursors, internuclear chromatin bridging, binuclearity affecting 3–7% of erythroblasts; Figure 30.7a), as well as by increased markers of haemolysis (elevated lactate dehydrogenase and bilirubin). The defining ultrastructural feature is a spongy ('Swiss cheese') appearance of the heterochromatin in the majority of erythroblasts on electron microscopy (Figure 30.7b).

Recognised to be AR, the first gene responsible for CDA type I (*CDAN1,* encoding codanin) was identified in 2002. Recently a second gene, *CDIN1*, was found to be responsible for some cases of CDA type I.

CDA type II

This is the most common subtype of CDA and was initially described as hereditary erythroblastic multinuclearity with a positive acidified serum lysis test (HEMPAS) in 1969. It is inherited as an AR trait. The anaemia is variable (Hb 80–110 g/L). Approximately 10% of cases require regular transfusions and some cases present with anaemia at birth. The clinical presentations include a variable degree of jaundice, hepatomegaly, splenomegaly and cirrhosis. Mental restriction has been reported in some cases.

Peripheral blood morphology shows moderate to marked red cell anisocytosis. BM features include normoblastic erythroid hyperplasia with usually more than 10% binucleate erythroblasts (Figure 30.8a). At the electron microscope level, the erythroid cells have a characteristic peripheral arrangement of the endoplasmic reticulum giving the appearance of a 'double membrane'

Table 30.9 Characteristics of common subtypes of congenital dyserythropoietic anaemia.

Feature	Type I	Type II	Type III
Inheritance	AR	AR	AD
Erythrocytes	Macrocytic	Normocytic	Macrocytic
Erythroblasts			
Light microscopy	Megaloblastic, internuclear chromatin bridges	Normoblastic, binuclearity	Megaloblastic, up to 12 nuclei/cell
Electron microscopy	'Swiss-cheese' appearance	Peripheral double membranes	Non-specific
Serology			
Ham test	Negative	Usually positive	Negative
Anti-i-agglutinabiliy	Normal/strong	Strong	Normal/strong
SDS-PAGE	Normal	Band 3 thinner and migrates faster than normal	Band 3 migrates faster than normal
Genes identified	*CDAN1* (15q15.2), *CDIN1* (15q14)	*SEC23B* (20p11.23)	*KIF23* (15q23)

(a) (b)

Figure 30.8 (a) CDA type II (HEMPAS). BM aspirate showing typical multinuclearity. (b) CDA type II. Electron micrographs of erythroblast showing peripheral arrangement of endoplasmic reticulum with 'double membrane' appearance.

(Figure 30.8b). Red cells from patients with CDA type II are haemolysed by some acidified sera, but not by the patient's own serum. In 2009 the gene encoding the secretory COPII component SEC23B was shown to be responsible for CDAII.

CDA type III

This subtype is rare. In one of the largest (Swedish) families investigated, the disease was characterised by giant multinucleated erythroblasts in the marrow (Figure 30.9). There appears to be an increased prevalence of lymphoproliferative disorders in CDA type III. CDA III exhibits AD transmission and is caused by variants in *KIF23*. *KIF23* encodes mitotic kinesin-like protein 1, which plays a critical role in cytokinesis during cell division.

Treatment

Those with mild anaemia require no major intervention. Folate supplementation should be given to prevent folate deficiency.

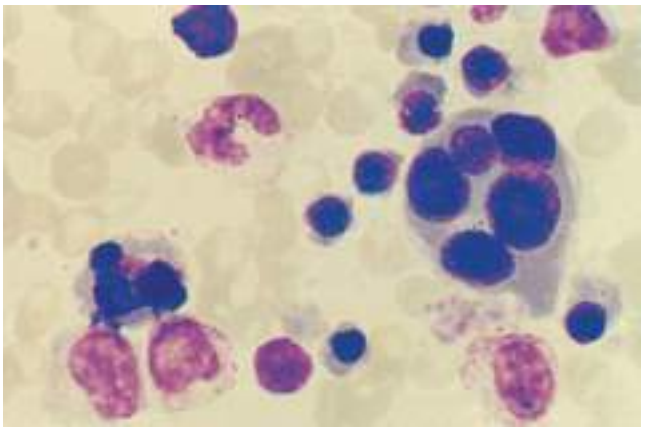

Figure 30.9 CDA type III. Giant multinucleated erythroblast from the marrow.

If regular transfusions are necessary, early attention to iron chelation is essential. Splenectomy may be of benefit in some patients (CDA type II) and there are rare case reports of successful HSCT. In CDA type I there are also case reports of improvement in the haemoglobin after treatment with interferon-α. The mechanism of this therapeutic benefit remains unclear.

Congenital and cyclical neutropenias

Congenital neutropenia is a heterogeneous disorder (Table 30.10). It includes Kostmann syndrome, which was first described in 1954. Although the original description by Kostmann was of an AR disorder, other congenital neutropenia subtypes (both sporadic and AD) have subsequently been included in this category. The neutropenia is usually recognised at birth and the neutrophil count is often below 0.2×10^9/L. The haemoglobin and platelet count are usually normal and the BM shows maturation arrest of myelopoiesis at the level of the promyelocyte/myelocyte (with abundant promyelocytes, but with selective reduction in myelocytes, metamyelocytes and neutrophils).

The neutropenias are associated with severe infections and early death. No patient has developed AA, but myeloid leukaemias (~25% by 25 years) can occur. The availability of G-CSF has revolutionised the outcome for these children. These patients can progress to MDS and leukaemia, usually with acquisition of secondary mutations including in the G-CSF receptor. The precise contribution of G-CSF therapy to the development of G-CSF receptor mutations remains unclear. For patients who become refractory to G-CSF or who develop leukaemia, HSCT may be appropriate and curative.

Cyclical neutropenia is characterised by a neutrophil count that usually reaches a nadir with a 21-day periodicity. Around the nadir, patients may develop fever and mouth ulcers. Cyclical neutropenia is usually AD. Linkage analysis in affected families resulted in the localisation of the disease gene to

Table 30.10 Genetic subtypes of neutropenia.

Subtype	Approximate percentage of patients	Chromosome location	Gene/protein product	Exons
Autosomal dominant	50–60	19p13.3	*ELANE*	6
	<2	1p22.1	*GFI1*	9
Autosomal recessive	10–15	1q21.3	*HAX1*	7
	~5	17q21.31	*G6PC3*	8
	Rare	1q21.2	*VPS45*	18
	Rare	1p34.3	*CSF3R*	19
	Rare	3p25.3	*JAG1*	2

NB: Some patients initially presenting as isolated neutropenia may turn out to be cryptic presentations of other syndromes, such as Wiskott–Aldrich syndrome.

19p13.3. Subsequent studies identified variants in the gene (*ELANE*) encoding neutrophil elastase. An extraordinary twist to the story was the identification of *ELANE* variants in many patients with congenital neutropenia as well. In cyclical neutropenia, the variants are usually clustered around the active site of the molecule, whereas the opposite face of the molecule tends to be mutated in congenital neutropenia. Neutrophil elastase is a serine protease that is synthesised predominantly at the promyelocytic stage and can be expected to be important in neutrophil development. Recent studies suggest that *ELANE* variants lead to accumulation of the non-functional protein, which in turn triggers an unfolded protein response leading to maturational arrest. The precise mechanism leading to maturation arrest of promyelocytes remains unclear. The original family described by Kostmann had AR severe congenital neutropenia and has been shown to be associated with biallelic variants in *HAX1*, predicted to lead to defects in cell death. Biallelic variants in *HAX1* account for approximately 10% of congenital neutropenia. The HAX1 protein is a critical regulator of the mitochondrial membrane potential and cellular viability. While there are data that suggest that HAX1 is important in controlling apoptosis, it is unclear why premature death of neutrophils is consistently associated with HAX1 deficiency. Variants in other genes (*GFI1, G6PC3* and *VPS45*) are also associated with SCN.

Thrombocytopenia with absent radii (TAR)

TAR is an AR disorder characterised by hypomegakaryocytic thrombocytopenia and bilateral radial aplasia. Babies with TAR often have haemorrhagic manifestations at birth, when the diagnosis is usually made because of the characteristic physical appearance combined with thrombocytopenia. Additional skeletal abnormalities (absent ulnae, absent humeri and clinodactyly) and other somatic abnormalities (microcephaly, hypertelorism, strabismus and heart defects) may be seen in some patients.

The platelet count is usually below 50×10^9/L. The leucocyte count can be normal or raised, sometimes up to 100×10^9/L ('leukaemoid reaction'). BM cellularity is normal and myeloid and erythroid lineages are normal or increased. Megakaryocytes are absent or decreased. Most patients bleed in infancy and then improve after the first year. The mainstay of management is prophylactic and therapeutic use of platelet transfusions. Patients with TAR have a very good prognosis after infancy. There have been no reports of AA or leukaemia.

In TAR patients, thrombopoietin levels are usually elevated and thrombopoietin receptor expression on the surface of TAR platelets is normal. Therefore, defective megakaryocytopoiesis/thrombocytopoiesis does not appear to be caused by a defect in thrombopoietin production. Recently it has been determined that compound inheritance of low-frequency regulatory SNP and a rare null variant in *RBM8A* (which encodes a subunit of the exon-junction complex) causes TAR.

Congenital amegakaryocytic thrombocytopenia (CAMT)

CAMT is a rare disorder that usually presents in infancy and is characterised by isolated thrombocytopenia and reduction/absence of megakaryocytes in the BM, usually with no somatic abnormalities. It is genetically heterogeneous with AR and X-linked subtypes. Approximately 50% of patients will develop AA, usually by the age of 5 years. For patients with severe thrombocytopenia or AA, the treatment of choice is HSCT, if a compatible donor is available.

In a subgroup of patients with CAMT, biallelic variants in the gene encoding the thrombopoietin receptor (*MPL*) have been identified (Table 30.11). As patients with *MPL* variants can also have abnormalities in the leucocyte count and haemoglobin

Table 30.11 Genetic subtypes of syndromic thrombocytopenias.

Subtype	Approximate percentage of patients	Chromosome location	Gene/locus	Exons
CAMT Autosomal recessive	Majority	1p34	*MPL*	11
TAR Autosomal recessive	Majority	1q21.1	*RBM8A*	6
Radio-ulnar synostosis Autosomal dominant	Major subset	7p15.2	*HOXA11*	2
	Major subset	3q26.2	*MECOM**	23

TAR = thrombocytopenia with absent radii.
* *MECOM* (MDS1 and EVI1 complex locus) variants can be associated with variable haematological features ranging from isolated thrombocytopenia to global BM failure, MDS and leukaemia.

level and central nervous system (CNS) abnormalities (e.g. cerebral and cerebellar hypoplasia), this highlights the important role of the thrombopoietin receptor in haemopoiesis in general and in CNS development. It also substantiates the genetic heterogeneity of CAMT.

New subtypes of inherited BM failure and overlapping syndromes

There are cases of BM failure where they are familial and/or have one or more extra-haemopoietic/somatic abnormality but which do not fit into the entities listed above. The availability of next-generation sequencing has made it possible to elucidate the genetic basis of some of these. Examples of these new entities include those associated with germline variants (Table 30.12) in *TPO*, *ERCC6L2*, *MYSM1*, *DUT*, *EXOC3L2, TP53* and *SP1*. The number of cases reported in each subtype is variable.

It is also notable that there are entities that were initially characterised in patients with myelodysplasia/leukaemia or other syndromic diseases but which can also present with peripheral cytopenias. This includes GATA2 deficiency and SAMD9/SAMD9L-related disease. In addition to MDS and leukaemia, these patients can have a variable number of extra-haemopoietic abnormalities. Germline variants in these genes are particularly prevalent in paediatric patients with MDS associated with monosomy 7. *GATA2* and *SAMD9/SAMD9L* are also included in the category of familial MDS/AML genes. Other genes in this familial MDS/AML category include: *RUNX1*, *CEBPA*, *TERC*, *TERT*, *SRP72, AKNRD26, ETV6*, *DDX41*, *RTEL1*, *PAX5*, *TP53*, *ACD*, *MECOM*, *HLTF*, *XPC and DHX34* (Table 30.12). This highlights the overlapping nature of the haematological (BMF, MDS and AML) and extra-haematological phenotypes produced by germline variants in these genes. It is likely that additional new entities of familial BM failure/MDS will be characterised in the future.

Table 30.12 New BMF and overlapping syndromes.

Subtype	Chromosome location	Gene product	Exons
Recently recognised BMF subtypes

* Variants in these genes can produce very diverse haematological features including AA, MDS and leukaemia. They can also produce a variable range of extra-haematopoietic abnormalities. For example: GATA2 deficiency can be associated with pulmonary alveolar proteinosis and primary lymphedema; SAMD9 disease with adrenal insufficiency, intrauterine growth restriction and genital abnormalities; SAMD9L disease with neurologic/cerebellar, ophthalmic abnormalities.

Conclusion

Since the identification of the first FA gene (*FANCC*) in 1992, there have been significant advances in our understanding of FA, DC and other BMF syndromes. This has facilitated diagnosis, as highlighted in Table 30.13. It can be anticipated that further studies of the pathophysiology of these disorders are likely to lead to a better understanding of normal haemopoiesis and how this becomes defective in many patients presenting with the more common forms of AA and MDS. Indeed, studies have already established a link between DC and AA and, in turn, to defective telomere maintenance. Equally, a link between DBA, SDS and MDS and, in turn, defective ribosome biogenesis has been recognised. These advances also suggest that new treatment strategies, based on targeting the primary defect in each syndrome, are likely to emerge in the future.

Table 30.13 Laboratory tests useful in the investigation of patients with BMF.

Test	Diagnostic value
Peripheral blood	
Fetal haemoglobin	High level suggestive of generalised BMF
DEB/MMC-induced chromosomal breakage	Increased in FA
Genetic analysis using next-generation sequencing	
FANCA–FANCW	Mutated in FA
DKC1, TERC, TERT, NOP10, NHP2, TINF2, TCAB1 USB1, CTC1, RTEL1, ACD, PARN, NAF1, ZCCHC8, NPM1, MDM4 POT1, RPA1, DCLRE1B and TYMS-ENOSF1	Mutated in DC and related disorders
SBDS, DNAJC21, EFL1, SRP54	Mutated in SDS and SDS-like disease
RPS19, RPS7, RPS10, RPS15, RPS17, RPS24, RPS26, RPS27, RPS28, RPS29, RPL5, RPL9, RPL11, RPL15, RPL18, RPL26, RPL27, RPL31, RPL35A, GATA1, TSR2, EPO	Mutated in DBA and DBA-like disease
CDAN1, CDIN1, SEC23B, KIF23, KLF1	Mutated in CDA and CDA-like disease
ELANE, HAX1, GFI1, G6PC3, VPS45, JAG1	Mutated in congenital and cyclic neutropenia
MPL, RBM8A, HOXA11 and MECOM	Mutated in CAMT and other syndromic thrombocytopenias
TPO, ERCC6L2, MYSM1, DUT, EXOC3L2, TP53 and SP1	Mutated in newly recognised BMF syndromes
RUNX1, CEBPA, GATA2, SAMD9, SAMD9L, TERC, TERT, SRP72, AKNRD26, ETV6, DDX41, RTEL1, PAX5, TP53, ACD, MECOM, HLTF, XPC and DHX34	Mutated in overlapping BMF/MDS/leukaemia syndromes
Mitochondrial DNA analysis	Deletions seen in PS
X-chromosome inactivation patterns	Skewed in carriers of X-linked DC
Ham test (CD59 analysis)	Abnormal in paroxysmal nocturnal haemoglobinuria
Telomere length	Short in AA, very short in DC
Constitutional karyotype	Abnormality suggestive of constitutional AA
Other investigations	
To identify somatic abnormalities	Presence of somatic/extra-haematopoietic abnormalities in association with AA is suggestive of constitutional/inherited AA
Skeletal survey	
Ultrasound of abdomen	
Pulmonary function tests	
Echocardiogram	
Exocrine pancreatic function	Abnormal in SDS and PS
Neutrophil chemotaxis	Abnormal in SDS
Fibroblast cultures	Abnormalities seen in DC

AA, aplastic anaemia; CAMT, congenital amegakaryocytic thrombocytopenia; CDA, congenital dyserythropoietic anaemia; DBA, Diamond–Blackfan anaemia; DC, dyskeratosis congenita; DEB/MMC, diepoxybutane/mitomycin-C; FA, Fanconi anaemia; PS, Pearson syndrome; SDS, Shwachman–Diamond syndrome.

Acknowledgements

I would like to thank my research colleagues past (Richard Beswick, Shirleny Cardosa, Laura Collopy, Michael Kirwan, Stuart Knight, Anna Marrone, Jasmin Sidhu, David Stevens and Philip Mason) and present (Jenna Alnajar, Jude Fitzgibbon, Upal Hossain, Hemanth Tummala, Amanda Walne and Tom Vulliamy) and all the patients and clinicians on whom research in our laboratory depends. The research has been supported by significant funding from the Wellcome Trust, Blood Cancer UK and the Medical Research Council UK.

Acquired aplastic anaemia

Characterisation and definition

Aplastic anaemia (AA), a rare bone marrow failure syndrome (BMFS), is defined by pancytopenia with a hypocellular bone marrow in the absence of an abnormal infiltrate and with no increase in reticulin. The term 'aplastic anaemia' encompasses different entities, but here we discuss acquired AA, most often idiopathic, though sometimes a drug or chemical or a virus infection is implicated. 'Inevitable' AA/myelosuppression occurs after treatment with cytotoxic drugs or radiation; it is dose-dependent and recovery is usually predictable and is discussed no further here.

AA is a bone marrow failure disorder and shows considerable overlap with clonal disorders of bone marrow failure, including myelodysplastic syndrome (MDS), acute myeloid leukaemia (AML), paroxysmal nocturnal haemoglobinuria (PNH) and T-large granular lymphocyte leukaemia/lymphoproliferative disorder (T-LGL), and a tendency itself to later evolve to MDS/AML (Figure 31.1). The inherited forms of AA, such as Fanconi anaemia (FA), dyskeratosis congenita (DC) and Shwachmann–Diamond syndrome (SDS), are rarer than acquired AA and are discussed in detail in Chapter 30. However, the importance of excluding an inherited form of AA and the increasing proportion of adults with apparent acquired AA with related inherited genetic lesions is highlighted in this chapter. In AA, there must be at least two of the following: (i) haemoglobin below 100 g/L, (ii) platelet count below 50×10^9/L and (iii) neutrophil count below 1.5×10^9/L. Patients with bilineage or trilineage cytopenias that are less severe than this are not classified as AA. However, they should have their blood counts monitored to determine whether they will develop AA later. The severity of the disease is graded into very severe, severe and nonsevere (or moderate) AA, according to the blood count parameters and bone marrow findings, as summarised in Table 31.1. The assessment of disease severity is important in treatment decisions, prediction of response to immunosuppressive therapy (IST) and is also of prognostic significance.

Epidemiology

Aetiology and incidence

Studies indicate an incidence of AA in the West of 2 per million per year. There is a twofold to threefold higher incidence rate in Asia. In a large prospective study from Thailand, an incidence of 3.9 per million was reported from the metropolitan area of Bangkok compared with 5 per million in the northeast region of Khonkaen. An incidence of 7.4 per million was reported from a prospective study from China, although this may represent an overestimate, as a bone marrow trephine was not required for the diagnosis of AA. The reasons for the differences in incidence are not known but may include environmental and genetic factors.

There is a biphasic age distribution, with peaks at 10–25 years and over 60 years; it is possible that some cases diagnosed in

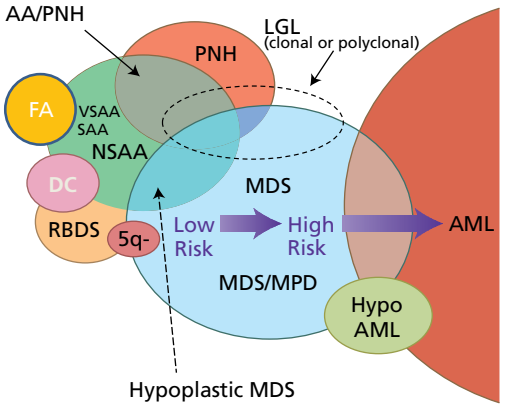

Figure 31.1 Overlapping bone marrow failure disorders. AA, aplastic anaemia; AML, acute myeloid leukaemia; DC, dyskeratosis congenita; FA, Fanconi anaemia; LGL, large granular lymphocytosis; NSAA, non-severe AA; PNH, paroxysmal nocturnal haemoglobinuria; RBDS, ribosomal dysgenesis syndromes; SAA, severe AA; VSAA, very severe AA.

older patients represent hypocellular MDS rather than AA. There is no significant difference in incidence between males and females.

Posthepatitic AA accounts for around 5–10% of cases; invariably such cases are negative for the known hepatitic viruses. Patients, typically young males, present with jaundice and hepatitis symptoms, then, on average 6 weeks later, develop pancytopenia when the liver function has usually improved or normalised. Posthepatitic AA is usually severe, but responds well to IST, and similar oligoclonal expansion of activated cytotoxic T cells is observed as in idiopathic AA, suggesting a common pathogenesis for the hepatitis and bone marrow failure. Rarely, AA may follow EBV-related infectious mononucleosis.

AA occurs in association with other systemic autoimmune disorders, especially eosinophilic fasciitis, but also systemic lupus erythematosus (SLE), Sjögren syndrome and coeliac disease. SLE can also produce pancytopenia with a cellular bone marrow or it may occasionally be associated with marrow fibrosis. Thymoma may be associated with AA, although typically related to pure red cell aplasia (PRCA). Fatal AA is almost invariably the outcome of transfusion-associated graft-versus-host disease (GVHD); it is well-documented clinically and can be reproduced *in vivo* in a mouse model.

The association between AA, other autoimmune disorders and TLGL, clonal proliferation of cytotoxic ($CD8^+$) T cells, has been known for decades and conceptualises the theory of immune-mediated marrow suppression by a dominant T cell clone. Somatic *STAT3* mutations in autoimmune T cells in a proportion (7%) of AA possibly induces a persistently dysregulated autoimmunity, which is amenable to immunosuppression, akin to LGL leukaemia.

AA can rarely occur in pregnancy, although this may be due to chance and other possible causes should always be sought. A retrospective review from Leiden over a 24-year period found a similar frequency of AA in pregnancy compared to that in the general population. However, due to the rarity of AA, this may not exclude a possible association in a larger number of patients. The disease may remit spontaneously after termination, whether spontaneous or therapeutic, and after delivery, but not in all cases. There is a risk of relapse in pregnancy in patients who have previously responded to IST. In contrast, after successful allogeneic haemopoietic stem cell transplantation (HSCT), pregnancy does not trigger relapse.

Pathogenesis and its clinical relevance

The haemopoietic defect in AA

AA is characterised by both quantitative and qualitative defects in the haemopoietic stem and progenitor cell (HSPC) compartment. The primitive long-term culture-initiating cells and more mature haemopoietic progenitors in the bone marrow (colony-forming cells) of all cell lineages are reduced or absent. In addition to the reduced numbers and impaired repopulating ability of bone marrow $CD34^+$ cells, these cells are more apoptotic than normal $CD34^+$ cells, as evidenced by transcriptome analysis. About 10–15% of patients with AA have shortened telomeres, as measured in blood leucocytes (see later).

The bone marrow stromal cell microenvironment functions normally in most patients as assessed by an *in vitro* system, although this does not examine individual cellular components of the stroma and thus defects in particular cells cannot be excluded. The frequencies of fibroblast colonies (CFU-F) are normal in AA, and mesenchymal stem cells showed normal phenotype as defined by $CD34^-$ $CD45^-$ $CD44^+$ $CD29^+$ $CD90^+$ $CD105^+$ $CD106^+$. The differentiation capacity of AA mesenchymal stem cells has not yet been formally evaluated. Cultured AA mesenchymal stem cells support *in vitro* haemopoiesis after addition of normal bone marrow mononuclear cells.

AA is not due to a deficiency of any known haemopoietic growth factor (HGF). Long-term marrow culture studies have shown normal mRNA expression and/or secretion of granulocyte/macrophage colony-stimulating factor, granulocyte colony-stimulating factor (G-CSF), interferon-gamma (IFN-γ), interleukin (IL)-6, stem cell factor and thrombopoietin (TPO) from stromal cells. Serum levels of most HGFs, including the above and erythropoietin, are markedly elevated. These observations explain the lack of striking effects of HGFs in most AA patients, although recent data suggest a role for synthetic TPO-mimetic eltrombopag in AA, possibly circumventing the inhibitory effect of IFN-gamma by binding to an alternate site on TPO receptor and enhancing HSPC function.

Table 31.1 Laboratory assessment of a newly presenting patient.

1. *Laboratory tests to confirm diagnosis*	
Full blood count	Pancytopenia with reticulocytopenia. Single cytopenia especially thrombocytopenia may precede pancytopenia. Raised MCV common.
Blood film examination	Toxic granulation of neutrophils, anisopoikilocytosis, macrocytosis. Exclude blasts, dysplastic neutrophils and hairy cells.
Liver function tests, vitamin B12 and folate	To detect preceding hepatitis; exclude and correct coexisting vitamin B12 or folate deficiency.
Virology	Post-hepatitic AA occurs in 5–10% cases, serology usually negative for known hepatitis viruses; HIV and parvovirus are very rare causes of AA; check CMV exposure for potential BMT candidates.
Antinuclear antibody and dsDNA	SLE is very rare cause of AA, and other autoimmune syndromes associated with pancytopenia.
Radiology	Chest X-ray to exclude infection; HRCT scan of chest to exclude pulmonary fibrosis if DC or familial BMF suspected. Abdominal ultrasound or CT scan: hepatic fibrosis in DC; splenomegaly or lymphadenothy indicate alternative diagnosis; abnormal or misplaced kidneys may occur in Fanconi anaemia.
BM examination	*Aspirate* fragments easily obtained, hypocellular fragments and trails. Reduced/absence of haemopoietic lineages. Dyserythropiesis common. Absence of dysplasia in granulocytic and megakaryocytic lineages. Lymphocytes, plasma cells, macrophages and mast cells often prominent. Iron stain to exclude ringed sideroblasts. CD34+ immunostain negative. *Trephine*: Good length (at least 1–2 cm) essential. Hypocellular (Figure 31.3). May be patchy cellularity. Absence of blasts. Lymphoid aggregates (reactive) are common. Reticulin stain negative. CD34 immunocytochemistry negative. CD61 useful to exclude dysplastic megakaryocytes.
2. *Tests to detect an associated abnormal clone*	
PNH clone	Screen for glycosyl phosphatidyl inositol (GPI)-anchored proteins on red cells, granulocytes (and monocytes) using six-colour flow cytometry, including fluorescent aerolysin (FLAER). Size of PNH clone will help distinguish haemolytic PNH from AA/PNH and sub-clinical PNH. PNH clone detected in up to 40% of AA patients.
Cytogenetic clone using metaphase cytogenetics (MC) and cytoFISH or Single Nucleotide Polymoprhism-Array Karyotyping (SNP-A)	Detected in up to 12% of AA patients in the absence of dysplastic changes. Monosomy 7 is typical of MDS and AA which has evolved to MDS. MC may fail due to hypocellular BM and small number of metaphases. Other cytogenetic abnormalities (del13q, del20q, +8) can be seen in morphologically typical AA. SNP-A can detect copy neutral loss of hetrozygosity (CN-LOH), especially in 6p (HLA locus) and is also helpful in cases of failed MC
T-large granular lymphocyte (T-LGL) clone	If blood/BM T-lymphocytosis, perform *TCR* gene rearrangement to detect clonal T-LGL; in this situation, exclude *STAT3* mutation.
3. *Tests to exclude an inherited bone marrow failure syndrome*	
DEB test	PB chromosomal breakage (spontaneous and DEB/MMC-induced) increased in Fanconi anaemia. Screen patients up to 60 years old (FA has rarely been diagnosed in 5th decade) and all BMT candidates.
PB telomere length	Flow FISH or multiplex qPCR analysis. Very short telomeres (<1st percentile for age) are indicative of DC. Telomere gene mutation analysis then indicated (including *TERC*, *TERT*, *TIN2*, *DKC1*).
Other IBMFS	Specific gene mutation analysis when suspected, e.g. *SBDS* for Schwachmann–Diamond anaemia, *GATA2* for Emberger's syndrome. See point number 6 for emerging technologies to detect other IBMFS.
4. *Emerging diagnostic tests*	
Somatic gene mutation panel	Next-generation sequencing technology to detect somatic mutations which may help distinguish AA from hypocellular MDS/AML at diagnosis and during the disease course

(*Continued*)

Table 31.1 (*Continued*)

IBMFS custom array mutation analysis using exome/whole genome sequencing or targeted cytopenia panel (National Genomic Test Directory, R91 cytopenia panel)	To detect known (exome sequencing/targeted sequencing) or unknown (whole genome sequencing) IBMFS. See Chapter 8.
5. *How severe is the aplastic anaemia?*	
Severe AA (Camitta *et al*., 1976)	BM cellularity <25%, or 25–50% with <30% residual haemopoietic cells and 2 out of 3 of the following: *6. neutrophils* $<0.5\times10^9$*/L* *7. platelets* $<20\times10^9$*/L* *8. absolute reticulocyte count* $<60\times10^9$*/L*
Very severe AA (Bacigalupo *et al*. 1988)	As for severe AA but neutrophils $<0.2\times10^9$/L.
Non-severe (moderate) AA	Patients not fulfilling the criteria for severe or very severe aplastic anaemia.
6. *Is there an alternative diagnosis?*	
In the presence of pancytopenia and a hypocellular BM, exclude other possible causes:	
Hypocellular MDS/AML, and hypoALL in children	These features occur in hypoMDS/AML but not in AA: dysplastic neutrophils, dysgranulopoiesis and dysmegakayopoiesis, blasts in PB or BM, ring sideroblasts, increased BM reticulin and ALIP.
Hodgkin or Non-Hodgkin lymphoma	Examine trephine carefully for foci of lymphoma and perform immunophenotyping and gene rearrangement analyses.
Myelofibrosis	Presence of splenomegaly, tear-drop poikilocytes and leucoerythroblastic changes on blood film, and increased BM reticulin and/or collagen are all features of myelofibrosis.
Mycobacterial infection, especially atypical forms	Other BM features of mycobacterial infection are granulomas, necrosis and increased reticulin.
Anorexia nervosa, starvation	Often presents with neutropenia before pancytopenia. BM features include stromal oedema and serous degeneration.
Thrombocytopenic disorders, e.g. ITP, amegakaryocytic thrombocytopenia (AMT)	Sometimes AA can present with isolated thrombocytopenia. BM in ITP usually shows normal or increased megakaryocytes, but occasionally reduced megakaryocytes. AMT can later progress to AA or MDS. Congenital AMT is due to *c-MPL* mutation.

The immune-mediated nature of acquired AA

In acquired AA, it is proposed that an initiating event, such as a virus or drug, provokes an aberrant immune response, triggering oligoclonal expansion of cytotoxic T cells that destroy HSPCs (Figure 31.2). HSCT or IST leads to complete or partial response by eradicating or suppressing pathogenic T cell clones. Relapse occurs with recurrence of the immune response, and the immunologically stressed and depleted stem-cell compartment also allows selection of abnormal haemopoietic clones that manifest as MDS and occasionally AML.

Strong evidence that AA has an autoimmune nature is based on the following observations:

1 Haematological recovery after IST with antithymocyte globulin (ATG) and ciclosporin (CSA) occurs in the majority of patients.

2 There are activated autoreactive oligoclonal $CD8^+$ T cells present in blood and bone marrow that release IFN-γ, tumour necrosis factor (TNF)-α and other cytokines that inhibit haemopoiesis.

3 Intracellular IFN-γ levels in T cells correlate with response to IST.

4 Increased Fas expression on bone marrow $CD34^+$ cells indicates increased apoptosis.

5 T cell repertoire analysis shows oligoclonal expansion of $CD8^+$ T cells in AA, MDS and PNH.

6 Transcription factor T-bet is upregulated and binds to the IFN-γ promoter, resulting in increased expression of IFN-γ.

7 $CD4^+$ $CD25^+$ $FOXP3^+$ regulatory T cells are impaired and clonally restricted Th1 are expanded inducing an inflammatory microenvironment.

Gene expression profiling in AA $CD34^+$ cells has shown that more than half the upregulated genes are related to the immune response, including genes for cytokines and cytokine receptors and signal transduction genes, as well as other immune response genes. Many apoptosis and cell death genes are upregulated and some antiapoptotic genes downregulated.

It is unclear why T cells are activated in AA. HLA-DR2 and its split HLA-DR15 and DRB1*1501 and 1502 alleles are

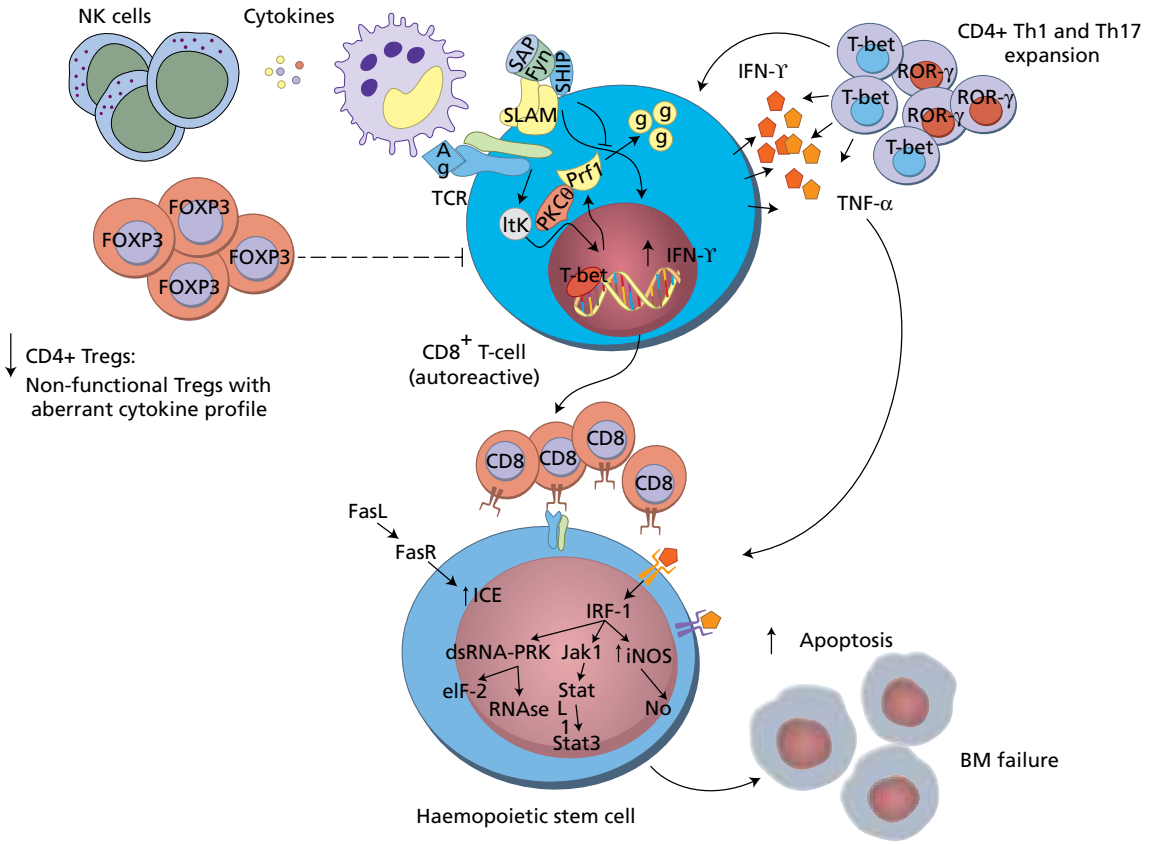

Figure 31.2 Immune-mediated aplastic anaemia. Following an insult, most likely viral, there is immune-mediated damage to stem cells, resulting in a pro-inflammatory response. The most important component comprises the $CD4^+$ T-cells, with expansion of Th1 (clonal) and Th17 cells, and reduced and dysfunctional regulatory T-cells (Tregs). This leads to oligoclonal expansion of cytotoxic $CD8^+$ T-cells, resulting in apoptotic death of stem cells (Source: Kordasti *et al.* 2012 [*Blood* **119**(9): 2033–43]. Reproduced with permission of American Society of Haematology.)

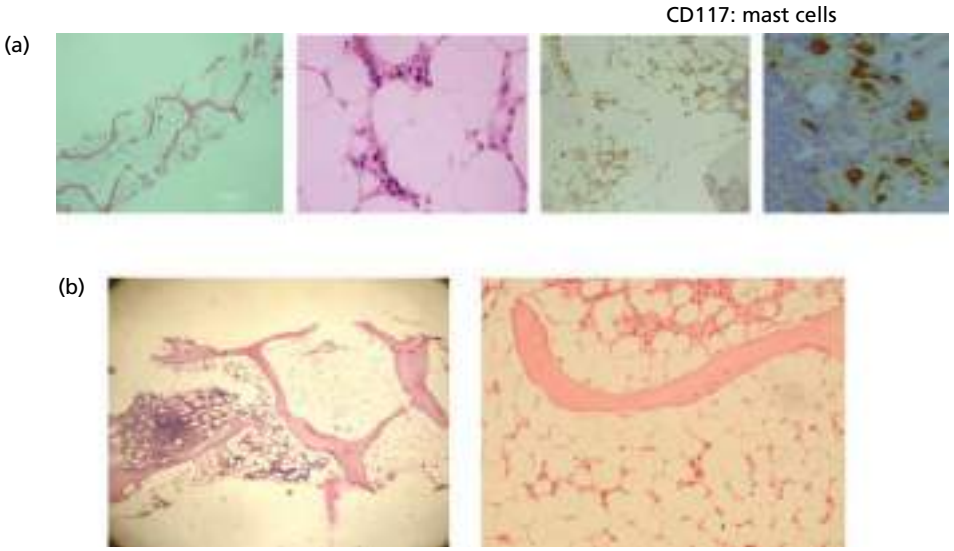

Figure 31.3 (a) BM trephine – severe AA; (b) Non-severe AA.

overrepresented in AA, as are class I HLA-B*4002 and HLA-A*0206, indicating a possible role for antigen recognition. There is correlation between ATG response and DRB1*1501, but most of these HLA data come from studies of Japanese patients. Loss of HLA expression, either by acquired copy neutral loss of heterozygosity (CN-LOH) on 6p or mutations on HLA loci, leads to escape of HSCs from activated cytotoxic T cells. Studies of cytokine gene polymorphisms that may reflect a heightened immune response in AA are limited; polymorphisms in the TNF-α promoter, IL-6 and IFN-γ genes have been reported, but a systematic assessment of all potentially relevant cytokine genes has not been reported.

The specific cytotoxic T-cell targets on HSPC in AA have not been identified. Potential candidates, identified by screening antibodies in patients' serum against a peptide library using leukaemia cell lines, include kinectin, DRS-1 (diazepam-binding inhibitor-related protein-1), PMS1 (post-meiotic segregation increased 1), moesin and hnRNPK (heterogeneous nuclear ribonucleoprotein K). However, the relevance of these findings is unclear, and they may represent epiphenomena rather than primary targets of cytotoxic T-cell attack.

Alternatively, a defect in the glycosylphosphatidylinositol (GPI) anchor may be the trigger for the immune response against normal progenitor cells through aberrant expression of intracellular GPI protein(s) while at the same time providing a protective mechanism for GPI-defective cells.

Detection of somatic mutations in AA

Using next-generation sequencing, two large studies have reported similar incidences (20–25%) of somatic (acquired) mutations in AA in genes associated with myeloid malignancies (e.g. *ASXL1, RUNX1* and *DNMT3A*). These mutations are predictive for later evolution to MDS/AML, especially in patients with long history of AA and also for worse survival following immunosuppressive therapy; in contrast, other mutations confer good prognosis (*BCOR, BCORL1* and *PIG-A*). Their further significance in AA is discussed later, but clonal haematopoiesis in AA seems ubiquitous and is present in a vast majority either as *PIG-A* mutations, cytogenetic abnormalities, loss of heterozygosisity of 6p locus or *HLA* mutations and somatic alterations of genes like *BCOR/BCORL1, DNMT3A* and *ASXL1* (see 'Suggested further reading').

Genetic predisposition to AA and short telomeres

Inherited forms of AA have long been regarded as very rare causes of acquired AA, including FA, DC and SDS (see Chapter 30 for detailed discussion). More recent awareness of these syndromes, with characterisation of the genetic mutations in these and other BMFS and the finding of very short telomeres in some patients with AA, indicate a more common occurrence than previously realised, and recognition that such cases may present later in adulthood.

The DC genes are involved in telomere maintenance, and all DC patients invariably have very short telomeres. About 10% of patients with apparent acquired AA have inherited mutations in *TERC*, *TERT*, with none or very mild mucocutaneous abnormalities. Families may have individuals with pulmonary fibrosis and hepatic cirrhosis, with or without cytopenia(s). SDS usually occurs in childhood with neutropenia but can present in adult life.

In addition to mutations in the DC genes, other factors such as 'stressed' haemopoiesis as a result of reduced stem cell numbers in AA, and environmental factors such as smoking, contribute to the shortened telomeres. Telomeres are assumed to be short in all organs, but they are only measured in blood leucocytes (the tissue for which there are sufficient age-matched controls). The consequences of telomere shortening include genomic instability, resulting in increased risk of malignant transformation (MDS, AML), bone marrow failure and defects in repair and regeneration (pulmonary fibrosis, cirrhosis). The clinical consequences of missing late-onset inherited forms of AA, as they often lack somatic anomalies, include likely mortality after allogeneic HSCT using standard conditioning regimens in FA due to the defect in DNA repair, and in DC due to the higher risk of liver and/or respiratory failure, and failure to screen potential family bone marrow donors for inherited bone marrow failure.

That not all patients with acquired AA respond to IST could be explained in pathogenetic terms by: (i) complete stem cell depletion due to a severe autoimmune attack, (ii) insufficient degree of IST and persistence of cytotoxic T cells or (iii) a non-immune basis for the bone marrow failure, of which one mechanism may be a genetic predisposition resulting in genomic instability. The presence of shortened telomeres in idiopathic AA does not preclude initial response to IST but predicts relapse after ATG and also late clonal disorders. There are insufficient data in patients with *TERC* or *TERT* mutations on response to IST (see also section 'Predictors of response to ATG').

Clinical features

Patients with AA most commonly present with symptoms of anaemia and skin or mucosal haemorrhage (ecchymoses or petechiae), including buccal haemorrhages, or visual disturbance due to retinal haemorrhage. Infection may be a presenting feature but is less common. There is no lymphadenopathy or hepatosplenomegaly in the absence of infection. An important careful history and clinical examination help to exclude an inherited form of AA, especially in children and young adults. This also applies to older patients as it has more recently been

realised that typical features of inherited BMFS may be absent and/or other features may be present in older patients. The findings of short stature, abnormal thumbs and forearms, café-au-lait spots and skeletal anomalies would raise the possibility of an inherited form of AA, specifically FA, although FA can present in adults without physical anomalies. Patients with FA most commonly present between the ages of 3 and 14 years, but can occasionally present later in their thirties or forties and very rarely early fifties. The findings of leucoplakia, nail dystrophy and pigmentation of the skin are characteristic of DC, with a median age at presentation of 7 years (range 6 months to 26 years). Some affected patients may have none of these clinical features and the diagnosis is made later after failure to respond to IST. For patients with AA and an inherited *TERC*/*TERT* mutation, the family history is very important as the pedigree may reveal pulmonary fibrosis, cirrhosis, osteoporosis, avascular necrosis of bone, low blood counts or cancer. A previous history of malabsorption or neutropenia may underlie a diagnosis of SDS in children or young adults, especially as the malabsorption often resolves in later life. A preceding history of jaundice, usually 2–3 months, strongly suggests sero-negative, posthepatitic AA.

Diagnostic investigations and differential diagnosis

To diagnose AA with certainty, it is important to consider other possible causes of pancytopenia with a hypocellular bone marrow and to exclude an inherited form of AA, as this will have important implications for treatment options, the choice of conditioning regimen and donor for HSCT, genetic screening and counselling of family members (Table 31.1). All patients should be screened by cytogenetics and for a PNH clone. See Table 31.1 and Figure 31.3 for summary of laboratory assessment of a newly presenting patient.

Management

General comments relating to the management of AA

Because AA is a rare disease, the haematologist responsible for the patient should contact a centre/specialist with expertise in AA soon after presentation to discuss a management plan for the patient. Patients should be offered the opportunity to be reviewed in a specialist centre. Whenever possible, patients should be enrolled into prospective national or international trials.

Prior to administration of specific treatment for the disease, the patient should be stabilised clinically in terms of controlling bleeding and treating infection. The presence of infection is an adverse factor for outcome after HSCT, although it may sometimes be necessary to proceed with HSCT in the presence of active infection, particularly fungal infection. In this setting, transplantation may offer the best chance of early neutrophil recovery, and delaying the transplant may risk progression of the fungal infection.

Supportive care

Transfusions

Support with red cell and platelet transfusions is essential for patients with AA to maintain a safe blood count. Current practice is to give prophylactic platelets when the platelet count is below 10×10^9/L (or higher in the presence of fever, sepsis or bleeding). Fatal haemorrhage, usually cerebral, is more common in patients who have less than 10×10^9/L platelets, extensive retinal haemorrhages, buccal haemorrhages or rapidly spreading purpura. Other important practical measures to help prevent bleeding include good dental hygiene, use of antifibrinolytics (e.g. tranexamic acid) and control of menorrhagia with appropriate hormone therapy.

A common problem in multitransfused AA patients is alloimmunisation to leucocytes present in red cell and platelet transfusions by generating HLA or non-HLA (minor histocompatibility) antibodies. Universal leucodepletion has probably reduced, but not eliminated the incidence of alloimmunisation; the incidence in AA was around 30–50% in the preleucodepletion era. Alloimmunisation can result in platelet refractoriness, as well as an increased risk of graft rejection after allogeneic BMT. Patients who become refractory to platelet transfusions should be screened for HLA antibodies, once other non-immune causes have been excluded, and if present HLA-matched platelets should be used. Novel approaches, including the use of HLA epitopematched platelets, are currently being evaluated in clinical trials in view of the shrinking HLA-typed donor pool.

Platelet transfusions should be given to maintain a safe platelet count and blood transfusions to allow normal daily activities. Transfusions should not be withheld for fear of sensitising the patient. Directed blood and platelet donations from family members should be avoided, as the recipient may become sensitised to minor histocompatibility antigens from the potential bone marrow donor, increasing the risk of graft rejection.

Even though there is no evidence base, the British Committee for Standards in Haematology now recommends empirically the use of irradiated blood components for all AA patients receiving ATG. The rationale for this is twofold. Firstly, animal data demonstrate that irradiation of all red cell and platelet transfusions before HSCT in addition to leucodepletion, further reduces the risk of sensitisation to minor histocompatibility antigens (and hence reduced risk of graft rejection after allogeneic HSCT). Secondly, irradiated blood products would abolish the potential risk of transfusion-associated GVHD associated with ATG therapy. Transfusion-associated GVHD has very rarely been reported after ATG.

Irradiated granulocyte transfusions are used to support patients with life-threatening neutropenia, especially with active fungal/mould disease or bacterial sepsis and not adequately responding to maximal antimicrobials. Adverse events, such as febrile reactions, HLA alloimmunisation and transfusion-related acute lung injury, are well-recognised complications following granulocyte transfusions.

Iron chelation therapy

Many AA patients require multiple red cell transfusions leading to transfusion haemosiderosis. Iron overload impacts adversely on outcome after allogeneic BMT. Iron chelation therapy should commence when the serum ferritin is above 1000 µg/L, although the evidence base for this is lacking. It may be difficult to deliver subcutaneous desferrioxamine to AA patients on account of local haemorrhage and infection from subcutaneous injections. Alternative oral agents include deferiprone and deferasirox (Exjade). Because of a high incidence of agranulocytosis with deferiprone, it is not used routinely in patients with AA. Results of a recent prospective study of deferasirox in 166 iron-overloaded AA patients showed the safety and also the ability to reduce ferritin (median fall in serum ferritin of 946 µg/L), although in view of renal toxicity of the drug, extra vigilance should be used in those on CSA.

Infections

Patients with AA are at risk of bacterial and fungal infections, depending in part on the degree of neutropenia. Very severe neutropenia (neutrophils $<0.2 \times 10^9$/L) carries a high risk. If there is severe neutropenia, either prophylactic non-absorbable antibiotics or oral quinolone are administered to reduce the potential pathogenic load from the gastrointestinal tract, although neither is standard practice in the USA. Oral hygiene is important. Entry sites for venous access are potential sources of systemic infection. Patients with AA are at high risk of fungal infection, including *Aspergillus*. Fluconazole provides no protection against *Aspergillus* species, for which the drugs of choice are itraconazole, which has clinically significant, but manageable or avoidable interactions with other drugs, and posaconazole, which has not yet been shown to be superior in efficacy to itraconazole in this setting.

Fever should be treated with broad-spectrum antibiotics without waiting for laboratory isolation of organisms, and with early introduction of systemic antifungal therapy if fever fails to respond to antibiotics. Chest radiography and CT scan of chest and sinuses should be part of the investigation of new or persistent fever. G-CSF is usually ineffective in severe AA due to a marked reduction or absence of myeloid progenitor cells, although it is reasonable to consider giving a short course in life-threatening infections.

Indications for treatment of AA

The two main treatment options for AA are allogeneic HSCT or IST with ATG and CSA, based on disease severity, age of the patient, availability of a matched sibling donor, patient comorbidities and patient choice (Figure 31.4). For patients with severe AA who are under 50 years of age, the first-line treatment is matched sibling donor HSCT. EBMT data show similar outcomes for patients aged 40–50 to those aged 30–40 years. However, comorbidities should be carefully assessed to determine fitness for up-front transplant instead of immunosuppressive therapy for patients, especially those aged 40–50 years. For all other patients who require treatment, namely those lacking HLA compatible sibling donor, non-severe AA or those older than >50 years, IST is the first option. Unrelated donor HSCT is indicated for adults after failure to respond to one course of IST, for those patients who lack a matched sibling donor. Upfront MUD HSCT may be considered in children who lack a MSD if a suitable donor is readily available.

The standard regimen for IST comprises the combination of horse ATG and CSA, although addition of Eltrombopag to IST for first-line treatment of SAA is becoming standard practice. This was initially based on single-arm study demonstrating better outcome and with more robust and early haematological response, included high complete response. This data was confirmed in a large prospective randomised controlled study comparing standard IST (horse ATG and CSA) with eltrombopag added to standard IST. The triple drug combination improved the rate, rapidity and strength of haematological response, without additional toxicities.

Corticosteroids should not be given to treat AA, except to prevent and treat serum sickness, as they are ineffective and encourage fungal and bacterial infections.

Immunosuppressive therapy

Antithymocyte globulin: properties, mechanism of action and administration

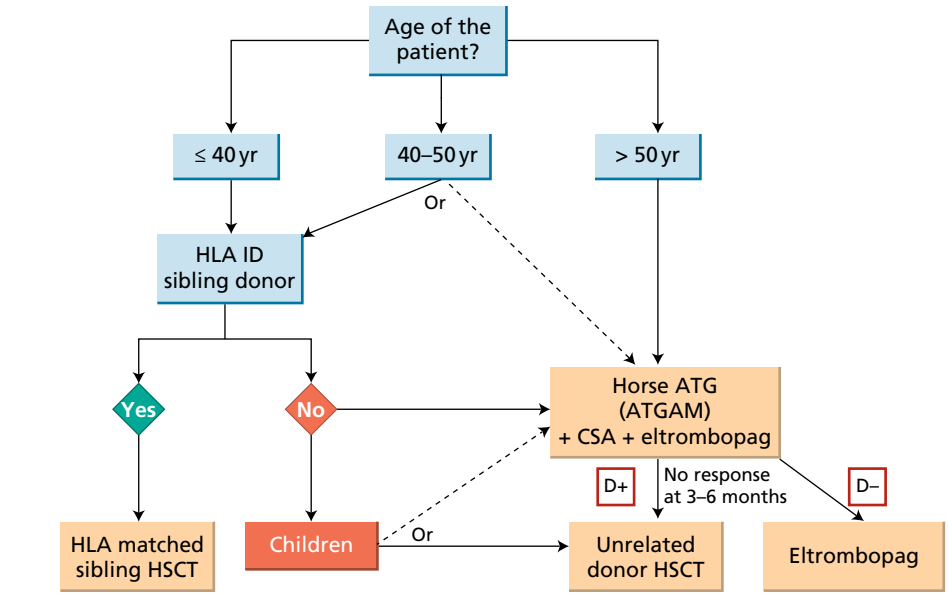
ATG is a polyclonal IgG antibody preparation produced by immunising horses or rabbits with human thymocytes. Its mechanism of action in AA is not entirely clear. Possible mechanisms include the following:

1 T cell depletion by complement-mediated lysis;

2 destruction of activated cytotoxic T lymphocytes by Fas-mediated apoptosis and antibody-dependent cellular cytotoxicity;

3 reduced apoptosis and Fas expression on AA $CD34^+$ bone marrow cells;

4 direct stimulation of normal and AA $CD34^+$ bone marrow cells and a mitogenic effect in the absence of complement resulting in release of HGFs;



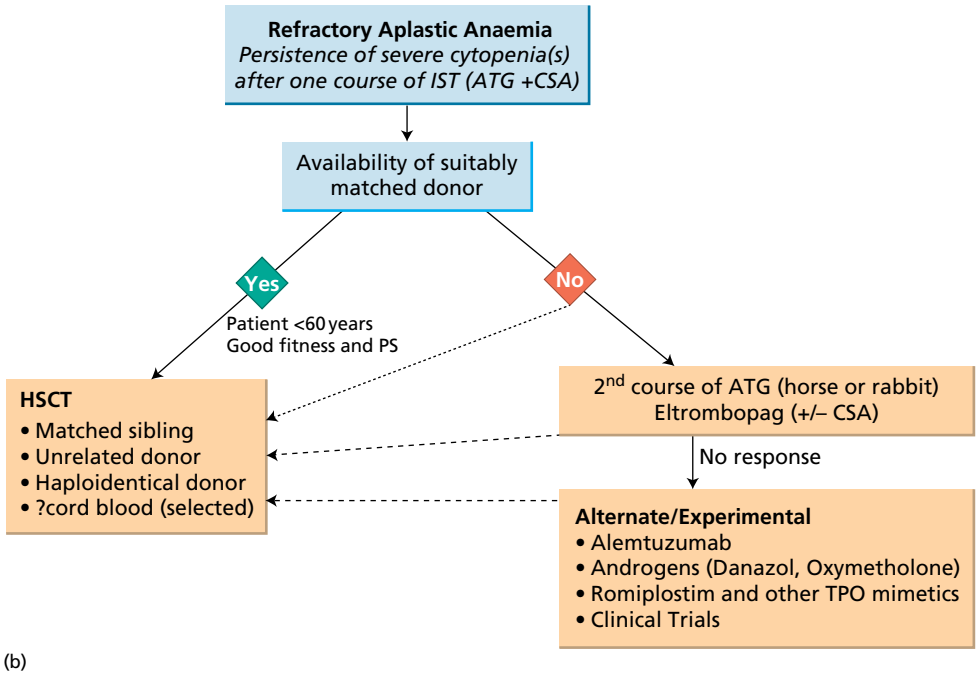


Figure 31.4 (a) Treatment of severe aplastic anaemia. (b) treatment of refractory severe aplastic anaemia. For patients age >50 years, who fail to respond to first-line IST, HSCT may be considered, using a matched sibling donor, or a suitably matched unrelated donor if no matched sibling is available.

5 direct stimulation of T regulatory cells has been demonstrated when normal bone marrow mononuclear cells are incubated with rabbit ATG.

In the UK, most of Europe and many other countries, the standard preparation of ATG has until recently been horse ATG (Lymphoglobuline, Genzyme). The rabbit preparation (Thymoglobuline, Genzyme) was usually reserved for second or subsequent courses. From June 2007, horse ATG (Lymphoglobuline) was withdrawn due to manufacturing difficulties in maintaining quality control, but another preparation of horse ATG (ATGAM, Pfizer) is now commonly used. Horse ATG is preferred to rabbit ATG as it results in a higher response rate (68% at 6 months compared to 37% for rabbit ATG, Table 31.2) and better survival, despite rabbit ATG being more immunosuppressive than horse ATG in terms of the degree and duration of lymphodepletion, indicating that different mechanisms are important in the mode of action of the two agents.

Table 31.2 Direct comparisons of horse and rabbit ATG with CSA as first-line treatment for aplastic anaemia in the last 10 years.

		N, preparation		Response at 6 months		Overall survival		
	Study design	**Horse ATG**	**Rabbit ATG**	**Horse ATG**	**Rabbit ATG**	**Horse ATG**	**Rabbit ATG**	**Comments**
Scheinberg, 2011	Prospective, randomised	60, ATGAM	60, Thymoglobulin	68%	37%	96%	76% at 3yr	Significant difference between ATG preparations
Marsh, 2012	Prospective	105, Lymphoglobulin	35, Thymoglobulin	67%	40%	86%	68% at 2yr	Matched pair analysis between two preparations; Significant differences between ATGs. More infective deaths with rabbit ATG.
Jeong, 2014	Retrospective	297, Lymphoglobulin	158, Thymoglobulin	60%	55%	96%	87%	Study in children. Significant difference in survival but not response. More infections with rabbit ATG.
Afable, 2011	Retrospective	67, ATGAM	20, Thymoglobulin	58%	45%	76%	64% at 2yr	No significant difference between ATGs but study likely under-powered.
Atta, 2010	Retrospective	42, Lymphoglobulin	29, Thymoglobulin	60%	35%	78%	55% at 2yr	Significant difference between ATG preparations.
Chen, 2013	Retrospective	42, Lymphoglobulin	53, Thymoglobulin	39%	45%	84%	83%	No significant difference between ATGs

ATG is a powerful immunosuppressive drug, given as an inpatient treatment and requires very careful monitoring, the prophylaxis and treatment of fevers and infections, as well as adequate (and sometimes intensive) platelet transfusion support. ATG is given as a daily intravenous infusion usually over 12–18 hours through a central venous catheter. Instead of giving a separate test dose, most centres give the first 100 mL of the first infusion very slowly over 1 hour to assess for possible anaphylaxis. Allergists maintain that this is inadequate to prevent anaphylaxis as the amounts delivered are relatively large. The dosage of horse ATG (ATGAM) is 40 mg/kg daily for 4 days and rabbit ATG is 3.75 mg/kg for 5 days.

Immediate side-effects are allergic and occur commonly, including fever, rigours, rash, hypertension or hypotension and fluid retention. Each daily dose should be preceded by intravenous methylprednisolone and chlorpheniramine. In the USA, patients are pretreated with diphenhydramine and pethidine if fever and chills have occurred. Platelet transfusions should be given to maintain a safe platelet count (ideally $>30\times10^9$/L; in the USA, a threshold of $>20\times10^9$/L is used). Prior to starting ATG, patients should be assessed to ensure adequate platelet increments with random donor platelets. Poor platelet increments should be investigated beforehand. Patients are often in isolation with reverse barrier nursing, but this is not standard practice in the USA. Fevers are treated with broad-spectrum antibiotics. Intravenous methylprednisolone (1–2 mg/kg) (or oral prednisolone) and paracetamol are given at least 30 minutes before each daily dose of ATG with reduction of the prednisolone dose by half every 5 days. Prednisolone is given to help prevent serum sickness. Serum sickness typically occurs between 7 and 14 days from the start of ATG treatment. The common symptoms of serum sickness include arthralgia, myalgia, rash, fever, mild proteinuria and platelet consumption, often necessitating increased platelet transfusion support.

There are no indications for routine use of daily G-CSF (administered for 3 months) with ATG and CSA as three prospective randomised studies comparing ATG, CSA and G-CSF with ATG and CSA alone demonstrated no difference in response and survival between the two groups, and there is concern about G-CSF stimulating low-level monosomy 7 clones. Attempts to augment responses and reduce relapse by incorporation of high-dose corticosteroids, mycophenolate mofetil (MMF), sirolimus or androgens to standard IST (ATG and CSA) have not met with any success.

Survival after ATG

Data from EBMT and large single centres confirm that over the last three decades overall survival after ATG therapy has improved steadily, with 5-year survival of around 80% reported (Table 31.2). The reasons for improved survival have been difficult to assess formally, but likely factors include: (i) improved supportive care for prevention and treatment of infections, especially superior antifungals and better availability and quality of blood products, (ii) the use of CSA with ATG, (iii) addition of eltrombopag in the frontline setting to ATG and CSA and (iv) successful second-line and rescue therapies, including another round of ATG, eltrombopag, unrelated donor (UD) HSCT in younger patients and allogeneic HSCT in older adults (see also Chapter 37).

Predictors of response to ATG

Patients with non-severe AA are more likely to respond than are patients with severe or very severe AA. Other predictors are younger age, absolute reticulocyte count (ARC) $>25\times10^9$/L and absolute lymphocyte count (ALC) $>1\times10^9$/L, which correlate with response to ATG. Same factors (age, disease severity and ARC) remain predictors of response for IST combined with Eltrombopag.

Several studies have examined whether the presence of a PNH clone is associated with response to ATG, with conflicting results. This may reflect differences in sensitivity of the test used to detect a PNH clone. Those using very sensitive tests to detect GPI-deficient clones of less than 0.003 cells show a strong correlation with response.

HLA type may also correlate with response to immunosuppressive therapy. A Japanese study showed that HLA-DRB1*1501 associated with response to CSA. Although HLA-DR15 or DRB1*1501 predicts response to ATG in white patients with MDS, no association was seen in AA patients. More recently, the same Japanese group demonstrated that of the 30 different DRB1 alleles, only DRB1*1501 and DRB1*1502 occurred more frequently in AA than in controls, and that response to ATG and CSA was only associated with DRB1*1501 in the presence of a PNH clone. Thus specific HLA haplotypes correlate with response to immunosuppressive therapy in Japanese patients, but similar studies in white Europeans are lacking.

Recent studies from NIH indicate that shortened telomere length does not preclude initial response to immunosuppressive therapy, but predicts relapse after ATG and is a risk factor for later cytogenetic abnormalities and evolution to MDS and AML. Thus telomere length at diagnosis may reflect depleted stem cell reserve so that prolonged stem cell division is not possible, resulting in later relapse; later clonal evolution reflects genomic instability of the critically shortened telomeres.

Repeat courses of ATG

A second course of immunosuppression may be administered (horse ATG, rabbit ATG or alemtuzumab). The response rate following a second course of ATG (horse or rabbit) for relapse is around 60%, but only about 35% for patients who did not respond to the first course. A study from Japan examined prospectively the outcome of 52 children who failed one course of horse ATG, and who went on to receive either a second course of horse ATG or an unrelated donor HSCT. The response to a

second course of ATG was only 11%, with a 5-year failure-free survival of only 9.5%. Another study has assessed the value of giving three courses of ATG. Amongst those patients who showed no response to the first or second courses, there were no sustained responses, but for those who had relapsed after two previous courses, all responded to a third. For patients receiving more than one course of ATG, the risk of anaphylaxis may be higher. Serum sickness is still unpredictable, though it may occur earlier following a second course of the same animal preparation of ATG.

Late complications after ATG

Relapse occurs in up to a third of patients when CSA is withdrawn at 6 months. A more prolonged course of CSA with a later slow tapering of the drug reduces the relapse risk to around 13–16%, although data from NIH show that a long course of CSA only delays but does not prevent relapse. About one-third of patients are CSA dependent and require a small dose long term. CSA can be continued for at least 12 months after a maximal response before starting to taper the drug, followed by a very slow taper, for example by 25 mg every 3 months.

Patients treated with ATG are also at risk of developing clonal disorders, such as PNH, MDS and AML. Long-term follow-up from a large NIH cohort showed 35% relapse at 5 years, and 10% risk of PNH and 15% risk of clonal evolution, excluding PNH, at 10 years. A previous study from NIH showed 20% risk at 10 years of clonal cytogenetic abnormalities after ATG. Reported risk factors for developing MDS/AML include repeated courses of ATG, older age, and high doses, prolonged duration of G-CSF with ATG and CSA, shortened telomeres and presence of acquired somatic mutations in genes known to be mutated in MDS/AML.

Although data is still not mature for long-term complications of eltrombopag used in combination with ATG, relapse and clonal evolution to MDS/AML were similar to IST alone but occurred earlier in the disease course

ATG treatment in older patients and children

For patients >60 years old, the response rate and survival rate are lower compared with younger patients, with a higher risk of bacterial and fungal infections, bleeding and significant cardiac events after ATG. Although there is no upper age limit for ATG treatment, consideration for treatment should be preceded by medical assessment to exclude significant comorbidities and hypocellular MDS. For older patients who are not candidates for ATG, CSA may be considered, but there is increased risk of renal toxicity and hypertension.

Excellent response to ATG is seen in children. Current response rates are around 75%, with 90% long-term survival, but issues of relapse and clonal evolution persist. In view of excellent outcomes after MUD HSCT in children using alemtuzumab-based regimens, upfront MUD HSCT may be considered instead of ATG when an MSD is not available. Eltrombopag with ATG did not seem to improve the response rate in children and hence additional rationale for upfront HSCT.

Other drugs used in AA Cyclophosphamide

High-dose (200 mg/kg) and recently 'moderate-dose' (120 mg/kg) cyclophosphamide (Cy) has been used to treat AA in the absence of stem cell support, following the observation that complete autologous haematological recovery occurs in a small number of patients undergoing allogeneic sibling BMT using Cy. Although durable responses were seen, the predictable and markedly prolonged cytopenias exposed patients to a high risk of fatal fungal infections and a significant increase in use of blood and platelet transfusions, days of intravenous antibiotics and amphotericin, and inpatient days in hospital. In addition, HDC treatment does not eliminate the risk of clonal events or relapse. Consequently, the use of Cy in the treatment of AA is not recommended.

Alemtuzumab

The anti-CD52 monoclonal antibody alemtuzumab (Campath-1H) is effective in other autoimmune disorders such as multiple sclerosis, autoimmune cytopenias and the vasculitides. NIH investigated the use of alemtuzumab monotherapy (10 mg intravenous for 10 days) without CSA in AA and induced heterogeneous responses; 56% in relapsed setting, 37% in refractory disease and 19% in treatment-naïve AA. Alemtuzumab can alternatively be given subcutaneously. The ease of administration, its efficacy even without concurrent use of CSA and the relatively good safety profile, makes alemtuzumab an alternative choice of IST in relapsed/refractory AA for salvaging transplant-ineligible patients.

Eltrombopag

Eltrombopag, an oral thrombopoietin mimetic, licensed in chronic immune thrombocytopenic purpura, induces platelet maturation and release by binding to c-MPL receptors on megakaryocytes (Chapters 40 and 45). In refractory severe AA, eltrombopag induced responses in 40% patients; responses included tri/bilineage, were robust and led to normalisation of cellularity. Trilineage responses, although surprising, might indicate stimulation of c-MPL receptors on remaining stem cells. The drug was well tolerated and there were no reports of increased reticulin or collagen fibrosis in the bone marrow, although new cytogenetic abnormalities, especially monosomy 7, were detected. The safety of eltrombopag needs to be evaluated further in prospective clinical trials, especially in view of the possible link to clonal evolution in refractory AA. The response seen with eltrombopag in refractory disease has led to design of prospective trials with incorporation of this agent along with ATG+CSA for first-line treatment of AA with remarkable improvement in outcome. Eltrombopag has now had FDA

approval for refractory SAA and also in combination with ATG and CSA in treatment naïve SAA.

Androgens

Androgens, such as oxymetholone, have been used historically for the treatment of AA prior to availability of ATG/CSA, subsequently as an adjunct to ATG and are still used in certain developing countries for first-line treatment of AA. Androgens lead to increased telomerase activity via aromatisation of oestradiol to steroids and hence induce responses in patients with telomeropathies who manifest as apparent acquired AA.

Haemopoietic stem cell transplantation

Outcomes following allogeneic HSCT for acquired AA, whether from a matched sibling donor (MSD) or a matched unrelated donor (MUD), have steadily improved over time. More recently, significant improvements have been observed for matched unrelated donor HSCT for AA patients failing immunosuppressive therapy, with 80–90% survival and the best results seen in younger patients (see also Chapter 37).

Allogeneic HSCT

Conditioning regimens

For MSD HSCT, the standard immunosuppressive, nonmyeloablative conditioning regimen for patients <30 years old is high-dose cyclophosphamide 200 mg/kg along with ATG, which results in survival of at least 80% in younger patients. For patients >30 years old, a fludarabine-based regimen is used, with a lower dose of cyclophosphamide, with either ATG ('FCATG') or alemtuzumab ('FCC'), to reduce rejection and GVHD, and improve outcomes. Alemtuzumab is associated with a lower incidence of GVHD, especially chronic GVHD compared to ATG. Standard GVHD prophylaxis is with CSA and methotrexate, although CSA alone is sufficient in the setting of alemtuzumab. Because AA patients are at risk of late graft failure, CSA is usually continued for 12 months after HSCT.

For MUD HSCT, the conditioning regimen is identical to that used for older patients undergoing MSD HSCT using either FCATG, with addition of low dose (2Gy) TBI, or FCC without TBI. Recent studies using alemtuzumab-based conditioning show 90% OS in children and around 80% in adults; and 70% in patients >50 years old. High-resolution HLA tissue typing is now routine for selection of MUDs.

Dose and source of haemopoietic stem cells

It is important to give at least 3×10^8 nucleated marrow cells/kg and $>2 \times 10^6$ $CD34^+$ cells/kg, because lower doses delay neutrophil engraftment and increase the risk of graft rejection. The strongly preferred stem cell source is BM for ATG-containing regimens, due to higher incidence of chronic GVHD and worse survival with PBSC, but either BM or PBSC can be used for alemtuzumab-based conditioning.

Chimerism

Using polymerase chain reaction for short tandem repeats on unfractionated bone marrow or peripheral blood mononuclear cells, the Dublin group, in collaboration with EBMT, reported mixed chimerism in 25% of HSCTs for AA. Patients with mixed chimerism may have either stable or progressive mixed chimerism. All the cases of graft failure occurred in the progressive mixed chimerism group, of whom 50% rejected their grafts. More often now, chimerism is examined in T-cells (CD3) and myeloid cells (CD15) and most patients have stable mixed T-cell chimerism with full donor myeloid chimerism when using alemtuzumab-based conditioning, with excellent survival and very low incidence of chronic GVHD, suggesting a state of tolerance may be achieved.

Graft-versus-host disease

GVHD (especially chronic) is one of the most serious complications, as it adversely impacts performance status, quality of life and survival after marrow transplantation, especially in a disease like AA where there is no advantage in having a graft versus-disease effect (Table 31.3), but the risk is reduced when using alemtuzumab-based conditioning.

The risk factors for chronic GVHD include: (i) history of prior acute GVHD, (ii) infusion of non-irradiated donor buffy coat cells (this manoeuvre was used previously to overcome the problem of graft rejection, but was abandoned because of the high incidence of chronic GVHD), (iii) older patient age, (iv) the use of peripheral blood stem cells and (v) the use of ATG compared with alemtuzumab-based conditioning regimens.

Long-term complications of HSCT

Fertility is usually well preserved when irradiation is not used in the conditioning regimen, and the chances of pregnancy or fathering a child are much higher in patients who receive a marrow transplant for AA than for haematological malignancies. Pregnancies in patients transplanted for AA usually have a successful outcome. Less long-term data are available using fludarabine with lower-dose Cy regimens, although cases of successful pregnancy have been reported. For patients of child-bearing age, referral to an assisted conception unit for discussions on fertility should be offered. Men should be offered sperm storage.

There is an increased frequency of solid tumours after HSCT for AA, but the risk is lower than in patients transplanted for haematological malignancies when irradiation is avoided. The

Table 31.3 Outcomes of HLA-matched sibling donor HSCT from recent studies using high dose cyclophosphamide (Cy) ± antithymocyte globulin (ATG) conditioning.

Study	Number of patients	Conditioning	Follow-up (years)	Overall survival	Acute GVHD	Chronic GVHD	Graft failure
Bacigalupo, 2012 EBMT study	1886	Cy±ATG predominantly		BM: 92% PB: 80%	BM: 11% PB: 17% (Gd II-IV)	BM: 11% PB: 22%	BM: 5.5% PB: 7.2%

risk is also lower in the absence of chronic GVHD. Monitoring of late effects should follow international guidelines, including routine surveillance for secondary malignancy, endocrine, metabolic, bone (including avascular necrosis) and cardiovascular risks.

Alternative donor HSCT

Umbilical cord blood transplantation

Experience in acquired AA is still limited. The largest study of unrelated cord blood transplantation (CBT) in acquired AA is reported by the combined EUROCORD/EBMT SAAWP. The main problem was engraftment failure in around 50% patients. A reduced intensity conditioning regimen is used. Because of the high risk of non-engraftment, a higher cell dose (EBMT recommendation is to use $>4 \times 10^7$ TNC/kg) is required compared to doses used in CBT for leukaemia and with no more than 2/6 HLA mismatches in the cord unit(s). As for haploidentical HSCT (see below), all patients must be screened for HLA antibodies that may be directed against HLA antigens present on the cord units and thereby increase the risk of rejection, so that only cord units lacking that antigen(s) are used.

Haploidentical HSCT

The key advantages of haploidentical HSCT are that a graft is available for most patients, the time to procure the graft is short and the cost is low. A novel approach is reduced intensity conditioning with high dose Cy given on day + 3 and + 4 posttransplant to prevent GVHD by depleting alloreactive donor T cells, but sparing quiescent, non-alloreactive T cells. This promising approach is undergoing further evaluation in AA and early data from prospective studies are encouraging.

Paroxysmal nocturnal haemoglobinuria

Introduction

Paroxysmal nocturnal haemoglobinuria (PNH) has fascinated haematologists since its first definitive description in 1882 by Paul Strübbing. PNH is unique as an acquired haemolytic disorder in which the defect is intrinsic to the red cell. Patients have a propensity to develop thromboses that are frequently life-threatening. PNH is also associated with bone marrow failure and indeed may provide a unique insight into the pathophysiology of a variety of BMFS. Development of the terminal complement inhibitor eculizumab has revolutionised the treatment of PNH, but in turn, has revealed further insights into the pathophysiology of the disease and into normal physiology. The treatment of PNH with eculizumab is not without problems in that a minority of patients have suboptimal responses and require modifications to maximise the benefits of therapy. Novel complement blockade with different targets in the complement pathway and easier modes of administration is revolutionising the field of complement therapeutics, with proof of concept studies done in PNH and two agents (ravulizumab and pegcetacoplan) recently approved for use in PNH

Pathophysiology

Glycosylphosphatidylinositol defect

PNH results from the expansion of an abnormal haemopoietic clone that arises following an acquired mutation in a gene critical for the biosynthesis of GPI structures. These highly conserved GPI anchors are glycolipid structures through which a large number of cell-surface antigens are attached to the cell membrane. Almost all patients with PNH have the same biosynthetic defect in one of the early steps of the pathway, namely the transfer of *N*-acetylglucosamine from UDP-*N*-acetylglucosamine to phosphatidylinositol. In 1993, Miyata and colleagues reported the cloning of the phosphatidylinositol glycan complementation class A (*PIGA*) gene, which is part of the enzyme complex involved in this step of the pathway and which has subsequently been shown to be mutated in almost all cases of acquired PNH reported to date.

Mutations of the *PIGA* gene are different between patients as they are acquired not inherited. It appears that the mutation rate of *PIGA* is similar to that of other genes and in fact, populations of PNH-like GPI-deficient cells can be observed at extremely low levels (1–10 per million cells) in most normal individuals, indicating that occasional haemopoietic stem cells by chance acquire *PIGA* mutations. Since the *PIGA* gene is located on the X chromosome (Xp22.1), each somatic cell, male or female, only has a single active copy and therefore a somatic mutation of this active gene leads to deficiency of GPI biosynthesis. GPI-deficient clones only expand if there is an additional factor that encourages their selection. The mechanism of this selective growth advantage of PNH clones, which could be a second genetic event, is of key importance in understanding the pathophysiology of PNH. A much more likely explanation is indicated by the association between PNH and other BMFS.

Association with bone marrow failure

PNH clones are detectable in up to 50% of patients withAA and in a smaller proportion of patients with myelodysplastic syndrome. This suggests that such BMFS are permissive for the expansion of PNH clones. There is overwhelming evidence that AA is an autoimmune disorder in which there is an aberrant immune attack, probably by CD8 cytotoxic T-cells directed against the haemopoietic stem cell. It would therefore appear likely that PNH stem cells, presumably due to GPI deficiency, evade this immune attack. This implies that either the immune attack in BMFS is, at least in part, directed through a GPI-linked structure or that the biology of the PNH stem cell is abnormal, protecting it from immune-mediated attack. Understanding PNH may well provide an insight into the mechanism of a variety of BMFS and provide a unique therapeutic target for these conditions.

Epidemiology

If PNH is defined as the presence of a PNH clone identified during the investigation of bone marrow failure, haemolysis or thrombosis, then the incidence of PNH in a series from the UK was found to be 1.3 newly diagnosed patients per million per year, and the prevalence 15.9 patients per million population. However, of these patients, 57% have less than 10% PNH neutrophils, indicating that they are unlikely to have clinically significant haemolysis and only one-third reported macroscopic haemoglobinuria. However, the identification of the PNH clone is important, even when it is small, as it suggests that the bone marrow failure is likely to be immune-mediated and because the PNH clone can evolve over time so that patients may be at risk of haemolysis and/or thrombosis.

Clinical features

Clinical triad

The clinical picture in PNH depends on the balance between three components: intravascular haemolysis (IVH), bone marrow failure and thrombotic complications. The chronicity of the disease, with a median survival of 10–20 years even prior to targeted therapy, causes continuous, high-level IVH leading to other complications, including renal disease and cholelithiasis.

Haemolysis

PNH, the disorder with perhaps the most intense chronic IVH, is characterised by episodes of haemoglobinuria, during which the patient's urine is often black and which, for unknown reasons, is often worse in the morning. This episodic haemoglobinuria is frequently associated with disabling symptoms including profound lethargy out of keeping with the patient's anaemia, abdominal pain sometimes requiring opiates, dysphagia that can be temporarily absolute and erectile dysfunction. The degree of haemolysis is associated with the size of the PNH clone and particularly the proportion of PNH type III (completely deficient) red cells. Macroscopic haemoglobinuria is rarely seen unless there are at least 10% type III red cells. However, patients with apparently identical PNH clones can have a wide range of disease severity, from very occasional attacks of haemoglobinuria without anaemia to severe recurrent or even continuous haemoglobinuria and transfusion dependence, suggesting that other important factors influence the severity of the symptoms. It is possible that this variation is due to the severity of underlying bone marrow failure, to an inherent variation in complement activity or to some other unidentified factor.

Many of the symptoms and complications of PNH result directly from IVH. Free plasma haemoglobin is immediately bound to haptoglobin and removed, explaining why haptoglobin is depleted in every patient. Free haemoglobin binds to and removes other gases such as nitric oxide (NO). This depletion of NO in PNH results in smooth muscle dysfunction, vasoconstriction, and pulmonary and systemic hypertension. This leads to dysphagia, abdominal discomfort, possibly due to intestinal spasm, erectile dysfunction, severe lethargy, pulmonary hypertension and possibly thrombosis, all classic

symptoms of PNH. This syndrome of NO consumption has only become clear since the development of eculizumab (see below), which stops intravascular haemolysis in almost all patients and abrogates the clinical features of PNH.

Bone marrow failure

The degree of anaemia and other cytopenias is a composite of the activity of IVH and the degree of underlying bone marrow failure. The platelet count in many patients is a suitable surrogate for marrow function, but in some patients, for example those with previous intra-abdominal thrombosis and subsequent hypersplenism, there may be other causes for a low platelet count. The presence of a PNH clone in patients with bone marrow failure probably indicates that there is a significant immune component to the marrow failure and may suggest that immune suppression is a reasonable therapeutic option. The degree of bone marrow failure will also impact on the efficacy of eculizumab, as this will only treat the component due to complement activity, such as IVH and thrombosis.

Thrombosis

Thrombosis occurs in 40–50% of patients with haemolytic PNH, with a predilection for certain veins, such as the hepatic veins (Budd–Chiari syndrome), other intra-abdominal veins or the cerebral veins (Table 31.4). Approximately 10% of patients present with a thrombosis as their initial clinical manifestation of PNH. Recent data indicate that the thrombotic tendency in PNH is in arterial as well as venous sites, including cerebrovascular events and myocardial infarctions at an early age. After the first thrombosis, patients have a 7.8-fold increased risk of dying compared with those patients who have not had a thrombosis. A classical clinical scenario is that of downward spiralling thrombotic events: after a first thrombosis, patients continue to experience further apparently discrete thromboses despite what would be considered adequate anticoagulation with warfarin and/or heparin until they eventually succumb. The cause of thrombosis in PNH is multifactorial including activation of PNH platelets by complement as well as IVH and NO consumption, which may lead to endothelial damage and thrombosis. It is now clear that there is a close relationship between the activation of both coagulation and complement with thrombin directly activating complement through the alternative pathway. This explains why frequently patients enter a spiral of multiple and increasingly severe thrombotic complications as the first thrombosis leads to complement activation leading to further thrombosis and more thrombin generation. Anticoagulants are relatively ineffective at preventing this circle of catastrophic thrombosis as they do not stop the activation of complement, whereas eculizumab stops the further activation of complement and usually interrupts this vicious circle of thrombosis.

Table 31.4 Sites of thrombotic events in haemolytic PNH.

Venous thrombosis	
Deep vein thrombosis	41 (33.1%)
Lower extremity	23 (18.5%)
Other	18 (14.5%)
Mesenteric/splenic vein thrombosis	23 (18.5%)
Hepatic/portal vein thrombosis	21 (16.9%)
Pulmonary embolus	8 (6.5%)
Cerebral/internal jugular thrombosis	7 (5.6%)
Superficial vein thrombosis	5 (4.0%)
Arterial thrombosis	
Cerebrovascular accident/TIA	17 (13.7%)
Myocardial infarction/unstable angina	2 (1.6%)
Total	124 (100%)

Renal disease

All patients with haemolytic PNH develop heavy renal tubular iron loading due to the continuous filtration of haemoglobin. This is evident on both magnetic resonance imaging (MRI) and post-mortem studies. The majority of patients will eventually develop chronic renal disease, with a minority progressing to established chronic renal failure requiring dialysis. In addition, during times of very intense IVH and haemoglobinuria, patients can rarely develop acute renal failure, which is potentially fully reversible, even though it may require dialysis. Some patients may develop repeated episodes of acute renal dysfunction. The use of nephrotoxic therapies, such as ciclosporin, adds to the renal insult, as do rare complications such as renal vein thrombosis.

Leukaemic transformation

There have been a number of case reports of myelodysplastic syndrome and acute myeloid leukaemia (AML) in patients with PNH, but only less than 5% of PNH patients in the larger series develop AML. This is similar to the incidence of AML in AA and since it seems the majority, if not all, patients with PNH have an underlying aplasia, then the rate of AML is no higher than would be expected, suggesting that the GPI deficiency has no impact on leukaemogenesis.

Spontaneous remission

PNH often develops in young adults between 20 and 40 years old. Historically, most patients with PNH have either died as a direct or indirect result of their disease or have suffered from the disease for the remainder of their life. In a series of 80 haemolytic PNH patients reported in 1995, initially diagnosed between 1940 and 1970, median survival was 10 years and 12 of the 35

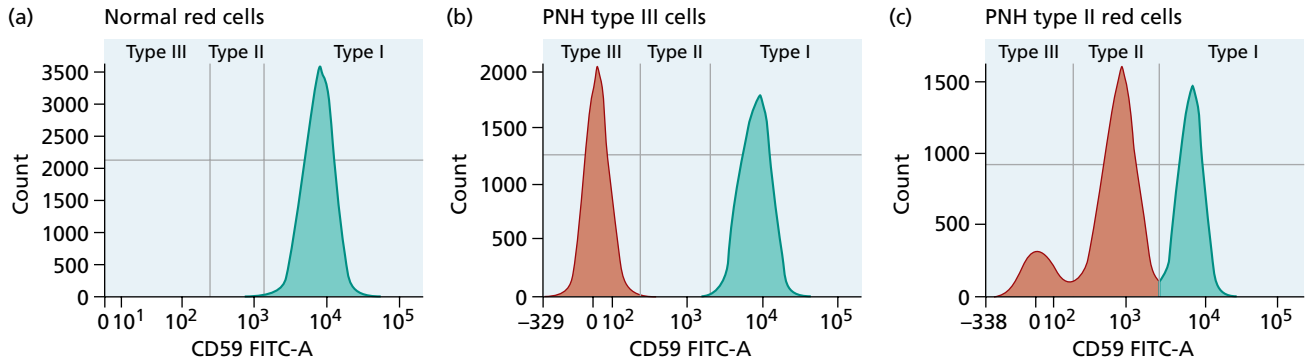

Figure 31.5 Identification of PNH red cells by flow cytometry: (a) GPI anchor protein (e.g. CD59) expression on normal red cells (type I). (b) A total of 46% of red cells are completely GPI anchor-deficient (type III). (c) a mixture of all three types of red cells are shown: type III, 10%; type II (partial GPI anchor expression), 54%; normal type I cells, 36% (Source: S.J. Richards. Reproduced with permission.)

patients surviving at least 10 years experienced spontaneous remission. Analysis of GPI-linked antigens on blood cells up to 20 years after spontaneous clinical remission demonstrated that the myeloid series was entirely normal with no residual PNH cells, whereas there was a small PNH clone in the lymphoid compartment (presumably these are long-lived memory cells). Early reports suggest that a proportion of patients treated with eculizumab have a progressive decrease in the size of their PNH clone, perhaps suggesting that remission may occur.

Investigation

The diagnosis of PNH was historically made by demonstrating the sensitivity of red cells to lysis by activated complement in the Ham test or similar. However, these tests only gave an indirect assessment of the proportion of PNH red cells and have been superseded by flow cytometry. Peripheral blood flow cytometric analysis requires analysis of at least two cell lineages (e.g. neutrophils and red cells), with a transmembrane marker to positively identify the cell type and at least two separate GPI-linked antigens to clearly separate PNH cells from their normal counterparts (Figures 31.5 and 31.6). In most patients, there is a population of red cells with complete deficiency of GPI-linked molecules (PNH type III cells, the most complement-sensitive cells) and, in some, an additional population with partial GPI deficiency (PNH type II cells, intermediate complement sensitivity). Type II and III are usually not evident in the neutrophils. The size of the PNH clone correlates with the risk of complications, such as thrombosis, and the severity of haemolysis. In addition, the evolution of the clone (either its expansion, leading to more haemolytic disease, or its reduction, ultimately leading to spontaneous remission) can be tracked.

Treatment

Supportive care

Conventional management in PNH has been supportive. The severity of haemolysis varies greatly between patients, in part dependent on the size of the PNH clone and the degree of underlying bone marrow failure. However, even patients with no evidence of clinically apparent marrow failure and large PNH clones can have highly variable levels of haemolysis. Some patients experience recurrent, even continuous, haemoglobinuria and are transfusion dependent, whereas others experience haemoglobinuria only rarely, or not at all, do not require any transfusions and have a well-compensated haemolytic anaemia.

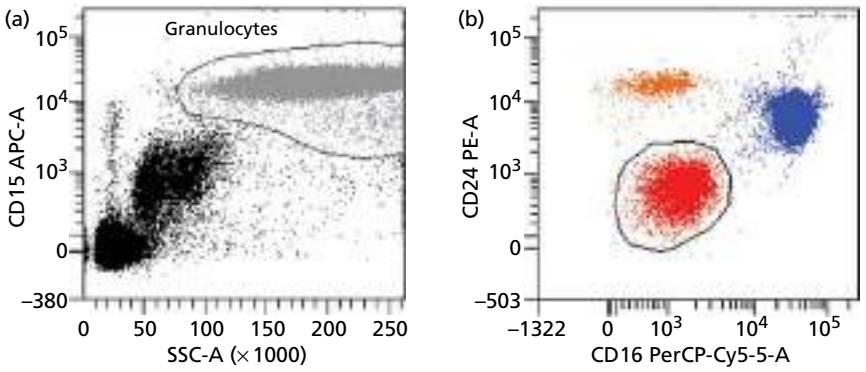

Figure 31.6 Identification of PNH granulocytes by multicolour flow cytometry: (a) granulocytes identified based on CD15 expression and side scatter. (b) analysis of CD16 and CD24 (both GPI-linked proteins) reveals a small population of PNH granulocytes (10%) that are deficient in both proteins (Source: S.J. Richards. Reproduced with permission.)

Patients with a significant degree of haemolysis should receive folic acid supplementation. The constant haemosiderinuria means that patients, even those who require regular transfusions, have a tendency to become iron deficient. This iron deficiency can result in failure of the marrow to compensate for the increased red cell destruction and therefore increasing anaemia. Iron supplementation has been reported to precipitate episodes of IVH, but usually patients tolerate oral iron supplements well and should be treated when iron deficiency is present.

Patients should be transfused according to their symptoms. Incidental infections lead to an increase in haemolysis, presumably due to activation of the complement system, and frequent sudden drops in the level of haemoglobin. These episodes are often associated with severe symptoms of abdominal pain, dysphagia and debilitating lethargy.

Corticosteroids have been widely used in the treatment of haemolysis in PNH. At high doses, steroids appear to have an effect of reducing the activity of complement and some patients report an improvement in symptoms. However, high doses are required to have a clinically useful effect and as the haemolysis in PNH is chronic, the required dose is too high. Steroids are therefore not generally recommended in PNH as the long-term side-effects outweigh the potential benefits.

Thrombosis

The major cause of morbidity and mortality in PNH is thrombosis, which usually affects the venous system, particularly the intra-abdominal and cerebral vessels, but also appears to result in arterial thrombosis (Table 31.4). The chance of developing a thrombosis depends on the size of the PNH clone and the severity of haemolysis, two variables that are closely related; half of patients with over 50% PNH neutrophils will develop a thrombosis at some point in their disease course. In most series, approximately one-third of patients will eventually die as a result of thrombosis. It appears that primary prophylaxis with warfarin is effective in preventing thrombosis, but carries a significant risk in this patient group. Aspirin does not appear to be protective against thrombosis and has no effect on the symptoms of PNH such as abdominal pain. It seems very likely that primary prophylaxis with warfarin is unnecessary for patients receiving the anticomplement monoclonal antibody eculizumab, as this agent significantly reduces the risk of thrombosis in PNH (see further on). Although there are no published data for the use of novel anticoagulants in PNH, these agents are increasingly used in clinical practice.

The treatment of established thrombosis is similar to the management of thrombosis in patients without PNH, except for the addition of immediate treatment with eculizumab (see further on). However, in view of the risk of recurrent thrombosis, patients should remain on lifelong anticoagulation after their first episode of thrombosis. Hepatic vein thrombosis (Budd–Chiari syndrome) is one of the more common thromboses seen in PNH and there have been reports of the successful lysis of such thromboses using tissue plasminogen activator; this should be considered even in patients who present with a relatively long history suggesting that their thrombosis occurred days or even weeks before. Current practice involves immediate use of eculizumab along with anticoagulation in acute Budd–Chiari syndrome, associated with PNH, to reduce mortality and long-term sequelae.

Allogeneic stem cell transplantation

The only curative strategy for PNH is allogeneic stem cell transplantation, but this carries a considerable risk of mortality. From the reported series and in view of the fact that a proportion of patients will eventually experience a spontaneous remission of PNH and with the advent of potentially effective novel therapies such as eculizumab, transplantation should only be considered in selected cases, such as those with a syngeneic donor or with associated bone marrow failure. In these patients, the indications for transplantation are similar to those for AA.

Complement blockade

The development of eculizumab (Soliris), a humanised monoclonal antibody that blocks the activation of terminal complement, has dramatically altered the management and prognosis in PNH. Eculizumab binds to C5 and stops it from being cleaved and, as long as trough plasma levels remain adequate, prevents any activation of terminal complement. Individuals with inherited terminal complement deficiency are either asymptomatic or present with recurrent *Neisseria meningitidis* (meningococcus) infections and this highlights the main concern with eculizumab. The clinical features of PNH are due largely to the absence of CD59 from haemopoietic cells and therefore the uncontrolled activity of terminal complement on PNH cells, making eculizumab an ideal candidate for the targeted therapy of PNH. In the initial study, 11 patients with transfusion-dependent haemolytic PNH were treated with eculizumab using a schedule designed to maintain trough levels to ensure that complement was completely blocked. The responses were dramatic, with an immediate resolution of the symptoms of IVH. This study was followed by a randomised placebo-controlled Phase III trial (TRIUMPH) and a non-randomised trial (SHEPHERD). In total, 195 patients were included in these three trials, which led to the licensing of eculizumab in the USA and Europe in 2007.

Ravulizumab (ALXN1210, Ultomiris), long-acting C5 inhibitor (given every 8 weekly) and modified from eculizumab (4 amino acid substituition), was shown to be non-inferior to eculizumab in 2 large pivotal phase 3 studies and led to its subsequent approval. Although C3-mediated extravascular haemolysis is likely to be similar as for eculizumab-treated patients, the 8 weekly administration is a major benefit for PNH

patients from convenience perspective in view of less frequent administration (6 infusions/year compared with 26 infusions/year for eculizumab)

Pegcetacoplan (C3 inhibitor, APL-2, Empaveli/Aspaveli) has been recently approved for treatment of PNH and clinical trial has shown superiority to eculizumab in patients with residual anaemia due to extravascular haemolysis.

Efficacy of eculizumab

Intravascular haemolysis

Eculizumab has a profound and immediate effect on IVH in PNH. The lactate dehydrogenase (LDH) concentration, which is typically as much as 10–20 times normal in PNH, falls immediately in almost all patients treated with eculizumab to normal or just above normal. In general, this results in increasing haemoglobin level which, depending on the degree of coexistent bone marrow failure as well as the extent of extravascular haemolysis (see below), will reach a plateau usually between 90 and 120 g/L. The most dramatic effect of eculizumab is on the symptoms, with resolution of the abdominal pain and dysphagia, and improvement in the severe lethargy and the other features of haemolysis. In the vast majority of patients, transfusion requirements improve, with over half of patients becoming transfusion-independent. The dramatic improvement in PNH-related symptoms is due to a marked reduction in NO consumption during therapy as a result of the improvement in IVH and thereby the reduction in free haemoglobin. This probably explains many of these benefits of the drug and provides insights into the pathophysiology of the symptoms of PNH. There is a dramatic and clinically significant improvement in the quality of life of patients as measured by validated questionnaires. There is now evidence that the adverse consequences of IVH, such as renal damage and pulmonary hypertension, are ameliorated by eculizumab.

Thrombosis

Eculizumab also protects patients from thrombosis. Compared with thrombosis before patients commencing eculizumab (effectively using patients as their own controls), the thrombotic rate reduces by fivefold to tenfold. In patients who have had a previous thrombosis and who are on anticoagulation, there is still a high recurrent thrombosis rate prior to starting eculizumab. However, since eculizumab became available, such recurrent thromboses are extremely uncommon. Patients who commence eculizumab during a 'spiral' of thrombotic events stop having further thromboses, indicating that eculizumab specifically targets the mechanism of thrombosis in PNH and that this is a more effective strategy than conventional anticoagulation alone. There is now increasing confidence that the catastrophic thrombotic complications of PNH can be much more successfully managed with a combination of eculizumab and anticoagulation. This observation will have an impact on the decision to use warfarin prophylaxis: in cases where there are concerns over the safety or requirement for warfarin prophylaxis, such as those with low platelets or with borderline PNH clone sizes, it is clearly safer to withhold anticoagulation as long as the use of eculizumab is an option for the patient should a thrombosis occur.

Renal dysfunction

In the 195 patients entering the eculizumab trials, renal dysfunction or damage was observed in 65% of patients before they were treated with eculizumab. In this series, 27% of patients had developed major clinical kidney disease within 10 years from their initial diagnosis of PNH and 21% of patients developed late-stage chronic kidney disease (stage 3 or 4 as defined by the Kidney Disease Outcomes Quality Initiative) or kidney failure (stage 5). The early analysis of patients treated with eculizumab suggests that many of the patients with early renal dysfunction (stages 1 and 2) will improve, and the deterioration in renal function in patients with advanced renal dysfunction (stages 3–5) is frequently stabilised. Thus eculizumab appears to have a beneficial effect on renal function in PNH and this is presumably due to the marked reduction in IVH and therefore in haemoglobinaemia and haemoglobinuria.

Eculizumab administration and dosing

The aim of treatment is to rapidly block complement and to maintain complement blockade continuously. The standard dosage schedule for eculizumab comprises a loading dose of 600 mg every week for 4 weeks, followed by 900 mg the next week and then 900 mg every 2 weeks indefinitely. In the majority of patients, this is adequate to maintain trough levels of eculizumab above 50 mg/L and therefore to block complement completely. In approximately 10–20% of patients, this dose is inadequate and patients break through complement blockade. Patients appear well with no signs of haemolysis until immediately before a dose of eculizumab, but then develop dark urine often with abdominal pain, sometimes with dysphagia, and a sudden deterioration in the laboratory measures of haemolysis, such as LDH and bilirubin, and a fall in the level of haemoglobin. In this situation, the maintenance dose of eculizumab is too low and an increase, either by reducing the interval or more conveniently by increasing the dose (from 900 mg every 2 weeks to 1200 mg every 2 weeks or even higher doses are usually effective), will raise trough levels of eculizumab above 50 mg/L and reestablish continuous control of haemolysis (Figures 31.7 and 31.8). This pharmacokinetic mediated breakthrough haemolysis (BTH) is not seen with long-acting C5 inhibitor ravulizumab, athough pharmacodynamic BTH due to complement amplifying conditions (CACs), like

Days		0*	1–8	9	10	11	12	13	0*	1	2
Urine scale	1 = Clear; 10 = Black	10	2–3	3	3	3	3	9	10	3	3
LDH	160–480 IU/L	2624	–	784	–	–	697	1687	2917	–	–
AST	0–40 IU/L	119	–	38	–	–	31	87	–	–	–
PK	C5 blocked >35 μg/mL	27	–	45	–	–	35	29	26	–	–
PD	No lysis <20%	71	–	1	–	–	2	56	56	–	–

*Eculizumab 900 mg

Figure 31.7 Breakthrough from complement blockade by eculizumab due to inadequate dose level. The urine is clear with lactate dehydrogenase (LDH) just above normal and no haemolytic activity in the patient's serum at day 12 after a 900-mg dose of eculizumab. On day 13, the patient suddenly begins to haemolyse as the level of eculizumab falls below 35 mg/L (the level at which complement is blocked). Immediately after the next dose (day 0), the haemolysis stops. Urine scale: patient assesses urine colour first thing in the morning (red or black urine at 6+). AST, aspartate aminotransferase; PD, pharmacodynamics (haemolytic potential of the patient's serum *in vitro*); PK, pharmacokinetics (serum level of eculizumab).

surgery, infection is seen with any pharmacological complement blockade and is less well understood.

Approximately 3% of Japanese individuals have a C5 polymorphism that prevents the binding of eculizumab/ravulizumab and means that they do not respond with no fall in their LDH after dosing.

Extravascular haemolysis (EVH) with eculizumab

Despite the impressive impact on IVH, most patients remain somewhat anaemic, maintaining their haemoglobin between 90 and 120 g/L. Virtually all have a persisting reticulocytosis and

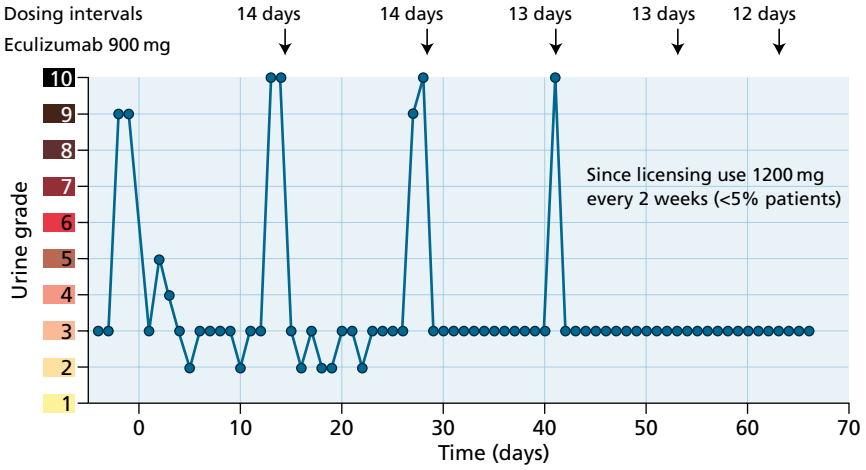

Figure 31.8 Urine colour with increasing eculizumab dose. Patient records early-morning urine colour according to scale on *y*-axis. He is breaking through from complement blockade for 2 days when receiving 900 mg eculizumab every 14 days. When the frequency of eculizumab 900 mg is increased to every 12 days, his breakthroughs cease. He is now maintained on 1200 mg eculizumab every 14 days.

many continue to have a raised bilirubin. These features are suggestive of ongoing extravascular haemolysis, which has previously been unreported in PNH. On further investigation, it transpires that approximately two-thirds of PNH patients on eculizumab develop a positive direct antiglobulin test to complement only. Flow cytometry demonstrates that the PNH red cells are coated by early complement components (C3b and C3d), possibly because PNH red cells, as well as being deficient in the principal controller of terminal complement, namely CD59, do not express the inhibitor of C3 convertase decay-accelerating factor (DAF). It appears that preventing terminal complement activation leads to a build-up of the early complement components, which accumulate on PNH red cells due to their deficiency of DAF. If intense, this extravascular haemolysis results in a poor increase in haemoglobin, and a minority of patients continuing to require transfusions. The recently approved C3 inhibitor pegcetacoplan has shown remarkable benefit in patients with residual anaemia due to EVH. The phase 3 trial compared eculizumab with pegcetacoplan and showed superiority via broad haemolysis control and hence improving haemoglobin and abolishing transfusion independency in 85% of patients. The drug is self-administed by subcutaneous infusion twice weekly and is fairly well tolerated.

Infectious risk with complement blockade

Eculizumab is generally very well tolerated with few infusion-related reactions. However, as noted above, blocking terminal complement activity would be expected to increase the risk of infection with *Neisseria meningitidis* (meningococcus). All patients commencing eculizumab should be vaccinated with a wide-spectrum meningococcal vaccine (ACWY Vax) and recently approved serotype B (Bexsero) vaccine. Although the risk of meningococcal infection is a concern, the observed risk is 0.25 cases of meningococcal infection per 100 patient years on eculizumab. However, when these infections occur they can be life-threatening and it is vitally important to impress on patients that they should seek medical help if they suffer any symptoms suggestive of infection, and these are usually of septicaemia rather than meningitis. Prophylaxis with penicillin is also recommended. There is no convincing evidence as yet of an increased risk to any other organism except for *N. meningitidis*. Patients on C3 inhibitors are theoretically at increased risk of infections with other encapsulated organisms and hence are additionally vaccinated against S.pneumonia and H.influenza.

Pregnancy in PNH

It is difficult to estimate the true risk of pregnancy in PNH but there is undoubtedly an increased risk of maternal morbidity and mortality. The reported maternal mortality, mainly from thrombosis, is between 12 and 21%, although this is likely an overestimate due to biassed reporting. In addition, an increased fetal loss rate has been reported, although again this is difficult to substantiate and is probably due to maternal factors. There have now been a number of successful pregnancies in women receiving eculizumab either later in pregnancy or throughout the pregnancy from conception to delivery. The reports to date are positive with little or no eculizumab crossing the placenta into the fetus. It does appear that the metabolism of eculizumab may be altered in pregnancy and women seem more likely to break through complement blockade and may need higher doses in the latter part of pregnancy. No safety data is available for ravulizumab and pegcetacoplan in pregnancy.

Prognosis

A series of 80 patients with haemolytic PNH diagnosed between 1940 and 1970 were reported in 1995 to reveal a median survival of approximately 10 years from initial diagnosis of PNH. A more recent series of 465 patients reported from France, including patients with small PNH clones as well as haemolytic PNH, reported a median survival of 22 years. The major causes of death in haemolytic PNH are thrombotic and since these are virtually abolished by eculizumab/ravulizumab therapy, and multiple reports have demonstrated that the survival of patients with PNH receiving eculizumab is very similar to an age-matched control population.

Future challenges and developments

The development of targeted therapy with C5 inhibitors (eculizumab/ravulizumab) and C3 inhibitors (pegcetacoplan) for PNH appears to alter the natural history of the disease and prevent morbidity and mortality. Newer anticomplement therapies, especially oral agents targeting specific proximal pathways like Factor D and Factor B are being evaluated in advanced Phase 3 trials. A global PNH registry has been established to document the changes in the natural history of the disease, as well as to record any unexpected complications of the newer therapeutic interventions. The current therapy of PNH controls rather than cures the disease. It is hoped that with more detailed understanding of the pathophysiology of PNH, a curative strategy may be developed.

Clinical significance of acquired somatic mutations in AA

The group at King's College Hospital, London, reported the first large study of acquired somatic mutations in AA patients using next-generation sequencing. Almost 20% of patients had mutations in myeloid-specific genes, most commonly *ASXL1, DNMT3A* and *BCOR*. Subsequently, a larger study from NIH,

Cleveland Clinic USA and Japan has confirmed similar results with *ASXL1, DNMT3A, BCOR* and *BCORL1* in 36% of AA patients. In both studies, the size of these mutated clones in AA was small in most patients and lower than found in MDS. The presence of somatic mutations was highly predictive of later evolution to MDS/AML (in 40% patients) compared to only 4% who lacked these mutations, for patients with a history of AA of >6 months. Mutations in *ASXL1* and *DNMT3A* were associated with worse response to immunosuppressive therapy and worse survival; in contrast, *BCOR/BCORL1* and *PIG-A* mutations conferred better response to IST and better survival. When all these mutations are combined with single nucleotide polymorphism (SNP-A) karyotyping, evidence of clonal haemopoiesis was demonstrated in 47% of AA patients. However, the interpretation of clonal haemopoiesis in AA is not straightforward. Age-related clonal haemopoiesis with mutations in especially *ASXL1* and *DNMT3A*, and others including *TET2, JAK2* but not *BCOR/BCORL1* or *PIG-A*, has been reported in 10% normal individuals older than 65 years, and increasing further with subsequent decades of life. In AA, analogous to PNH and abnormal cytogenetic clones, the level of these clones may fluctuate over time and may be selected in the context of immune dysregulation in the setting of bone marrow failure through increased proliferative pressure on the residual haemopoietic stem cell/progenitors. A possible unifying explanation is that the low-level 'age-related' clones represent a predilection (founder) stage that requires subsequent cooperating mutations for clonal expansion and disease, alongside the increased telomere attrition seen in AA. The RACE trial (below) showed that nearly 30% of SAA patients had somatic mutations with VAF >1% at diagnosis and this increased to up to 66% at 6 months and did not adversely impact haematological responses or 2-year outcome, including clonal evolution. This indicated the ubiquitous nature of clonal haematopoiesis in AA and the caution needed by physicians in overinterpreting somatic mutations in isolation, especially in treatment decisions.

Eltrombopag added to IST in first-line treatment of AA

The utility of Eltrombopag in inducing haematological responses in 40% of multiply pre-treated refractory AA was demonstrated in 2012, and subsequently led to its evaluation in first-line setting to utilise its HSPCs stimulatory properties. A single-arm NIH study showed its utility in the upfront setting when used in combination with conventional IST. The RACE trial, an international, investigator-driven, open-label, phase III, randomised trial evaluated 197 patients with acquired SAA (aged 15 years or older) who had not received prior immunosuppressive treatment. Patients were randomised to receive either standard immunosuppression (horse ATG 40 mg/kg × 4 days and CSA 5 mg/kg/day) or standard immunosuppression + eltrombopag at the dose of 150 mg/day from day +14 until 6 months. The primary endpoint of the study was complete response (CR) at 3 months- defined as haemoglobin 10 g/dL, neutrophil count $>1 \times 10^9$/L and platelet count $>100 \times 10^9$/L. Patients who received the combination of hATG, CSA plus eltrombopag had a significantly higher complete response rate at 3 months compared to patients treated with horse ATG and CSA alone (22 versus 10%). These higher response rates were sustained at 6 months (overall response of 41% with standard treatment versus 68% with standard treatment + Eltrombopag). The median time to first response was 9 months with standard treatment versus 3 months with standard treatment + eltrombopag. In addition, eltrombopag was generally well-tolerated, with a similar occurrence of adverse events in the two treatment arms. Although triple-drug therapy is the standard of care in USA for treatment naïve SAA, regulatory approval would facilitate its use in Europe and other countries.

CHAPTER 32

Acute myeloid leukaemia

32

Tumas Beinortas[1], Paolo Gallipoli[2] and Brian J P Huntly[1]

Epidemiology and demographics

Acute myeloid leukaemia (AML) is the commonest acute leukaemia in adults and has the shortest survival. AML has an incidence of around 5 cases per 100,000 population per year and is ~1.4 times more common in males. Age is by far the most significant risk factor for developing AML; AML incidence increases from 1/100,000 per annum in children and then peaks at around 28/100,000 cases per annum in 80–84-year-olds (Figure 32.1). Aromatic hydrocarbons, such as benzene are currently the only proven occupational or lifestyle factor that causes AML, although associations with smoking, obesity and fungicide exposure have also been reported. Therapy-related AML (tAML) as a result of chemoradiotherapy or immunotherapy for another malignancy is well described and, due to the increased use of adjuvant chemotherapy for breast and colon cancer, its incidence is on the rise. Clonal haematopoiesis of indeterminate potential (CHIP) (Chapter 38), is the phenomenon of expansion of clones containing somatic mutations in individuals with no overt evidence of haematological disease. Although a risk factor for AML, where its presence may precede disease development by many decades, progression is not an inevitable outcome, and factors that facilitate progression are yet to be determined.

Due to improvements in induction and consolidation therapy, stem cell transplant (SCT) delivery and supportive care, AML survival has improved dramatically for younger patients. In patients aged between 15 and 39 years, 5-year survival increased from 41% in 1990–1999 to 63% in 2010–2017 in the USA. However, recent 5-year survival (2010–2017) in patients >70 remained dismal at only 5%, with these figures not only reflecting both patient co-morbidities and limited treatment options, but also worse disease biology. Despite this, expanding adoption of more intensive treatments for older patients, improved supportive care and recent developments of less toxic targeted-AML therapies are finally starting to improve outcomes in older AML patients.

Clinical presentation

AML is characterised by an overproduction of immature myeloid blasts at the expense of mature granulocytes, lymphocytes, red cells and platelets. Fatigue, anorexia, weight loss and night sweats are common constitutional symptoms in people with AML, while extensive marrow infiltration can occasionally manifest in bone pain. The consequent bone marrow failure may cause symptoms of anaemia (fatigue, shortness of breath, light-headedness, pallor, headaches or feeling cold), thrombocytopenia (easy or spontaneous bruising, petechiae, bleeding gums, epistaxis and heavy periods) and neutropenia (susceptibility to bacterial, fungal, viral or protozoal infections). White cell counts (WCC) vary significantly and around 10% of AML patients present with hyperleucocytosis (WCC >100 × 10^9/L).

Hepatomegaly, splenomegaly and lymphadenopathy can occur but are generally uncommon in AML. Gum infiltration and hypertrophy are common in AML that has monocytic or myelomonocytic differentiation and *Leukaemia cutis* – cutaneous infiltration by leukaemic cells – is seen in 10–15% of cases, and up to 50% of cases of acute

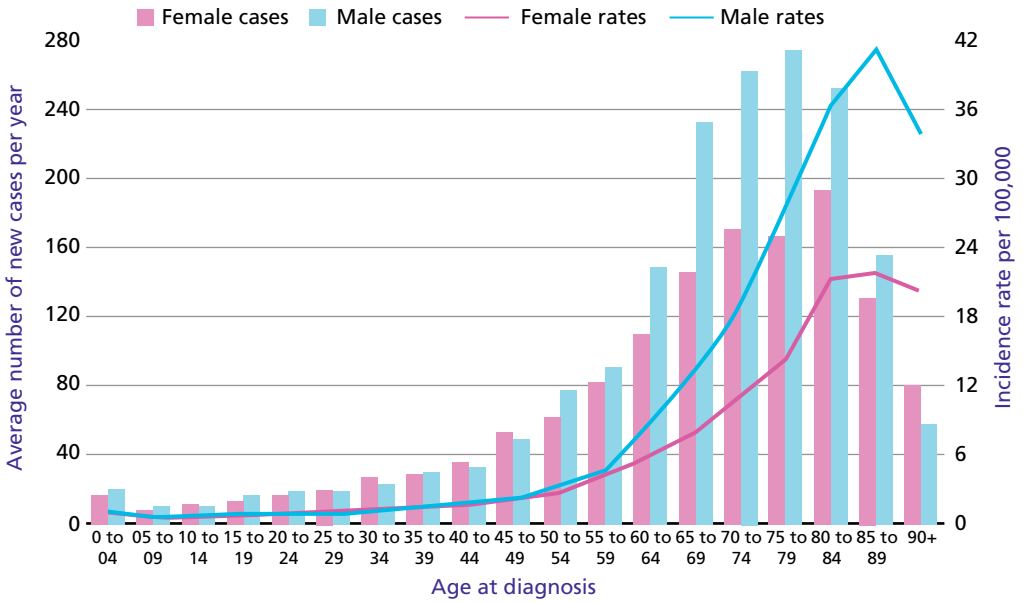

Figure 32.1 Incidence of AML per age group and sex in UK in 2017 (Source: Data from Cancer Research UK.)

myelomonocytic leukaemia. Central nervous system infiltration is a rare manifestation of AML (<1% of cases) with poor prognosis and is more frequent at relapse (~3% of cases). AML can occasionally present with extramedullary masses – termed myeloid sarcoma or chloroma. The t(8;21)/*RUNX1::RUNX1T* translocation is the commonest cytogenetic abnormality associated with myeloid sarcoma, although inv(16)/*CBFB::MYH11* also demonstrates an increased incidence.

Specific problems may include: leucostasis, tumour lysis syndrome and disseminated intravascular coagulation (DIC). In contrast to the ~5% chance of death within the first week in patients without hyperleucocytosis, hyperleucocytosis is associated with an up to 20% risk of death, owing to thromboembolic, pulmonary and neurological complications. Leucostasis is rare but can manifest in blurred vision due to retinal bleeds, mucosal bleeding and neurological symptoms ranging from vertigo, headaches to stroke-like symptoms, seizures and coma in the most severe cases. Clinical or laboratory tumour lysis syndrome is seen in around 15% cases with induction chemotherapy, especially if pre-therapy WCC $>25 \times 10^{\wedge}9$/L. DIC is a common presenting feature and cause of death in acute promyelocytic leukaemia (APML), but its risks can be almost reversed by prompt treatment with all-trans retinoic acid (ATRA). DIC is uncommon in other non-APML subtypes of AML, but occurs in up to 40% of AML with hyperleucocytosis, where it should be managed with platelet and coagulation factor support.

Molecular pathogenesis and genetic abnormalities

AML is characterised by recurrent genetic abnormalities at the chromosome and single-gene level. These heterogeneous lesions cooperate to generate the uniform phenotype of AML: clonal expansion, differentiation block and increased survival of myeloid progenitors. AML can develop secondary to antecedent haematological malignancies such as myelodysplastic syndrome (MDS) or myeloproliferative neoplasm (MPN) (secondary AML, sAML, ~10–20% of all AML cases) or following treatment for another cancer (particularly alkylating agents or topoisomerase II inhibitors) (tAML ~10–15% of cases). However, most AML cases develop sporadically (*de novo* AML), although the recently described process of clonal haematopoiesis (CH) (Chapter 38) suggests that, in many, this is the culmination of many decades of clonal growth and progression. Initial insight into genetic anomalies in AML came from the characterisation of recurrent balanced chromosomal rearrangements, loss or gain of chromosomal material or of entire chromosomes/chromosome arms. The advent of massively parallel genomic sequencing techniques has propelled the understanding of the molecular landscape of AML through identification of multiple driver mutations and members of different biological pathways that underlie AML development. AML was the first cancer to be sequenced and due to the ease of obtaining tumour tissue, remains one of the most sequenced human neoplasms. Genetic alterations in AML occur non-randomly: certain genetic aberrations sequentially co-occur or are mutually exclusive, suggesting that AML develops following the engagement/disablement of set pathways. The observation of CH suggests that, in many cases, this process occurs over many decades.

Cytogenetic abnormalities

Balanced chromosomal rearrangements underlie AML pathogenesis in about one-third of cases (Figure 32.2). Chromosomal

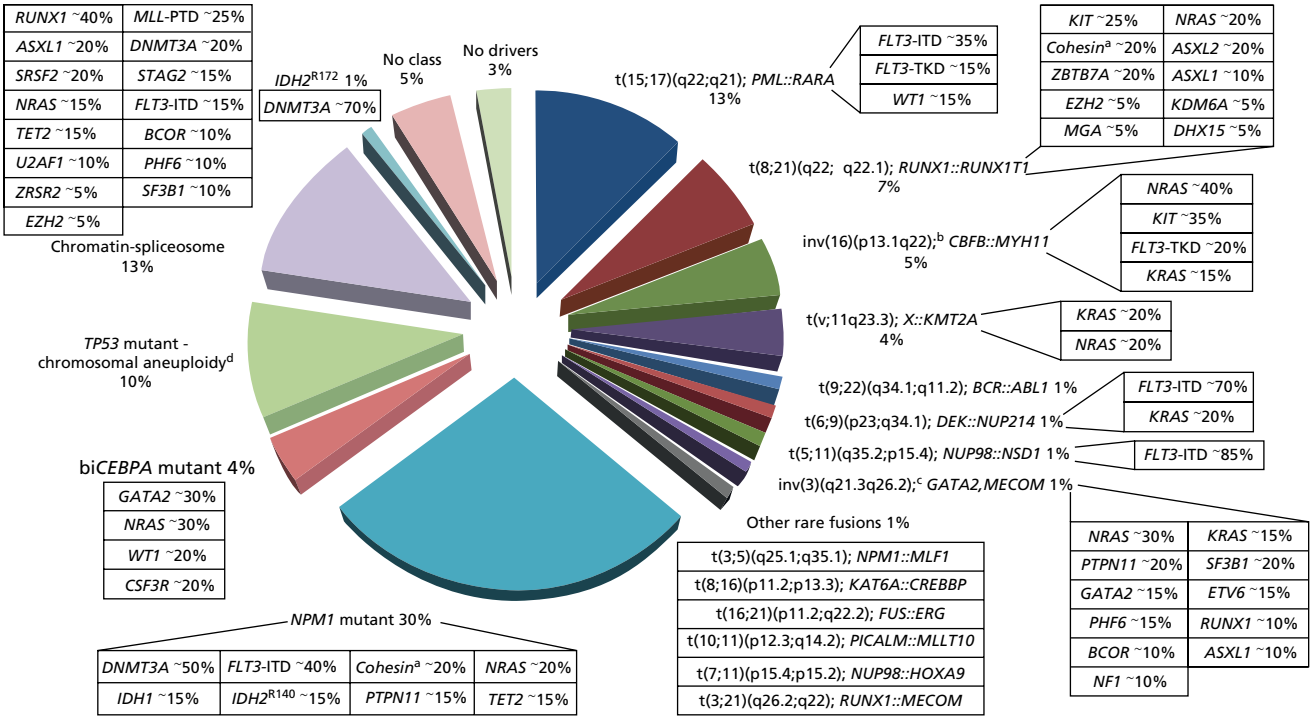

Figure 32.2 Molecular landscape of AML in younger adults (Source: Grimwade *et al.* 2016; Döhner *et al.* 2017.)

rearrangements or inversions in AML result in chimeric oncoproteins and frequently target myeloid transcription factors (for example, *RUNX1, RARA* or *CBFβ*), epigenetic regulators (*KMT2A, KMT3A* and *NSD1*) or nuclear pore complex members (*NUP98* and *NUP214*). Novel fusion proteins can exert their leukaemogenic effects through either disruption or alteration of native target protein function.

Core-binding factor leukaemia – Translocation between chromosomes 8 and 21, the t(8;21) leading to the *RUNX1::RUNX1T1* fusion and inversion of chromosome 16 (inv16), that rearranges to generate the *CBFB::MYH11* fusion, occur in ~12% of AML cases and confer favourable prognosis. Both result in the disruption of subunits of the core-binding factor complex (*RUNX1::CBFB*) necessary for the maturation of myeloid cells.

PML::RARA – *RARA* (retinoic acid receptor α) is a transcription factor regulating the expression of genes involved in myeloid differentiation. The *PML::RARA* fusion, a hallmark of acute promyelocytic leukaemia (APML), results from the t(15;17). This resultant fusion protein leads to the recruitment of transcriptional repressor proteins to RARA targets and subsequent maturation block in myeloid cells. Notably, *RARA* can have other fusion partners, which account for a minority of APML cases.

KMT2A rearrangements – *KMT2A* (also known as *MLL1*) is a chromatin methyltransferase that acts as a co-activator of gene expression in early haematopoiesis. *KMT2A* rearrangements in AML can occur with over 70 different partners, but *AF4, AF9, AF10* and *ENL* account for more than 75% of cases. *KMT2A* fusions positively enhance the function of the super-elongation complex and DOT1L methyltransferase to increase transcription at critical leukaemia genes where they require the co-factor Menin to bind.

Aneuploidies and unbalanced chromosomal abnormalities – Recurrent structural chromosome abnormalities are also frequently found in AML. Aneuploidies (loss or gain of entire chromosomes) and unbalanced chromosomal rearrangements (deletions and/or duplications) occur in around 20% of AML. Loss events are more common than gain in AML. Loss of chromosome 7 (−7) is the commonest monosomy in AML and occurs in around 5% of all AML patients, while +8 is the commonest trisomy (~10% prevalence). Loss of material from chromosome 5 long arm (5q), 7q and 17p are the commonest loss of chromosome material events. While the molecular consequences of gain of chromosomal material are less well understood, loss leads to the haploinsufficiency of tumour suppressor genes. In 17p loss, one copy of the *TP53* gene, a key tumour suppressor gene (*TSG*), is lost generating genetic instability, development of further karyotypic anomalies, and generates an AML with particularly poor risk. The situation is more complex to generalise in regions with potentially large regions of loss, such as del 7q and 5q, but this almost certainly also leads to loss of TSGs, such as *MLL3, CUX1, EZH2,* etc.

'Complex' Karyotype – The presence of more than three chromosome aberrations (excluding t(15;17), t(8;21), inv(16) and *KMT2A*-rearrangements) constitutes AML with a complex

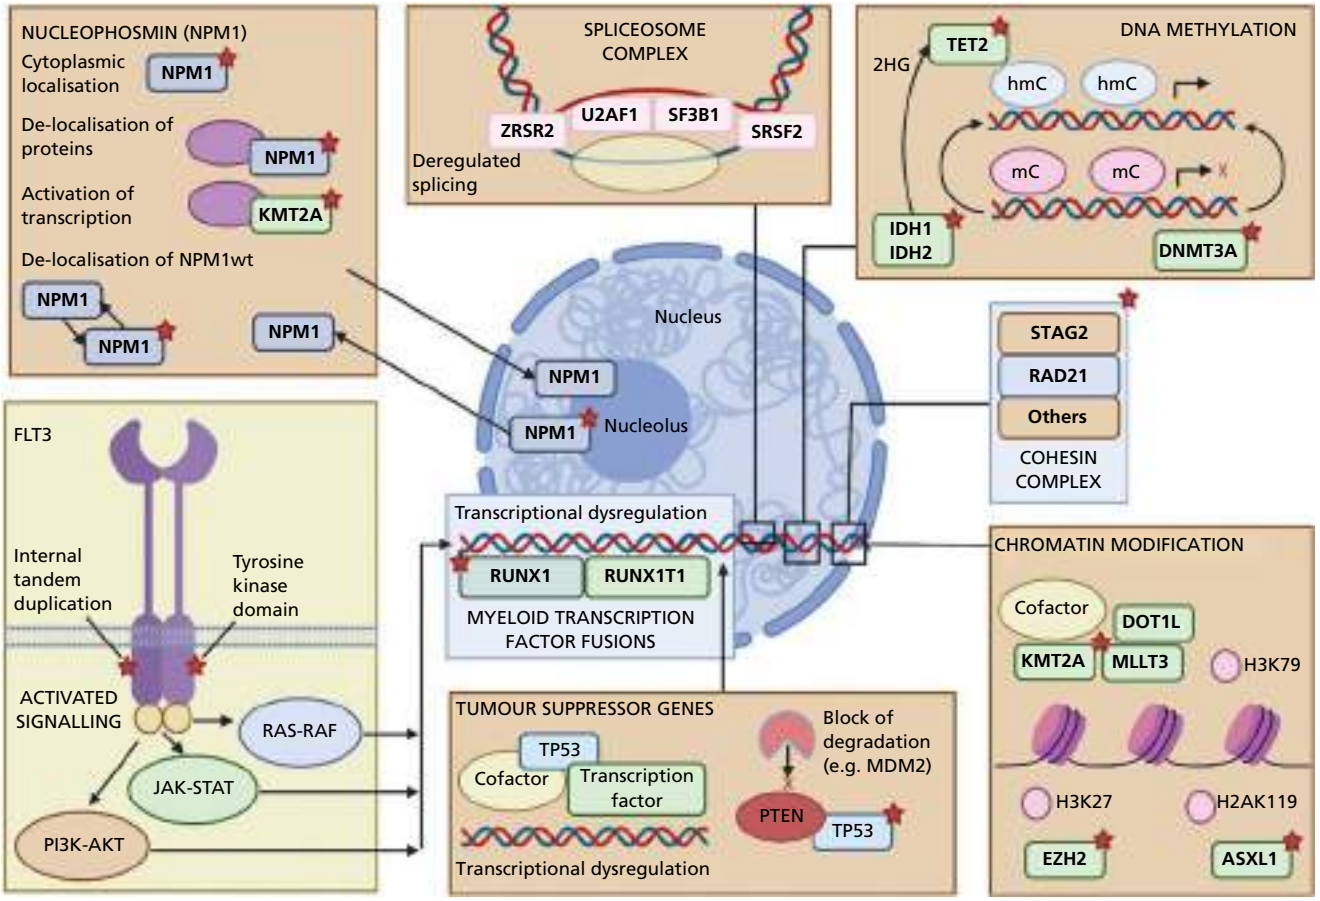

Figure 32.3 Functional classification of common driver mutations in AML (Adapted from Döhner et al, N Engl J Med, 2015, using BioRender.)

karyotype. This accounts for ~10–12% of all AML cases and its incidence dramatically increases with age. Due to its requirement for genome integrity, *TP53* is often mutated/lost in complex karyotype AML and there is a higher incidence of prior exposure to alkylating agents, topoisomerase II inhibitors and radiotherapy. Complex karyotype AML is associated with a very poor prognosis.

Somatic point mutations

More than 100 driver genes have been identified in AML. As with chromosomal rearrangements, isolated mutation can provide Haematopoietic stem and progenitor cell (HSPC) clones with a proliferative advantage, however on their own they are insufficient to induce leukaemia. With currently used DNA sequencing panels, driver mutations are identified in at least 96% of AML cases. Two or more driver mutations are detected in 86% of AML patients and AML patients carry an average of between three and five molecular lesions. The pattern of co-mutation in AML is not random: mutations co-occur at frequencies higher than would be expected by chance and can also be mutually exclusive, suggesting cooperative activation of specific core downstream developmental pathways in AML. Mutations in key AML driver genes can be divided in 8 functional categories (Figure 32.3).

Nucleophosmin 1 (~25% cases)- Nucleophosmin 1 (NPM1) is a nucleolar protein involved in mRNA transport, ribosome synthesis, chromatin remodelling, apoptosis and genome stability. *NPM1* mutations are one of the most common genetic aberrations in AML but have not been detected in any human cancers other than AML. They appear specific for *de novo* AML, are almost always mutually exclusive with chromosomal translocations or structural alterations (normal-karyotype AML) and are late events in leukaemogenesis. *NPM1* mutations cause cytoplasmic dislocation of the protein and are associated with expression of stem cell genetic programmes, such as *HOXA* and *HOXB* genes and reduced apoptosis.

Signalling cascade (collectively ~60% AML) – Mutations constitutively activating Ras-MAPK-STAT5 signalling pathway maintain AML blast proliferation, cell survival programmes and are amongst the commonest genetic alterations in AML. Fms-like tyrosine kinase 3 (*FLT3*) is a receptor tyrosine kinase and is one

of the most commonly mutated genes in AML. *FLT3* internal tandem duplication (*FLT3::ITD*) and *FLT3* tyrosine kinase domain point mutations (*FLT3::TKD*) are found in 25 and 7% of AML cases, respectively. While *FLT3::ITD* is associated with adverse prognosis, *FLT3::TKD* influence on AML prognosis remains uncertain. Mutations in other signalling pathways members *cKIT, KRAS, NRAS, PTPN11* and *NF1* are also seen at lower frequency. Signalling mutations co-occur with multiple other mutations and are particularly common with chromosomal translocations. In general, they alter the risk stratification of patients that carry them, although this may be modified in the future by available therapies targeting these pathways.

Epigenetic modifiers (collectively ~80%) – Mutations in epigenetic modifiers are amongst the earliest events in AML pathogenesis and are the most commonly found mutations in CH. Mutations occur in both regulators of DNA methylation and histone regulation. *DNMT3A* is a DNA methyltransferase and is mutated in around 20% of AML cases. The mutations are heterogeneous, but the commonest (~60% of cases) occurs in codon R882, which generates a dominant-negative protein able to bind to and inactive the wild type DNMT3A. Abrogation of DNMT3A function in HSCs appears to favour self-renewal over differentiation during stress, although the mechanism that drives this is not yet clear. *TET2* is a DNA demethylase, which removes methyl groups by converting them into a hydroxymethyl group and is mutated in ~15% of AML. *TET2* mutations appear to facilitate stem-like transcriptional programmes. *ASXL1* mutations occur in ~6% of AML cases, are more common in elderly, secondary AML, and may be independent adverse prognosis risk factor due to increased resistance to chemotherapy. *ASXL1* interacts with the chromatin-modifying polycomb repressive complex 2 (PRC2) members *EZH2* and *SUZ12*, that are also mutated in AML, and the BAP1 deubiquitinase to regulate deposition of the repressive histone marks H3K27me3 and H2AK119Ub and expression of leukaemia genes such as the *HOXA* cluster genes and *IRF8*. Mutations in isocitrate dehydrogenases *IDH1* and *IDH2* (respectively ~7 and 9% of AML) generate neomorphic enzymes that further process α-ketoglutarate to 2-hydroxygluterate (2-HG), an oncometabolite that inhibits α-ketoglutarate-dependent dioxygenase enzymes such as TET2. *IDH1* and *IDH2* mutations are mutually exclusive of *TET2* mutations but can be targeted by novel specific inhibitors Ivosidenib and Enasidenib, respectively.

Spliceosome regulators – Mutations in spliceosome genes (*SRSF2, SF3B1, U2AF1* and *ZRSR2*) occur in ~15–20% of AML and are considered to be pathognomonic of AML that has arisen from MDS. The mutations are therefore early founder mutations in leukaemogenesis and alter splicing of multiple target proteins via usage of alternative cryptic 3′ splice sites (*SF3B1* mutations), exon skipping (*U2AF1*) or exon inclusion (*SRSF2*).

Myeloid transcription factors – RUNX1 and CEBPA are two pivotal transcription factors controlling haematopoiesis and differentiation, and are commonly mutated in AML, each at frequencies of up to ~10% of cases. RUNX1 is a core binding family master transcription factor that controls haematopoietic differentiation, ribosome biogenesis, cell cycle and TP53 function. Point mutations in *RUNX1* are seen across *de novo* AML, therapy-related AML and AML resulting from MDS or MPN and disrupt normal RUNX1 production and function and are associated with poor-prognosis disease. *CEPBA* mutations can occur at both N and C-domains and are associated with favourable prognosis only when they occur in-frame in the basic leucine-zipper (bZIP) region, regardless of being biallelic or monoallelic mutations. Notably, mutations of both *RUNX1* and *CEBPA* can be inherited through the germline (see below).

Tumour suppressor genes (TSG) – Archetypal TSG lesion include *TP53* mutations, that are detected in ~10% of AML cases. *TP53* mutations alter the DNA damage response to genotoxic stress and are strongly associated with tAML, complex karyotype and disease of dismal prognosis, regardless of other prognostic factors.

Cohesin complex – The multisubunit Cohesin complex is responsible for sister chromatid cohesion in mitosis, homologous recombination, DNA looping to permit gene-regulation and DNA damage response. Mutations in Cohesin complex members (*STAG2, RAD21, SMC3, SMC1A*) occur in ~10% of AML, and preliminary results suggest their mutation causes dysregulated differentiation and stem-cell programmes via altered transcriptional regulation.

Germline mutations

It is now increasingly recognised that some mutations predisposing to AML and MDS are inherited through the germline. This emphasises the clinical importance of taking a detailed personal and family history of bleeding episodes and of other haematological and non-haematological malignancies. Identification may permit genetic counselling and necessitates germline testing for family haematopoietic stem cell donors. Germline mutations predisposing to AML can also predispose to platelet disorders, organ dysfunction and other malignancies (Table 32.1). Notably, mutations found in homologous DNA recombination repair pathway and familial cancer syndromes (*BRCA1* and *BRCA2, CHEK2, TP53, PALB2* and Lynch syndrome mutations) are found in around 20% of AML cases and may prompt screening of other family members. Bone marrow failure syndromes, many of which predispose to AML, are discussed in Chapter 30.

Germline mutations in master myeloid transcription factors *RUNX1, CEBPA* and *GATA2* were the first to be implicated in familial AML. Patients with germline *RUNX1* mutation have familial platelet disorder with around 44% risk of lifetime penetrance to myeloid malignancy, usually in adulthood. Nearly 10% of AMLs with biallelic *CEBPA* mutations harbour germline mutations. Germline *CEBPA* mutations usually occur in the 5′ end of the gene and cause AML with nearly complete

Table 32.1 Commoner germline predisposition to AML.

Gene or pathway	Haematologic malignancy	Additional haematologic abnormality	Other malignancies	Additional symptoms	Syndrome
CEBPA	AML	No common abnormalities noted	No other malignancies are common	None observed	Familial AML with mutated *CEBPA*
DDX41	MDS and AML; less commonly lymphoma	Cytopenia	No other malignancies are common	None observed	Familial AML with mutated *DDX41*
GATA2	MDS and AML	Immunodeficiency, bone marrow failure, monocytopenia and B cell lymphopenia	No other malignancies are common	Lymphoedema, pulmonary alveolar proteinosis and congenital deafness	Emberger syndrome (OMIM 614038) and MonoMac syndrome (OMIM 614172)
RUNX1	MDS and AML; less commonly T-ALL	Thrombocytopenia and decreased platelet function	No other malignancies are common	None observed	Familial platelet disorder with propensity for myeloid malignancy (OMIM 601399)
ETV6	ALL, MDS, AML	Thrombocytopenia and decreased platelet function	No other malignancies are common	None observed	Thrombocytopenia 5 (OMIM 616216)
ANKRD26	AML	Lifelong thrombocytopenia and various platelet dysfunctions	Not described	None observed	Thrombocytopenia 2 (OMIM 188000)
TP53	MDS and AML	Not observed	Osteosarcoma, breast cancer, soft tissue sarcoma, brain tumours and adrenocortical carcinoma	None observed	Li Fraumeni Syndrome (OMIM 151623)
Trisomy 21	AML and ALL	Transient abnormal myelopoiesis	No other malignancies are common	Mental retardation, cardiac abnormalities and facial dysmorphologies	Down syndrome (OMIM 190685)

(*Source:* Adapted from Klco J, Mullighan CG *Nat. Rev. Cancer* 2021 https://www.nature.com/articles/s41568-020-00315-z/tables/1.)

penetrance in young adulthood, but generally have a good prognosis. Along with many other syndromes, germline *GATA2* mutations predispose to MDS and AML with at least 33% lifetime risk. Germline mutations in the RNA helicase *DDX41*, cause MDS and AML with long latency but *DDX41 R525H* mutation also commonly arises somatically. Children with Down's syndrome have 150-times higher risk of AML in the first 5 years of life. Myeloid leukaemia associated with Down syndrome is a separate classification in both ICC 2022 and WHO 2022 and is predominantly magakaryoblastic in morphology. Transient abnormal myelopoiesis develops within the first 6 months of life in 30% of children with trisomy 21 (which can be mosaic), invariably accompanied by mutation in exons 2 or 3 of *GATA1*, with 20–30% progressing to AML upon acquisition of further somatic mutations. Common germline predisposition genes are shown in Table 32.1.

Clonal evolution and disease relapse

Morphological complete remission (CR) will be achieved following induction therapy in most AML patients. However, relapse eventually occurs in the majority of these patients and is the chief cause of AML mortality. Although the mechanisms are still poorly understood, leukaemic cells can acquire new genetic mutations and epigenetic modifications or rely on the microenvironment to survive, adapt and regrow following AML therapy. An important substrate in this ability is intratumoural heterogeneity; multiple leukaemic subclones are known to exist in a single patient. Moreover, specific leukaemia stem or initiating cells (LSC) have been demonstrated in AML. Growing evidence suggests that relapse can occur from dominant clones or subclones evident at diagnosis or from clones that have evolved during treatment. Indeed, particularly related to the more targeted therapies available, we are developing biological insights into adaptive treatment resistance and the scientific basis for relapse at both the genetic and non-genetic levels. Finally, recent studies have also shown a significant non-cell autonomous component to the development of resistance, driven by the AML microenvironment.

Genomic clonal architecture can be computationally inferred from bulk DNA sequencing of AML using variant allele frequencies (VAF). The advent of single-cell DNA sequencing and its application to longitudinal samples from the same patient has further allowed greater resolution of clonal evolution and the genetic lesions driving this. For example, resistance that develops to AML patients treated with FLT3 inhibitors is often accompanied by the expansion of clones that either demonstrate a resistant *FLT3* F691L mutation or mutation of downstream MAPK-RAS signalling pathway intermediates (*NRAS* and *KRAS*), which both restore downstream FLT3 signalling. Similar mutations that prevent binding of inhibitors to mutant IDH1 and 2 have also been described, as has the phenomenon of 'isoform switching'. In this scenario, an *IDH1*-mutated AML patient treated with the IDH1 inhibitor Ivosedenib develops an *IDH2* mutation to restore 2HG production and aberrant leukaemic transcriptional programmes, or vice-versa for an *IDH2*-mutated patient.

Clonal evolution can be linear, branched or simultaneously exploit both patterns (Figure 32.4). Clones responsible for disease relapse often pre-exist at low levels and are selected for by treatment or arise early in treatment (for example *NRAS*-mutated clones). Genetic clonal evolution seems to be an early event upon treatment initiation, before overt disease relapse and may provide a window for intervention in the future. However, often no new detectable genetic abnormalities are detected at AML relapse and mutations cannot alone explain disease refractoriness. Therefore, investigations of non-genetic mechanisms of resistance, including the role of the microenvironment, are urgently required.

Disease classification

Over the past decade, AML has undergone a radical shift from morphological and phenotypic classification to a primarily genetic classification of the disease. There are currently two independent, but greatly overlapping, classification systems for AML: the International Consensus Classification (ICC) and the World Health organisation (WHO) systems, both of which were updated in 2022. Given its extensive integration with prognostication and therapeutic frameworks, the ICC AML classification will be used in this chapter.

Recurrent genetic abnormalities, if present, are the most important diagnostic attributes in the hierarchical approach to AML diagnosis taking precedence over purely karyotypic or phenotypic criterion (Table 32.2). More than 10% myeloid blast count in PB or BM is sufficient to establish a diagnosis of AML in the presence of a recurrent genetic abnormality. Recognition that high blast count MDS patients often derive benefit from AML therapies, has led to the softening of the boundary between AML and MDS. As a result, cases with 10–19% myeloid blasts in BM or PB without recurrent AML-defining genetic abnormalities are classified as MDS/AML. Owing to its particularly poor prognosis, AML with mutated *TP53* constitutes its own diagnostic entity. AML with mutations in splicing proteins (*SF3B1, SRSF2, U2AF1* and *ZRSR2*), certain epigenetic regulators (*EZH2, BCOR* and *ASXL1), RUNX1* or *STAG2* are associated with preceding MDS or MDS/MPN in at least 95% of cases. In the absence of AML-defining recurrent genetic abnormalities or a *TP53* mutation, mutations in these genes classify the disease as AML with myelodysplasia-related gene mutation. Cases with complex karyotype or myelodysplasia-related karyotypic changes but lacking *TP53* mutation or myelodysplasia-related gene mutations are classified as AML with myelodysplasia-related cytogenetic abnormality. Finally, cases not meeting criteria for any of the above groups are classified as AML not otherwise specified, regardless of their phenotypic features. This decision tree is shown graphically in Figure 32.5.

Although AML can develop through several biological trajectories (*de novo*, therapy-related, secondary to prior MDS or MPN or on the background of germline predisposition), genetic characteristics demonstrate the best correlation with disease prognosis and therefore provide the most relevance for disease classification. Current AML classification applies the biological context within which AML develops as a diagnostic qualifier to the AML-defining lesions. Therapy-related AML includes exposure to previous radiotherapy, cytotoxic therapy or immune-therapy for non-myeloid malignancy and constitutes around 10–15% of AML cases. Notably, germline mutations do occur in the therapy-related setting and taking a detailed family history as well as a full diagnostic work-up remains important. Prior MDS or MDS/MPN are added as

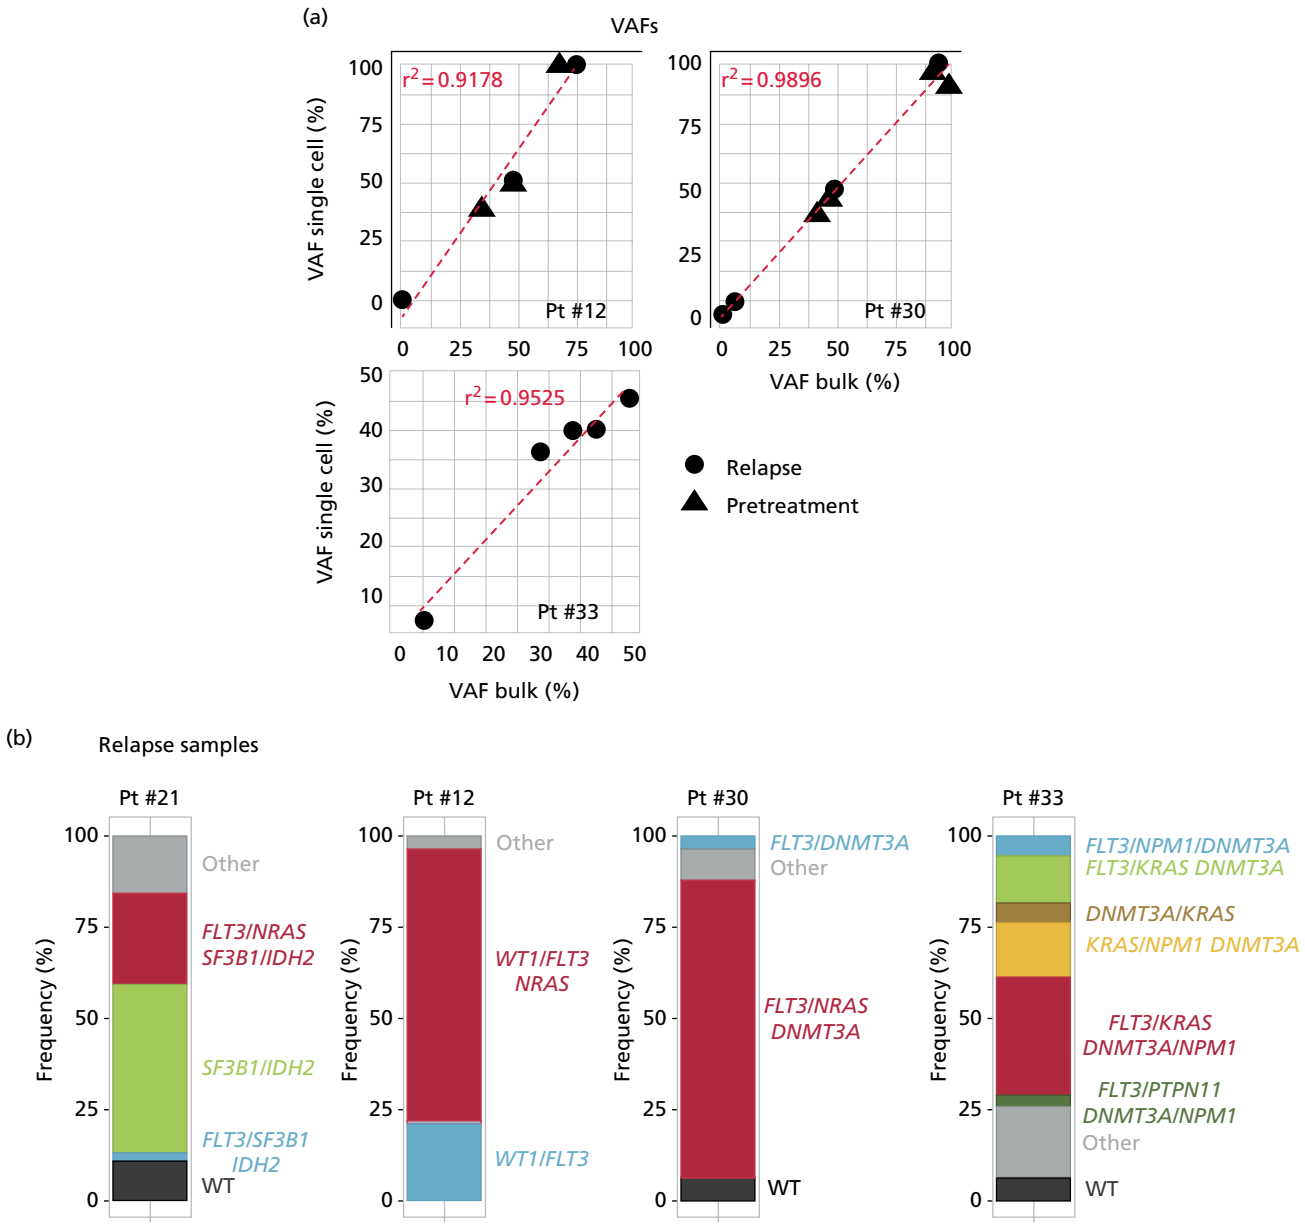

Figure 32.4 Examples of different patterns of genetic clonal evolution. *Patient #12* exhibits linear clonal evolution where at diagnosis only single AML clone exists bearing *FLT3* and *WT1* mutations. Early acquisition of *NRAS* mutation in this clone leads to treatment resistance and expansion of FLT3/WT1/NRAS clone. *Patient #30* exhibits branched evolution where selective pressure from gilteritinib leads to the suppression and disappearance of dominant *FLT3/DNMT3A* clone but permits the expansion of resistant *FLT3/DNMT3A/NRAS* subclone, which is present at low levels at the time of diagnosis. *Patient #21* exhibits both branched and linear polyclonal evolution. Acquisition of *NRAS* mutations bypasses the FLT3 inhibition effect of silencing MAPK-RAS signalling. *SF3B1/IDH2* clones expands under the selective advantage of FLT3 inhibition (Source: Taken from McMahon *et al. Cancer Dis.* 2019 https://cancerdiscovery.aacrjournals.org/content/9/8/1050.) (*Continued*)

qualifiers if they were diagnosed using standard diagnostics more than 3 months prior to the development of AML. Germline predisposition should be considered for AML patients of all ages, but especially if a person had 2 or more malignancies, AML is diagnosed at a young age, there is a family history within two generations of other haematological malignancy or solid malignancy at younger age (below 50) or in the presence of specific mutations.

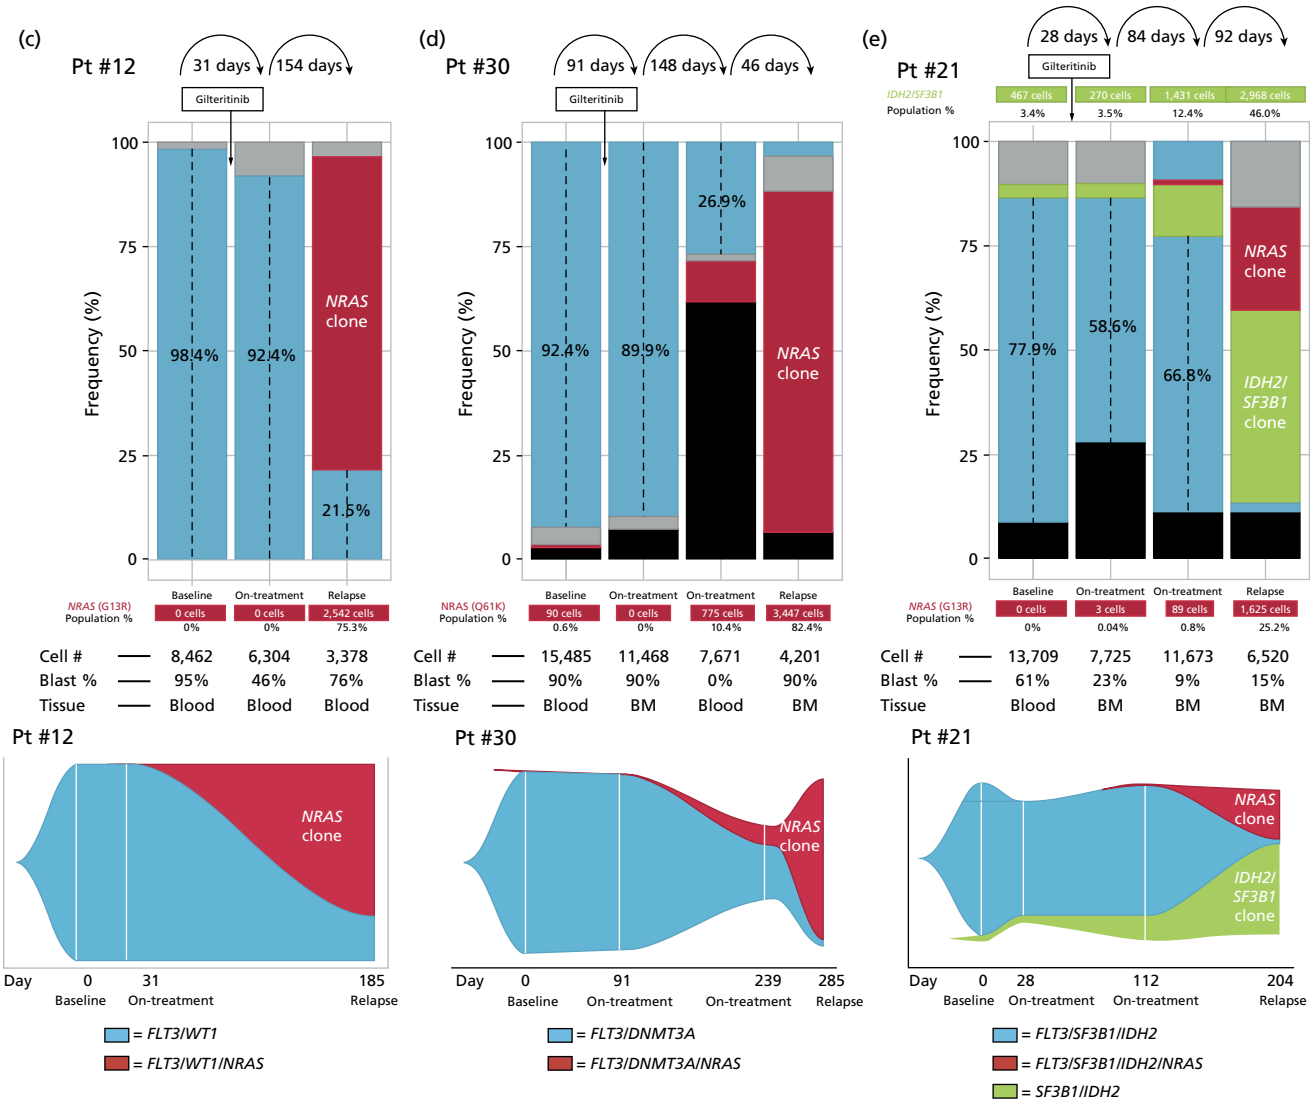

Figure 32.4 (*Continued*)

Diagnostic workup

An optimal diagnostic approach to AML is outlined in Table 32.3.

Recognition of familial myeloid neoplasms requires that physicians take a thorough patient and family history to assess for typical signs and symptoms, including data on malignancies, prior treatment and previous bleeding episodes.

If possible, patient should be consented for biobanking for wide indications and samples from diagnosis and various time points in treatment should be stored. Permanent infertility develops almost invariably with intensive AML treatments. Patients should be explicitly informed about this toxicity and should be offered cryopreservation of oocytes or sperm before treatment.

Flow cytometry of bone marrow aspirate or peripheral blood (if high circulating blast count) is essential for AML diagnosis and also establishes leukaemia-associated immunophenotype (LAIP), which can later be used for minimal residual disease (MRD) tracking. Baseline qPCR testing for NPM1 mutated, *CBFB::MYH11* or *RUNX1::RUNX1T1* AML is useful for later MRD disease tracking.

Prognostication

AML patients can have widely differing outcomes, that range from death within a few days of presentation to complete cure. The main cause of death for AML patients is treatment resistance: failure to achieve remission (refractoriness) or, more commonly, relapse. The genetics of individual AML cases can assign patients to discrete prognostic categories and is the

Categories designated AML (if ‡20% blasts in BM or PB) or MDS/AML (if 10–19% blasts in BM or PB)	*Myeloid proliferations related to Down syndrome*
• AML with mutated *TP53*	• Transient abnormal myelopoiesis associated with Down syndrome
• AML with myelodysplasia-related gene mutations (*ASXL1*, *BCRO*, *RUNX1*, *SF3B1*, *SRSF2*, *STAG2. U2AF1*, *ZRSR2*)	• Myeloid leukaemia associated with Down syndrome
• AML with myelodysplasia-related cytogenetic abnormalities†††	*Blastic plasmacytoid dendritic cell neoplasm*
• AML not otherwise specified	

BM, bone marrow; MPAL, mixed phenotype acute leukaemia; PB, peripheral blood.
* *RARA* has also other rare translocations causing APL, which should be reported. For example *IRF2BP2::RARA*, *NPM1::RARA*, *ZBTB16::RARA*, cryptic inv(17), *STAT5B::RARA*, *STAT3::RARA*, *TBL1XR1::RARA*, *FIP1L1::RARA*, *BCOR::RARA*.
** KMT2 has over 70 translocation partners in AML and should be reported. The commoner ones are *AFF1::KMT2A*, *AFDN::KMT2A*, *MLLT10::KMT2A*, *TET1::KMT2A*, *KMT2A::ELL*, *KMT2A::MLLT1*.
*** There are other recurring translocation events in AML involving *MECOM* and should be reported accordingly, eg. AML with t(3;8)(q26.2;q24.2)/*MYC*, *MECOM*.
**** Other rare recurring translocations: AML with t(1;3)(p36.3;q21.3)/*PRDM16::RPN1*; AML (megakaryoblastic) with t(1;22)(p13.3;q13.1)/*RBM15::MRTFA*; AML with t(3;5)(q25.3;q35.1)/*NPM1::MLF1*; AML with t(5;11)(q35.2;p15.4)/*NUP98::NSD1*; AML with t(7;12)(q36.3;p13.2)/*ETV6::MNX1*; AML with t(8;16)(p11.2;p13.3)/*KAT6A::CREBBP*; AML with t(10;11)(p12.3;q14.2)/*PICALM::MLLT10*; AML with t(11;12)(p15.4;p13.3)/*NUP98::KMD5A*; AML with *NUP98* and other partners; AML with t(16;21)(p11.2;q22.2)/*FUS::ERG*; AML with t(16;21)(q24.3;q22.1)/*RUNX1::CBFA2T3*; AML with inv(16)(p13.3q24.3)/*CBFA2T3::GLIS2*.
† Monoallelic or biallelic.
‡ *BCR::ABL1* AML requires ≥20% of blasts to avoid overlap with CML in accelerated phase. History of previous CML precludes diagnosis of AML with *BCR::ABL1* and should be classified as CML in blast phase if PB or BM blast count is ≥20%.
††† Complex karyotype (≥3 unrelated chromosome abnormalities, excluding hyperdiploid karyotypes without structural abnormalities) or unrelated clonal abnormalities (del(5q)/t(5q)/add(5q); -7/del(7q); -8; del(12p)/t(12p)/(add)(12p); i(17q), -17/add(17p) or del(17p); del(20q); and/or idic(X)(q13).

most powerful prognostic factor, explaining two-thirds of the variability in overall survival (OS). Other important disease characteristics relate to whether the disease is primary or secondary and to the haemoglobin, platelet and white blood cell count and peripheral blood blast percentage. Patient-specific characteristics not related to the disease are also important prognostic factors, with the most important being ECOG/WHO performance status, creatinine and albumin. Age in itself reflects a composite of multiple prognostic cofactors, such as performance status, comorbidities, a higher chance of therapy-related AML or AML developing from myelodysplasia/MPN and an increased frequency of potentially high-risk mutations (e.g. *RUNX1, ASXL1, BCOR, STAG2, USAF1, ZRSF2, SRSF2, SF3B1* and *EZH2*). Removal of age from the AML prognostication models did not significantly alter the accuracy of prediction. Therefore, patient's age should be considered only secondary to other factors when decisions about treatment intensity are made.

In 2022, the European Leukaemia Network (ELN 2022) updated a risk-stratification framework, based on genetics, which

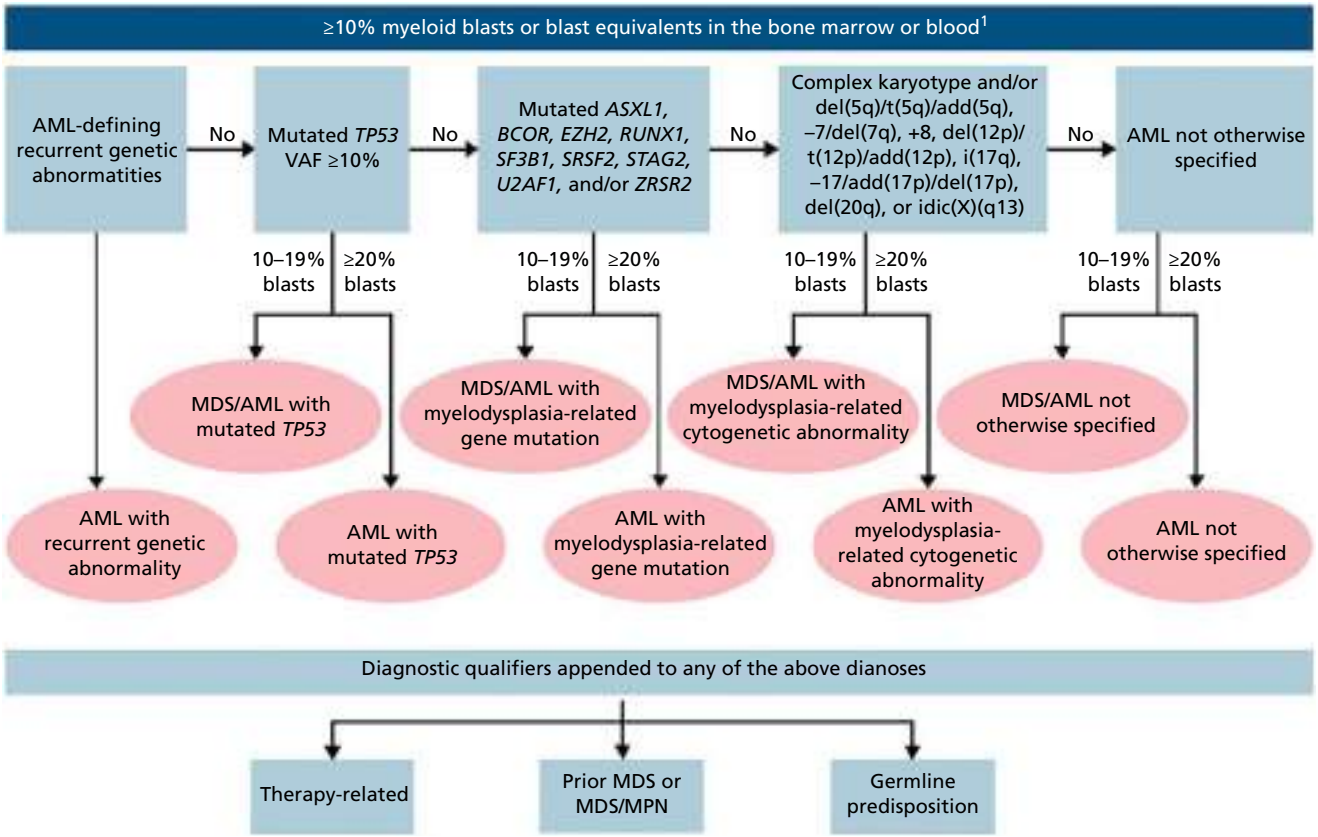

Figure 32.5 Hierarchical approach to the classification of AML from the International Consensus Classification 2022. Germline predisposition qualifier should include the name of the mutated germline gene or syndrome. Examples of how diagnostic qualifiers are addended: 1. *AML with in-frame mutation in the bZIP domain of the CEBPA gene, germline CEBPA mutation* 2. *AML with mutated TP53, therapy-related; AML with myelodysplasia-related gene, prior myelodysplastic syndrome* (Source: Döhner *et al. Blood* 2022).

Table 32.3 Diagnostic workup of AML.

History	• Comorbidities including prior malignancy (personal history of ≥2 cancers, one of which haematological, is indication for germline testing)
	• Bleeding history to identify germ line predisposition to platelet and myeloid disorders
	• Family history to identify germline myeloid neoplasms:
	  ○ Another relative within two generations with another haematopoietic malignancy, or
	  ○ Another relative within two generations with a solid tumour diagnosed at age 50 or younger, or
	  ○ Another relative within two generations with other haematopoietic abnormalities
	• ECOG performance status or WHO score
	• Pre-existing haematological disorder
	• History of chemotherapy, immunotherapy or radiotherapy treatment, smoking, benzene exposure

Examination	Full clinical examination with particular consideration for presence and source of infection, skin (*leukaemia cutis*, thrombocytopenia and Sweet syndrome), CNS involvement, testicular involvement, syndromic feature that would suggest germline predisposition
Blood tests	• Full blood count • Blood film (blast count from at least 200 leucocytes) • Biochemistry (creatinine, urea, sodium, potassium, calcium, phosphate, magnesium, alanine transferase, alkaline phosphatase, bilirubin, albumin, glucose, lactate dehydrogenase, uric acid and total cholesterol) • Clotting (PT, APTT ± INR) • Hepatitis A, B, C, HIV-1, EBV, CMV, VZV, HSV screen • *If potential allogeneic stem cell transplant candidate*: CMV IgG before first transfusion, HLA genotyping and donor search

(*Continued*)

Table 32.3 (*Continued*)

Other tests	• ECG • Chest Xray • Echocardiogram (especially if anthracycline therapy considered) • Pregnancy test (in females of childbearing age) • Biobanking • Lumbar puncture if clinical and/or radiological suspicion of CNS disease	
Bone marrow aspirate ± trephine biopsy,***		
Morphology	Blast count from at least 500 cells from bone marrow smear	
Immunophenotyping	Panel should be comprehensive enough to distinguish AML, B-ALL, T-ALL, early precursor T-ALL and acute leukaemias of ambiguous lineage.	
	Diagnosis of AML. Cell-surface and cytoplasmic markers	
	Precursors	CD34, CD117 and HLA-DR
	Myeloid markers	CD33, CD13 and cytoplasmic MPO
	Myeloid maturation markers	CD11b, CD15, CD65 and CD64,
	Monocytic markers	CD14, CD36, CD64, CD11c, CD4 and CD38
	Megakaryocytic markers	CD41 (glycoprotein IIb/IIIa), CD61 (glycoprotein IIIa) and CD36
	Erythroid markers	CD235a (glycophorin A), CD71 and CD36
	Diagnosis of MPAL	
	Myeloid lineage	MPO (flow cytometry, immunohistochemistry, or cytochemistry) or monocytic differentiation (at least 2 of the following: nonspecific esterase cytochemistry, CD11c, CD14, CD64 and lysozyme) or at least 2 myeloid markers
	T-lineage	Strong cytoplasmic CD3 (with antibodies to CD3 ε chain) or surface CD3
	B-lineage	Strong CD19 with at least 1 of the following strongly expressed: cytoplasmic CD79a, cCD22 or CD10 or weak CD19 with at least 2 of the following strongly expressed: CD79a, cCD22 or CD10
	Core MRD markers	
	CD34, CD117, CD45, CD33, CD13, CD56, CD7 and HLA-DR	
	If monocytic, additionally: CD64, CD11b and CD4	
Genetic tests	Cytogenetics	AML karyotype (at least 20 metaphases)
		FISH/PCR for *CBFB::MYH11* [inv(16)(p13.1q22)], *RUNX1::RUNX1T1* [(8;21)(q22;q22.1)], *BCR::ABL1* t(9;22)(q34.1;q11.2) and other available fusion genes. Specific FISH panels are available for paediatric AMLs.
		If suspicion of APML: FISH/PCR *PML::RARA* [t(15;17)(q24.1;q21.2)]
	Mutation screening***	Essential to identify targetable lesions (*FLT3::ITD*, *FLT3::TKD* hotspot, *IDH1* and *IDH2*) and necessary for diagnostic accuracy: *NPM1*, *CEBPA* (specifying whether in frame of bZIP or other mutation), *DDX41*, *TP53*, *ASXL1*, *BCOR*, *EZH2*, *RUNX1*, *SF3B1*, *SRSF2*, *STAG2*, *U2AF1* and *ZRSR2*
		Desirable to identify potential MRD targets or CH origin of the disease:
		ANKRD26, *BCORL1*, *BRAF*, *CBL*, *CSF3R*, *DNMT3A*, *ETV6*, *GATA2*, *JAK2*, *KIT*, *KRAS*, *NRAS*, *NF1*, *PHF6*, *PPM1D*, *PTPN11*, *RAD21*, *SETBP1*, *TET2* and *WT1*
	Whole genome sequencing	Tumour (bone marrow aspirate or peripheral blood with high blast count) AND
		germline (skin biopsy preferred; saliva or buccal swab acceptable if blasts cleared from PB)

CMV, cytomegalovirus; EBV, Epstein Barr virus; HSV, herpes simplex virus; MPAL, mixed phenotype acute leukaemia; MPO, myeloperoxidase; NGS, next generation sequencing; VAF, variant allele frequency; VZV, varicella zoster virus.

* Trephine biopsy compulsory if no aspirate obtained ('dry tap') – perform trephine roll or touch preparations on the slide. Tissue biopsy of extramedullary disease if no apparent bone marrow or peripheral blood involvement.

** Peripheral blood is accetable alernative if high blast count ($>2 \times 10^6$/mL) and aspirate not feasible.

*** NGS myeloid panels are becoming more mainstream and part of upfront investigations.

Table 32.4 2022 ELN AML risk stratification by genetics.

Risk category	Genetic abnormality
Favourable	t(8;21)(q22;q22.1)/*RUNX1::RUNX1T1* inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB::MYH11* Mutated *NPM1* without *FLT3::ITD* bZIP in-frame mutated *CEBPA*
Intermediate	Mutated *NPM1* with *FLT3::ITD* Wild-type *NPM1* with *FLT3::ITD* (without adverse-risk genetic lesions) t(9;11)(p21.3;q23.3)/*MLLT3::KMT2A* Cytogenetic and/or molecular abnormalities not classified as favourable or adverse
Adverse	t(6;9)(p23.3;q34.1)/*DEK::NUP214* t(v;11q23.3)/*KMT2A*-rearranged excluding *KMT2A* partial tandem duplication t(9;22)(q34.1;q11.2)/*BCR::ABL1* t(8;16)(p11.2;p13.3)/*KAT6A::CREBBP* inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2, MECOM(EVI1)* t(3q26.2;v)/*MECOM*(*EVI1*)-rearranged −5 or del(5q); −7; −17/abn(17p) Complex karyotype, monosomal karyotype Mutated *ASXL1, BCOR, EZH2, RUNX1, SF3B1, SRSF2, STAG2, U2AF1* and/or *ZRSR2* in the absence of favourable risk mutations Mutated *TP53*

(*Source:* Taken from Döhner *et al. Blood* 2022.)

is currently the most widely adopted system for pre-treatment AML prognostication. It classifies patients into favourable-, intermediate- and adverse- risk categories based on the underlying genetic abnormalities (Table 32.4). Notably, early classification of *NPM1*-mutated, *RUNX1::RUNX1T1*, *CBFB::MYH11 or KMT2A-rearranged AML* can be modified by MRD status during treatment. *NPM1*-mutated AML with adverse risk cytogenetic abnormalities reclassifies AML into adverse risk. Adverse risk cytogenetic abnormalities exclude multiple trisomies (or polysomies). Patients with *CBFB::MYH11* or *CEBPA* mutation(s) have very favourable prognosis with 5-year OS of around 70%. In contrast, *TP53* mutations are associated with dismal outcomes and in combination with complex karyotype constitutes the subtype of AML with the worst prognosis.

The impact of genetic factors on AML prognosis is combinatorial and may be modified by the co-occurrence of other genetic abnormalities (Figure 32.6). However, next generation sequencing (NGS) studies suggest that the ELN 2022 genetic prognostication framework, which largely considers only a single genetic alteration (with the exception of *FLT3* and *NPM1* co-mutation), is likely too simplistic, given that an average case of newly diagnosed AML has 3–5 acquired mutations. Current and future work are trying to develop better classification and prognostication systems that take into account not only the genetic combinatorial diversity of AML, but also evidence-based individually tailored prognostication and treatment decisions. These require large databases (*'knowledge banks'*) of thousands of patients that link disease genomics and clinical data. Utilisation of a knowledge bank approach has already been demonstrated to provide superior predictions of likelihood of remission, relapse and mortality at individual level, as compared with standard prognostication methods. International effort is underway to compile such systematised databases.

Although pre-treatment genetics provide powerful prognostic information, these are static and do not take into account subsequent variable such as treatment-response. It is likely that combination with dynamic measures, such as minimal residual disease (also known as measurable residual disease, both MRD) will further refine clinical decision-making tools to aid personalised and optimal therapy in AML.

Treatment

Treatment aspirations

The first decision in managing a patient with AML is to set individualised treatment goals. Given the wide distribution of patients across the spectrum of age and performance-status, these goals range from simple supportive care all the way to full curative intent. In addition, these goals might alter during treatment and need to be continuously reassessed, taking into account the patient's wishes at every stage. There is little doubt, based on the evidence from several multicentre trials, that in younger patients (<65 years) with no or little comorbidities an intensive therapy approach aiming to cure provides longer-term benefit. However, as only a selected minority of older patients (>65 years) have been historically entered into trials of intensive therapy, the trial-derived information regarding intensive therapy is less likely applicable in this age group. Moreover, given disease biology is often less favourable in elderly patients and the majority of older patients are considered unfit for intensive therapy because of comorbidities, a therapeutic approach that carries a reduced risk of toxicity, preserves quality of life while still providing a degree of disease control is preferable. Although historically this has often meant a palliative treatment approach, based on supportive care with limited low-intensity therapeutic options, the recent development of newer more targeted therapies has started to change life expectancy across all AML patients. Randomised phase 3 trial evidence of prolonged survival has recently been demonstrated in elderly AML patients, although chances of long-term cure still remain low.

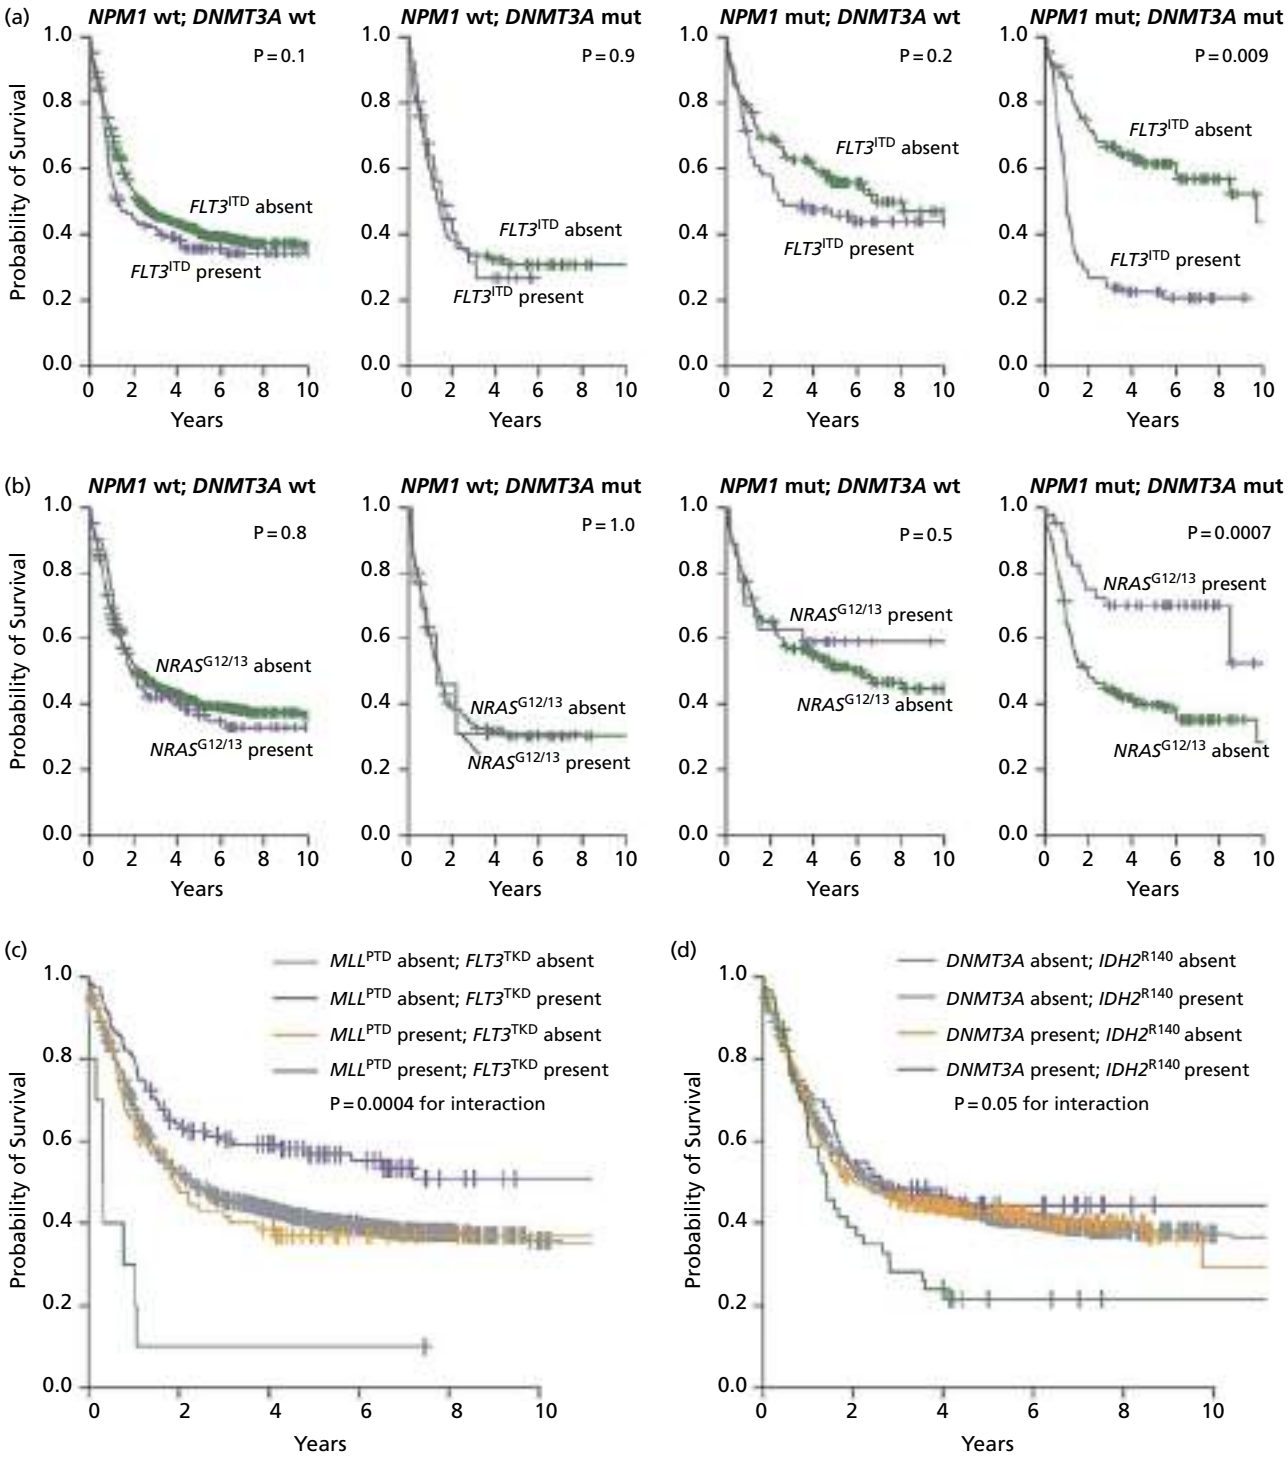

Figure 32.6 Examples of the influence of gene-gene interaction for AML prognosis. (a) *NPM1* and *FLT::ITD* mutated AML have significantly worse prognosis with co-mutated *DNMT3A* than with wild-type *DNMT3A*. (b) *NPM1* and *NRAS* mutated AML have significantly better prognosis with co-mutated *DNMT3A* than with wild-type *DNMT3A*. (c) Partial tandem duplication (PTD) of the MLL gene and *FLT3* tyrosine kinase co-mutation result in very poor prognosis compared to these aberrations occuring in isolation. (d) *DNMT3A* and $IDH2^{R140}$ co-mutation results in poorer prognosis compared to these aberrations occuring in isolation (Source: Taken from Papaemmanuil *et al. NEJM* 2016 https://www.nejm.org/doi/full/10.1056/nejmoa1516192.)

Treatment strategy

The first aim in AML therapy is to reduce disease bulk, aiming to classically achieve a complete (morphological) remission (CR) and thus allow the recovery of normal bone marrow function. Achieving CR approximately reduces tumour burden by 2 logs (from ~10^{12} to 10^{10} leukaemic cells) and is defined as the achievement of <5% blasts in a cellular marrow durable for at least 28 days with a peripheral neutrophil count of $\geq 1 \times 10^9$/L and platelet count above 100×10^9/L and absence of extramedullary disease. When CR is not associated with full peripheral count recovery, a CRi (CR with incomplete count recovery) is attained. CRi may reflect a pre-existent dysplastic state or the effect of over-treatment and has been shown to be associated with reduced OS. However, morphological assessment of remission has low sensitivity and is now routinely complemented by the use of more sensitive techniques to assess residual disease, such as flow cytometry and molecular monitoring of AML-associated mutations/chromosomal aberrations, which are respectively capable of detecting residual malignant cells at a level of 1 in 10^4 – 1 in 10^{6-7}. Although these techniques are not always applicable, evidence is now compelling that achievement of deeper response, i.e. MRD negative (MRD−), is associated with better long-term outcomes, suggesting achievement of a MRD− CR should be the optimal aim of induction therapy.

Following induction therapy, clinical experience has demonstrated that further consolidation therapy is required to reduce relapse risk. The choice of consolidation therapy to be used in an individual patient is guided by a variety of clinical and biological features and will likely vary between patients. This usually consists of one or more of several options such as further blocks of intensive therapy, stem cell transplantation or in some instances continuous maintenance therapy.

Induction

The choice of induction therapy depends on several factors, i.e. disease biology, patient's age, comorbidities and preferences. The recent approval of less toxic more targeted therapies has also expanded the options available, particularly for less fit patients. The option of entering patients into clinical trials should always be considered. These trials often also provide access to novel therapies in combination with standard approved drugs to improve CR ± MRD rates and trial entry has been shown to consistently result in better patient long-term OS.

Standard intensive chemotherapy (IC)

The standard backbone of induction therapy for young, fit AML patients has not really changed across the last 40 years and consists of a combination of daunorubicin and cytarabine (DA). Historically daunorubicin has been given for 3 days at a dose of 45–60 mg/m^2, with Cytarabine (Ara-C) given for 7–10 days as a continuous infusion or by bolus doses of 100–200 mg/m^2 daily ('7 + 3'). Many clinical trials have been conducted to test variations on this standard of care. Other anthracycline alternatives to daunorubicin (doxorubicin, mitoxantrone, idarubicin and aclarubicin) or different doses are yet to demonstrate consistent superiority. Particularly, recent studies have explored the role of intensification of the daunorubicin dose to 90 mg/m^2, but no obvious superiority has been shown. Similarly, higher doses of Cytarabine have also failed to demonstrate a consistent benefit. Regarding optimal delivery of these two drugs, CPX-351 (Vyxeos) has shown promising results in AML subgroups as will be discussed later. An alternative induction regimen is the FLAG-Ida combination (fludarabine/Ara-C/G-CSF and idarubicin). This increased intensity regimen results in reduced relapse rates, but generally at the expense of increased and more prolonged myelosuppression.

Using the treatment approaches outlined above, 75–85% of patients under 60 years and 50–60% of older patients will enter morphological CR. Of those that do, about 70% will have required one course to achieve CR. If an incomplete response is obtained, then a second course of the same combination is indicated. If patients fail to achieve a substantial reduction in marrow blasts (to <15% blasts) in the first course or fail to enter CR with a second course, they should be considered refractory to the drugs used up to that point and alternative treatment options, ideally a clinical trial of agents working through different mechanisms, should be considered. Nevertheless, these patients have an overall higher risk of rapid relapse and would immediately be candidates for allogeneic stem cell transplant (SCT) at consolidation. Assessment of MRD status post-induction has recently emerged as an important adjunct to define depth of response and remission status with important implications for the choice of consolidation therapy.

Several factors influence the prospects of achieving remission – with age, performance status and poor-risk disease being perhaps the strongest. However, as performance status and poor-risk disease are significantly linked with age, it is difficult to fully separate out these variables. Conceptual criteria proposed by an Italian panel of experts (Ferrara fitness criteria) have been shown to accurately predict fitness for intensive chemotherapy. Treatment-related mortality (TRM) rates rise from <5% to around 15% in Ferrara fit and unfit patients respectively, with a subsequent effect on long-term OS of patients. Improvement in supportive care and the introduction of less intensive but still effective therapy might reduce the incidence of TRM which remains an inevitable but highly unsatisfactory outcome of induction therapy for a proportion of patients.

The increased understanding of AML molecular features and biology has led to the development of novel therapies such as small inhibitors targeting activating *FLT3*-mutations and neomorphic *IDH*-mutations (see later sections), therapies targeting

the antiapoptotic machinery of AML cells (BCL2 inhibitors) or antibody-drug conjugates targeting antigen expressed specifically on AML blasts such as CD33. Some of these have now been studied as an adjunct to standard daunorubicin/cytarabine IC schedules or as backbone for alternative induction therapy, mostly with positive results and have become standard of therapy in specific subgroup of patients.

Midostaurin and FLT3 inhibition

Midostaurin, an oral multitargeted tyrosine kinase inhibitor active in patients with activating *FLT3*-mutations (both TKD and ITD), has been studied as an adjunct to standard 7+3 induction in adults with *FLT3* mutations aged <60. In the multicentre RATIFY Trial, Midostaurin was added at a dose of 50 mg twice daily from day 8 to 21 during induction and 'consolidation' and then alone as 'maintenance' at the same dose for 1 year. Although CR rates were similar in the midostaurin and placebo groups, survival was longer with midostaurin, largely reflecting a lower relapse rate. The effects were seen regardless of ITD allelic ratio or type of *FLT3* mutation (ITD or a TKD). There was no difference in proportions of patients progressing to stem cell transplant between the two arms and Midostaurin superiority was also significant after censoring at time of transplant. Survival was superior with Midostaurin if SCT was performed in first complete remission (CR1) but not later suggesting that the beneficial effect of Midostaurin is lost following frank relapse. Overall, these data suggest that addition of Midostaurin is able to reduce relapse risk and improve survival in *FLT3*-mutant AML patient most likely through achieving deeper responses regardless of subsequent consolidation. Based on these data, the addition of Midostaurin to standard induction is now considered standard therapy for adults aged <60 with newly diagnosed AML and *FLT3* mutations and subsequent phase 2 trials suggest that similar benefit is seen also in patients >60 years old who are able to tolerate standard induction therapy. Recently more potent and specific FLT3 TKI such as Gilteritinib, Crenolanib and Quizartinib have entered clinical use with evidence of significant efficacy in the relapsed/refractory setting. These are now currently being combined with chemotherapy and compared to chemotherapy and Midostaurin, with results awaited.

Gemtuzumab ozogamicin

CD33 is a cell surface antigen commonly expressed on AML cells, and normal myeloid progenitors, including stem cells. Gemtuzumab ozogamicin (GO) is an antibody-drug conjugate (ADC) to CD33 conjugated with the toxin calicheamicin. GO (Mylotarg®; Pfizer) alone has shown high efficacy against acute promyelocytic leukaemia (APML) presumably because of the heavy expression of CD33 in APML. However, as a single agent, it is not particularly effective against other subtypes of AML. There has therefore been much interest in adding GO to induction treatment. Similar to Midostaurin, GO does not appear to improve CR rates, but reduces the risk of relapse and thereby improves survival in specific patient subgroups. A recent patient-based meta-analysis of the five randomised trials in adults where GO was added to induction confirms the overall reduction in relapse and the survival benefit specifically in non-adverse-risk patients. Interestingly, there does not appear to be a clear correlation between CD33 expression levels in AML and sensitivity to GO. Therefore, GO therapy is not assigned on the basis of CD33 expression levels. Based on these data currently GO is licensed for use in CD33 positive AML with favourable- or intermediate-risk profile and has become standard of therapy for this patient group. However, despite its efficacy in APML it remains unlicensed in this setting.

CPX-351 (Vyxeos)

CPX-351 (Vyxeos®; Jazz Pharmaceuticals, Inc.) is a liposomal encapsulation of cytarabine and daunorubicin at a fixed 5:1 synergistic molar ratio demonstrated to be optimal for anti-leukaemic activity. A recent Phase 3 trial in patients aged 60–75 and fit for intensive therapy, with either therapy-related, secondary AML or AML with MDS-like cytogenetic abnormalities demonstrated higher CR rates with CPX-351 compared to standard induction, which translated into improved long-term survival rates (5-year survival 18% in CPX-351 vs 8% in 7 + 3 group). Interestingly, Vyxeos was also better tolerated, with reduced early mortality rates. A higher proportion of patients proceeded to SCT after CPX-351 therapy, with these patients showing the largest benefit. Benefits were seen in some patients from high-risk groups such as those harbouring *RUNX1* and *ASXL1* mutations, however, other covariates such as poorer performance status, previous hypomethylating agents and adverse cytogenetics, particularly *TP53* mutations were associated with poorer rates of CR and survival with no obvious benefit from CPX-351. Based on the overall evidence from this phase 3 trial, CPX-351 is now approved for patients with therapy-related AML (t-AML) or AML with MDS-related changes regardless of age.

Induction therapy in the unfit patient – Venetoclax and hypomethylating agents (HMA)/LDAC

Previously, low-dose cytarabine (LDAC) at 20 mg/m^2 for 10 days every 28 days and HMA (Azacitidine and Decitabine given for 5–10 days every 4 weeks) have been the main therapies used in

patients unfit for intensive chemotherapy. HMA have shown superior efficacy compared to LDAC in terms of CR rates and durability of response, with Azacitidine providing a survival advantage compared to conventional care regimens (standard chemotherapy, LDAC or best supportive care) in elderly, >65 years old, AML patients in the AML001 trial. The recent development of Venetoclax, an oral inhibitor of the anti-apoptotic protein BCL-2, has further changed the treatment algorithms in this patient population. BCL-2, the founding member of the BCL-2 family of anti-apoptotic proteins, appears to be highly expressed in many AML subtypes and promotes AML cells survival and resistance to therapy. Although as a single agent Venetoclax appears to have limited efficacy, its combination with either HMA or LDAC is synergistic in eliminating AML cells. Two large phase 3 trials in AML across all age groups considered unfit for standard induction therapy, the VIALE-A and VIALE-C trial, have recently reported the efficacy of respectively, Venetoclax and Azacitdine and Venetoclax and LDAC, compared to single agent HMA or LDAC therapy. In both trials, the Venetoclax combinations provided higher CR rates and deeper responses which resulted in significant improvement in OS, most notable in the Venetoclax and Azacitidine arm. Interestingly Venetoclax combinations appeared to be particularly effective in specific subtypes of AML, i.e. those carrying *NPM1c* and *IDH* mutations, where MRD-negative remission have often been observed. Additionally, a plateau in survival curves could be observed at around 30–40% in the Venetoclax and Azacitidine (Ven/Aza) combination arm, although longer follow-up will be needed to draw definite conclusions. Similar to that is observed in patients treated with IC (see below), achievement of flow MRD negativity at any time-point following Ven/Aza is associated with improved OS of 84.6% at 18 months. In addition, this combination experimentally targets leukaemia stem cells (LSC), possibly through inhibition of their specific dependency on oxidative phosphorylative metabolism. Resistance to Venetoclax has been described in patients with mutations in signalling kinases/pathways such as *FLT3* and *RAS*, and durable responses are low in patients with *TP53*-mutations, despite their initial sensitivity, where they have a CR rate of over 50%. Although Ven/Aza is generally associated with lower TRM than standard intensive chemotherapy, Ven/Aza combinations are not without toxicity, in particular prolonged cytopenias. As such, these combinations are better defined as 'intermediate' rather than 'low' intensity and might not always be tolerable for the frailest patients. Moreover, they are currently offered as continuous therapy with attendant financial and compliance implications, although in reality, only a minority of patients are able to continue on therapy beyond 12 months. An MRD-directed treatment de-escalation has been suggested as possible in specific cases carrying sensitive genotypes following at least 12 cycles of therapy but will require further studies to be fully supported in routine clinical practice. Whether such combination could provide similar or even improved disease control in the more sensitive subtypes of AML compared to standard IC is currently being addressed in clinical trials including in the UK in *NPM1c* mutant AML through the VICTOR study. Finally, the addition of other novel therapies such as FLT3 inhibitors to the Ven/Aza backbone is currently being trialled in early-phase trials with very positive response rates although at the expense of increased toxicity. Moreover, a recent phase 3 trial of the FLT3 inhibitor Gilteritinib in combination with Azacitidine versus Azacitidine on its own failed to show improved survival rates, despite increased responses in newly diagnosed FLT3 mutant AML patients unfit for IC. As a result, Venetoclax/HMA remains the standard of care for all AML patients unfit for IC currently.

Consolidation therapy

Following the achievement of remission, the priority in AML patients is to prevent subsequent relapse. While optimisation of induction treatment will also affect depth of remission and subsequent risk of relapse, historical experience has shown us that patients require consolidation therapy for full curative intent. The options for consolidation therapy are either further chemotherapy at a similar intensity level to induction therapy and/or chemo/chemoradiotherapy followed by allogeneic SCT or rarely, in selected cases, autologous SCT. More recently, maintenance therapy has also started to be used in specific group of patients. The choice of consolidation therapy is arguably the most important one in the therapeutic journey of AML patients. It has to balance the risk of relapse against the TRM and cumulative morbidity associated with further chemotherapy and transplantation. Historically, prognostic features at diagnosis have been used to estimate relapse risk in individual patients; however, more recently response to therapy via MRD monitoring has been shown to be the best predictor of outcome in many instances, and currently a combination of both prognostic markers at diagnosis and MRD assessment at informative time points is used to guide decisions alongside patient-specific factors. Although this represents a first significant step towards precision medicine in AML, considerable inter-patient heterogeneity in driver mutations and depth of response still renders evidence-based personalisation of care challenging. In addition, current ELN criteria are mostly relevant to the selection of postremission therapies for younger, fit and transplant-eligible patients with *de novo* AML treated with conventional cytarabine/anthracycline-based induction. They have less relevance for elderly patients as they do not take relevant clinical features into account, nor do they capture clinical/biological predictor of response to novel therapies such as venetoclax. As a result, they fail to properly categorise many adverse-risk patients. Several efforts recently have been made to leverage 'big data' from thousands of AML patients to study how large

knowledge banks of matched genomic–clinical data can help clinical decision-making, with large international efforts such as the HARMONY consortium aiming to capture the entire heterogeneity of AML through studies involving >10,000 patients. Such studies would be very welcome clinical decision support tools to inform individualised patient treatment choices.

MRD risk-adapted therapy

A key feature of risk stratification that has recently been clearly established is the assessment of individual patient response using highly sensitive techniques to measure MRD. MRD assessment is now becoming standard-of-care to guide risk-adapted consolidation therapy with the dual aims of a reduction in toxicity and an optimisation of response. Multiple studies have shown significant correlation between MRD quantified by molecular techniques (RT-qPCR and NGS) or multiparameter flow cytometry (MFC) and outcome. MRD assessment provides further refinement to risk prediction and can be applied to several aspects of the post-remission decision-making process: (i) assessment of the quality of response to improve risk stratification and enhance postconsolidation choice (e.g. SCT versus no-SCT); (ii) post-treatment serial monitoring to anticipate overt relapse and plan pre-emptive therapy; (iii) pre-SCT assessment and post-transplant surveillance monitoring to assess the risk of relapse, inform immunosuppression and the utilisation of donor lymphocyte infusions; and (iv) identification of markers to track treatment response in the context of targeted-therapy approaches.

MRD Modality – Molecular and flow cytometry are the most frequently used modalities to monitor MRD; however, NGS is also being increasingly adopted. Molecular testing by RT-qPCR provides a robust, highly sensitive (generally 1 AML cell in 10^{6-7} normal cells in BM and one log less in peripheral blood) and standardised assay. It can, however, only be used in around 50% of cases that have an informative leukaemia-specific genetic marker (i.e. fusion gene, *NPM1* mutation, etc.) amenable to MRD detection. Flow cytometry MRD is based on the identification at diagnosis of leukaemia-associated aberrant immunophenotypes (LAIPs). These can be described in the majority, around 90%, of cases at diagnosis. These LAIPs are characterised by expression of antigens not normally seen in combination on normal haemopoietic cells; either aberrant antigen expression or co-expression of antigens normally associated with different stages of maturation or absence of specific antigens expression. The greatest advantage of flow-cytometry-based MRD monitoring is its applicability to the vast majority of AML cases, although sensitivity tends to fall below molecular monitoring at 1 in 10^4 or 1 in 10^5 cells. Standardisation also remains an issue with flow MRD, although this is likely to improve over the coming years. NGS can, theoretically, be applied to all leukaemia-specific genetic aberrations. However, not all genes are suitable for MRD detection, either because they may be lost at relapse (eg, *FLT3*) or because they are associated with age-related clonal haematopoiesis and may represent pre-leukaemic clones rather than true MRD (*DNMT3A, TET2, ASXL1*). Standardisation of NGS MRD assessment is also required to support its widespread clinical use and currently, it remains mostly used within clinical studies.

MRD assessment can be performed at different time points, i.e. after induction and achievement of CR or after completion of consolidation therapy and subsequently to monitor for molecular relapse. The best timepoint depends on the risk profile of specific AML patients and often sequential MRD assessment at different times, focusing on an increase or decrease rather than a single result, is necessary before actioning therapeutic changes. Despite these caveats, MRD positivity after induction has been clearly demonstrated to carry a high positive predictive value for subsequent morphologic relapse, regardless of pre-treatment risk group allocation. For intermediate-risk AML, where individual patient risk profile can be quite variable, MRD has been clearly shown to separate patients into two groups with very different OS long-term. MRD positivity using RT-qPCR for *NPM1c* mutations in patients with intermediate-risk AML in CR after two courses of induction treated within UK NCRI AML trials have been shown to be highly predictive for subsequent relapse risk, with a 86% cumulative incidence of relapse vs 34% for MRD negative patients (Figure 32.7). Multivariate analysis indicated persistent *NPM1c* positivity in blood was the only predictor of relapse regardless of *FLT3* mutation status.

Similarly, for patients without *NPM1c* mutations, MFC MRD after course 2 was able to dichotomise a low- and high-risk group, although the separation was less marked (cumulative incidence of relapse was 89% for MRD >0.1%, 58% for MRD positive <0.1 and 50% for MRD negative). Based on these data, there is now wide support in the clinical community to change therapeutic approaches in patients with intermediate-risk AML at diagnosis and MRD positivity after induction and consider allogeneic transplantation in first remission where possible. In favourable-risk AML such as core-binding factor mutants, MRD positivity after induction is also associated with increased relapse risk, often up to 50%, although given their continued chemosensitivity and the risk-benefit ratio, this patient group is usually not considered for SCT in CR1. MRD positivity before allogeneic transplant has also been associated with worse outcome; however, there is some evidence that achieving rapid donor chimerism, possibly through modulation of transplant conditioning and/or immunosuppression, might abrogate the adverse impact of pre-transplant MRD. Finally, although it is conceivable that MRD negative response correlates with deeper

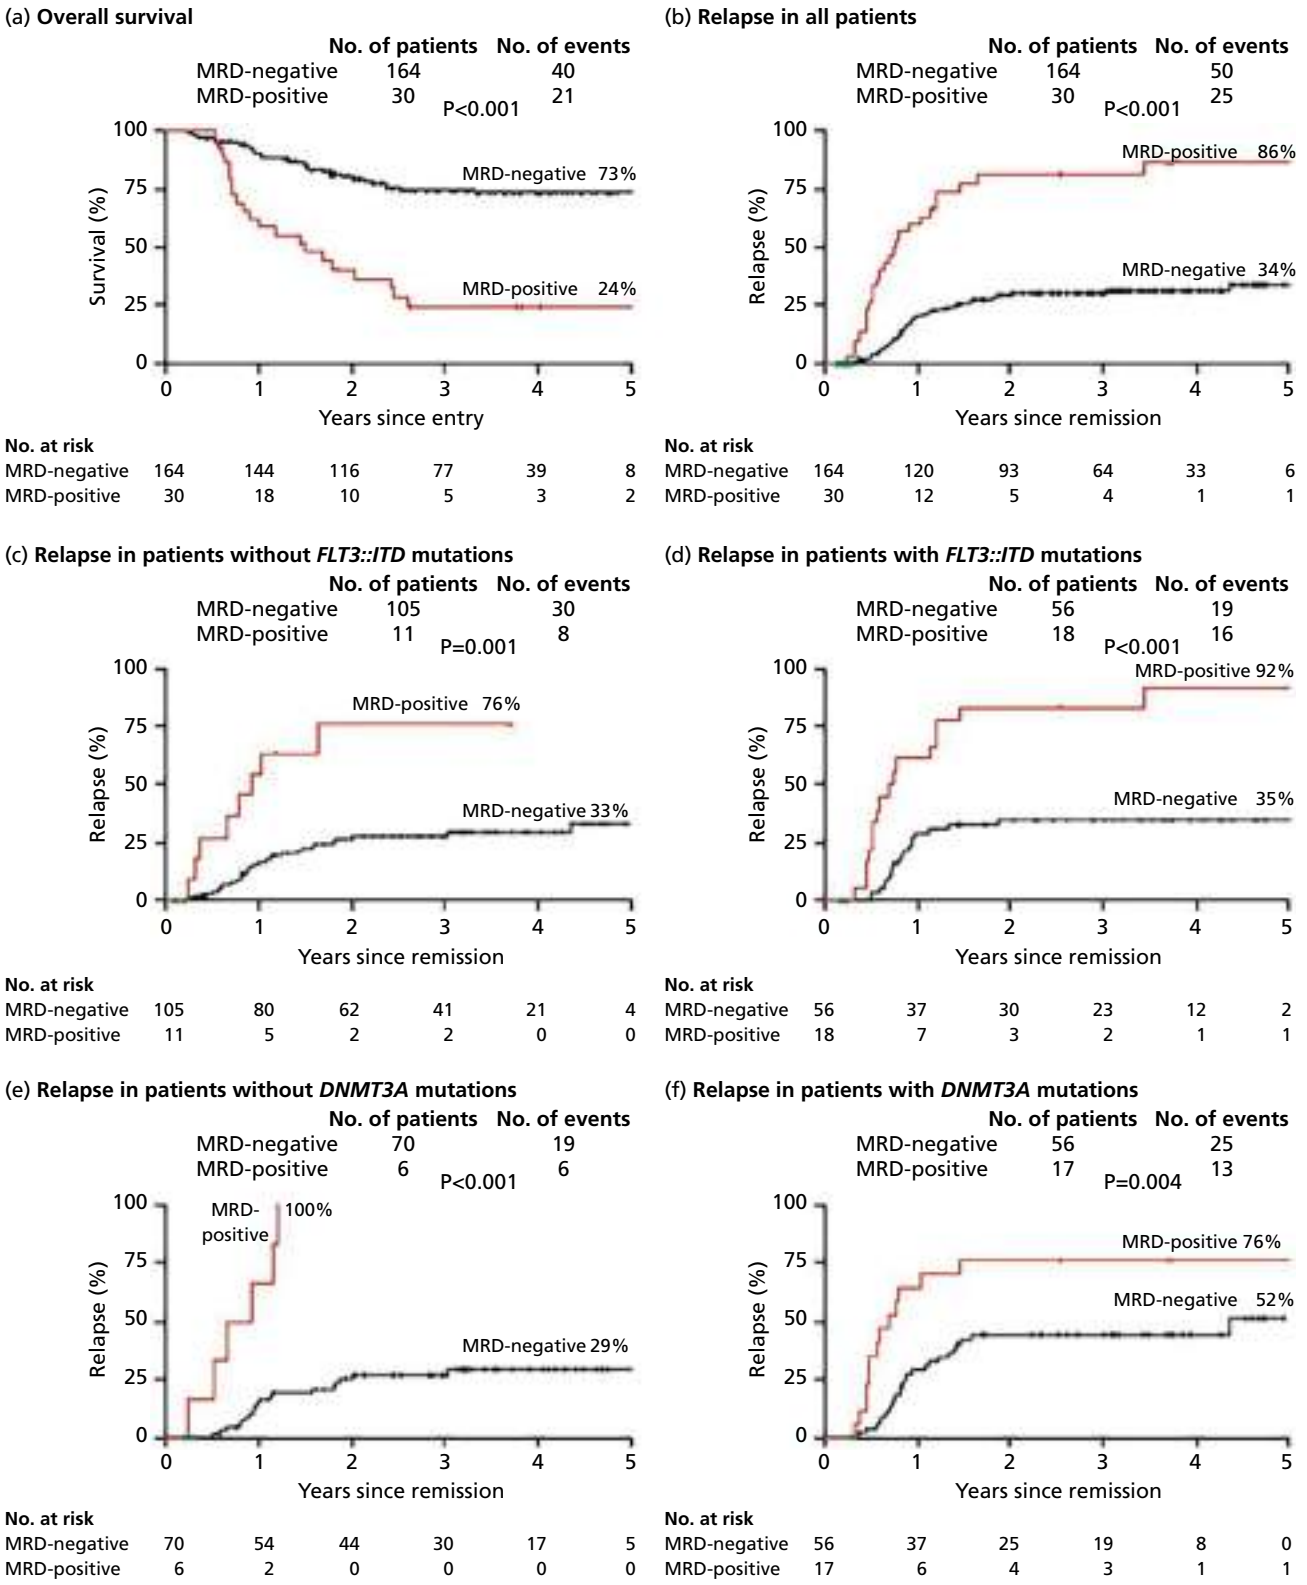

Figure 32.7 Utility of MRD analysis in NPM1-mutated AML patients. Panels (a) and (b) demonstrate the predictive role of MRD-positivity in defining patient survival (a) and risk of relapse (b). How these risks are further modified by co-mutation with *FLT3::ITD* and *DNMT3A* are shown in panels (c) and (d) and (e) and (f) respectively (Source: Reproduced from Dillon *et al.* Blood 2020/American Society of Haematology.)

remissions and better patient outcomes regardless of therapy used, it is noticeable that the prognostic value of MRD monitoring has been mostly studied in patients treated with intensive standard induction chemotherapy and therefore our ability to extrapolate these findings onto patients treated with different approaches, such as novel intermediate intensity therapy will require further validation.

Consolidation treatment – chemotherapy

Optimal consolidation therapy should be an individualised decision based on patient-specific risk profiles, including response to therapy at the morphological and MRD level. The options available are further chemotherapy at the same level of intensity of induction or chemo/radiotherapy followed by allogeneic SCT, or in a small number of cases, autologous SCT. More recently, maintenance therapy has also been shown to be beneficial in specific settings following both standard consolidation chemotherapy or transplant.

Chemotherapy will usually involve a further one or two courses containing high-dose Ara-C (generally 3 g/m^2 twice daily on alternate days over 5 days). Higher doses of cytarabine appear particularly beneficial for patients with more sensitive disease, such as those with favourable cytogenetics. UK NCRI trials have also shown that reducing the Ara-C dose to 1.5 g/m^2 might be as effective, with a more favourable toxicity profile, and currently, most centres will use this dose routinely in patients >60. More recently, the NCRI group has also assessed whether reducing consolidation to 1 single course following two induction courses is possible without prejudicing outcome. Although there was no significant survival advantage by giving two consolidation courses of high-dose Ara-C, 5-year relapse rates were significantly lower following two courses of consolidation (58 versus 50%). Moreover, subset analysis showed that patient with more favourable and chemosensitive disease might especially derive survival benefit from two consolidation courses. Based on this and given the use of MRD to adapt therapy in less chemosensitive patients, it seems appropriate to use two courses of consolidation as standard consolidation in patients showing deep response to standard chemotherapy, unless this course of action is countered by concerns regarding toxicity.

Stem cell transplantation

The availability and safety of allogeneic SCT options have hugely increased with use of alternative donors, improved tissue-typing and volunteer unrelated donor availability and improvement in conditioning regimens (details covered in Chapter 37). Therefore, for the majority of young patients where curative intent is desired, SCT should be an option. However, while there is little doubt that allogeneic SCT is the most effective treatment modality to prevent leukaemic relapse in fit patients, the reduced risk of relapse gained with transplant has always to be balanced relative to SCT increased toxicity and risk of non-relapse mortality (NRM)/morbidity and to the likelihood of achieving remission with chemotherapy alone. Assessing this balance is currently difficult. Proper randomised trials to quantitate the relative benefit are generally lacking and trials that do involve transplant may be influenced by subjective selection biases regarding how truly comparable the comparator groups are. Moreover, many other variables such as the type of conditioning used, mutational profile and biology of disease and MRD status before transplant are also likely confounding factors. Many studies suggest that, in intermediate/adverse risk AML, relapse risk is on average reduced from ~45–50–~20–25% with transplant. However, partially offsetting this reduced risk, there is an increase in NRM and the possibility of graft versus host disease (GVHD) which is highly variable depending on patient fitness, donor source (blood versus bone marrow) and degree of match (fully versus partially matched), conditioning regimen and other factors such as CMV status, donor sex etc. This NRM risk is generally ~20% although higher levels might be acceptable if the relapse risk is particularly high. Based on these data, it is generally felt that proceeding with SCT in CR1 for favourable risk AML patients is not indicated, given their relapse risk is generally <40% with standard consolidation chemotherapy and they can generally be salvaged at relapse and offered a SCT in second CR (CR2). Conversely, in adverse risk disease, where relapse risk is generally >60%, but can be as high as 90% if MRD positive, the risk-benefit ratio in fit patients is generally in favour of proceeding with allogeneic SCT in most instances, even when NRM is >20%. AML patients within the intermediate-risk group represent the most difficult group to risk assess; however, recent evidence has demonstrated that MRD monitoring can provide objective guidance to risk-adapt for SCT therapy in this group, dependent on its presence or absence. Overall the expectation of cure for recipients of SCT is around 60% from the time of transplantation in intermediate/adverse risk AML patients although again this is modulated by several of the factors mentioned above. Although allogeneic SCT is the preferred option due to its additional graft versus leukaemia (GvL) effect, autologous SCT has been used for those patients lacking a donor and for consolidation in intermediate-risk disease with MRD negative CR, with equivalent OS to allogenic SCT, with the increased relapse rate balanced by the reduction in NRM to about 5–10%.

Maintenance therapy

AML therapy has historically consisted of blocks of chemotherapy with or without SCT consolidation followed by monitoring for relapse. This reflects the cumulative toxicity of standard chemotherapy and that, unlike other haematological

malignancies, evidence supporting the benefit of maintenance chemotherapy was lacking. The recent development of novel therapies such as FLT3 inhibitors or HMA, including oral preparations, may alter this paradigm given that these therapies have demonstrated efficacy as single agents, particularly in low disease bulk, and are less toxic than standard chemotherapy. The phase 3 QUAZAR study has recently reported that an oral formulation of azacitidine (CC-486, Onureg®), given as maintenance therapy in patients with intermediate- or high-risk AML >55 years in first remission after IC and not candidates for SCT improved median OS compared to placebo by 10 months with good quality of life, with this difference being maintained at last follow-up. Moreover, in a recent post-hoc analysis, Onureg improved survival independently of *NPM1* and *FLT3* mutational status at diagnosis and MRD status following IC, thus suggesting that its benefits are likely applicable to most AML subgroups. This treatment has now been approved by the FDA and EMA. FLT3 inhibitors have also been used as maintenance therapy based on their efficacy and relatively low toxicity. In the RATIFY trial patients in CR who did not proceed to SCT were given Midostaurin maintenance for 12 4-weeks cycles. This treatment was well tolerated but an unplanned post-hoc subset analysis was inconclusive with regards to the value of maintenance therapy. Nevertheless, Midostaurin maintenance is currently approved in patients not proceeding to SCT and routinely used in this setting. Post-SCT maintenance is also currently being investigated using similar approaches. So far, small studies in the post-transplant setting have failed to show convincing evidence of benefit from maintenance strategy using Azacitidine or Midostaurin, although the multikinase inhibitor Sorafenib was shown to reduce relapse risk in randomised trials post SCT in *FLT3*^{ITD} mutant patients. More recently however the randomised, double-blind MORPHO study has failed to show significant benefit in terms of relapse free survival for the more potent FLT3 inhibitor gilteritinib post SCT. However subgroup analysis of patients who had detectable MRD pre- or post-SCT showed benefit from gilteritinib maintenance. It does therefore appear that the benefit of maintenance therapy post-transplant is limited to specific subgroups, such as those with detectable MRD, and will likely be the subject of future studies.

Acute promyelocytic leukaemia

APML represents a special case, as the presence of the t(15;17)/*PML::RARA* translocation predicts sensitivity to treatment with all-*trans* retinoic acid (ATRA) and arsenic trioxide (ATO). APML is also particularly sensitive to anthracyclines and more recently has been shown to be highly sensitive to GO. The combination of ATRA and idarubicin is expected to provide survival rates in excess of 80%. Although maintenance therapy with courses of ATRA and orally available agents such as methotrexate and 6-mercaptopurine has been shown to provide additional benefit in some studies, the role of maintenance, particularly in patients who are molecularly negative after consolidation (currently >95% of cases) is in doubt. Moreover, a pivotal study from the Italian AML study group (GIMEMA) and the German–Austrian Acute Myeloid Leukaemia Study Group and Study Alliance Leukaemia in low- and intermediate-risk APML patients, i.e. those with presenting white cell count $<10\times10^9$/L, has demonstrated that the combination of ATRA and ATO alone can produce very impressive survival rates of over 95%. This has been confirmed in a similar UK NCRI trial which used less frequent arsenic dosing and included high-risk patients. These two trials have further changed the landscape of APML treatment and currently, the standard of care, at least for the 75% of low-risk patients, is a 'chemotherapy-free' combination of arsenic trioxide and ATRA. This will become even more attractive once oral formulations of arsenic become routinely available. One caveat with the 'chemotherapy-free' approach is the increased risk of differentiation syndrome, which is normally reduced by the inclusion of chemotherapy in regimens. This syndrome is accurately characterised by the presence of unexplained fever, weight gain, respiratory distress, interstitial pulmonary infiltrates, and pleural or pericardial effusion, with or without hyperleucocytosis. No single sign or symptom itself may be considered diagnostic of the syndrome, but at the signs of the earliest manifestations of suspected differentiation syndrome (e.g. unexplained respiratory distress), anti-leukaemic therapy should be interrupted and treatment with dexamethasone 10 mg i.v. 12-hourly should be initiated and continued until disappearance of symptoms and signs, and for a minimum of 3 days, given the fulminant nature of differentiation syndrome if left to progress. Although the chemotherapy-free approach is still not routinely used in high-risk patients (defined as those with presenting white counts $>10\times10^9$/L), it is however feasible if combined with a brief exposure to Gemtuzumab ozogamicin or idarubicin to reduce the risk of differentiation syndrome.

Previously, molecular monitoring in APML by RT-qPCR has provided a paradigm for molecular MRD monitoring in other AML subtypes. While the majority of patients (~95%) achieve molecular remission, approximately 10–25% will ultimately relapse following ATRA and anthracycline-based protocols. The majority of relapses can be predicted by re-emergence of *PML-RARA* transcripts detected in sequential bone marrow MRD monitoring samples, which are usually performed 3-monthly. However, as treatment protocols for APML have steadily improved, current consensus is that in patients with low-risk disease with rapid achievement of molecular remission, there is little benefit in post-therapy MRD monitoring. In high-risk patients, however, sequential MRD monitoring until 3 years post-treatment is recommended, due to the up to 25% risk of relapse and the ability of a rising MRD level to identify

impending overt relapse. This strategy therefore allows the institution of treatment intervention at the time of low disease bulk with the attendant reduced risk of bleeding and other complications compared to salvage at frank relapse.

Novel agents

Improved understanding of the molecular drivers and biology of AML has led to the development of multiple novel therapies. Most of these are currently in use in early phase trials for relapsed/refractory AML patient, although the most promising are now being also tested, often in combination with standard therapies, in untreated patients in phase 3 trials with the aim to improve outcomes in the diagnostic setting.

Epigenetic therapies

Aberrant transcription is a cardinal feature of AML and mutations that alter epigenetic regulators and transcription factors are highly recurrent in AML. Numerous epigenetic therapies have been developed and are currently being tested in AML. Amongst those more advanced in clinical development are the IDH1/2 inhibitors. IDH1/2 are metabolic enzymes recurrently mutated in 10–20% of AML patients. *IDH* mutations are gain-of-function mutations generating the 'oncometabolite' 2-hydroxyglutarate (2-HG), which inhibits multiple dioxygenase enzymes, including TET, Jumonji-C histone lysine demethylases and prolyl hydroxylase enzymes, resulting in increased DNA and histone methylation and aberrant transcription causing differentiation arrest. Inhibitors specific for the mutant proteins have been developed, which lead to a significant decrease in 2-HG levels and reverse the differentiation block in leukaemic blasts. Inhibitors of both IDH1 (Ivosidenib, Tibsovo™) and IDH2 (Enasidenib, Idhifa™) are now FDA-approved based on early phase trials results where they demonstrated relatively high remission rates in relapsed/refractory (R/R) *IDH*-mutant patients. Both inhibitors demonstrated good tolerability, although a specific side effect is the IDH-inhibitor-associated differentiation syndrome; similar in its clinical presentation to differentiation syndrome in APML following ATRA therapy and managed with corticosteroids and drug interruption. However, preliminary reports from a phase III study comparing Enasidenib to conventional care in R/R AML patients have failed to show a survival benefit (IDHENTIFY NCT02577406). Interest has now therefore shifted towards incorporating these inhibitors in combination therapies, the most advanced of which takes advantage of preclinical synergism between IDH inhibition and Azacitidine. Recently the AGILE trial, comparing the combination of Ivosidenib and Azacitidine versus Azacitidine alone in newly diagnosed *IDH1*-mutant AML patient unfit for IC has reported improved survival for the combination treatment (median overall 24.0 months with Ivosidenib and Azacitidine and 7.9 months with placebo and Azacitidine), leading to its FDA approval in this setting. However, this study has attracted some criticism as only two patients in the Azacitidine arm went on to receive Ivosidenib at relapse despite the latter being approved in the relapsed setting. Whether a sequential approach might be more tolerable in patients unfit for IC, who are often treated without curative intent, without jeopardising their survival rates remains to be proven. Interestingly with regards to this, the randomised phase 2 trial comparing Enasidenib plus Azacitidine versus Azacitidine alone in patients with newly diagnosed, mutant-*IDH2* AML has failed to show an improvement in survival, despite higher rates of response in the combination arm. This was due to the use of subsequent AML therapy in most patients randomly assigned to Azacitidine therapy, including Enasidenib in about a third of the patients. Finally, neither of the above trials used the Venetoclax/Azacitidine regime as a comparator, despite this being the current standard of care in this patient group. Given the evidence that *IDH*-mutant AML is particularly sensitive to Venetoclax/Azacitidine combinations, these trials have failed to clarify what is the best upfront therapy in *IDH*-mutant AML patients unfit for IC. Interestingly, given *IDH*-mutant AML sensitivity to Venetoclax-based therapies, early phase studies combining Venetoclax with either Enasidenib or Ivosidenib are currently ongoing, and it will be worth further considering if concomitant or sequential treatment with IDH inhibitors, Venetoclax and Azacitidine might further improve patient outcomes.

MLL-mutant AML has also been extensively studied as a subtype sensitive to epigenetic therapies. Amongst many partner proteins MLL-fusions requires the Menin co-factor to bind at critical genes and the DOT1L methyltransferase activation of these genes. DOT1L inhibition reduces the expression of critical MLL-fusion protein target genes, including the *HOXA* cluster and *MEIS1*, causing reduced proliferation and survival of AML cells, while its role in adult haematopoiesis is less critical thus providing a therapeutic window. Pinometostat (EPZ-5676) is the most clinically-advanced DOT1L inhibitor and has so far shown good tolerability with some remissions observed in early-phase trials in both paediatric and adult settings. Currently, combination trials with both hypomethylating agents and standard cytotoxic chemotherapy are underway. The main limitation of Pinometostat is its poor pharmacokinetics, requiring continuous infusion of up to 28 days. Novel orally available DOT1L inhibitors with improved pharmacokinetics are currently being developed.

The adaptor protein Menin binds to both the N-terminus of wild-type MLL and MLL-fusion proteins and is required for aberrant gene expression. Preliminary data from the ongoing trial of KO-539 (KOMET-001 NCT04067336), which acts by

disrupting the Menin-MLL interaction, has shown evidence of remarkable efficacy, even at low doses, in R/R disease regardless of mutational profile. In addition, a recently reported trial of the compound SNDX-5613 (Revumenib) in the relapse refractory setting for predominantly MLL1/KMT2A-r or NPM1c- mutated AML (AUGMENT-101 NCT04065399), has documented an excellent 53% combined response rate, with an overall CR/CRh rate of 30%.

Therapies targeting specific transcription factors

TP53 is a transcription factor with multiple roles in regulating cell cycle, apoptosis, DNA repair and metabolism and is recurrently mutated in ~10% of AML. *TP53* mutations are enriched in therapy-related AML and are associated with a particularly dismal prognosis, predicting poor response to standard cytotoxic chemotherapy. Eprenetapopt (APR-246) is a small molecule that selectively induces apoptosis in *TP53*-mutant cancer cells, through thermodynamic stabilisation of the p53 protein and shifting it towards a functional conformation. Promising Phase I studies with eprenetapopt in AML patients have demonstrated clinical activity and reactivation of p53-dependent pathways. Recently a phase 1/2 trial assessing the combination of Azacitidine and Eprenetapopt specifically in *TP53*-mutant myeloid malignancies has reported very promising response rates of 44% with median survival in excess of 10 months which compares positively with historical controls in this high-risk group. Eprenetapopt has now been granted breakthrough therapy designation for the treatment of patients with *TP53*-mutant myeloid malignancies by the FDA, in combination with Azacitidine.

Immunological therapies

Antibody treatment

The success achieved through allogeneic SCT in curing AML is proof of its sensitivity to cellular immunological therapies. Moreover, the efficacy of GO also suggests sensitivity of AML to antibody therapies. Despite this, immunological therapies targeting AML have generally lagged well behind those targeting lymphoid malignancies. However, recently, several novel antibody therapies have emerged targeting either immune checkpoint proteins (CD47) or Tumour Necrosis Factor (TNF) receptor ligand (CD70). These are currently at different stages of development with variable efficacy results and will likely require ongoing optimisation to fulfil their potential. Bispecific T-Cell engagers (BiTEs) or Dual Affinity Retargeting Proteins (DARTs) are novel immunological therapies that bring together effector cells (T-cells) with target cells expressing specific markers. Blinatumomab (CD3xCD19 BiTE) is a paradigmatic example of this concept and is currently licensed for Acute Lymphoblastic Leukaemia therapy. Similar DARTs targeting AML antigens such as CD123 and CD33 are also being developed with results regarding their efficacy and tolerability awaited.

Cellular immunotherapies

Chimeric antigen receptor T-cells (CAR-T) and T-cell receptor rearranged donor T-cells, are also starting to find their niche in AML therapy. They already have a well-established role in lymphoid malignancies; however, their development in AML has been hindered by the lack of a truly AML-specific target. CD33, CD123 and CLL-1 are currently all being studied as promising targets but their expression on normal HSC has thus far limited their utility. This, together with challenges in manufacturing CAR-T cells for AML patients in a timely fashion and the immunosuppressive environment created by AML, have proven the main difficulties. The incorporation of 'safety switches' to modulate activity of the CAR-T cells, identification of leukaemia neoantigens amongst the targets and use of alternative effector cells, such allogeneic modified T or NK cells, are currently being used as possible solutions. Finally enhancing immune responses via the use of immune checkpoint inhibitors or other small molecule inhibitors affecting immune milieu will likely overcome the immunosuppressive environment generated by AML and increase the efficacy of cellular therapies.

For all novel therapies, it is important to note that given their targeted nature, and often poor cytotoxicity in comparison to standard chemotherapy, assessing their responses as single agents predominantly in terms of remission rates in frank relapsed/refractory disease might be inappropriate. The experience with GO has clearly shown that novel therapies that do not affect remission rates can still significantly improve patient OS when used in combination. Novel methods of assessing response are therefore required, perhaps based on predictive biomarkers and early use in rational combinations is also to be encouraged. Finally, the identification of AML genotypes sensitive to specific agents is necessary, so that their use is limited to the patients most likely to benefit from them, thus moving AML therapy towards a more personalised, precision medicine approach.

Resistance and relapse

With current intensive therapeutic approaches over 80% of young (<60) AML patients will enter complete remission, dropping to around 60% in the >60s. Thus, a sizeable proportion of patients are refractory to current induction AML therapy. Moreover, of those entering remission, around 50% or more will relapse. Unfortunately, the choice of therapy in this setting cannot be guided by strong evidence, as most of the clinical studies

on relapse are single-arm. The fundamental decision when managing patients with refractory or relapsed disease is to establish clearly the aim of therapy, i.e. whether attempting curative therapy or adopting a palliative approach, aiming to achieve a degree of disease control while optimising quality of life. Reinduction chemotherapy is unlikely to provide durable disease control even in favourable-risk patients. It is, therefore, advisable whenever possible to consolidate a second remission with allogeneic SCT, if feasible, as this has been shown to be associated with improved long-term survival. If not feasible, an autologous transplant might provide a valid alternative, particularly if MRD-negative remission is achieved. Consolidation with a second allogeneic SCT can also be used in patients who have already received one in first remission, however for those relapsing within 6 months from the first transplant alternative approaches are required.

Whether the advent of novel therapeutics will change the outlook for refractory/relapsed disease remains to be seen. Certainly, some of the novel therapies discussed above have shown, albeit in single-arm studies, very promising response rates with improved tolerability compared to standard chemotherapy, and at least for the FLT3 inhibitor Gilteritinib, there is phase 3 trial evidence of its superiority compared to standard therapies in *FLT3*-mutant patients with R/R disease. It is conceivable that novel therapies, including those already approved for frontline therapy such as Venetoclax, might be better tolerated and a few retrospective studies have shown the activity of Venetoclax-based therapy at relapse in a proportion of AML patients. As a result, an increased percentage of patients could be bridged to transplant and would therefore be eligible to be treated with curative intent at relapse. Finally, it is hoped that the usage of novel therapies upfront at diagnosis may decrease the likelihood of R/R disease, thus reducing the scale of the problem.

APML is again a special case. In patients with suspected relapse of APML, it is important to confirm *PML::RARA* positivity, to exclude the possibility of therapy-related MDS/AML and to identify patients likely to benefit from molecularly targeted therapy. Patients can respond again to retinoic acid and chemotherapy, but recently arsenic trioxide and the CD33-directed immunoconjugate GO have been found to be effective. Remission rates above 80% have been reported; interestingly, following consolidation therapy, a similar proportion can be returned to RT-qPCR negativity. This permits the opportunity for autologous transplantation, the successful outcome of which depends on the graft and, preferably, the patient being molecularly negative. For patients who remain molecularly positive following salvage, allogeneic SCT is indicated. Arsenic trioxide is now the standard first-line salvage approach in *PML::RARA+ APML*; indeed some relapsed patients can be cured with ATRA + ATO protocols, raising questions as to whether consolidation with an autograft is necessary in all patients who go back into molecular remission.

Future directions

Classification and risk stratification

The last decade has seen an unprecedented progress in the classification and risk stratification of AML patients mostly driven by our improved ability to detect somatic mutations and link these to patterns of clinical outcome. It is plausible that in the next decade, this will be further refined through the application of epigenetic, metabolic and proteomic characterisation of AML samples. These multi-omic approaches will help improve disease classification, identify predictive biomarkers of response and move towards a more personalised approach to AML therapy. It is also likely that single-cell approaches, as already shown for single-cell genomics, will allow further understanding of disease heterogeneity within patients which might have implications for defining the best combination therapies for each patient. All these data will be then leveraged through knowledge banks algorithms that can help devising personally tailored therapeutic decisions. This will require significant investments to remain up to date as the therapeutic armamentarium expands and molecular understanding of AML deepens and will also face significant logistical and regulatory hurdles.

Therapy

The advantages of a deeper understanding of the molecular and biological features of AML will remain untapped unless novel therapies are devised and tested within large clinical trials to assess their efficacy and the most rational way to deploy them. Future trials will have to incorporate the knowledge generated via different approaches from the diagnostic material to guide therapy choices while adapting these choices in *real-time* based on further assessment of response (MRD) and changing disease biology at different time points along the therapeutic journey of each patient. While such a precision medicine approach is eminently feasible, as already shown by the Leukaemia and Lymphoma Society-sponsored 'Beat AML' trial, the increasing number of new treatments available will demand novel approaches to clinical trial design to ensure more rapid progress. This, in turn, will require much greater international collaboration to provide sufficient numbers of the patient subgroups and at different stages of disease (presentation, relapse, etc.) and different statistical methods to allow us to draw conclusions from these studies. It is also possible that in the future, if we can fully understand the trajectories of AML development, we may be able to intervene earlier, at the stage of CH or of an antecedent myeloid neoplasm, such as an MPN or MDS and prevent or delay beyond the human lifespan the development of AML. We are living through extraordinary times in the field of AML biology and therapy but will need to devise creative solutions to fully translate the benefit of these technological and knowledge-based advancements into improved patient care and outcomes.

CHAPTER 33

Chronic myeloid leukaemia

33

David T O Yeung and Timothy P Hughes

Department of Haematology, Royal Adelaide Hospital, Adelaide Medical School, and Precision Medicine Theme, South Australian Health and Medical Research Institute, Adelaide, South Australia, Australia

Introduction

Chronic myeloid leukaemia (chronic granulocytic leukaemia) is a myeloproliferative neoplasm characterised by rearrangement of the long arms of chromosome 9 and 22, resulting in the Philadelphia (Ph) chromosome, creating the fusion oncogene *BCR::ABL1*. This genetic event that encodes for a constitutively active tyrosine kinase occurs in a haemopoietic progenitor and confers proliferative and antiapoptotic effects. The natural history of untreated CML is triphasic. It most commonly presents in chronic phase (CP), characterised by markedly increased myeloid activity, resulting in increased numbers of morphologically and functionally normal granulocytes, predominantly comprised of neutrophils and myelocytes. Basophilia is a distinct feature of CML, although eosinophilia is also usually present. Thrombocytosis is commonly seen. Without effective treatment, CP-CML invariably progress over 5–10 years, with rising blast percentage, cumulating in marrow failure and cytopenia. Historically, a transitory, accelerated phase (AP) may precede blast phase (BP) disease, though the most recent WHO classification no longer recognise CML-AP as a distinct identity. In CML-BP (blast crisis or blastic transformation), the disease clinically resembles acute leukaemia and the outcome is dismal. The risk of disease progression has been dramatically reduced in the era of tyrosine kinase inhibitor (TKI) therapy. Although therapy is expected to be lifelong in many, a significant proportion of patients who achieve deep molecular remission are able to cease their TKI therapy entirely without losing their remission status, and treatment-free remission is now an accepted long-term goal of therapy for most patients.

Epidemiology and aetiology

The incidence of CML in developed nations has been relatively stable over the last decade and remains at 1–2:100,000, with a slight male predominance. The disease is most commonly diagnosed in the fifth and sixth decades of life in developed countries. In the developing world, presentations in the third and fourth decades are more common, possibly reflecting younger population demographics. CML is rare in the paediatric population.

Apart from exposure to ionising radiation (evidence derived from epidemiological studies of Hiroshima and Nagasaki atomic bomb survivors), there is no other known risk factor leading to the development of CML, whether inherited or acquired.

Clinical features, natural history, laboratory haematology and cytogenetics

The laboratory features of CML in its various phases, as defined in the two most commonly used classifications, are summarised in Table 33.1. The European Leukaemia Net (ELN)/MD Anderson Cancer Centre criteria were used to define CP in many pivotal TKI studies and still have relevance for interpretation of clinical data. The WHO classification is increasingly gaining acceptance; its 2022 revision no longer recognises a separate disease entity of accelerated phase CML, placing more emphasis on high-risk features associated with progression to blast phase from chronic phase. An important distinction between the two is the higher myeloblast count for

Table 33.1 Definition of advanced phase CML disease.

	ELN	WHO
Accelerated phase	PB or BM blast 15–29% PB basophils ≥20% PB or BM blast + promyelocytes ≥30% Clonal evolution Platelets ≤100 × 109/L unrelated to therapy	The WHO (2022) no longer recognises accelerated phase CML as a separate entity
Blast crisis	PB or BM blast ≥30% Extramedullary blast proliferation, apart from spleen	PB or BM blast 20% or more Extramedullary blast proliferation The presence of increased lymphoblasts in peripheral blood or bone marrow.

BM, bone marrow; PB, peripheral blood.

CML-BP, set by the ELN (30% rather than 20% used by WHO), and a role for excess promyelocytes in the determination of CML-AP (Table 33.1).

Chronic phase

The majority of patients (around 95%) are diagnosed with CML-CP. Many are asymptomatic and the diagnosis is often incidental to investigation for an unrelated medical problem. The most common presentations include unintentional weight loss, night sweats, fatigue and splenomegaly (which may cause early satiety and anorexia). The most striking haematological abnormality is usually a leucocytosis, with the differential heavily favouring mature neutrophils, band forms and myelocytes. Eosinophilia is common, and absolute basophilia is usually present (Figure 33.1a). Absolute monocytosis is uncommon and, if present, usually associates with the e1a2 breakpoint (see below). Rarely, patients may present with a marked thrombocytosis with only mild leucocytosis. Unlike other myeloproliferative disorders, CML is rarely associated with arterial or venous thromboses. Dysplasia is uncommon in CML, and if present, should prompt consideration of atypical CML (MDS/MPN with neutrophilia in WHO 2022) as a differential diagnosis.

The CML-CP marrow is usually grossly hypercellular as a result of markedly increased myeloid activity (Figure 33.1b). Myeloid maturation is normal or slightly left-shifted, and blasts are usually less than 5%. The myeloid-to-erythroid ratio is markedly increased and megakaryocyte numbers may be either decreased or increased compared to the normal marrow; small, hypolobated forms are common. Increased reticulin fibres are seen in 30% of cases and correlate with larger spleen size. Pseudo-Gaucher cells and sea blue histiocytes may be seen secondary to increased numbers of phagocytic cells amidst increased cell turnover.

Accelerated phase (AP)

While CML-CP is characterised by over-production of myeloid cells, essentially with normal morphology and function, AP disease is characterised by either impaired differentiation or drug resistance. There may be an increased myeloblast percentage in peripheral blood or marrow, as well as increasing leucocytosis, splenomegaly, basophilia or thrombocytosis, despite ongoing therapy. Thrombocytopenia, unrelated to therapy, may herald progressive marrow failure. Cytogenetic abnormalities additional to those found in the baseline Ph^+ clone are often present at progression to AP, a phenomenon termed clonal evolution. These abnormalities frequently include duplication of the Ph chromosome, trisomy 8 or 19 and isochromosome 17q. CML-AP usually progresses to CML-BP within 1–2 years without appropriate treatment. In its 2022 revision, the WHO no longer recognises CML-AP as a separate disease entity, though this term continues to be used clinically, especially in the context of historical data.

Blastic phase (BP)

CML-BP is characterised by rapidly rising blast counts and uninhibited growth of myeloid precursors with absence of maturation or differentiation, resulting in marrow failure and cytopenia. Morphologically, CML-BP is indistinguishable from other cases of acute leukaemia. In ~70% of cases, the blasts are of myeloid lineage by morphology and immunophenotype, and may express antigens associated with granulocytic, monocytic, megakaryocytic or erythroid differentiation. Aberrant expression of lymphoid markers (e.g. CD7) is common. Blasts in the remaining 25–30% of cases usually express lymphoid antigens of B lineage. Aberrant expression of myeloid antigens in CML lymphoid BP is also quite common.

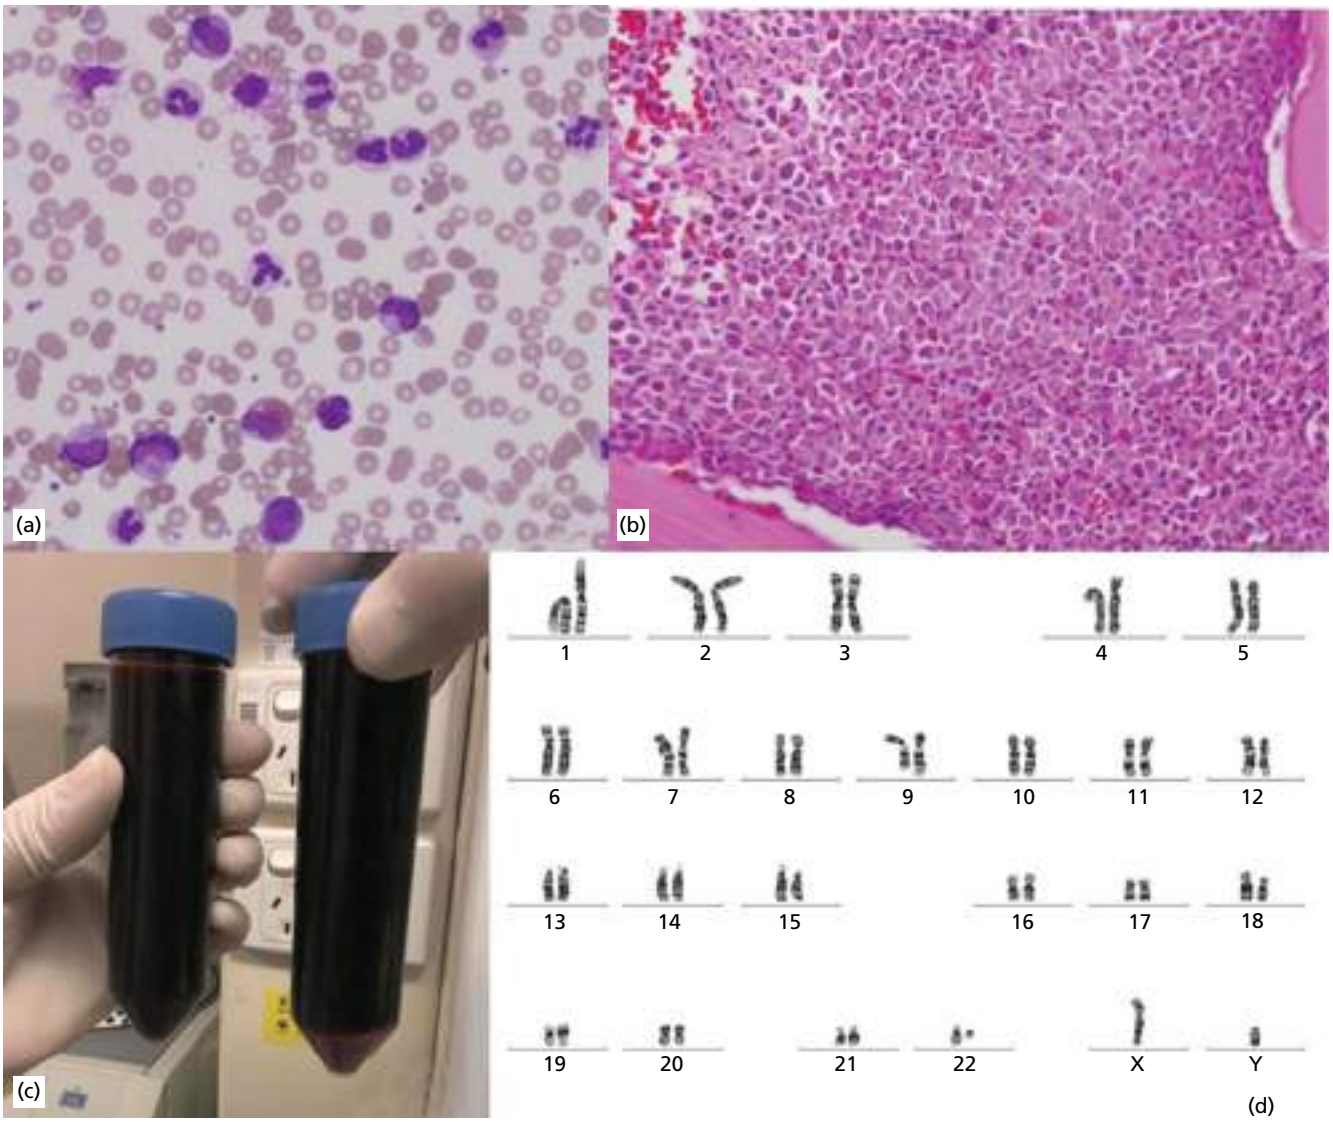

Figure 33.1 (a) Blood film from a newly diagnosed CML-CP patient aged 47 years. Leucocytosis is prominent, with increased neutrophils and myelocytes, but no obvious dysplastic features. Several myelocytes, a basophil and an eosinophil can be seen towards the bottom of the photomicrograph. (b) A grossly hyper-cellular marrow trephine from the same patient. (c) Whole blood is processed prior to RQ-PCR. Red cell lysis agent is added to whole blood and a white cell pellet is obtained after centrifugation. On the right, a newly diagnosed CML patient yielded a sizeable white cell pellet at the bottom of the tube, compared to that of a normal control on the left. (d) Karyogram showing the translocation t(9;22) (Source: (d) Ms. Sarah Moore, SA Pathology, Adelaide, Australia. Reproduced with permission.)

The WHO 2022 also recognises t(9;22) as a defining genetic abnormality in de novo AML, although distinguishing these cases from patients presenting in myeloid blast crisis of CML may be challenging.

Cytogenetics and molecular biology

The diagnosis of CML rests on demonstration of the Ph chromosome with cytogenetic analysis, or the *BCR::ABL1* fusion gene with RT-QPCR (reverse transcriptase quantitative polymerase chain reaction, also known as RQ-PCR, qRT-PCR or QPCR), in the context of compatible blood and marrow morphology. Cytogenetics and RQ-PCR offer complementary information and both tests should be performed routinely at diagnosis.

The Ph chromosome was first linked to CML in 1960 by Peter Nowell and David Hungerford in Philadelphia. Janet Rowley in 1973 showed this to be a result of a reciprocal translocation between the long arms of chromosome 9 and 22 (Figure 33.1d).

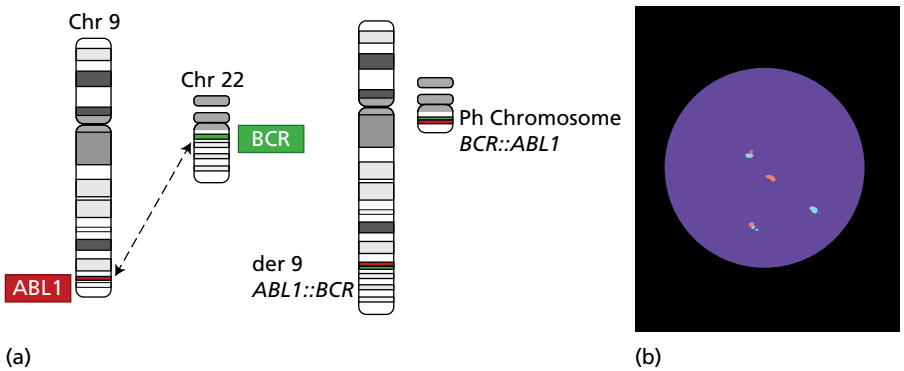

Figure 33.2 (a) The t(9;22) translocation leads to juxtaposition of genetic material from chromosomes 9 and 22, with formation of two fusion genes *BCR::ABL1* and *ABL1::BCR*, the former being crucial to the pathogenesis of CML and Ph+ ALL. (b) Fluorescence *in-situ* localisation. Hybridisation of an oligonucleotide sequence complementary to the *BCR* gene attached to a fluorophore (green in this case) leads to its localisation in a metaphase spread. The same can be done for *ABL1* (red in this case). A normal cell has two red and two green signals. A t(9;22) translocation event will juxtapose red and green fluorophores (with some probe sets seen as two fused yellow signals), one from *BCR::ABL1* and one from *ABL::BCR (*the two signals to the left of the picture). The remaining red and green signals originate from the normal chromosome, which Is not rearranged (Source: (b) Ms. Sarah Moore, SA Pathology, Adelaide, Australia. Reproduced with permission. FISH probe set from Abbott Diagnostics, Vysis LSI BCR/ABL Dual Colour, Dual Fusion Translocation Probe.)

This event, now denoted as t(9;22)(q34;q11), is known to fuse the *BCR* (breakpoint cluster region) and *ABL1* genes together. The resulting *BCR::ABL1* fusion gene encodes a constitutively active tyrosine kinase that is central to the pathogenesis of Ph^+ leukaemias (Figure 33.2a). Variant translocations, where *BCR::ABL1* resides on a third chromosome, is seen in ~5–10% of patients and may be cryptic, discernible only with fluorescent *in situ* hybridisation (FISH) analysis (Figure 33.2b). Amplification of *BCR::ABL1* can result from duplication of the Ph chromosome, which, along with trisomy 8, i(17q) and trisomy 19, leads to increased risk of blastic transformation, and together these are referred to as major route cytogenetic lesions. Chromosome 3 abnormalities, and in particular changes involving the 3q26.2 locus where the *EVI* gene resides, are also associated with disease resistance. Cytogenetic analysis at diagnosis, therefore, remains important for prognostication as these changes are not discernible on FISH or RQ-PCR. Apart from CML, t(9;22) is also seen in a significant proportion of adult *de novo* high-risk acute lymphoblastic leukaemia cases. The finding of t(9;22) in *de novo* AML is rare. Although recognised in the current WHO classification, it is challenging to distinguish this from an undiagnosed antecedent CML-CP.

The breakpoints of the *BCR* and *ABL1* genes usually occur within the introns of each gene and are unique to each individual (Figure 33.3). The *ABL1* breakpoint is almost invariably located in the intron between exons 1a/1b and 2, whereas the *BCR* breakpoint usually occurs in an intron between exons 13–15. The resulting fusion transcripts are named e13a2 and e14a2 transcripts (previously known as b2a2 and b3a2); both may coexist in one individual due to alternate splicing. These transcripts encode for a 210 kDa protein product (p210), seen in the majority of CML patients. A breakpoint immediately downstream of the first *BCR* exon produces the e1a2 transcript, which encodes the p190 *BCR::ABL1* protein. This is more commonly seen in Ph^+ ALL and is infrequent in CML. Rarely, the *BCR* breakpoint occurs between exons 17–20, leading to the larger p230 protein from the e19a2 transcript, often associated with a more prominent neutrophilia and thrombocytosis. Other transcripts such as e6a2, e8a2 and e18a2 are also occasionally reported.

The translocation is carried by the leukaemic stem cell population, such that both myeloid and lymphoid progeny may carry t(9;22) in an affected individual. ABL1 is a tyrosine kinase with multiple substrates. Its activity is tightly regulated by the phosphorylation status of critical tyrosine residues on ABL1 itself. Juxtaposition of BCR and ABL1 promotes dimerisation of *BCR::ABL1* proteins through a coiled-coil domain in BCR and formation of tetramers through subsequent dimerisation of dimers (Figure 33.4). Critical tyrosine residues are brought into close proximity with adjacent ABL1 kinase domains, leading to autophosphorylation and activation. In addition, native ABL1 is usually regulated by autoinhibition mediated by intramolecular binding of an N-terminus myristate moiety into the kinase domain. This myristate moiety is lost through the translocation event. These modifications lead to constitutive activation of ABL1, which through downstream messengers, results in cellular effects such as loss of growth inhibition,

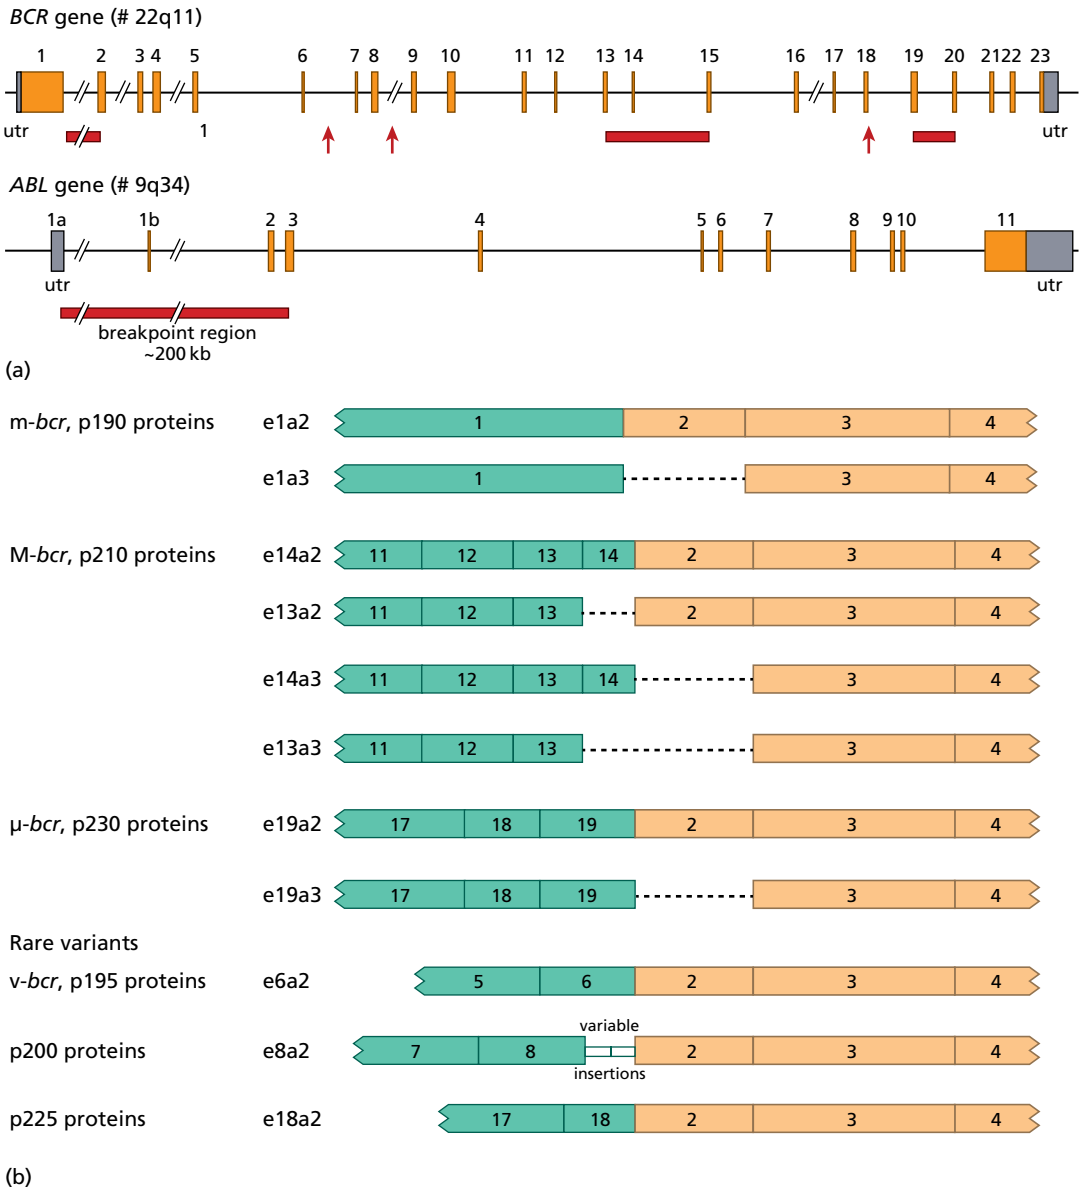

Figure 33.3 (a and b) Formation of the *BCR::ABL1* fusion gene. Breakpoint in the *ABL1* gene almost invariably occurs in the intron between exons 1–2. In contrast, breakpoints in the *BCR* gene may occur in introns between exons 1–2, 13–15 and 19–20. These regions are also known as the m-*BCR,* M-*BCR* and μ-*BCR* regions, respectively, and in turn yield the p190, p210 and p230 *BCR::ABL1* proteins. The e13a2 and e14a2 (also known as b2a2 and b3a2 respectively) transcripts are most commonly encountered in CML, whereas Ph+ ALL cases are usually associated with the e1a2 transcript. The e13a2 and e14a2 transcripts may coexist in the same patient secondary to alternative splicing in patients with the genomic e14a2 breakpoint. Other breakpoints (v-*BCR*) are also occasionally encountered (Source: Weerkamp *et al.* (2009) *Leukemia*. **23**: 1106–17. Reproduced with permission of Nature Publishing.)

decreased apoptosis and decreased adherence to bone marrow stromal cells. Many of the downstream pathways are well-studied and involve proteins including RAS/RAF/MEK/ERK, PI3K/AKT, STAT and MYC. *BCR::ABL1* also leads to genomic instability and facilitates disease transformation through accumulation of subsequent genetic lesions. DNA damage, such as double-stranded breaks, are mediated through increased ROS (reactive oxygen species) generated by *BCR::ABL1*. The repair mechanisms secondary to ROS-associated DNA damage in *BCR::ABL1* positive cells are more error-prone compared to normal mammalian cells, which in turn contributes to genomic instability.

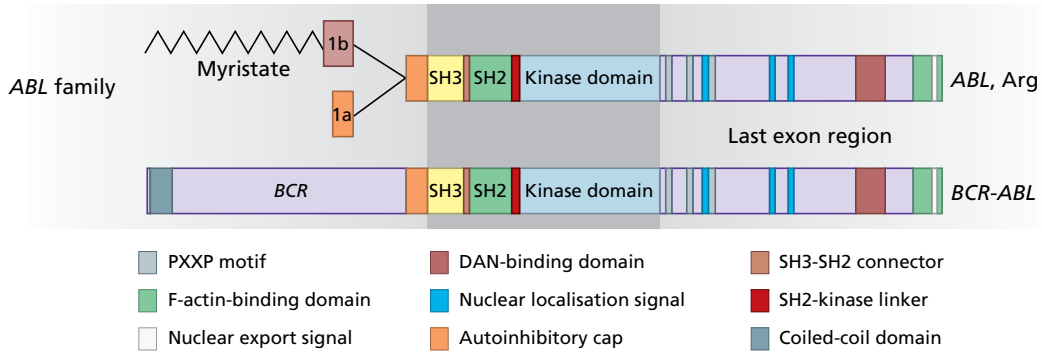

Figure 33.4 The native ABL1 protein possesses either an auto-inhibitory cap region encoded by exon 1a, or a myristate moiety encoded by exon 1b. The myristate moiety can fold over and bind to a pocket on the same ABL1 molecule to exert an auto-inhibitory effect. Replacement of exon 1a/b with BCR not only leads to loss of auto-inhibition, but also leads to tetramerisation through introduction of the coiled-coil domain in *BCR*, resulting in cross phosphorylation of critical tyrosine residues on neighbouring ABL1 and constitutive activation (Source: Hantschel and Superti-Furga (2004) *Nat. Rev. Mol. Cell. Biol.* **5**: 33–44). Reproduced with permission of Nature.)

Measurement of residual disease and monitoring with cytogenetics and *BCR::ABL1* RQ-PCR

CML patients receiving therapy are commonly monitored with blood counts, marrow cytogenetics and molecular assays. A complete haematological response (CHR), the first treatment milestone, is achieved with normalisation of blood counts and morphology, as well as resolution of splenomegaly. Achieving CHR from treatment with cytotoxic agents (such as hydroxycarbamide) has little or no impact on the risk of transformation and can only be regarded as a short-term goal of therapy or palliative treatment.

When patients are successfully treated with tyrosine kinase inhibitors that specifically target the Ph^+ clone, the risk of transformation starts to fall when a reduction in the overall number of leukaemic cells can be achieved. This can be assessed through bone marrow cytogenetics, or Fluorescent *in situ* Hybridisation (FISH). However, assessment of RQ-PCR for *BCR::ABL1* in the peripheral blood is a more sensitive disease monitoring tool. Due to its demonstrated clinical significance correlated with specific transcript levels, and the ease of use, RQ-PCR has gained wide acceptance. *BCR::ABL1* RNA transcripts, measured from a peripheral blood sample, correlates well with the number of residual Ph^+ cells on marrow cytogenetics. The transcript numbers of a control gene such as *BCR, ABL1* or *GUSB* are usually measured from the same sample. The test result is reported as a ratio of *BCR::ABL1* transcripts numbers to control gene transcript numbers, as a percentage. As RNA is labile, control gene transcript numbers differentiate acceptable specimens from those subjected to degradation from transport and storage.

Reporting results on the International Scale (IS) allow inter-patient and intra-patient comparability between different laboratories through the use of a simple conversion factor. By convention, 100% IS is a diagnostic baseline value derived from 30 diagnostic samples from the IRIS (International Randomised Study of Interferon and STI571) study. As well as a ratio, it is also common to describe the residual tumour burden as a $\log_{10}$ reduction from the standardised baseline, with 10, 1, 0.1% being a MR1, MR2 and MR3 log disease reduction, respectively (Figure 33.5). A MR2 response, or *BCR::ABL1* of ≤1% IS, is a convenient and reliable

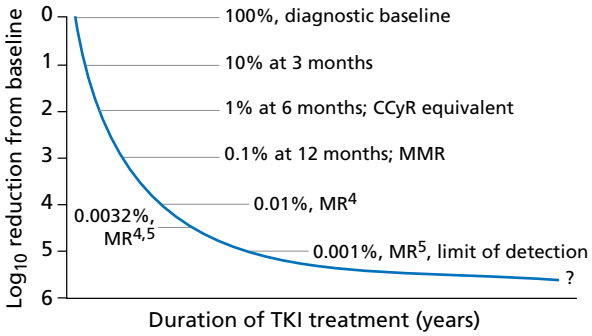

Figure 33.5 Idealised optimal reduction in *BCR::ABL1* over duration of TKI treatment. A RQ-PCR value of 100% on the international scale is derived from the baseline value of a subgroup of patients in the IRIS study. After 3 months of TKI treatment, patients should have a *BCR::ABL1* value below 10% (termed early molecular response – EMR). After 6 months, patients should achieve *BCR::ABL1* ≤1%, which is a surrogate for CCyR. After 12 months of therapy, the optimal response is considered MMR or *BCR::ABL1* ≤0.1%. Deeper molecular responses may follow after a variable period. MR^5 or $MR^{4.5}$ act as a platform for patients who wish to be considered for an attempt at treatment-free remission. RQ-PCR assays or digital PCR assays with sensitivity to >5 logs below the diagnostic baseline are not routinely available but are actively being studied in the research setting.

surrogate for CCyR. MR3, or *BCR::ABL1* of ≤0.1% IS, is a milestone response also referred to as major molecular response (MMR, orMMolR), associated with significantly superior event-free survival. Deeper responses, such as MR^4, $MR^{4.5}$ and MR^5 have also recently been defined as equivalent to *BCR::ABL1* of ≤0.01% IS, 0.0032% IS and 0.001% IS, respectively.

In general, patients receiving TKI therapy should have RQ-PCR testing every 3 months for the first 2 years, then every 3–6 months if MMR is achieved. Testing RQ-PCR monthly within the first 3 months of starting therapy may give an additional indication of how sensitive the disease is to treatment. This may be calculated as the halving-time – the number of days it takes for the *BCR::ABL1* to reduce by 50%, with shorter halving-time indicating more sensitive disease. Patients who fail to achieve time-dependent treatment targets (see later) may benefit from more frequent testing. An increase of RQ-PCR value of more than fivefold, or confirmed loss of previously achieved milestones, may be a consequence of treatment resistance and is worthy of further investigation.

Treatment

Oral cytotoxics, such as hydroxycarbamide (hydroxyurea), are used commonly for cytoreduction of leucocytosis before confirmation of diagnosis (leukapheresis can also be used in more extreme cases where symptoms or signs suggesting leucocytosis are present). During the initial cytoreduction phase, it is common to co-administer allopurinol to blunt any rise in serum urate and to monitor for electrolyte disturbances carefully.

Once diagnosis is confirmed, definitive treatment with a TKI should commence. Historical treatments such as oral busulfan have no role in the current treatment landscape. Although interferon-α was the gold standard treatment in the pre-TKI era and can induce durable complete cytogenetic response in ~20% of patients, it is now infrequently prescribed due to its toxicity profile, limiting generalised use except in pregnancy where TKIs must be avoided. However, pegylated interferon, a modified interferon that has slower clearance and a more favourable toxicity and efficacy profile, has resulted in a reemergence of its use. The role of pegylated interferon as a low-dose adjunct to TKIs is currently being examined in several clinical studies.

TKI treatment has transformed a previously fatal disease for many into a manageable chronic illness with excellent long-term survival and is the standard of care in CML-CP and AP. A recent Swedish population-based study suggested that the years of life lost attributable to a diagnosis of CML-CP in the TKI era to be minimal, observing a similar life expectancy in CML patients as compared with aged-matched population controls. Patients with CML-BP may be treated either with a TKI alone or in combination with chemotherapy, though duration of response tends to be short without consolidation with an allogeneic stem cell transplant.

The characteristics of the five most commonly used TKIs are discussed below. Imatinib was the first TKI to be approved for the treatment of CML and Ph+ ALL. It was followed by the discovery of second-generation TKIs such as nilotinib, dasatinib and bosutinib, and subsequently the third-generation TKI ponatinib. TKIs inhibit the kinase activity of *BCR::ABL1* through their binding to the ATP-binding pocket. A more recently discovered class of ABL inhibitors called STAMP – Specifically Targeting the ABL Myristoyl Pocket – shows therapeutic promise and will be discussed later in the chapter. The lead compound in the class, asciminib, has recently been approved for use in CML-CP patients with resistance or intolerance to 2 or more ATP pocket-binding TKIs.

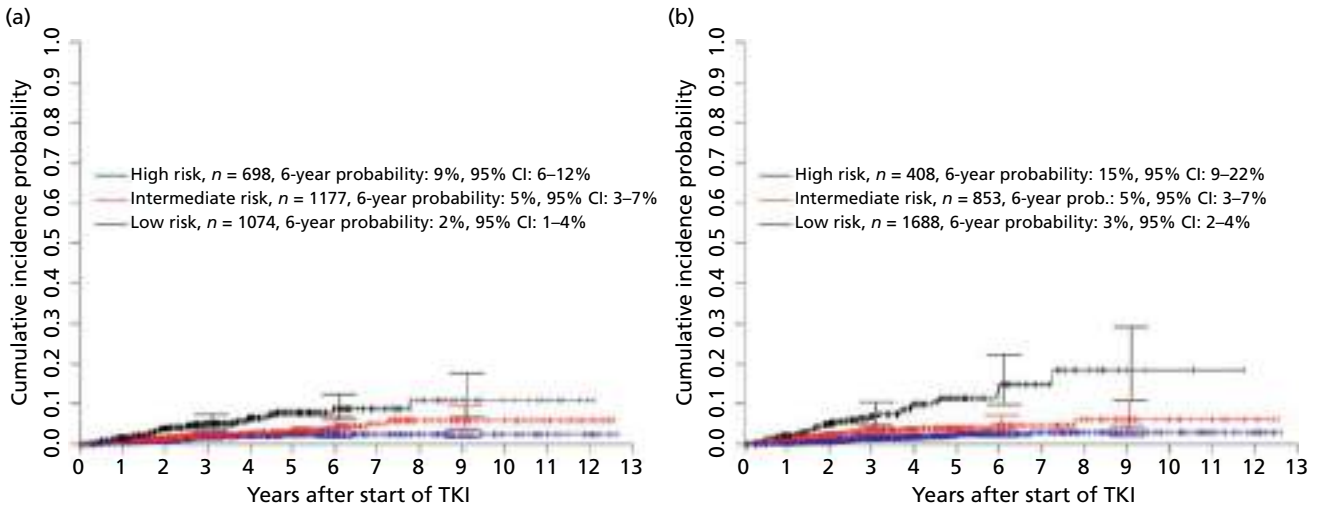
Haematological toxicities (anaemia, thrombocytopenia and/or neutropenia) are commonly encountered in the first few months of TKI treatment and usually improve with time as repopulation of the marrow by normal Ph-negative clones occurs. Dose intensity, especially in the initial months of treatment, is critical to the long-term success of TKI treatment. Supportive measures, such as colony growth-stimulating factor (GCSF, EPO) or transfusion support may be used as temporary adjuncts to allow for ongoing TKI treatment. Screening for past or chronic hepatitis B virus (HBV) infection is recommended, as HBV reactivation associated with TKI treatment resulting in fulminant hepatitis had been reported.

Assessment of CML risk score

The likelihood of a patient achieving the desired therapeutic outcome with TKI therapy may be predicted using clinical scoring systems. The Sokal score was developed in the 1980s for such a purpose, but has still proven to be relevant in the TKI era. Recently, the EUTOS Long-Term Survival (ELTS) score has been accepted as the preferred scoring system as it was developed in a TKI-treated population. Like the Sokal score, three groups are identified – patients at low, intermediate and high risk of disease progression. The variables measured at diagnosis to calculate the Sokal score and the ELTS score are the same; age, spleen size (measured in cm below the costal margin in the midclavicular line), platelet count and peripheral blood blast percentage. However, ELTS gives different weighting to each variable and has proven to be better at discriminating between different risk cohorts (Figure 33.6).

Imatinib

Imatinib was the first TKI to be licensed for use in CML, and for this reason, commonly referred to as a first-generation TKI. It competitively inhibits tyrosine kinases including c-kit, ABL1, ARG (*ABL2*), c-FMS and PDGFRB. It binds to inactivated forms of *BCR::ABL1* by occupying the ATP-binding pocket and



Number of patients still at risk (n) at different years of observation

Number of patients still at risk (n) at different years of observation

Year	*0*	*3*	*6*	*9*
Low risk, n	1688	935	302	86
Intermediate risk, n	853	427	115	34
High risk, n	408	177	43	6

Figure 33.6 Clinical risk scores in chronic phase CML predict cumulative incidence probabilities of death due to CML. Both the Sokal (Figure 33.6 (a) and the ELTS (Figure 33.6 (b) scores combine age, spleen size (measured in cm below the costal margin in the midclavicular line), platelet count and peripheral blood blast percentage into a single risk score to stratify patients into low, intermediate versus high risk of disease progression. The ELTS score has improved ability to discriminate patients at high risk of disease progression in the TKI era (Source: Adapted from Pfirrmann M, Clark RE, Prejzner W *et al.* (2020) The EUTOS long-term survival (ELTS) score is superior to the Sokal score for predicting survival in chronic myeloid leukaemia. *Leukemia* **34**: 2138–49. prevents conformational changes (such as repositioning of the 'activation loop') required for *BCR::ABL1* activation.

The Phase III IRIS trial enrolled treatment-naïve CML-CP patients and randomised them to receive either imatinib 400 mg daily, versus interferon-α and low-dose cytarabine. The superiority of the imatinib arm was demonstrated unequivocally, leading to crossover of 89.2% of the control arm patients by 2 years of follow-up. After 10 years, 83% of patients randomised to the imatinib arm were still alive. However, it is important to note that only around 50% of those patients were still receiving imatinib. Many patients had switched to another TKI because of intolerance or treatment failure.

As the IRIS study was the first to demonstrate the effectiveness of TKIs in CML, it was also in a position to examine the prognostic significance of treatment milestones. For instance, the 5-year analysis showed progression-free survival (defined in IRIS as progression to AP/BC, loss of a CHR or major cytogenetic response) to be 97% for patients who achieved CCyR by 12 months, versus 93% for patients who achieved only PCyR and 81% for patients who achieved less than PCyR. Of the patients who achieved CCyR, those who achieved the even deeper response of MMR had a PFS of 100%. Results from other TKI studies subsequently confirmed the prognostic utility of these molecular milestone responses, independent of the TKI chosen for treatment. (Figure 33.7).

Even though imatinib treatment has proved highly successful for many, ~40–50% of patients who start imatinib therapy will discontinue – about half for intolerance and half for resistance. The most common resistance mechanism identified is kinase domain mutations (see below). Clonal evolution, such as acquisition of an extra copy of the Ph^+ chromosome or development of isochromosome 17q may also be involved. Non-adherence, whether intentional, due to toxicity or financial pressures, or unintentional, is also a significant contributor to therapeutic failure. Some mechanisms of treatment failure are illustrated in Figure 33.8.

The most common starting dose of imatinib is 400 mg daily. A dose of 600 mg daily may lead to higher molecular responses and is well tolerated in many patients. However, randomised studies comparing imatinib 400 mg daily to 800 mg daily have not demonstrated a clear benefit to justify the uniform use of higher doses. The more common toxicities of imatinib tend to be gastrointestinal disturbances (nausea, vomiting, anorexia, diarrhoea and dyspepsia) and oedema (periorbital, facial and pedal). Judicious use of

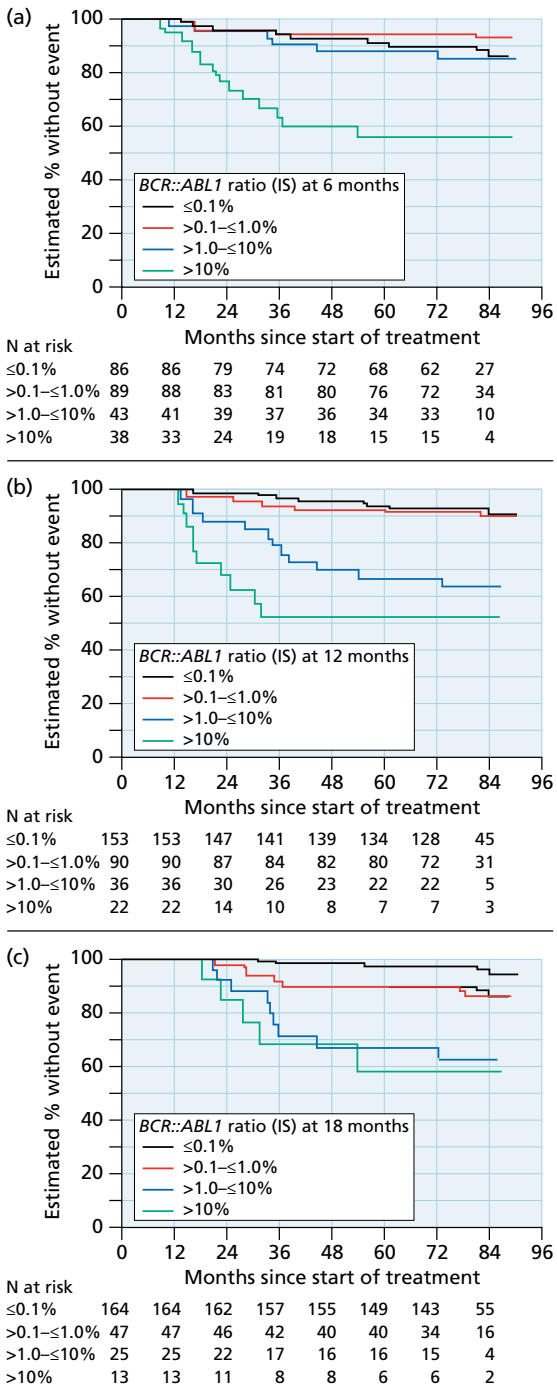

Figure 33.7 Event-free survival (EFS) from the IRIS cohort. The majority of IRIS patients enjoy excellent EFS. However, patients *BCR::ABL1* RQ-PCR of >10%, >1% and >0.1% at (a) 6, (b) 12 and (c) 18 months after starting therapy had inferior EFS. Events in this analysis included (i) loss of complete haematologic response, (ii) loss of major cytogenetic response, (iii) progression to AP/BC or (iv) death due to any cause (Source: Hughes *et al.* (2010) *Blood* **116**: 3758–65. Reproduced with permission of American Society of Haematology.)

diuretics, prokinetic agents and taking imatinib with a full meal may ameliorate these symptoms. Haematological toxicities (anaemia, neutropenia and thrombocytopenia) are commonly associated with TKIs and tend to be most severe at treatment initiation. Cardiac toxicity, an initial concern, appears minimal with long-term clinical follow-up. Unlike the second and third-generation, TKIs there is no evidence that the risk of cardiovascular events is increased by imatinib.

Nilotinib

Nilotinib is a second-generation TKI that is approved for frontline therapy as well as in patients with imatinib-resistance or -intolerance. In addition to *BCR::ABL1*, it also inhibits PDGFR and c-kit. It is active against a range of imatinib-resistant kinase domain mutations, except for T315I, F359V/C, E255K/V and Y253H/F (see later section for full details of mutation analysis). It is administered as a twice-daily dose on an empty stomach. Treatment is usually well tolerated apart from cytopenias at treatment initiation. Common associated biochemical abnormalities include elevations in serum liver enzymes, lipase and amylase and hyperbilirubinaemia (thought to be secondary to decreased hepatic bilirubin excretion into bile and is generally reversible). Pancreatitis is an uncommon, but notable idiosyncratic toxicity. The incidence of cross intolerance with imatinib is low with regards to non-haematological side-effects. Although all TKIs can prolong QTc interval, the effect of nilotinib is perhaps the best documented, especially where increased serum drug concentration results from enhanced absorption, when nilotinib is taken with a fatty meal.

The data surrounding frontline use of nilotinib came from the Phase III ENESTnd study, which showed CML-CP patients (at either 300 mg BID or 400 mg BID) have decreased risk of disease transformation to AP/BP, reduced risk of kinase domain mutation acquisition, and higher achievement of MMR/MR[4.5], compared to imatinib-treated patients. Nilotinib-treated patients were also more likely to achieve early molecular response (EMR; *BCR::ABL1* <10% at 3 months), a surrogate for progression-free survival (PFS) (Figure 33.9). However, overall survival differences were marginal between imatinib and nilotinib. While efficacy was similar in the nilotinib 300 mg BID and 400 mg BID arms, toxicity is more common at higher doses. Consequently, first-line patients are usually given 300 mg BID. Nilotinib-treated patients have higher incidence of hyperglycaemia and dyslipidaemia, and accelerated development of arterial occlusive disease is a major concern. This manifests as ischaemic heart disease, strokes and peripheral arterial occlusive disease and was shown to be significantly more common in both nilotinib arms compared to the imatinib arm in the ENESTnd study. A recent update showed the higher annual rate of vascular events associated with nilotinib treatment persists over the full 10 years of the study, with vascular events reported

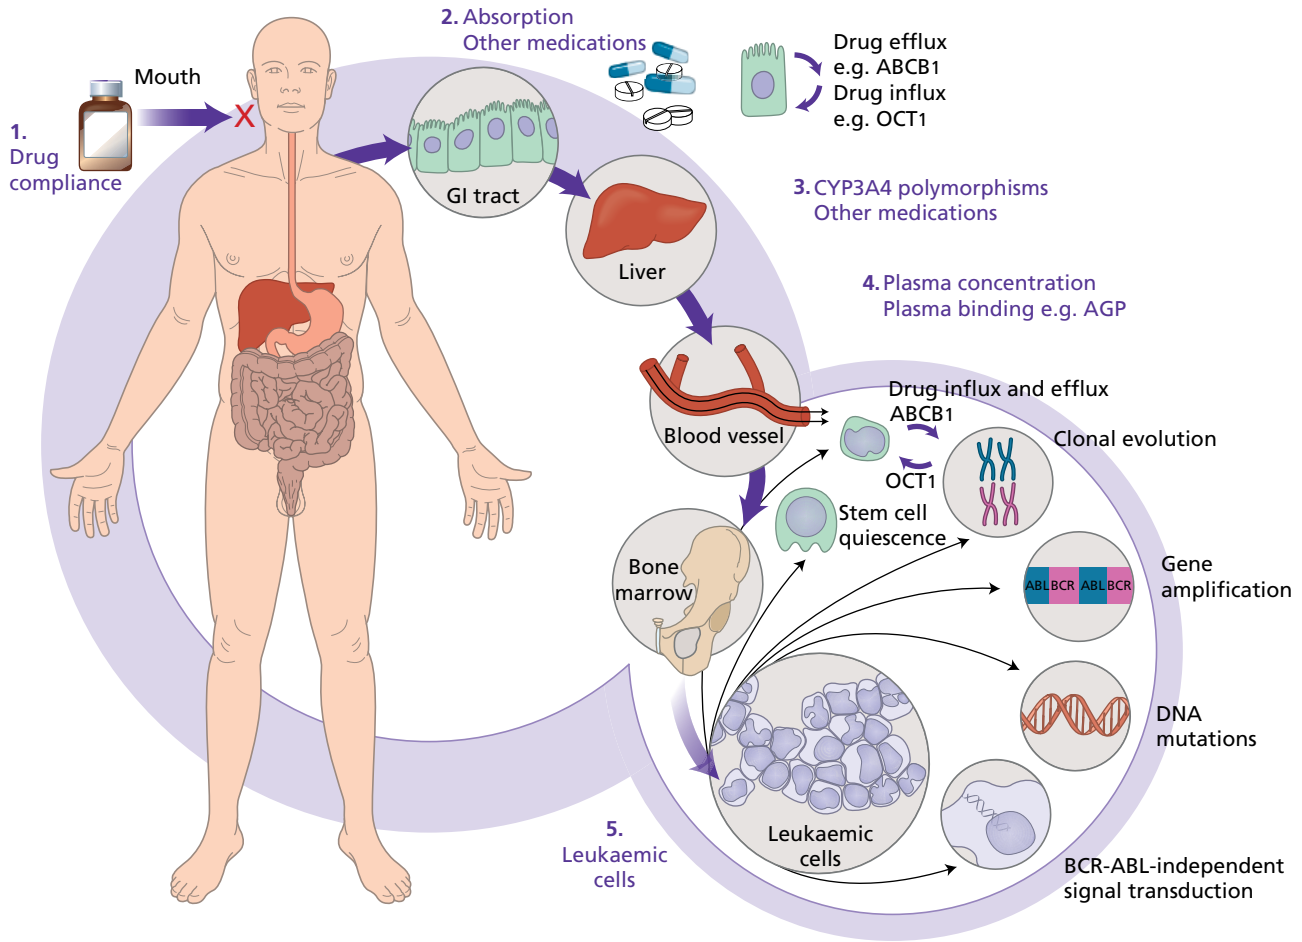

Figure 33.8 Mechanisms are implicated in treatment resistance. These factors include host factors drug compliance; absorption and metabolism. Concomitant medications that may interfere with pharmacokinetics. Factors, such as drug efflux, *BCR::ABL1* amplification and kinase domain mutations, as well as *BCR::ABL1* independent signalling contribute to leukaemia specific mechanisms of resistance. AGP, α-1 acid glycoprotein (Source: Apperley (2007) *Lancet Oncol.* **8**(11): 1018–29. Reproduced with permission of Elsevier.)

in 16.5, 23.5 and 3.6% of patients, respectively, in the nilotinib 300 mg BID, nilotinib 400 mg BID and imatinib arms. The Framingham risk score, which sums up predisposing risk factors for cardiovascular events such as smoking, hypertension, dyslipidaemia, age and being male, was predictive of cardiovascular events on nilotinib treatment. Proactively addressing modifiable risk factors with lifestyle modifications, and pharmacotherapy when appropriate, are all necessary to minimise morbidity and mortality from cardiovascular complications for nilotinib-treated patients.

Dasatinib

Dasatinib is a second-generation TKI and a dual Src/ABL inhibitor which also inhibits a number of other tyrosine kinases. It is approved for frontline treatment of CML-CP, as well as cases resistant or intolerant to at least one prior TKI in all phases, and for Ph^+ ALL. The initial registration studies used a twice-daily treatment regime based upon dasatinib having a short plasma half-life. However, dasatinib should be given as a single daily dose (100 mg for CP and 140 mg for advanced phases), taken with or without food due to reduced incidence of toxicity without a reduction in efficacy compared with the twice-daily regimen. In the Phase III DASISION study, dasatinib-treated patients had superior achievement of MMR and $MR^{4.5}$ compared to imatinib treatment, though no significant difference in overall survival and progression-free survival was demonstrated. Interestingly, the number of patients who developed kinase domain mutations was similar in both arms, with a higher number of T315I cases in dasatinib-treated patients. In the second-line setting, dasatinib is active against a range of imatinib-resistant mutations, although it is inactive against *T315I/A*, *V299L* and *F317V/C* mutations.

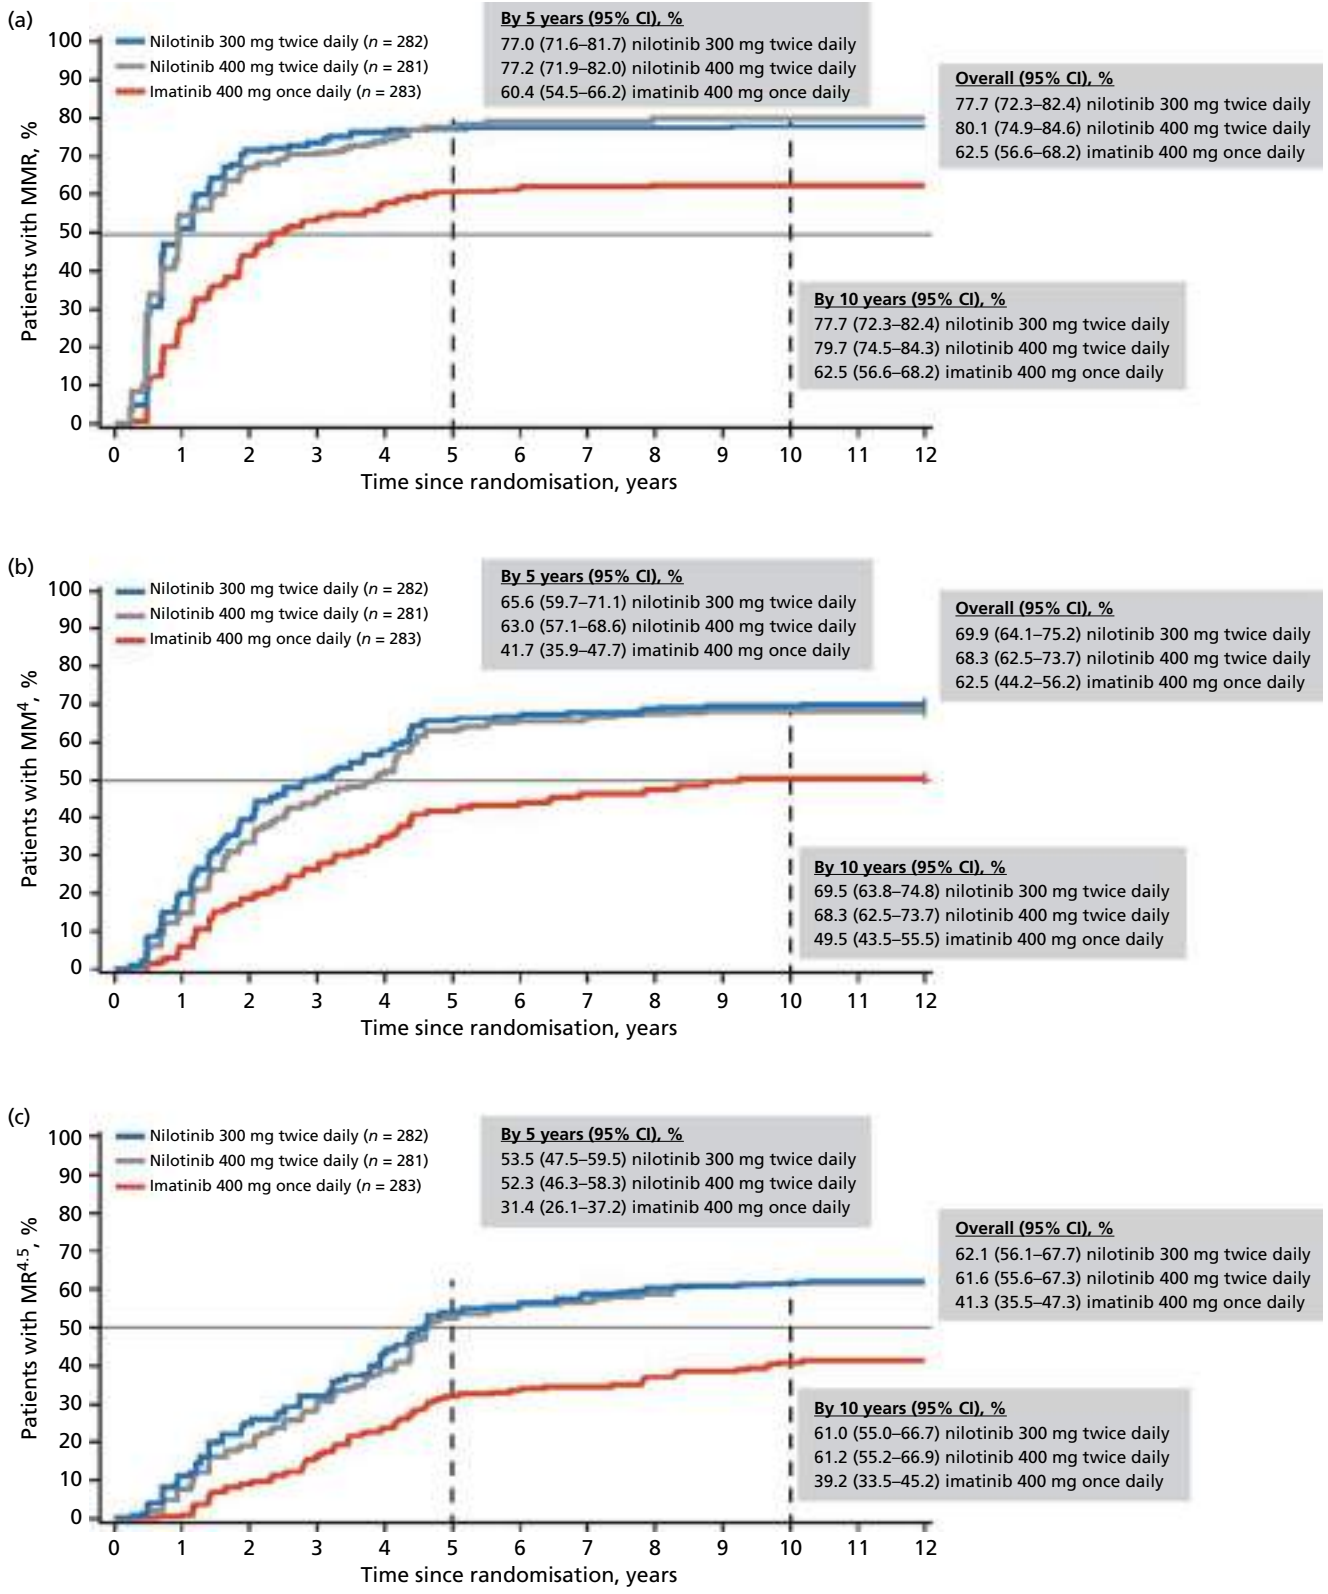

Figure 33.9 Results from the randomised ENESTnd study comparing the second generation TKI, nilotinib, to imatinib, in newly diagnosed CML-CP patients. Achievement of MMR, MR4 and MR4.5 in panels (a), (b) and (c) respectively. Subjects were randomised to three arms – nilotinib 300 mg BID, nilotinib 400 mg BID versus imatinib 400 mg OD. Patients who received nilotinib had superior probability of achieving MMR and $MR^{4.5}$. Similarly, data from the Phase III DASISION study showed that patients assigned to the second-generation TKI dasatinib had better molecular responses compared to patients receiving imatinib (Source: Kantarjian *et al.* (2021) *Leukemia*. **35**: 440–53. Reproduced with permission from Nature Publishing under a Creative Commons license for Open Access.)

Idiosyncratically, dasatinib causes pleural effusions in some patients. The most important risk factor appears to be age, with patients over 70 years of age having an incidence of over 50%. Onset of pleural effusions are unpredictable and may first present months to years after treatment commencement, though the risk is cumulative with increasing duration of treatment. The pleural fluid is usually an exudate, often associated with lymphocytosis which may be oligoclonal, suggesting a degree of immune dysregulation in its aetiology. Usual treatment of symptomatic, dasatinib-induced and pleural effusions include a brief treatment interruption and judicious use of thoracentesis as necessary. A short course of prednisolone can be used as immunomodulation, but no firm evidence exists to demonstrate the effectiveness of this approach. Switching to an alternate TKI may be necessary in some patients, if pleural effusions do not resolve with these simple measures. Occasionally, the pleural effusion may persist after switching to another TKI. Pulmonary hypertension (PAH) appears to be a rare complication of dasatinib therapy, though given the difficulty in diagnosing PAH and its inconsistent symptoms, the true incidence is difficult to ascertain. This is usually, but not always, reversible upon dasatinib cessation, although pulmonary arterial pressures may not return to normal. Other idiosyncratic side effects associated with dasatinib treatment include pericardial effusions, lymph node follicular hyperplasia and peripheral blood lymphocytosis. It also inhibits platelet activation *in vitro*, though it is unclear whether this is clinically relevant in the general case.

The safety and efficacy of lower doses of dasatinib are currently being assessed. In one single institution study, dasatinib given at 50 mg daily was associated with similar efficacy and substantially lower risk of toxicity, including pleural effusions, as compared to historical controls using 100 mg daily. These data are awaiting further confirmation. Data also exist to suggest a correlation between dasatinib trough plasma levels, and the risk of pleural effusions. In the French-Canadian OPTIM study, patients with dasatinib trough levels ≥3nM were randomised to having serial dose reductions aiming for a plasma trough <3nM, versus no intervention. The cumulative incidence of pleural effusion at 36 months was 45% in patients with a dasatinib trough level ≥3nM without dose reduction, versus 11% in those who had a dose reduction. Molecular response was similar regardless of starting plasma trough dasatinib level. The lack of availability of laboratories that offer a dasatinib trough assay may hamper widespread adoption of this approach.

Bosutinib

Bosutinib is a second-generation TKI approved for the frontline treatment of CML patients as well as in cases of intolerance or resistance to other TKI, for all disease phases. Its efficacy in the frontline setting was demonstrated in the Phase II BFORE study where 536 newly diagnosed CML-CP patients were randomised to bosutinib versus imatinib in a 1:1 ratio, both at 400 mg daily. The primary endpoint, MMR at 12 months was significantly higher in bosutinib-treated patients (47.2%) as compared with imatinib-treated patients (36.9%). Disease progression rate to CML-AP/CML-BP was 1.6 versus 2.5%, respectively, in patients treated with bosutinib and imatinib.

Bosutinib is also approved in the second-line setting, though clinical evidence suggests inferior responses for patients with the V299L, L248V and F359C (and perhaps G250E) mutations. The T315I mutant clone is totally resistant to bosutinib. The Phase 4 BYOND study recently reported a 12-month MMR rate of 70.5% in 163 CML patients resistant or intolerant to at least one prior TKI treatment. Patients received 500 mg daily of bosutinib on this study, and those with the *T315I* and *V299L* mutations were excluded.

Unlike the other second-generation TKIs, Bosutinib has not been associated with an increased risk of vaso-occlusive events. The main toxicities observed are gastrointestinal, particularly diarrhoea and elevated liver enzymes. (Grade III diarrhoea was observed in 7.8% of patients in the BFORE study). These toxicities are quite common in the first and second year of therapy, leading to a discontinuation rate due to adverse events of around 20–25%. These toxicities can often be managed successfully with dose reductions over the first few months of therapy.

Ponatinib

Ponatinib, a third-generation TKI, and was the first drug approved for use against the *T315I* mutation – a mutation that confer resistance to all other available TKIs. Ponatinib is often effective in patients with resistance or intolerance to at least one previous line of treatment in all phases of CML disease, as well as Ph^+ ALL, especially in patients with T315I as the only known mechanism of resistance. Cases with compound mutations (where more than one kinase domain point mutation is present in the same *BCR::ABL1* transcript), especially those involving the *E255K/V* mutation, are often resistant to ponatinib. Rash, elevated lipase, pancreatitis and headaches seem to be common non-haematological toxicities of the drug. Of significant concern, 27% of patients who participated in early clinical studies reported having had either arterial or venous thrombotic events. The EPIC study that randomised newly diagnosed CML-CP patients to imatinib versus ponatinib was prematurely terminated due to these concerns. The recently reported OPTIC study suggested a correlation between dose and risk of vascular events. This dose-finding study in CML-CP patients either resistant or intolerant to other TKIs randomised to a ponatinib starting dose of 45, 30 versus 15 mg. Patients assigned to the 45 and 30 mg arms were dose reduced to 15 mg once *BCR::ABL1* falls below 1%. This was achieved in 44.1, 29.0 and 23.1% of patients in these 3 arms respectively. The exposure-adjusted rates of arterial occlusive events were 5.6, 3.6 and 2.1% respectively, with a median follow-up of 32 months. The molecular response was superior in the cohort who were initially started on ponatinib at a dose of 45 mg/day. All 3 arms had significantly

lower rates of vascular events compared to earlier studies, such as the PACE trial, where higher doses than 15 mg/day were often maintained long-term. As with nilotinib, proactive identification and management of cardiac and vascular disease risk factors are strongly advised for patients receiving ponatinib.

Asciminib

Asciminib (earlier designated as ABL001) is a TKI with a different mode of action compared to all of the currently available TKIs. Rather than competitively blocking ATP binding, asciminib binds to a myristoyl pocket on Abl which leads to inactivation of kinase activity. Its sponsor, Novartis, has coined the term STAMP (Specifically Targeting the ABL Myristoyl Pocket) to differentiate it from TKIs that bind to the ATP-binding pocket. Asciminib selectively binds to *ABL1*, *ARG* (*ABL2*) and *BCR::ABL1*, with significantly less off-target effects that are a major issue for all of the ATP competitive TKIs. In the phase I study, asciminib demonstrated a good safety profile and proved to be efficacious in many patients who were intolerant and/or resistant to several TKIs. In the Phase III randomised ASCEMBL study, it was shown to be superior to bosutinib in patients who had failed at least 2 other TKIs and is now approved for use in the third-line setting in many jurisdictions. Resistance to asciminib has been observed, in some case this is due to mutations within the myristoyl pocket, such as V468F, P465S, I502L and A337V. The kinase domain mutations that lead to resistance to ATP-competitive TKIs are often sensitive to asciminib, though T315I and F359V are less sensitive to asciminib than the native form of *BCR::ABL1*. An expanded arm of the Phase I study used a higher dose of asciminib (200 mg twice daily to specifically target T315I, as compared to the standard dose of 40 mg twice daily) showed good efficacy and comparable toxicity to the standard dose. This is also an approved indication in many jurisdictions. The most common toxicity observed with asciminib therapy has been thrombocytopenia and an abnormally elevated lipase which is sometimes associated with clinical pancreatitis. Asciminib represents a promising new therapeutic option for many CML patients and the ASC4FIRST study has recently demonstrated superior efficacy for achievement of MMR versus investigator selected TKI (68% versus 49% at week 48) in the first line setting.

Choice of TKI upfront

Currently, imatinib, nilotinib (300 mg BID), dasatinib and bosutinib (400 mg/day) are available in most countries for up-front treatment in CML-CP. All four are reasonable options. Although the second-generation TKIs lead to improved molecular responses, all four lead to similar long-term overall survival. The choice of therapy for each individual patient would rest mainly on a patient's comorbidities and their risk of disease transformation, as well as the priority placed on achievement of deep molecular responses and opportunities for a subsequent attempt at treatment cessation.

The second generation TKIs may be reasonable choices in patients with high ELTS risk. The daily dosing of dasatinib may be more convenient in younger patients at higher risk of non-compliance, and there is emerging data that a reduced dose of 50 mg daily may be well tolerated even in the elderly and shows equivalent efficacy to the standard dose of 100 mg daily. Dasatinib should generally be avoided in patients with significant coexisting cardiopulmonary disease who risk decompensation with pleural effusion and pulmonary hypertension. Bosutinib is also taken once a day, though its side effect of diarrhoea may be troubling for patients. Nilotinib appears to have a similar efficacy with regards to achievement of deep molecular responses compared to dasatinib and may be ideal in patients for whom the opportunity to cease treatment is a high priority (e.g. women planning to start a family). However, its twice-daily dosing away from food is challenging for many patients and may exacerbate nonadherence. Nilotinib should be avoided in patients with previous vascular events and poorly controlled cardiovascular risk factors, especially at the higher dose of 400 mg BID.

Imatinib, in contrast, appears to have a favourable long-term toxicity profile. While side-effects are common and cause significant discomfort, most patients learn to manage these symptoms. In older patients with pre-existing vascular or respiratory problems, imatinib would often be a better choice. However, patients who receive imatinib upfront at a dose of 400 mg daily are at higher risk of transformation to AP/BP, in comparison to those who receive up-front nilotinib or dasatinib.

Incorporation of both imatinib and a second-generation TKI into a combined treatment strategy may be a reasonable compromise to enhance safety and retain efficacy. For instance, the Australasian TIDEL-II study started newly diagnosed CML-CP patients on imatinib 600 mg daily. Patients were assessed against time-dependent molecular targets (*BCR::ABL1* $\leq$10%, $\leq$1% and $\leq$0.1% at 3, 6 and 12 months, respectively). Patients who failed these targets switched to nilotinib with or without a trial of imatinib 800 mg/day, as did patients with imatinib intolerance or loss of response. The 24-month MMR, MR4.5 and the 3-year overall and progression-free survival from TIDEL-II were similar to that achieved by patients who received a second-generation TKI up front. However, this strategy allowed many patients to stay on imatinib. Over the first 2 years of study treatment, ~50% of patients remained on imatinib and ~30% of patients switched to nilotinib, while ~20% had discontinued study treatment.

In the paediatric setting, the bulk of evidence and experience concerns the use of imatinib, where the efficacy and side-effect profile are very similar to that seen in adults. Imatinib, as with other TKIs, is dosed according to body surface area in children (260–340 mg/m^2/day). The second-generation TKIs dasatinib and nilotinib are also approved for use for paediatric CML in many jurisdictions, dosed at 60 mg/m^2/day and 230 mg/m^2 twice a day for the 2 agents respectively. It is important to monitor for growth, pubertal and physical development of children treated with TKIs, as various degrees of growth deceleration have been

reported. Imatinib is known to cause altered vitamin D metabolism, hypocalcaemia, hypophosphataemia and decreased bone remodelling, all factors that may lead to stunted growth. Growth and maturation may also be affected through interference with sex hormone metabolism, and endocrinology assessment may be necessary in children with delayed maturation. Cardiovascular toxicities have generally not been as much a concern here as in adult CML patients although longer-term follow-up is limited.

Treatment goals

For CML-CP patients treated with TKIs, disease-specific survival is excellent and overall survival is similar to age-matched controls. However, despite the introduction of increasingly potent TKIs, survival for patients with CML-BP has not improved dramatically, and prevention of disease transformation is therefore of paramount importance. There is a reliable correlation between time-dependent reductions in tumour burden (measured by RQ-PCR or cytogenetics) and survival. Milestone responses, such as achievement of *BCR::ABL1* levels below 10% (IS) at 3 months, 1% (IS) at 6 months and below 0.1% (IS) at 12 months, differentiate patients at high risk of disease transformation from patients with optimal treatment response. MMR at 12 months in particular has been adopted as surrogate end points for many clinical trials.

Consensus statements concerning optimal time-dependent treatment targets are available. The two most widely used are published by the US-based NCCN (National Comprehensive Cancer Network) and the ELN (European Leukaemia Net), with subtle differences between the two. The ELN stratify responses at 3, 6 and 12 months after therapy commencement into three categories – Optimal, Warning and Failure. Optimal response is associated with favourable long-term survival. Conversely, patients who fail any of the time-dependent targets are at high risk of disease progression should they continue with the same treatment. Patients who have received a 'warning' are in the intermediate category and these patients should be closely monitored and counselled to adhere to therapy. Similarly, the NCCN uses a traffic light system where patients at highest risk of disease progression belong to the red category, versus patients with possible/emerging TKI resistance in the yellow category, versus patients who have achieved their treatment targets in green.

The relevant milestones are summarised in Table 33.2. Treatment recommendations are based on consensus expert opinions, as good-quality evidence demonstrating the benefit of interventions is not currently available. Interventions based on early molecular responses are a particularly contentious issue. Patients who record a *BCR::ABL1* IS >10%, 3 months after starting therapy have inferior overall survival, a high risk of disease transformation (between 8 and 12%), and inferior achievement of MMR/MR$^{4.5}$ (Figure 33.10). ELN recommendations advise that a *BCR::ABL1* level >10% (IS) at 3 months, if confirmed on a second test, is consistent with treatment failure. Interestingly, data from the Adelaide cohort of imatinib-treated patients suggest that patients with *BCR::ABL1* >10% at 3 months may be further risk stratified, based on an individual patient's *BCR::ABL1* halving time. Patients with a halving time of >76 days were at the highest risk of treatment failure. The German CML IV study group came to the similar conclusion that the early velocity of an individual patient's *BCR::ABL1* drop may add additional prognostic information to RQ-PCR measurements at single time points.

A check for medication adherence and drug interactions are advised for any patient who have not achieved their treatment targets (NCCN Green/ ELN Optimal). Mutational analysis is useful and may guide TKI selection for subsequent line therapy. Continuing imatinib at a dose of 400 mg daily is generally not recommended, although an increase in the imatinib dose to 600 mg daily is an effective strategy for some patients.

Table 33.2 Consensus time-dependent molecular targets from the US National Comprehensive Cancer Network, 2021 edition; and the European Leukaemia Net, 2020 edition. Refer to text for recommended management options for each category.

Time point	*BCR::ABL1* QPCR	NCCN	ELN
3 months	>10%	Possible TKI resistance	Failure, if confirmed within 1–3 months
	≤10%	TKI-sensitive disease	Optimal
6 months	>10%	TKI-resistant disease	Failure
	>1% but ≤10%	TKI-sensitive disease	Warning
	≤1%	TKI-sensitive disease	Optimal
12 months	>10%	TKI-resistant disease	Failure
	>1% but ≤10%	Possible TKI resistance	Failure
	>0.1% but ≤1%	TKI-sensitive disease. Response optimal for survival but not TFR	Warning
	≤0.1%	TKI-sensitive disease	Optimal

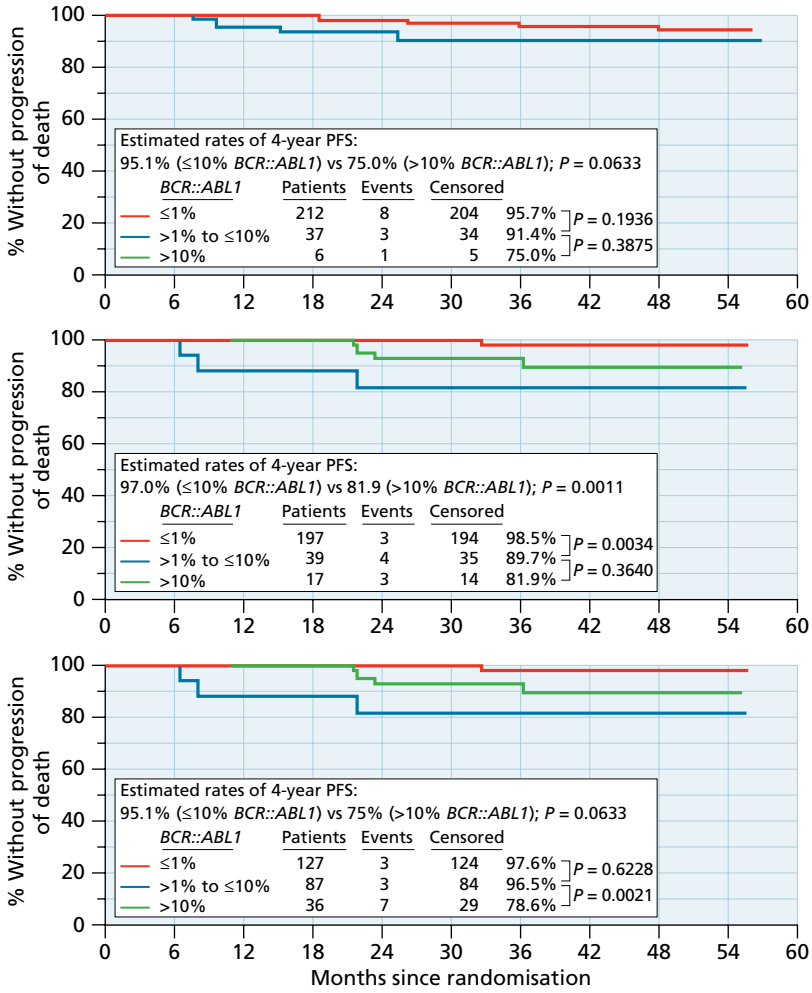

Figure 33.10 Patients failing to achieve an early molecular response experience inferior survival regardless of frontline therapy received. These results from the ENESTnd study showed progression-free survival to be 75.0, 81.9 and 78.6% in the nilotinib 300 mg BID, nilotinib 400 mg BID and imatinib 400 mg OD arms, respectively, in patients with *BCR::ABL1* >10% at 6 months. (Top panel – nilotinib 300 mg BID, middle panel – nilotinib 400 mg BID, bottom panel – imatinib 400 mg OD). In comparison, patients with *BCR::ABL1* ≤1% 6 months after starting therapy enjoyed 4-year progression-free survival of 95.7–98.5%. The same conclusion can be drawn from the landmark analyses from the DASISION study comparing imatinib to dasatinib (Source: Hughes *et al.* (2014) *Blood* **27**; **123**(9): 1353–60. Reproduced with permission of American Society of Haematology.)

For patients in the NCCN yellow and ELN warning category, switching to an alternative TKI is not mandatory in the absence of a resistant kinase domain mutation, especially if there is a clear downward trend in the *BCR::ABL1* QPCR. Selection of an alternative TKI depends on the priority for early treatment discontinuation as well as the patient's comorbidity, matched for tolerance of likely toxicities. For patients in the NCCN Red/ELN Failure category, switching to an alternative TKI is recommended. Workup for allogeneic stem cell transplant may be warranted in patients otherwise fit for the procedure, and where no benefit is demonstrated with alternative TKI therapy.

Duration of treatment

With the success of TKI therapy, an increasing number of patients achieve deep and durable molecular responses. Although it was originally assumed that patients would need to continue TKI therapy indefinitely to prevent late disease relapses, a number of patients have since participated in treatment cessation studies and have achieved treatment-free remissions (TFR). TFR – defined as the maintenance of MMR in the absence of further treatment in patients who have previously achieved sustained DMR with TKIs – is now the goal of CML treatment for many patients. Eliminating the need for further TKI therapy not only minimises the impact of existing side-effects and removes the potential for long-term complications, but also decreases the overall financial burden associated with drug costs.

Two of the earliest treatment cessation studies were the French STIM study and the Australian TWISTER study (Figure 33.11), where imatinib-treated CML-CP patients who had undetectable *BCR::ABL1* (with assays of >5 log sensitivity) for an uninterrupted period of 2 years stopped imatinib and were monitored monthly with RQ-PCR. Rapid molecular relapse (i.e. RQ-PCR moving from undetectable to positive) was noted in 60% of patients, mostly occurring within the first 6 months after stopping. All relapses were sensitive to imatinib re-challenge, with most patients re-establishing deep molecular response, and no disease transformation was reported.

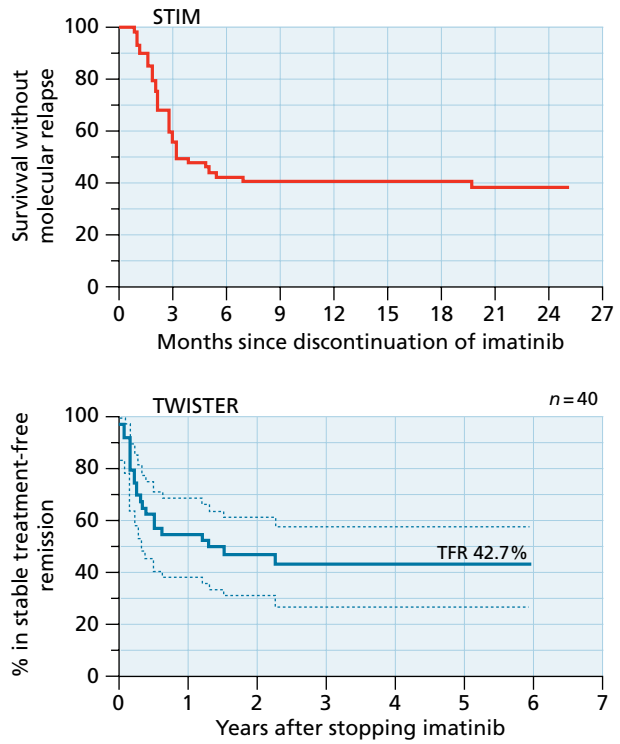

Figure 33.11 For patients with deep molecular responses, a trial of TKI cessation may lead to durable treatment-free remissions (TFR). The STIM (top panel) and TWISTER (bottom panel) studies both showed the rate of TFR in patients who maintained MR^5 for 2 continuous years prior to trial of therapy cessation to be ~40% (Source: (Top panel) Hughes *et al.* (2014) *Blood* **123**(9): 1353–60. (Bottom panel) Ross *et al.* (2013) *Blood* **122**(4): 515–22. Reproduced with permission of American Society of Haematology.)

The remaining 40% have remained in a deep molecular remission off treatment, many for over 10 years. There have been, as yet, no late relapses reported in this group, raising the possibility that TFRs may truly be durable in the long term. These data are corroborated by a number of subsequent studies involving patients treated with imatinib as well as second-generation TKIs. Interestingly, the proportion of patients who remain in TFR falls between 40 and 60% long-term, regardless of the potency of TKI used initially for treatment. Indeed, the biological determinants of successful treatment cessation remain elusive, but appear to correlate with total TKI treatment duration as well as duration of a deep molecular response. This may relate to senescence of Ph+ clones over long periods of TKI treatment. Additionally, patients with a more rapid reduction in *BCR::ABL1* transcripts during their first 3 months of TKI treatment, as well as patients with the e14a2 transcript, appear to have a higher TFR success rate. Not all patients who experience early molecular relapse require retreatment. In about a third of these patients, RQ-PCR becomes detectable, but remains below 0.1%, even without treatment.

Given that a number of studies with differing TFR eligibility criteria all led to similar TFR success rates, there is still uncertainty regarding the minimum criteria a patient has to achieve before being offered a TFR attempt (Table 33.3). For instance, the ENESTfreedom study allowed TFR attempts with a minimum of 3 years of nilotinib treatment, including a 12-month period of MR4.0 response and MR4.5 to be achieved immediately prior to treatment cessation. This information has since been included as part of nilotinib's approved product information in US and EU. However, the consensus criteria for TFR is more conservative, with the example from the ELN 2020 guidelines representing a reasonable approach (Table 33.4). CML-CP patients with no prior history of treatment resistance, who have had TKI therapy totalling 5 year or more, and have been in DMR for 2–3 years, are eligible for TFR in this guideline. An alternative approach to toxicity minimisation may be dose reduction. Recently, the UK DESTINY study showed that patients with stable DMR may safely reduce their TKI dose by 50% for 12 months, before a planned discontinuation. Patients in stable MR^4 in this study showed a particularly high molecular recurrence-free survival rate (RFS) of 76% at 24 months. However, whether an initial dose de-escalation strategy improves rates of successful long-term TFR remains uncertain in the absence of randomised trial comparison with conventional TFR approaches.

Further studies are currently underway to examine whether adjunctive therapy such as pegylated interferon will be of benefit just prior to or in the initial period of therapy cessation. The optimal criteria for a second TFR attempt in patients who previously had one failed attempt at TFR also remains to be determined. Of note, current recommendations for TFR should not be extrapolated to patients with current or previous advanced-phase disease.

Treatment resistance

Treatment resistance may be encountered in ~10–20% of patients receiving TKI in the frontline setting (an additional ~10–20% of patients fail therapy because of varying degrees of toxicity, and some are better classified as failing therapy because of intolerance, though the two frequently overlap). Kinase domain mutations are identified in 30–50% of cases and are the most frequently identified mechanism of treatment resistance. These point mutations result in amino acid changes, which decrease binding affinity of TKIs (Figure 33.12). The consequence is restoration of constitutive kinase activity. Imatinib appears to be susceptible to the widest range of mutations – over 50 have been documented. The second-generation TKIs are active against most imatinib-resistant mutations, though the T315I mutation confers resistance to all TKIs except ponatinib and asciminib. This threonine residue at position 315 in the ATP binding pocket is critical to the binding of most TKIs and is substituted for isoleucine in ~10–15% of mutations. Other commonly/encountered mutations of note include the *V299L*

Table 33.3 Summary of representative treatment-free remission studies in the context of second-generation TKIs. Regardless of the TKI used in the initial treatment, once a patient achieves deep molecular response and maintains this for 12 or more months, the probability of sustaining molecular response upon treatment cessation is ~45–60%, similar to results reported by imatinib-stopping studies.

Study	*n**	TKI and line of treatment	Median duration of treatment with TKI (total and second-generation	Qualifying DMR	Median duration of DMR	Definition of molecular relapse	Percentage (%) of patients in TFR
First-line DADI[39]	58	Dasatinib, first	40 months	MR4.0 for ≥1 yr	23 months	Loss of MR4.0	55 at 12 months
DADI[40,41]	63	Dasatinib, second	82 months and 17 months	MR4.0 for ≥1 yr	NR	Loss of MR4.0	44 at 36 months
D-STOP[42]	54	Dasatinib, first and second	92 months and NR	MR4.0 for ≥2 yrs	51 months	Loss of MR4.0	63 at 12 months
DASFREE[43]	84	Dasatinib, first and second	69 months and NR†	MR4.5 for ≥2 yrs	28 months	Loss of MMR	46 at 24 months
STOP 2G-TKI[44]	30 (each TKI)	Dasatinib and nilotinib, first and second	76 months and 39 months	UMRD for ≥2 yrs	29 months	Loss of MMR	54 at 48 months
STAT2 (ref.[45])	78	Nilotinib, second	99 months and 25 months	MR4.5 for ≥2 yrs	51 months	Loss of MR4.5	63 at 36 months
ENESTop[46]	126	Nilotinib, second	88 months and 53 months	MR4.5 for ≥1 yrs	32 months	Loss of MR4.0	53 at 96 weeks
ENESTfreedom[47,48]	190	Nilotinib, first	44 months	MR4.5 for ≥1 yr	30 months	Loss of MMR	49 at 96 weeks

DMR, deep molecular response; MR4.0/4.5, deep molecular response with *BCR::ABL1* mRNA levels in peripheral blood of ≤0.01%/0.0032%; MMR, major molecular response; NR, not reported; TFR, treatment-free remission; TKI, tyrosine-kinase inhibitor; UMRD, undetectable minimal residual disease.

* *n* refers to the number of patients in the study of TKI discontinuation for whom outcomes were reported.

† The total duration since diagnosis is provided, which approximates TKI duration.

Table 33.4 Consensus ELN 2020 criteria for treatment free remission (TFR) attempts.

Mandatory
- CML in first CP only (data are lacking outside this setting)
- Motivated patient with structured communication
- Access to high-quality quantitative PCR using the International Scale (IS) with rapid turn-around of PCR test results
- Patient's agreement to more frequent monitoring after stopping treatment. This means monthly for the first 6 months, every 2 months for months 6–12, and every 3 months thereafter.

Minimal (stop allowed)
- First-line therapy or second-line if intolerance was the only reason for changing TKI
- Typical e13a2 or e14a2 *BCR::ABL1* transcripts
- Duration of TKI therapy >5 years (>4 years for 2GTKI)
- Duration of DMR (MR4 or better) >2 years
- No prior treatment failure

Optimal (stop recommended for consideration)
- Duration of TKI therapy >5 years
- Duration of DMR > 3 years if MR4
- Duration of DMR > 2 years if MR4.5

(*Source:* Adopted from Hochhaus A, Baccarani M, Silver RT *et al.* (2020) European LeukemiaNet 2020 recommendations for treating chronic myeloid leukaemia. *Leukemia*. **34**: 966–984. https://doi.org/10.1038/s41375-020-0776-2. Used with permission under an open access Creative Commons License.)

and *F317V/C* mutations resistant to dasatinib, and the *Y253H*, *E255K/V* and *F359C/V* mutations resistant to nilotinib. Mutational analysis should be performed when a patient fails to reach their time-dependent targets or has loss of a previously achieved response. Most importantly, screening for kinase domain mutations should always be done in patients who are resistant to a TKI, prior to selecting the most suitable TKI for ongoing therapy. Sanger sequencing is the traditional diagnostic method for mutation analysis. It is relatively cheap and more widely available, but can only detect mutant clones if they are present in >10–15% of the total *BCR::ABL1*+ population, and only when the total *BCR::ABL1* is >0.1% IS. Matrix-assisted laser desorption/ionisation with time of flight (MALDI-TOF, MassArray) is a specialised technique with a sensitivity as low as 0.1%, but only for specific mutations. Next-generation sequencing can detect mutations with a sensitivity as low as 3% and has recently been endorsed by the ELN for kinase domain mutation analysis. Data are also accumulating to suggests that advanced phase CML may be associated with mutations in certain molecular driver genes e.g. *ASXL1*. Screening for these mutations in patients with high-risk disease via NGS may, in the future, also give warnings of impending disease progression.

Advanced phase diseases

In advanced phase CML, TKI monotherapy is much less effective compared to CML-CP. Although a number of patients can achieve complete haematological responses, these are rarely durable without follow-up combination chemotherapy and allogeneic HSCT. Fortunately, over 90% of CML patients are diagnosed in CP, and with effective TKI treatment, only ~5% of these patients transform to AP/BP.

Evidence regarding the use of TKIs in *de novo* CML-AP is scant. In the STI571 0109 study, imatinib 600 mg daily led to a CCyR of 20%. In this study, response rates of AP patients with both clonal evolution and increased blast counts were inferior to those with either feature alone. Extrapolating from data with frontline TKI use in CML-CP patients, the more potent second-generation TKIs should be superior to imatinib in CML-AP. In the MD Anderson Cancer Centre cohort of 51 patients, imatinib led to overall survival of 87% at 3 years, with 46% of patients achieving MMR by 18 months. In contrast, patients treated with second-generation TKIs had a 3-year overall survival of 95%, with an 18-month MMR rate of 56%. It is reasonable therefore to treat CML-AP patients with TKI monotherapy in the first-line setting.

Outcomes for CML-BP patients remain dismal, even with potent TKIs, and patients invariably develop resistance to TKI monotherapy. Patients with lymphoid BP are best treated with Ph^+ ALL induction chemotherapy regimens. TKIs are of benefit when used prior to or in combination with chemotherapy, though this may compound marrow toxicity and delay cell count recovery. Whether TKIs have effective CNS penetration is unclear and standard ALL CNS prophylaxis should be offered. Combination of TKI with blinatumomab is an emerging treatment approach, although experience in lymphoid BP remains limited. Myeloid BP is best treated with AML-type induction regimens, with combinations such as cytarabine and an anthracycline. As with lymphoid BP, TKIs in combination with chemotherapy are generally preferred. Treatment responses in CML-BP are rarely durable and transplant-eligible patients should proceed to allogeneic HSCT once a second chronic phase has been established.

In patients with significant comorbidities or those otherwise unfit for chemotherapy, TKI monotherapy would be a reasonable option. As with CML-AP, there is a paucity of data regarding the use of TKI monotherapy in *de novo* CML-BP. In one Phase II study, 154 treatment-naïve CML myeloid BP patients were treated with imatinib. This led to CHR lasting for ≥4 weeks in 8.8%, and CCyR in 8.1%.

For patients who progressed to AP/BP from CP while on treatment, the choice of the subsequent agent should be directed by results of the mutation analysis. About a third of these patients will achieve CCyR with a second-line agent. The T315I mutation is one of the most commonly found mutations in this context and will preclude successful use of all second-generation TKIs. The PACE study included patients with treatment resistance to

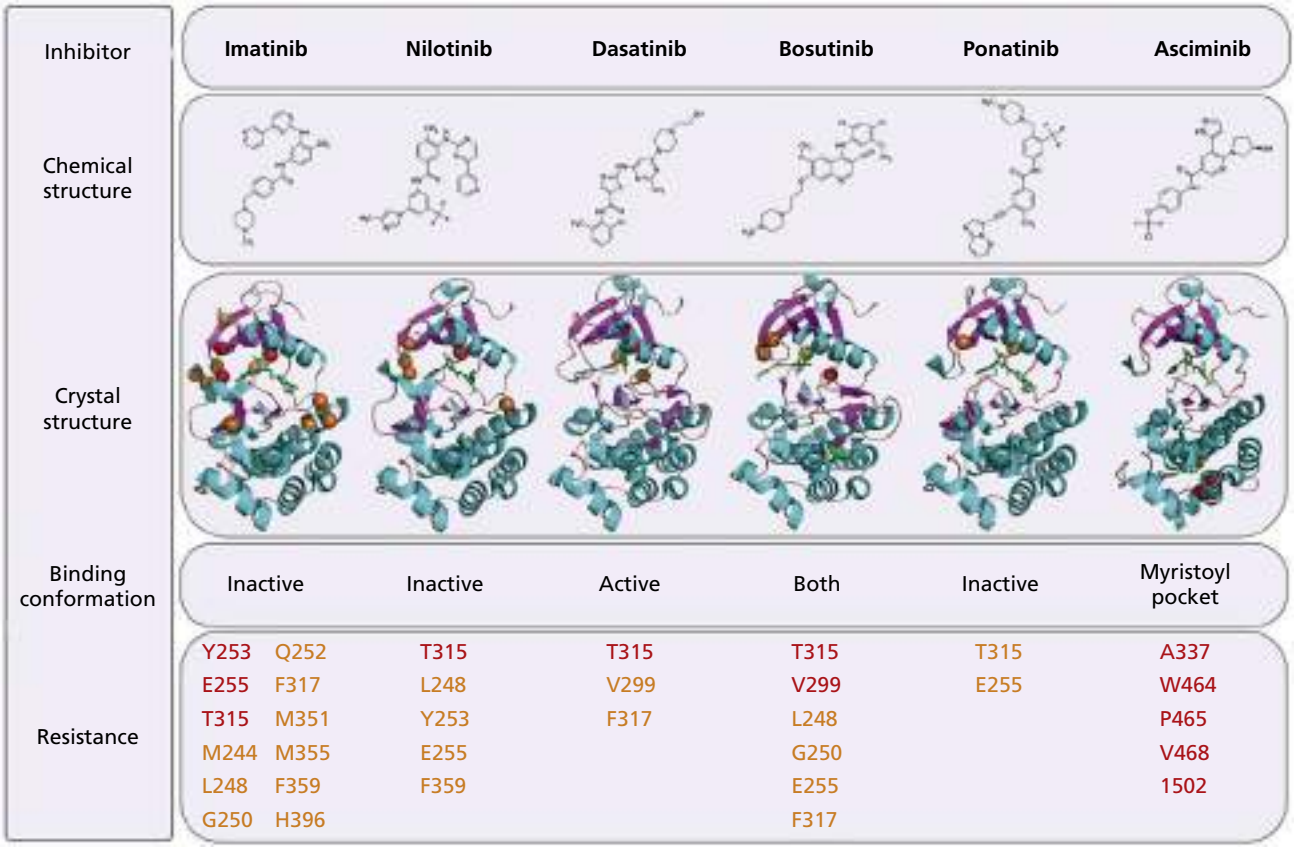

Figure 33.12 Chemical structures of *BCR::ABL* inhibitors currently in clinical use, and the published X-ray crystallographic structures of ABL1 as complexed with these drugs. Bottom panel lists mutations that confer resistance to these specific inhibitors. (High-level listed in red; in orange are mutations that have relative resistance compared to native *BCR::ABL*. Of note, even though both T315I and E255K/V mutated *BCR::ABL* is less sensitive to ponatinib compared to native *BCR::ABL*, these mutations alone do not generally confer resistance to ponatinib in the clinical setting. Rather, resistance is conferred when both mutations are present in compound configuration. Reprinted with permission from Braun TP, Eide CA and Druker BJ. Response and Resistance to *BCR::ABL1*-Targeted Therapies (Source: *Cancer Cell*. 2020; **37**(4): 530–42. doi: 10.1016/j.ccell.2020.03.006.)

either nilotinib or dasatinib, or who had the T315I mutation; ~30% of myeloid BP and ~30–50% of lymphoid BP patients achieved complete haematological response and cytogenetic response with ponatinib treatment. However, median duration of response is only ~5 months.

Fertility preservation and pregnancy

The long-term effect of TKIs on prospective fertility is not known. An increasing number of children had been fathered by male patients receiving imatinib, dasatinib, nilotinib and bosutinib without increased congenital or developmental abnormalities compared to the general population. There is insufficient data regarding ponatinib and asciminib to know whether fathering children is safe for male patients receiving these drugs. In contrast, effective contraception is advised for female patients receiving any of the TKIs as they are all associated with a higher risk of birth defects.

Female patients wishing to conceive electively should ideally achieve and maintain a deep molecular response to allow a trial of cessation, using standard TFR criteria, that will allow for conception. The appropriate washout period between TKI cessation and attempting to conceive is unknown, though pharmacokinetic data would suggest a week should suffice. Regular haematological and molecular monitoring during this period and the subsequent pregnancy is advised. TKIs should be restarted postpartum for patients with loss of molecular response. Should patients require treatment while still pregnant (e.g. loss of complete haematological response with moderate or marked leucocytosis and/or thrombocytosis) interferon-α would be a reasonable choice in the second or third trimester. Regular leucapheresis may be an alternative. Data regarding the use of hydroxycarbamide (hydroxycarbamide

hydroxyurea) in this setting are scant and busulfan should be avoided. Cases also exist where imatinib had been used successfully in the second and third trimester, though experience here is again limited. TKIs should be stopped in women who accidentally conceive while taking TKIs, though the course of action should be individualised. Breastfeeding is contraindicated while on TKI treatment.

Haemopoietic stem cell transplantation

Prior to the introduction of TKIs, CML (especially CML-CP) was one of the most common indications for allogeneic HSCT. Although optimised protocols for HSCT in CML-CP can result in transplant-related mortality as low as ~5–10%, TKIs are still a better option for the vast majority of these patients. Consequently, HSCT is now usually reserved for patients with advanced phase disease or therapeutic failure to all available TKIs.

Allogeneic HSCT outcomes may be predicted using the EBMT risk score, which includes variables such as patient age, stage of disease, donor type (related versus unrelated), stem cell source (PB versus BM) and length of diagnosis (>12 versus <12 months). The bulk of transplant outcome data came from patients who underwent myeloablative conditioning, which usually consists of high-dose cyclophosphamide and either busulfan or total body irradiation. The experience with reduced-intensity conditioning in CML had been steadily increasing and is preferred for older patients.

Problems common to HSCT in other diseases are also applicable in CML. Transplant-related mortality, graft-versus-host disease and relapse-related mortality are significant problems. Many centres will use TKI therapy post allogeneic HSCT and in cases where there is evidence of residual leukaemia by molecular monitoring, though the role for TKIs in this setting has not been fully evaluated. Unlike CML-CP patients, bone marrow RQ-PCR may be a more sensitive marker for minimal residual disease in CML-AP/BP. Donor lymphocyte infusions may be of benefit in patients with disease relapse post-transplant. However, exacerbation of GVHD may be a concern.

Atypical CML/chronic neutrophilic leukaemia

Occasionally patients present with a blood picture suggestive of CML, but the Philadelphia chromosome and the *BCR::ABL1* fusion gene are both undetected (see also Chapters 10 and 35). After exclusion of cryptic variant t(9;22) and atypical *BCR::ABL1* transcripts, a diagnosis of either atypical chronic myeloid leukaemia (aCML, now classified as MDS/MPN with neutrophilia in the current WHO classification) or chronic neutrophilic leukaemia (CNL) may be appropriate.

Atypical CML is an overlap syndrome with features of both myeloproliferative and myelodysplastic disorders. Patients usually present with leucocytosis, with a predominant increase in neutrophils and their precursors. Maturation is dysplastic, and in contrast to CML and chronic myelomonocytic leukaemia (CMML), basophilia, monocytosis and eosinophilia are rare. Patients with aCML fare poorly and often die from marrow failure or transformation to AML.

Like CML and aCML, CNL is characterised by leucocytosis with a predominant neutrophilia. However, unlike aCML, neutrophil morphology is normal in CNL. Neutrophil precursors such as metamyelocytes, myelocytes and promyelocytes are <10% of circulating cells in CNL, which differentiates this disease from CML. The course of CNL is variable, though neutrophilia is usually progressive, accompanied by cytopenia of other lineages resulting in marrow failure, or transformation to AML.

Recurrent genetic lesions have been found in the *CSF3R* and *SETBP1* genes in a number of CNL and aCML patients. The *CSF3R* T618I activating mutation is present in ~80% of CNL cases and forms a criteria for diagnosis. *CSF3R* T618I driven disease is sensitive to ruxolitinib which may be appropriate treatment in selected cases. Mutations in *CSF3R* at other loci are implicated in severe congenital neutropenia. In contrast to CNL, the mutation profile of aCML is more variable. Genes mutated in other myeloid malignancies, such as *SETBP1, ASXL1, N/K-RAS, SRSF2* and *TET2* are commonly observed in aCML. Mutations in *CBL, CSF3R, JAK2* and *ETNK1* are observed but less frequently encountered. The *CSF3R* mutations seen with aCML include the proximal membrane mutation T640N, as well as nonsense and frameshift mutations that result in truncation of the cytoplasmic tail of *CSF3R* (e.g. D771fs, S783fs, Y752X and W791X).

Future prospects

Although the treatment outcome for CML patients has dramatically improved in the last decade, a number of challenges remain. Early transformation to CML-BP remains the outstanding cause of CML-related death. A number of emerging biomarkers with prognostic significance are currently under investigation, and early identification of patients who are at high risk of transformation should become possible. Perhaps more challenging will be the task of finding effective therapies for high-risk patients thus identified and in patients with *de novo* CML-BP. This may rely on the clinical development of small molecule inhibitors with novel mechanisms of action and synergistic activity against *BCR::ABL1*+ cells (Figure 33.13). Advances in allogeneic HSCT, such as continuing decreases in transplant-related mortality and improvements in supportive care, may also be important for this group. At the other end of the spectrum, an increasing number of patients achieve stable and deep molecular responses. Selection of patients likely to be able to stop therapy without relapse, finding the optimal consolidating therapy ahead of a second TFR attempt in patients who have already had one unsuccessful attempt at TFR, as well as strategies to boost the overall TFR rate are all increasingly important priorities for future research.

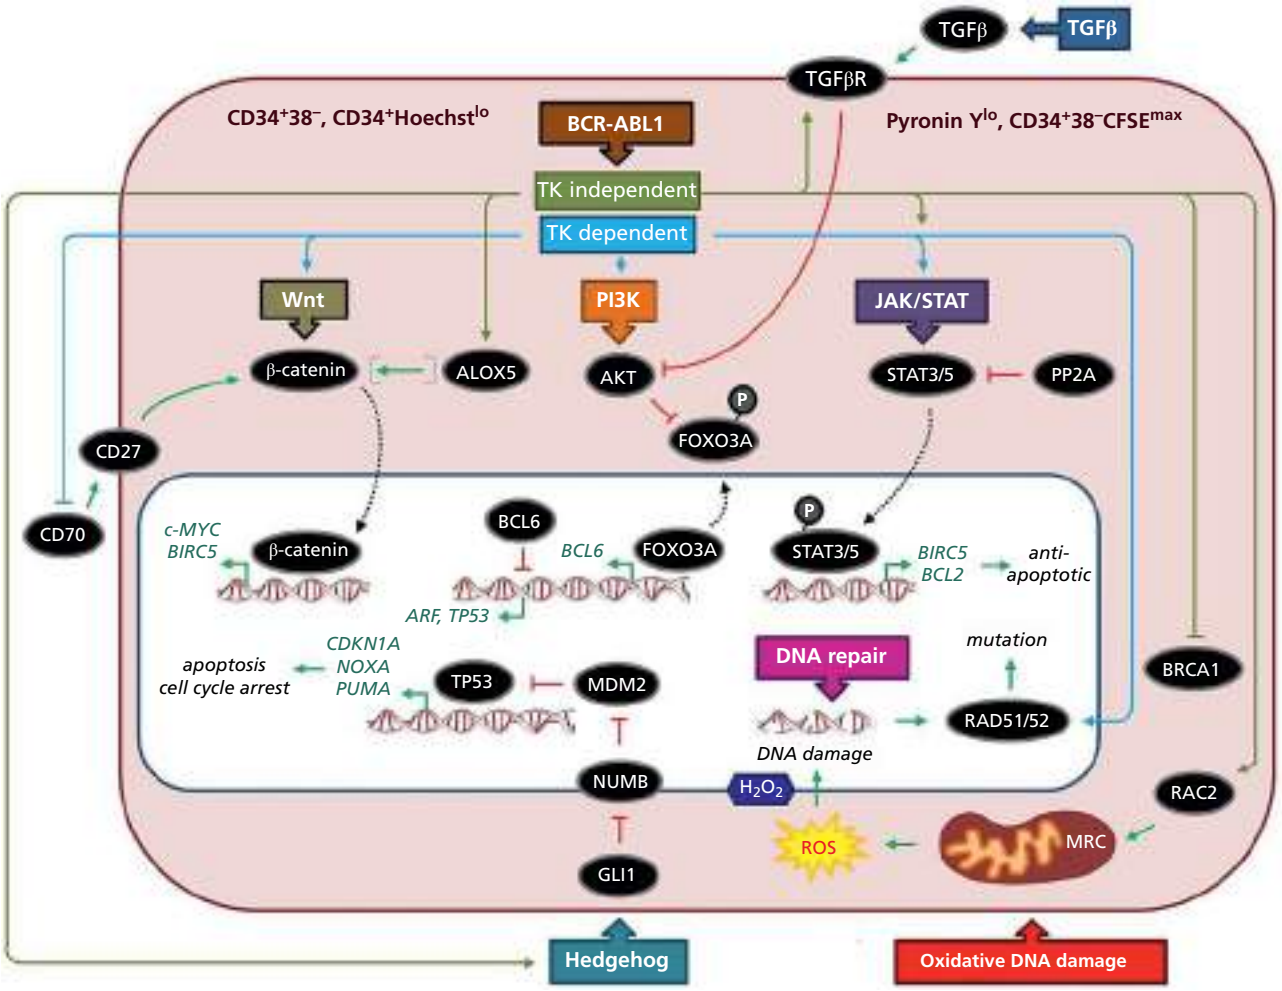

Figure 33.13 A number of critical pathways contribute to CP CML leukaemic stem cells being quiescent and refractory to apoptosis, persistent even with *BCR::ABL*1 inhibition from TKI treatment and prone to DNA damage. They may be identified immunophenotypically as CD34+CD38− Ph+ cells. Targeting some of these signals may be critical to improving therapeutic success in advanced phase CML, as well as patients with failure to achieve treatment-free remission. A number of small molecule inhibitors with activity against some of these targets are already in clinical use, such as ruxolitnib against JAK2 (Source: From Holyoake and Vetrie (2017) *Blood* **129**(12): 1595–606.)

CHAPTER 34

The myelodysplastic syndromes

34

Johanna Ungerstedt, Magnus Tobiasson and Eva Hellström Lindberg

Department of Haematology, Karolinska Institute and Karolinska University Hospital, Stockholm, Sweden

Introduction

The myelodysplastic syndromes (MDS) constitute a spectrum of myeloid malignancies with variable degrees of cytopenia and morphologic dysplasia and with a considerable risk for progression to acute myeloid leukaemia (AML). MDS cancer cells display profound molecular and biological heterogeneity leading to different clinical features and propensities for clinical stability or progression. Understanding disease biology is thus key for understanding the disease. MDS patients present with a large variety of disease manifestations from very indolent to frankly aggressive. Clinical management therefore necessitates knowledge about a broad spectrum of diagnostic, prognostic and therapeutic procedures.

Although MDS encompasses a number of heterogeneous subcategories, they share a common origin in the hemopoietic stem and progenitor cell (HSPC). The degree of cytopenia partly defines the WHO subcategories but certain MDS and mixed MDS/MPN subgroups may also present with increased white blood cell, monocyte and platelet counts. Moreover, a diagnosis of MDS can be made in patients with mild or borderline anaemia if definitive morphologic or cytogenetic findings are present.

The most recent WHO Classification from 2022 encompasses MDS, mixed MDS-myeloproliferative syndromes (MDS MPN), secondary myeloid neoplasms and MDS of childhood. This chapter will cover all these entities, in the general sections of this chapter termed 'MDS'.

History and classification

Patients who today are diagnosed as MDS were for decades considered a diagnostic challenge. The disease features were dominated by treatment-refractory cytopenias and patients often had a dismal outcome. The high propensity of leukaemic progression initially led to the term 'preleukaemia' being coined in 1953. Haematopathological studies revealed morphological abnormalities that with time were identified as dysplastic features and which were considered either pathognomonic or supportive for the diagnosis. The bone marrow frequently showed an increased percentage of myeloblasts, but not to the extent that the criteria for AML were met. Due to the somewhat subjective nature for defining bone marrow dysplasia, it took several international consensus meetings before MDS was recognised as a separate entity within the first French-American-British (FAB) MDS classification, published in 1982. This classification divided patients with cytopenia and bone marrow dysplasia into five categories; those without excess of myeloblasts with or without the presence of ring sideroblasts, two groups with excess of myeloblasts 5–19 and 20–29%, respectively, and finally patients with monocytosis, termed chronic myelomonocytic leukaemia, CMML. The subsequent WHO classification was first published in 2001 and contained two major changes; the boarder against acute myeloid leukaemia was lowered from 30 to 20% bone marrow myeloblasts, and the '5q- syndrome' was introduced as a separate entity. Moreover, the overlap condition mixed myelodysplastic myeloproliferative syndromes (MDS/MPN) was introduced as a separate category. The WHO classification

Table 34.1 The WHO 2016 classification of MDS and MDS/MPN.

Myelodysplastic/ myeloproliferative neoplasms (MDS/MPN)	Myelodysplastic syndromes (MDS)
Chronic myelomonocytic leukaemia (CMML)	MDS with single lineage dysplasia
Atypical chronic myeloid leukaemia (aCML), *BCR::ABL12*	MDS with ring sideroblasts (MDS-RS)
Juvenile myelomonocytic leukaemia (JMML)	MDS-RS and single lineage dysplasia
MDS/MPN with ring sideroblasts and thrombocytosis (MDS/ MPN-RS-T)	MDS-RS and multilineage dysplasia
MDS/MPN, unclassifiable	MDS with excess blasts
	MDS with isolated del(5q)
	MDS, unclassifiable
	Provisional entity: Refractory cytopenia of childhood
	Myeloid neoplasms with germ line predisposition

has been revised both in 2008, 2016 and 2022. An alternative classification system has also recently been proposed (International Consensus Classification of Myeloid Neoplasms and Acute Leukaemias), which broadly parallels the WHO system, and for the purposes of this chapter, the WHO classification system will be used. The classification systems stimulated the development of international prognostic scoring systems (IPSS) for patients with MDS, the initial publication in 2007, the revised IPSS (IPSS-R) in 2013, and recently the molecular IPSS-M. These will be described below. Table 34.1 shows the WHO 2022 classification of MDS and MDS/MPN.

Demographics and clinical presentation

Information about the incidence of MDS is based on large academic registries and population-based national cancer registries. Recent population-based studies report median ages of presentation of 75–76 years. European national registries report annual incidences of approximately 3–4 per 100,000. Irrespective of whether population-based or academic, all registries show a sharp increase of incidence with age, making MDS and its related disorders common blood cancers in the elderly population.

At diagnosis, the majority of patients with MDS have symptoms related to cytopenia, and these usually increase with time. Anaemia is the most frequently occurring cytopenia. According to a large population-based registry 11 and 42% of newly diagnosed patients had Hb levels <8 and 8–10 g/dL, respectively, and 50% needed erythrocyte transfusions, 40% had platelet counts below 100×10^9/L, 5% received platelet transfusions and 20% had neutrophil counts $<0.8 \times 10^9$/L. Hence, symptoms of anaemia dominate the initial clinical picture, while bleeding complications and infections become more pronounced during the course of disease.

A portion of MDS patients present with systemic inflammatory and autoimmune diagnoses (SIAD) before, in conjunction with, or after the diagnosis of MDS. Systemic vasculitis is reported in 32%, connective tissue disease in 25%, inflammatory arthritis in 23%, and neutrophilic disorders in 10% of these cases. There is a significant association between CMML and systemic vasculitis, which will be further discussed below. Other manifestations encompass fever, skin abnormalities including Sweet syndrome, and bleeding due to dysregulated coagulation. It is important to recognise the MDS diagnosis in these patients, as intervention with corticosteroids or azacitidine may relieve symptoms.

Studies on the quality of life (QoL) in MDS uniformly show a significant impact of disease on QoL and everyday life. Anaemia is strongly associated with fatigue, dyspnea and reduced exercise capacity, and pancytopenia adds on a risk of infection, bruising and bleeding. Severe MDS implies frequent transfusions leading to high dependency on the health care system and patients often feel that they are 'on a short leach'. Treatment of higher-risk MDS also necessitates frequent and regular visits for long periods, even in case of successful outcome. To live with the anticipated risk of disease, progression is associated with significant anxiety. An American study showed that the three most frequently reported symptoms were fatigue, pain and worry. A prospective European Registry study comparing patients with lower-risk MDS with an age- and sex-matched reference population reported moderate/severe problems in the dimensions of pain/discomfort (50%), mobility (41%), anxiety/depression (38%) and usual activities (36%). Limitations were more frequent in older patients, in females, and in those with high comorbidity burden or red blood cells transfusion need.

Aetiology

The cellular origin of MDS lies within the HSPC compartment and can usually be tracked back to the multipotent haematopoietic stem cell. Disease-propagating cells accumulate in the bone marrow as a result of a complex interplay between genetic and epigenetic alterations, the bone marrow microenvironment, the immune system and exogenous factors. It has recently been shown that this process can develop over several years and even decades.

Germline predisposition to myeloid neoplasms

MDS was previously considered a malignancy only rarely associated with germline predisposition. Exceptions were childhood conditions and syndromes, such as Diamond–Blackfan anaemia, Fanconi anaemia, Shwachman–Diamond syndrome and Kostmann´s disease, which will be described below in the

section about paediatric MDS. Another group of inherited MDS are the rare congenital sideroblastic anaemia (CSA) caused by mutations in genes involved in the iron and mitochondrial pathways. The most common of these are caused by germline mutations in *ALAS2,* followed by *SLC25A38, GLRX5, SLC25A38, HSPA9, HSCB, ABCB7* and others. The latter is interesting since the *SF3B1* mutations underlying acquired MDS with ring sideroblasts lead to miss-splicing and marked downregulation of *ABCB7*.

With the rapid development of genomics in haematology, it has become increasingly clear that also adult myelodysplastic syndromes can develop on the basis inherited mutations in germline DNA. Individuals with germline predisposition exhibit an increased risk to develop of myeloid neoplasms, mainly AML and MDS. Estimates suggest that between 5 and 10% of patients with MDS or AML carry pathogenic germline variants.

Myeloid neoplasms (MNs) with germline predisposition were recognised in a separate entity of 'Secondary Myeloid Neoplasms' in the WHO 2022 Classification. Germline mutations are divided into those predisposing to MN without a pre-existing disorder, mutations with pre-existing platelet dysfunction and mutations associated with organ dysfunction. *GATA2* and *RUNX1* mutations are relatively common and mandate continuous surveillance of asymptomatic carriers, due to the high risk of developing MN. Mutations in the telomerase complex usually imply a complicated clinical presentation with multi-organ involvement including lung and liver failure, in addition to a high risk to develop bone marrow failure or myeloid neoplasms. Heterozygous mutations in the *SAMD9* and *SAMD9L* genes comprising both loss and gain of function are associated with a range of haematological, immunological and neurological symptoms. These genes are located on chromosome 7 and render a high risk of progression to monosomy 7 MDS. Interestingly, development of monosomy 7 or 7q- may be associated with deletion of the mutated allele and reversion of the haematological features. More recently, identified homozygous mutations in *ERCC6L2* were shown to predispose to the development of somatic *TP53* mutations and severe MDS or AML. Recently, heterozygous mutations in *DDX41* (DEAD-box Helicase 41) were described as one of the most common predisposing mutations in MDS, probably present in as much as 3% of unselected adult patients. *DDX41* germline mutations predispose to MN at higher ages than most other predisposing mutations, making it an important gene to analyse in potential adult sibling donors. A summary of germline predisposition genes and subsequent diseases is found in Table 34.2.

Identification of a germline predisposition in a patient with MDS can be of crucial clinical significance. It may tailor therapy and dictate the selection of donor and conditioning regimen for allogeneic HSCT. It may also, depending on the risk for MN associated with a specific mutation, imply a recommendation to investigate first-degree relatives and to offer relevant regular controls for healthy carriers to allow for early intervention if MN develops. Several collaborative groups have recently published practical guideline programmes for diagnosis and management of germline conditions. However, new knowledge will likely be presented over the next years.

Myeloid neoplasms post cytotoxic therapy

Treatment with chemotherapeutic agents or irradiation for another primary cancer or other medical condition can induce genetic damage to the HSPC compartment and subsequent development of MDS or AML, in the WHO 2022 classified as myeloid neoplasms post cytotoxic therapy (MN-pCT). Large epidemiological studies indicate that around 10% of adult MDS patients should be classified as MN-pCT. The current WHO classification group all MN-pCT in one category, irrespective of the percentage of myeloblasts or cytogenetic features, and of the time between previous treatment and diagnosis of MDS. This may be a useful simplification but becomes less relevant when an elderly patient develops i.e. MDS-RS decades after a previous treatment for cancer. Altogether, patients with MN-pCT have a shorter expected overall survival than patients with *de novo* MDS with corresponding risk categories, but MN-pCT usually display a higher degree of complexity with regard to chromosomal and mutational patterns. It is likely that future classifications and risk scores for tMN to a higher extent will include mutational profiles. With few exceptions, MN-pCT should if possible be considered for curative therapeutic regimens.

MDS developing from clonal haemopoiesis of indeterminate potential

Clonal haemopoiesis of indeterminate potential (CHIP) is a relatively new field within haematology and will be described elsewhere in the textbook. CHIP may be present in the absence of cytopenia but may also co-exist with cytopenia without fulfiling the criteria for MDS (clonal cytopenia of unknown significance, CCUS). While some large epidemiological studies have shown that individuals with CHIP have a higher risk of developing cardiovascular disease and myeloid neoplasms, others have failed to show a strong correlation. The most frequent CHIP mutations encompass *TET2*, *DNMT3A* and *ASXL1,* but mutations in several other genes have also been described. Recent studies using next-generation sequencing tools allowing for detection of clones down to 1–2% show that close to 50% of individuals above 70 years carry CHIP clones, but whether such clones predispose for MN or simply should be viewed as normal ageing is not yet known. The frequent finding of CHIP in middle-aged and elderly individuals may also add to the understanding of MN-pCT; silent haematopoietic clones may be resistant to the cytotoxic exposure for the primary cancer and have the potential to undergo selective expansion and transformation.

Table 34.2 Germline mutations predisposing to myeloid neoplasms. Within each category, genes are listed in alphabetical order. Estimated risks for myeloid neoplasm are not given as the literature report large variations.

Disease/gene	Comment
*Germ line mutations predisposing to myeloid neoplasms**	
ANKRD26	Adults. Pre-existing thrombocytopenia
CEBPA	Children-adults. Mainly AML
DDX41	Adults. Secondary acquired *DDX41* mutation
ETV6	Adults. Pre-existing thrombocytopenia. Mainly ALL
GATA 2	Children-adults. Bone marrow failure common
RUNX1	Children-adults. Pre-existing thrombocytopenia
SAMD9/SAMD9L	Children-adults. Immune defects, neurological manifestations
TET2	Only rare families reported
*Classical inherited bone marrow failure syndromes***	
Fanconi anaemia	Children. More than 20 FA genes reported
Schwachman Diamond syndrome	Children-adults. High risk of somatic *TP53* mutations
Severe congenital neutropenia	Children-adults. *ELANE*, *G6PC3*, *HAX1*, *JAGN1* and others
Diamond Blackfan anaemia	Children. Frequent craniofacial, urogenital malformation and cardiac defects. Ribosomal genes *RPS19*. Rare cases *GATA1*
Telomere biology disorders	Children-adults. *DKC1*, *TERT*, *TERC* and several other genes. Variable presentation, often multi-organ failure
Down syndrome	
Trisomy 21	Children. Mainly AML
DNA repair syndromes and TP53	
ERCC6L2	Adults. BM failure and high risk of somatic *TP53* mutations
Li Fraumeni syndrome	Children-young adults. Constitutional *TP53*. Solid tumours and leukaemia.
RAS pathway mutations	
JMML in Neurofibromatosis type 1 (NF1) syndrome & CBL syndrome	Germline RAS pathway mutations and acquired biallelic inactivation of the gene
Noonan syndrome with myeloproliferation	Young children. RAS pathway mutation with myeloproliferation. Spontaneously resolves <1 year of age

Bloom syndrome, an autosomal recessive disorder with BLM mutation leading to genomic instability and propensity for early cancer, may be mentioned but leads to a broad range of cancer including but not enriched for leukaemia and lymphoma. Note that JMML most frequently is associated with somatic mutations in RAS pathway genes, only JMML associated with NF1 is associated with germline RAS mutations.
* Lymphoid neoplasms also reported
** usually with multi-organ engagement
(*Source:* Sahoo *et al.* 2020.)

However, it is clear that MN-pCT can develop also in children and adults without pre-existing CHIP.

Age

The most significant risk factor for MDS is age, but whether age itself should be considered an aetiological factor is not confirmed. The incidence of MDS increases sharply from 70 years and onwards, and the curve is different from other myeloid diseases such as acute and chronic myeloid leukaemia which are more frequent also in younger adults. CHIP could be one reason for the increasing incidence, but unknown changes in the immune system and in the bone marrow microenvironment also contribute.

Pathogenesis

The mechanisms by which MDS emerges are not fully understood but modern techniques such as NGS, gene expression analyses, epigenetic studies of DNA methylation and histone modifications as well as new possibilities of cell sorting and imaging have greatly increased our knowledge. Several dysfunctional intracellular pathways have been identified in the MDS cells e.g. aberrant RNA splicing, epigenetic regulation, ribosomal function and apoptosis. In addition to the intrinsic factors, it has been demonstrated that the immune system is dysregulated and most likely contributes to disease features. Disturbances in the bone marrow niche are another extrinsic factor with a potential pathogenetic role (Figure 34.1).

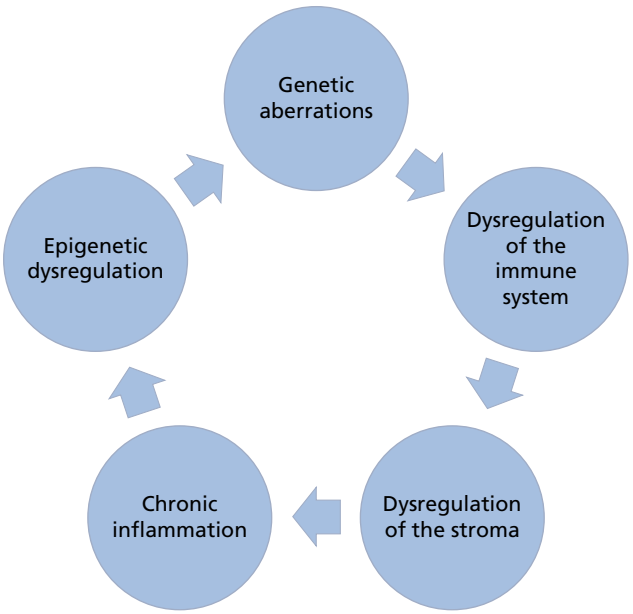

Figure 34.1 Schematic overview of pathways contributing to the pathogenesis of MDS and MDS/MPN.

Stem cells and differentiation

An important feature in MDS is the disturbed haemopoietic differentiation. In contrast to acute leukaemia where a differentiation block prevents cells from maturing, there is usually no complete differentiation block in MDS. MDS progenitors may differentiate into mature blood cells able to enter the circulation, but the maturation process is ineffective resulting in a lack of functional cells in the blood. This disturbed differentiation is reflected by the characteristic morphological dysplasia of bone marrow precursors.

The lack of effective differentiation may lead to progressive expansion of the immature cell compartment. In higher-risk patients, this is reflected as a morphological increase of marrow blasts but also in lower-risk patients without morphological increase of marrow blasts there may be an expansion of HSPC.

Modern cell sorting and sequencing technologies have allowed the identification of driver mutations in HSPC from MDS bone marrow samples. Using xenograft models, patient-derived stem and progenitor cells have been demonstrated to establish the MDS disease following transplantation into immune-deficient mice. While data from higher-risk MDS is more ambiguous, studies of lower-risk MDS provide evidence that the disease is initiated in rare multipotent haematopoietic stem cells and propagated to progenitor and precursor cells further down in the differentiation tree. There is thus a gradual expansion of a new parallel haematopoiesis which over time will dominate the bone marrow at the expense of the increasingly suppressed original haematopoiesis. The fact that MDS clearly is a disease that is propagated from the stem cell compartment, provides an explanation why MDS is so difficult to cure by chemotherapy only and why stem cell targeting therapy e.g. allogeneic stem cell transplantation is needed for complete cure.

Apoptosis

There is an expansion of immature cells in the bone marrow parallel to a reduction in the number of mature cells entering the blood. An important feature mediating this paradoxical phenomenon is increased apoptosis (programmed cell death) of haematopoietic precursor cells, which is more prominent in lower-risk MDS than in advanced MDS. Apoptosis can be initiated extrinsically by various cytokines, notably tumour necrosis factor (TNF)-α, Fas-ligand and TNF-related apoptosis-inducing ligand (TRAIL) that are frequently upregulated in MDS, serving as negative regulators of haematopoiesis. In addition, extrinsic stimuli may involve cytotoxic T cells and signals from bone marrow stromal cells, likely via activation of similar pathways. Apoptosis may also be activated through intrinsic pathways activated by DNA damage and mitochondrial dysfunction leading to cytochrome *c* release and caspase activation.

Genetics

The genetic landscape of MDS is today very well delineated thanks to novel technologies that have allowed a detailed characterisation of the MDS genome. Early studies identified structural chromosomal aberrations (e.g. del 5q and monosomy 7) using metaphase karyotyping, FISH and later SnP-arrays. Later, next-generation sequencing (e.g. whole genome sequencing, whole exome sequencing and targeted gene panels) have also allowed the identifications of point mutations.

Chromosomal aberrations

Around 50% of patients have structural chromosomal aberrations which can be detected using conventional karyotyping (G-banding). The frequency of cytogenetic aberrations is lower in MDS/MPN and CMML (around 30%). In contrast to AML where aberrations are dominated by balanced translocations (e.g. t[8;21] and t[15;17]), aberrations seen in MDS and MDS/MPN are usually unbalanced (e.g. del 5q, monosomy 7 and del 20q) resulting in copy number abnormalities (CNA). Changes can appear as single aberrations or part of a complex karyotype (≥3 aberrations). A complex karyotype is often accompanied by *TP53* mutations and associated with very poor prognosis. Single-nucleotide polymorphism arrays (SnP-arrays) can detect smaller abnormalities (down to <20 k base pairs) that are not detected by standard karyotyping. SnP-arrays can also detect copy-neutral loss of heterozygosity (LOH) or uniparental disomy (UPD).

Somatic mutations

Whole-genome, whole exome and targeted panel sequencing have allowed a detailed characterisation of the MDS genome and identification of somatic heterozygous driver mutations. MDS patients have on average 2–3 driver mutations in the coding region, with a range from 0 to 10. This is significantly fewer mutations compared to many solid cancers but more than in some other haematological cancers such as chronic myeloid leukaemia. Around 50 genes have been reported to be recurrently mutated in MDS, with highly recurrent mutations shown in Table 34.3. Patients with higher-risk MDS disease as well as patients with MDS/MPN including CMML, have on average more mutations compared to patients with lower-risk MDS. Importantly, the number of mutations is in itself a prognostic factor and is included in the recently published prognostic score IPSS-M.

Driver mutations identified in MDS can be categorised into functional groups, each group providing a distinct contribution to disease pathogenesis. The most commonly mutated groups of genes encompass the spliceosome, DNA methylation, histone acetylation, transcription factors and genes involved in signalling (Figure 34.2).

Combinations of mutations and chromosomal aberrations are sometimes enriched, such as *SF3B1* mutation with either *JAK2, TET2* or *ASXL1*, and complex karyotype with *TP53*, whereas other mutations seem to be mutually exclusive e.g. spliceosome and cohesin factor mutations, and *TET2* with *IDH1* or *IDH2*.

The spliceosome mutations are more common in MDS than in any other myeloid neoplasm and probably cause several of the dysplastic features. These mutations contribute to pathogenesis through the resulting downstream RNA missplicing of specific genes. Different spliceosome mutations lead to completely different disease features; *SF3B1* to ring sideroblasts (MDS-RS), SRSF2 to monocytic dysplasia, and *U2AF1* to leukaemic transformation.

Mutations in genes involved in DNA methylation and histone modification (epigenetic regulation) e.g. *TET2, DNMT3A, IDH1/2, EZH2* and *ASXL1* are found in up to 60–70% of all

Table 34.3 Somatic mutations in MDS and MDS/MPN. Colour code represent the percentage of patients with a specific disease harbouring the mutation, where white colour represents 0–1% mutation frequency, very light blue 2–5%, light blue 5–15%, blue 16–24%, dark blue 25–40%, very dark blue 41–70% mutated, and night dark blue >70% mutation frequency.

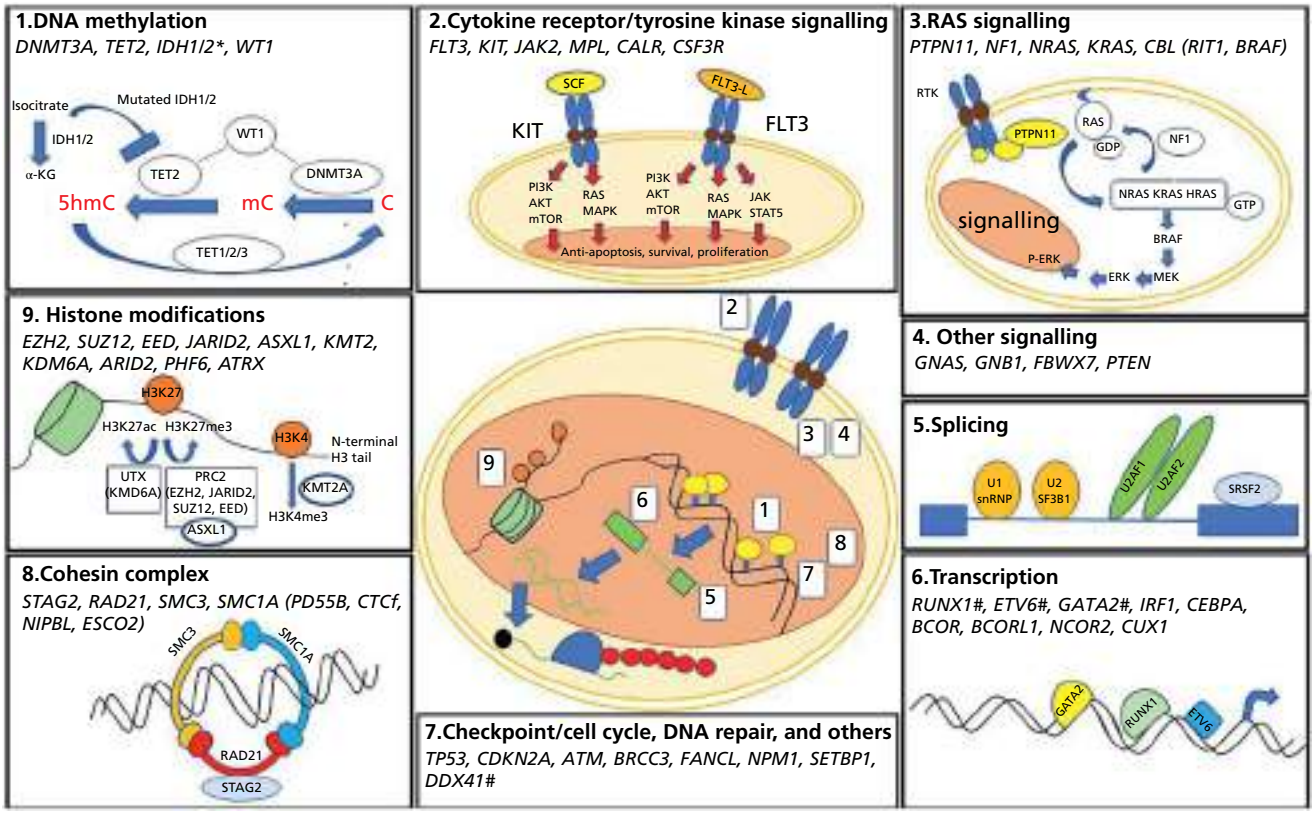

Figure 34.2 Major driver genes and their pathways in MDS and MDS/MPN. The numbers 1—9 in the central figure represent the cellular location of the respective pathway 1—9 described in the outer circle of figures. *mutaded IDH1 and *IDH2* but not the unmutated forms, affect DNA methylation. #germline variants are implicated in the predisposition to MDS and AML (Source: Gene list and pathways adapted from Ogawa S, *Blood* 2019.)

MDS patients (Table 34.3 and Figure 34.2). *TET2* and *DNMT3A* are also the most common mutations in CHIP individuals and may constitute early events in MDS pathogenesis.

Mutations in *TP53* are, as in cancer in general, associated with poor prognosis. *TP53* mutations are frequently found in association with complex karyotypes, but can also be associated with certain germline mutations, and with isolated del(5q), as discussed below. Importantly, a recent large study shows that mainly bi-allelic *TP53* mutations, i.e. two or more mutations, or deletion of the wild-type allele by loss of heterozygosity (LOH) or concomitant 17p deletion have a deleterious impact on prognosis and this is recognised in the WHO 2022 classification as a separate entity. This adds a challenge to diagnostic DNA sequencing in clinical routine.

Genes involved in the cohesin complex are mutated in 10–15% of MDS patients. Examples of cohesin genes are *STAG2*, *RAD21* and *SMC1A* and mutations in these genes are mutually exclusive (Table 34.3, Figure 34.2). The cohesin complex regulates large chromosomal formations and is probably important for regulating the access of transcription factors to the DNA.

RUNX1, GATA2, ETV6 and BCOR are transcription factors that likely directly interact with the differentiation process. Interestingly, several of these also appear as germline mutations (Tables 34.2 and 34.3, Figure 34.2).

Genes coding for proteins involved in signalling e.g. RAS-pathway mutations, *JAK2, KIT, CBL* and *MPL* are regulators of proliferation and more commonly mutated in MDS/MPN than in MDS. Mutations in these genes result in hyperproliferative haematopoiesis. RAS-pathway-driven hyperproliferation is relatively common in childhood MDS and related disorders (Tables 34.2 and 34.3, Figure 34.2).

Epigenetics

The epigenome consists of DNA methylation and histone modifications. The MDS epigenome exhibit, as cancer genomes in general, global hypomethylation and promoter hypermethylation. The characteristics of the MDS epigenome may in part be explained by mutations in epigenetic regulators as described above; however, the dysregulated epigenome can also be a consequence of stochastic epigenetic drift seen with increasing age where cells gradually diverge from each other. Potentially, environmental factors e.g. chronic inflammation may facilitate the epigenetic drift.

Immune dysregulation

Immunological abnormalities are commonly encountered in MDS, suggesting that they may play a role in the pathogenesis of the disease. This is particularly apparent in cases of hypoplastic MDS that may have features in common with aplastic anaemia. A hypocellular bone marrow is seen in approximately 10% of MDS patients and is recognised as a distinct entity in WHO 2022 (hypoplastic MDS) and may indeed represent one end of the MDS spectrum that biologically resembles or overlaps with aplastic anaemia. The other main reason for hypoplastic MDS is bone marrow failure caused by germline mutations, as previously discussed. Hypoplastic MDS is characterised by a pathological immune response, resulting in autoimmune destruction of normal HSPCs. In addition, acquired mutations in the PIGA gene characteristic of paroxysmal nocturnal haemoglobinuria (PNH) may develop, presumably through expansion of small clones in an otherwise hypoplastic marrow, suggesting that PNH is part of this spectrum. Conversely, dysplastic clones carrying cytogenetic abnormalities or point mutations can emerge in both aplastic anaemia and PNH after treatment and may evolve into (or result in) MDS over time.

Expanded CD8+ cytotoxic T-cell clones can occasionally become neoplastic, resulting in the diagnosis of T-cell large granular lymphocytic leukaemia (T-LGL) that also falls into the overlap spectrum of bone marrow failure states (Figure 34.3). T-LGL clones have been demonstrated in a relatively large proportion of MDS at diagnosis, but do not seem to influence prognosis, clinical picture or response to treatment. In addition to clonal T-cells, it is also described that MDS patients may have separate plasma cell clones (monoclonal gammopathy of undetermined significance) and sometimes overt myeloma.

A role for the immune system in the pathogenesis of MDS and MDS/MPN is also indicated by the high incidence of autoimmune disease of 10–25%. Patient with MDS/MPN and in particular CMML have a high incidence of inflammatory symptoms e.g. arthritis, vasculitis and skin lesions, compared to age-matched controls. However, the most persuasive evidence for immune dysregulation in MDS arguably comes from the recognition that patients with some forms of the disease, notably hypocellular MDS, like aplastic anaemia, respond well to immunosuppressive therapy with antithymocyte globulin and/or cyclosporin resulting in durable haematological recovery and abrogation of T-cell clones.

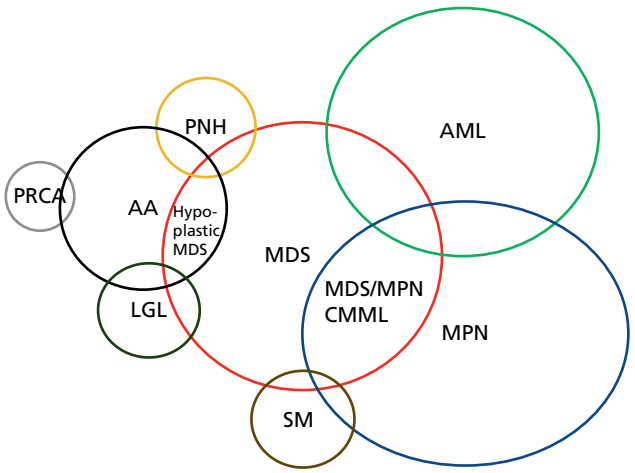

Figure 34.3 Myeloid neoplasms depicting the overlap between disease entities. AML acute myeloic leukaemia, MDS myelodysplastic syndromes, MPN myeloproliferative neoplasms, CMML chronic myelomonocytic leukaemia, SM systemic mastocytosis (can occur with another myeloid disease frequently MDS or MPN, most frequently CMML, T-LGL T-cell large granular lymphocytic leukaemia), PNH paroxysmal nocturnal haemoglobinuria, PRCA pure red cell anaemia, AA aplastic anaemia.

Bone marrow niche dysregulation

The bone marrow microenvironment in MDS frequently shows abnormal features including hypercellularity, abnormal localisation of immature precursors (ALIPs), vascular remodelling and fibrosis. Molecular characterisation of stromal niche cells has revealed genetic, epigenetic and transcriptional alterations. Co-culture models also indicate that MDS niche cells are functionally abnormal, supporting MDS but not healthy HSPC. The bone marrow niche in MDS is pro-inflammatory with increased concentrations of pro-inflammatory cytokines e.g. TNF, IL-6 and S100A8/A9. These factors may induce genotoxic stress, a potential mechanism for malignant transformation.

Specific disease entities within the MDS classification

MDS with low blasts and isolated 5q deletion

MDS with an isolated deletion of the long arm of chromosome 5 (MDS-5q) was early recognised as an MDS entity with specific clinical features. Patients present with severe markedly macrocytic anaemia, hypoplastic erythropoiesis, typical bone marrow morphology with hypolobated megakaryocytes and slightly elevated platelet counts. The WHO classification accepts one additional karyotypic abnormality as long as chromosome 7 is not involved, the most common being trisomy 8. Haploinsufficiency of casein kinase (*CK1α*, a gene within the common deleted region of del(5q) MDS) appear to be of central importance for the phenotype. The drug lenalidomide induces ubiquitination of *CK1α* by the E3 ubiquitin ligase cereblon, resulting in *CK1α* degradation and sensitivity to lenalidomide. Erythropoietin-stimulating agents (ESAs) should, as for other lower-risk MDS be considered first-line treatment for the anaemia of these patients, but lenalidomide can lead to

complete clinical and cytogenetic remission and is licensed as second-line treatment for del(5q) MDS. However, as HSC show a relative resistance to lenalidomide treatment is not curative and resistance often develops with time. Importantly, 15–20% of 5q- syndrome patient develop *TP53* mutated subclones and as these cells are completely resistant to lenalidomide, mutated cells can be selected during treatment. *TP53* mutated leukaemic transformation of 5q- syndrome is a serious and usually fatal complication and it is recommended that patients should be checked for mutational status before and during lenalidomide treatment and that allogeneic SCT should be considered an option in *TP53* mutated patients. Around 50% of del(5q) deletions in MDS are not associated with a 5q- syndrome, but with a complex karyotype, very high-risk MDS and frequent multi-hit *TP53* mutations. These patients have a dismal prognosis even after allogeneic stem cell transplant.

MDS with low blasts and *SF3B1* mutation (MDS-SF3B1)

MDS-SF3B1 is another genetically-defined MDS subset in the WHO 2022 classification following two pivotal papers published 2011 describing recurrent mutations in splicing factor 3b subunit 1 (*SF3B1*) in more than 80% of patients with MDS associated with ≥5% bone marrow ring sideroblasts (RS) i.e. erythroblasts with iron-filled mitochondrial localising around the nucleus. The remaining MDS with RS are classified as wild-type SF3B1 and ≥15% RS. MDS-SF3B1 patients present with slowly developing macrocytic anaemia, normal or slightly elevated platelet count and typically normal karyotype. The risk for progression to higher-risk MDS and leukaemic transformation is low. Untreated, anaemia will in most cases progress and lead to chronic transfusion need. Before the introduction of erythropoietin treatment and iron chelation, the most common fatal complication for these patients was progressive iron overload and organ failure, but with modern treatment, these patients can survive for decades. *SF3B1* mutations lead to missplicing of RNA with subsequent RNA decay and under-expression of genes involved in erythropoiesis, mitochondrial function and iron transport. The characteristic mitochondrial ferritin accumulation in MDS-RS is associated with missplicing and reduced expression of the iron transporter protein gene *ABCB7,* and mechanistic studies link *ABCB7* expression to defective erythropoiesis. Recent studies have tracked back the *SF3B1* mutations to multipotent haemopoietic stem cells, making MDS-RS a true HSC disease. *SF3B1* is often the only driver mutation, but can also be accompanied by CHIP mutations, primarily *TET2* and *DNMT3A*. Primary treatment of MDS-RS is erythropoietin, which if introduced before the onset of a regular transfusion need can lead to normal or at least un-transfused haemoglobin levels in a high proportion of patients, with a response duration of several years. In addition, increased levels of the transforming growth factor beta (TGFβ) superfamily inhibitors of erythropoiesis can be targeted by luspatercept, a recombinant fusion protein, considered to bind transforming growth factor β superfamily ligands and reduce SMAD2 and SMAD3 signalling, reduce erythroid hyperplasia, and enhance erythroid maturation and haemoglobin levels. Luspatercept was recently approved as second-line treatment for MDS-associated anaemia, with particularly high rates of response in MDS-SF3B1.

Hypoplastic MDS

MDS presenting with severe pancytopenia and hypoplastic bone marrow is another subtype of MDS, however more heterogeneous than 5q- syndrome and MDS-RS. Bone marrow cellularity is lower than the average for the age of the specific patient and often <30%. The median age is lower than for MDS in general. Karyotype is often normal, but abnormalities involving chromosome 7 can also be found. This subtype of MDS may be difficult to differ from aplastic anaemia, and bone marrow biopsy with immunohistochemistry is mandatory, as is next-generation sequencing analysis (NGS). A proportion of patients with hypoplastic MDS show predisposing germline variants including *GATA-1, DDX41* and *SAMD9/SAMD9L* variants, and mutations in telomere genes, but in others, the mechanism seems to be similar to that of aplastic anaemia. Some patients, provided no germline background or adverse genetic aberration can be detected may respond to immunosuppression.

Myelodysplastic myeloproliferative overlap diseases (MDS/MPN)

In the 2022 WHO classification, the MDS/MPN category consists of four specific proliferative disease entities (see Table 34.1); Chronic myelomonocytic leukaemia (CMML), Myelodysplastic/myeloproliferative neoplasm with neutrophilia, Myelodysplastic/myeloproliferative neoplasm with *SF3B1* mutation and thrombocytosis and Myelodysplastic/myeloproliferative neoplasm, not otherwise specified (MDS/MPN-NOS). Juvenile myelomonocytic leukaemia, JMML, is a specific entity described more in detail below in the context of paediatric MDS.

Chronic myelomonocytic leukaemia

CMML is the largest subgroup within the MDS/MPN category, with an incidence of 0.4 per 100 000 inhabitants. Two-thirds of patients are male, and the median age of disease onset is 70 years. The risk of AML transformation is around 15–20% thus less than in other MDS, whereas inflammation and autoimmune disease are frequent, occurring in 20–30% of patients.

For CMML diagnosis, persistent monocytosis >0.5 × 10^9/L and constituting more than 10% of leucocyte count with no other explanation of monocytosis, is required. If monocytes are 0.5-<1 × 10^9/L, dysplasia in at least one lineage as well as an acquired clonal cytogenetic or molecular abnormality, is required for diagnosis.

There are two subtypes of CMML, a myeloproliferative (MD-CMML) with leucocyte count ≥13 × 10^9/L or myelodysplastic (MD-CMML) with leucocyte count <13 × 10^9/L, a nomenclature that originates from the 1994 FAB classification. MP-CMML has a worse prognosis compared to MD-CMML. The recent WHO classification divides CMML into subgroups CMML-1 and CMML-2 based on the combined percentage of blasts plus promonocytes in bone marrow and blood. Overall survival for CMML is 12–24 months; however, some patients may live more than 10 years. The karyotype is normal in 70% of cases, but most patients harbour myeloid mutations, with *TET2* being the most common. Over 85% of patients have at least one mutation in *TET2*, *SRSF2* or *ASXL1* (Table 34.3). There is no specific treatment for CMML, however non-proliferative CMML have been included in hypomethylating trials and have similar response rates as other MDS. Recently, a large retrospective study has shown that there is a survival benefit for HMA treatment in higher blast count CMML. In proliferative CMML, hydroxycarbamide is used. Allogeneic stem cell transplantation is the only potential cure.

MDS/MPN-NOS

The disease entity of MDS/MPN-NOS was first established in the 2001 WHO classification as an MDS/MPD with thrombocytosis and leucocytosis. With the current definition, MDS/MPN-NOS accounts for around 2–5% of myeloid malignancies. The diagnosis requires at least one lineage of dysplasia in combination with myeloproliferation, without fulfiling the criteria for CMML or other MDS/MPN. About 70% of patients have a normal karyotype, and molecularly there is no distinct pattern however *ASXL1* mutations are common, 30–55% of patients, followed by *TET2*, *SRSF2*, *SETBP1* and *JAK2* mutations (Table 34.3). Overall survival is poor, around 12–32 months, and age >60 years, thrombocytosis, and bone marrow myeloblasts over 5% blasts indicate poor outcome.

There are no specific treatment recommendations for MDS/MPN-NOS. Hypomethylating agents are less effective than in MDS, 20–30%. Immunomodulatory regimens like interferon and more recently Ruxolitinib plus azacitidine have been assessed in clinical trials. In addition, there are conflicting reports about the outcome after allogeneic stem cell transplantation, likely because only a very small proportion of patients, around 5%, are eligible for this treatment.

Myelodysplastic/myeloproliferative neoplasm with neutrophilia (MDS/MPN-N)

MDS/MPN-N (previously atypical CML) is a disease with a poor survival and high risk of leukaemic transformation, and it is recommended that in fit patients, allogeneic stem cell transplant should be performed. About 65% of patients have a normal karyotype. The most common myeloid mutations are *SETBP1, ASXL1, NRAS, KRAS, SRSF2* and *TET2*, involving *JAK/STAT* and *MAPK* signalling pathways, and notably the classic MPN mutations *JAK2, MPL* and *CALR* are rarely found (Table 34.3).

MDS/MPN with *SF3B1* mutation and thrombocytosis (MDS/MPN-SF3B1-T)

MDS/MPN-SF3B1-T is associated with anaemia, bone marrow dyserythropoiesis, SF3B1 mutation and typically ring sideroblasts accounting for at least 15% of erythroid precursors. The term MDS/MPN with ring sideroblasts and thrombocytosis is an acceptable term to be used for cases with wild-type SF3B1 and ≥15% ring sideroblasts. Platelet count is ≥450 × 10^9/L and megakaryocytes are large and atypical. The karyotype is usually normal. JAK2V617F is present in around 50% of cases, whereas CALR and MPL are rare (Table 34.3).

The prognosis of MDS/MPN-SF3B1-T is similar to that of *SF3B1* mutated MDS-RS, the latter usually preceding the myeloproliferative transformation. Most patients will be scored as low risk according to IPSS-R. The risk for thrombosis is similar to that in essential thrombocythemia (ET). Treatment involves erythropoiesis-stimulating agents for anaemia, and frequently aspirin and hydroxycarbamide to reduce platelet count and reduce the risk of thrombosis. The use of cytoreductive treatment, however, is debated and may aggravate anaemia, however, if cytoreduction is needed, hydroxycarbamide is the drug of choice. Further studies are needed with regard to specific treatment for MDS/MPN-RS-T. Symptoms of thrombocythemia like erythromelalgia, headache and vasomotor symptoms, and arterial as well as venous thrombosis, occur at similar frequencies as in ET.

Myelodysplasia of childhood

Childhood MDS is uncommon, around 1–4 per million children and represent 5% of haematological malignancies in children. JMML will be described separately below and myeloid proliferation associated with Down syndrome is grouped with Down syndrome-related myeloid leukaemia. The WHO 2022 recognises childhood MDS as a distinct category, separated into low and high-blast groups. Around 30% of childhood MDS cases are associated with inherited bone marrow failure syndromes or conditions that predispose to myeloid disease or germline aberrations predisposing to MDS or AML with *GATA2*,

ETV5, SRP72, SAMD9 and *SAMD9-L*, and *RUNX1* and *ANKRD26* (Table 34.2). From a genetic perspective, childhood MDS is quite different from adult MDS as many of the common myeloid mutations found in adult MDS and AML are rarely found in children, whereas RAS pathway mutations and SETBP1, ASXL1 and RUNX1 are common in both adult and childhood MDS. Monosomy 7 or del(7q) are found in 20–30% of childhood MDS and is an absolute indication for urgent allogeneic stem cell transplantation.

Juvenile myelomonocytic leukaemia

Juvenile myelomonocytic leukaemia (JMML) is a clonal disorder characterised by proliferation of granulocytic and monocytic lineages. JMML accounts for 40% of childhood MDS with an incidence of around 1.3 per million and a median onset of 2 years of age. Two-thirds of cases are boys. Most patients present with constitutional symptoms or infection and have a marked hepatosplenomegaly. Enlarged lymph nodes and tonsils as well as skin infiltration are common, and in the blood leucocytosis with neutrophilia, monocytosis and presence of myeloid precursors may be seen. The bone marrow is hypercellular with slight dysplastic features and myeloblasts frequently less than 5%. The most common chromosomal aberration is monosomy 7, seen in 25% of patients. JMML is characterised by hyperactivation of the RAS signal transduction pathway with molecular alterations in *PTPN11, NRAS, KRAS, NF1* or *CBL* genes (Table 34.3, Figure 34.2). In JMML, RAS pathway mutations are heterozygous and somatic, while JMML in neurofibromatosis type 1 (NF1) and JMML in children with CBL syndrome are characterised by germline RAS disease followed by acquired biallelic inactivation of the gene (Table 34.2). It should be noted that RAS pathway mutations are common in Noonan syndrome, and that myeloproliferation resembling JMML may occur very early in life however is frequently benign and resolves spontaneously before age 1 year. Adverse prognostic markers in JMML are high HbF synthesis, older age and thrombocytopenia. Approximately 60% of JMML patients who undergo allogeneic stem cell transplant achieve a long-term remission.

Diagnostic workup

European recommendations for patient management including diagnostic and prognostic work-up and treatment recommendation are well described at the MDS-Europe website, endorsed by the European Haematology Association.

Patient history and differential diagnoses

There are several non-clonal causes of cytopenia, bone marrow hypoplasia and marrow dysplasia to consider before establishing a diagnosis of MDS. Family history includes haematological disorders, cancer at early age, familial liver and lung disorders and special signs of genetic predisposition traits: early grey hair, excessive warts, nail dystrophy and short stature. Case history should cover previous and current chemical and drug exposure, marked weight loss, thyroid or other autoimmune diseases, recent infections and antibiotic treatment. Even the presence of ring sideroblasts is not a definitive sign of clonal disease, as they can be caused by non-clonal causes including lead intoxication, exposure to pyridoxine, or copper deficiency, excess zinc that decreases copper levels, or isoniazid, chloramphenicol or linezolid therapy. Physical examination may reveal splenomegaly and enlarged lymph nodes, or skin lesions indicative of Sweets syndrome, and vasculitis. Blood tests include vitamin B12, folic acid, and iron status, serum electrophoresis and ANA screen, as well as screening for HIV and hepatitis. In case of microcytic anaemia, the rare variant of acquired HbH disease (associated with *ATRX* mutation) should be considered. Flow cytometry of blood may exclude paroxysmal nocturnal haemoglobinuria (PNH) and the presence of large granular lymphocytic leukaemia (LGL) including T-cell receptor clonality. In case of isolated anaemia, assessment of parvovirous B19 in bone marrow could be considered. Clonal cytopenia of uncertain significance, CCUS, is presently considered a separate condition but is likely to be included under the umbrella of MDS in the future. Table 34.4 shows a comprehensive list of differential diagnoses.

Examination of blood and bone marrow cells

Examination of blood cells

Macrocytic anaemia is a predominant finding in MDS and may occur alone or in combination with either neutropenia or thrombocytopenia or both. Importantly, the haemoglobin value may be within the normal range, but significantly lower than normal for the specific individual. Some patients develop macrocytosis years before the onset of anaemia and aberrant red cell morphology or increased ferritin may be early indicators of ineffective erythropoiesis and MDS.

The red cells show anisocytosis and poikilocytosis and tend to be macrocytic and oval-shaped (Figure 34.4). Basophilic stippling (presence of many basophilic granulae in the erythrocyte cytoplasm) may also be seen. Occasionally, circulating and dysplastic erythroblasts are observed in the peripheral blood. Neutropenia is common and neutrophils often exhibit reduced granulation due to a defective formation of secondary granules. Complete agranulaity is highly specific for MDS. Pseudo-Pelger–Huët neutrophils are also frequent (these are neutrophils with dense clumping of the chromatin, and hypolobulated or non-lobulated) nucleus. Monocytosis is by definition present in CMML and monocytes are often morphologically abnormal (Figure 34.4). Monocytosis may also appear in MDS over time, especially in TET2 mutated cases, without suspicion of progression to CMML.

Table 34.4 Differential diagnoses to MDS and MDS/MPN.

Differential diagnosis	Diagnostic tests
Aplastic anaemia, pure red cell aplasia	Histology, cytology, parvovirus B19
Metastatic carcinoma	Histology, immunohistochemistry
Toxic bone marrow injury (alcohol, lead, zinc, copper deficiency, drugs)	History, lab tests See separate list
Reactive bone marrow changes (infections e.g. sepsis, HIV, hepatitis, tuberculosis and other chronic infections, autoimmune diseases, thyroid disease)	Cytology, history, lab tests
Paroxysmal nocturnal haemoglobinuria (PNH)	Immunophenotyping
Immune thrombocytopenia	History, disease course
Megaloblastic anaemia	Vitamin B12/folic acid concentration
Hypersplenic syndromes	History/clinical features (splenomegaly)
Acute leukaemia (especially erythroleukaemia, FAB-M6)	Cytology, histology, immunophenotyping, genetic and molecular genetic testing
Myeloproliferative neoplasms	Histology, cytogenetic and molecular genetic testing
Hairy cell leukaemia, large granular lymphocytic leukaemia (LGL-leukaemia)	Cytology, immunophenotyping, molecular genetic testing (*BRAF* and *STAT3*), T cell receptor
Congenital dyserythropoietic anaemia (rare)	Molecular genetic testing
Idiopathic Cytopenia of Undetermined Significance (ICUS)	See ICUS minimal diagnostic criteria
Clonal Cytopenia of Undetermined Significance (CCUS)	See CCUS

(*Source:* Adapted from MDS Right Europe, www.mds-europe.org/right.)

While often reduced in MDS in general, basophils and eosinophils may be increased in MDS/MPN.

Circulating myeloblasts may be found in all categories of MDS but are usually indicative of MDS with increased blasts. Finally, platelet count is frequently reduced, and platelets may show dysplasia with hypogranulated and/or giant forms. In CMML, circulating monoblasts (large round/oval nuclei, open chromatin, prominent nucleoli, abundant cytoplasm, variable basophilic and some azurophilic granules) and promonocytes may be present (Figure 34.4).

Examination of bone marrow

A bone marrow examination encompassing morphology and histopathology is mandatory in the diagnostic process. The ability to diagnose MDS is critically dependent on optimal staining of the marrow slides. There is often considerable interobserver variation, particularly where the dysplastic changes are subtle, but better consistency amongst observers in identifying cells, such as ring sideroblasts, pseudo-Pelger–Huët cells, micromegakaryocytes and when myeloblasts are clearly increased.

MDS bone marrow is hypercellular in the majority of patients, due to ineffective but hyperplastic erythropoiesis and granulocytopoiesis, but can be normocellular or, in 10–20% of cases, hypocellular. When assessing dysplasia, a minimum of 500 cells (with at least 100 of these non-erythroid cells) should be examined to gain an accurate and representative differential count. Dysplasia is defined by 10% or more cells of a certain lineage showing dysplastic features.

The myeloblast count is crucial for accurate disease classification, prognostication and treatment decisions and is primarily established on bone marrow smears and not on histology sections. However, when fibrosis or hypoplasia is present, myeloblast count should be assessed by immune histochemistry on biopsy sections. Myeloblasts may be agranular or granular and are distinguished from dysplastic promyelocytes, both of which may be granulated and have nucleoli, by the presence of a clearly identifiable Golgi zone in the latter (Figure 34.4).

Erythropoiesis may vary from normoblastic to megaloblastic. In MDS-RS, the erythroblasts are often poorly haemoglobinised or show cytoplasmic vacuolisation (Figure 34.4). The list of dysplastic features of erythrocytes is considerable and may include bi- or multinuclearity, bridging between nuclei, nuclear budding and fragmentation, increased pyknosis and basophilic stippling (Figure 34.4). Cytochemical iron staining should be performed in all cases of suspected MDS in order to quantify iron stores and to detect and enumerate ring sideroblasts (Figure 34.4) and pathological non-ring forms. Erythropoiesis may occasionally be severely reduced or absent. Granulopoiesis is usually hyperplastic and dysplastic including defective granulation, agranular or hypogranular cells or the presence of pseudo-Chediak–Higashi granules and nuclear hypo- or hyperlobulation (Figure 34.4). Prominent basophilic and eosinophilic differentiation and increased numbers of myeloblasts may be

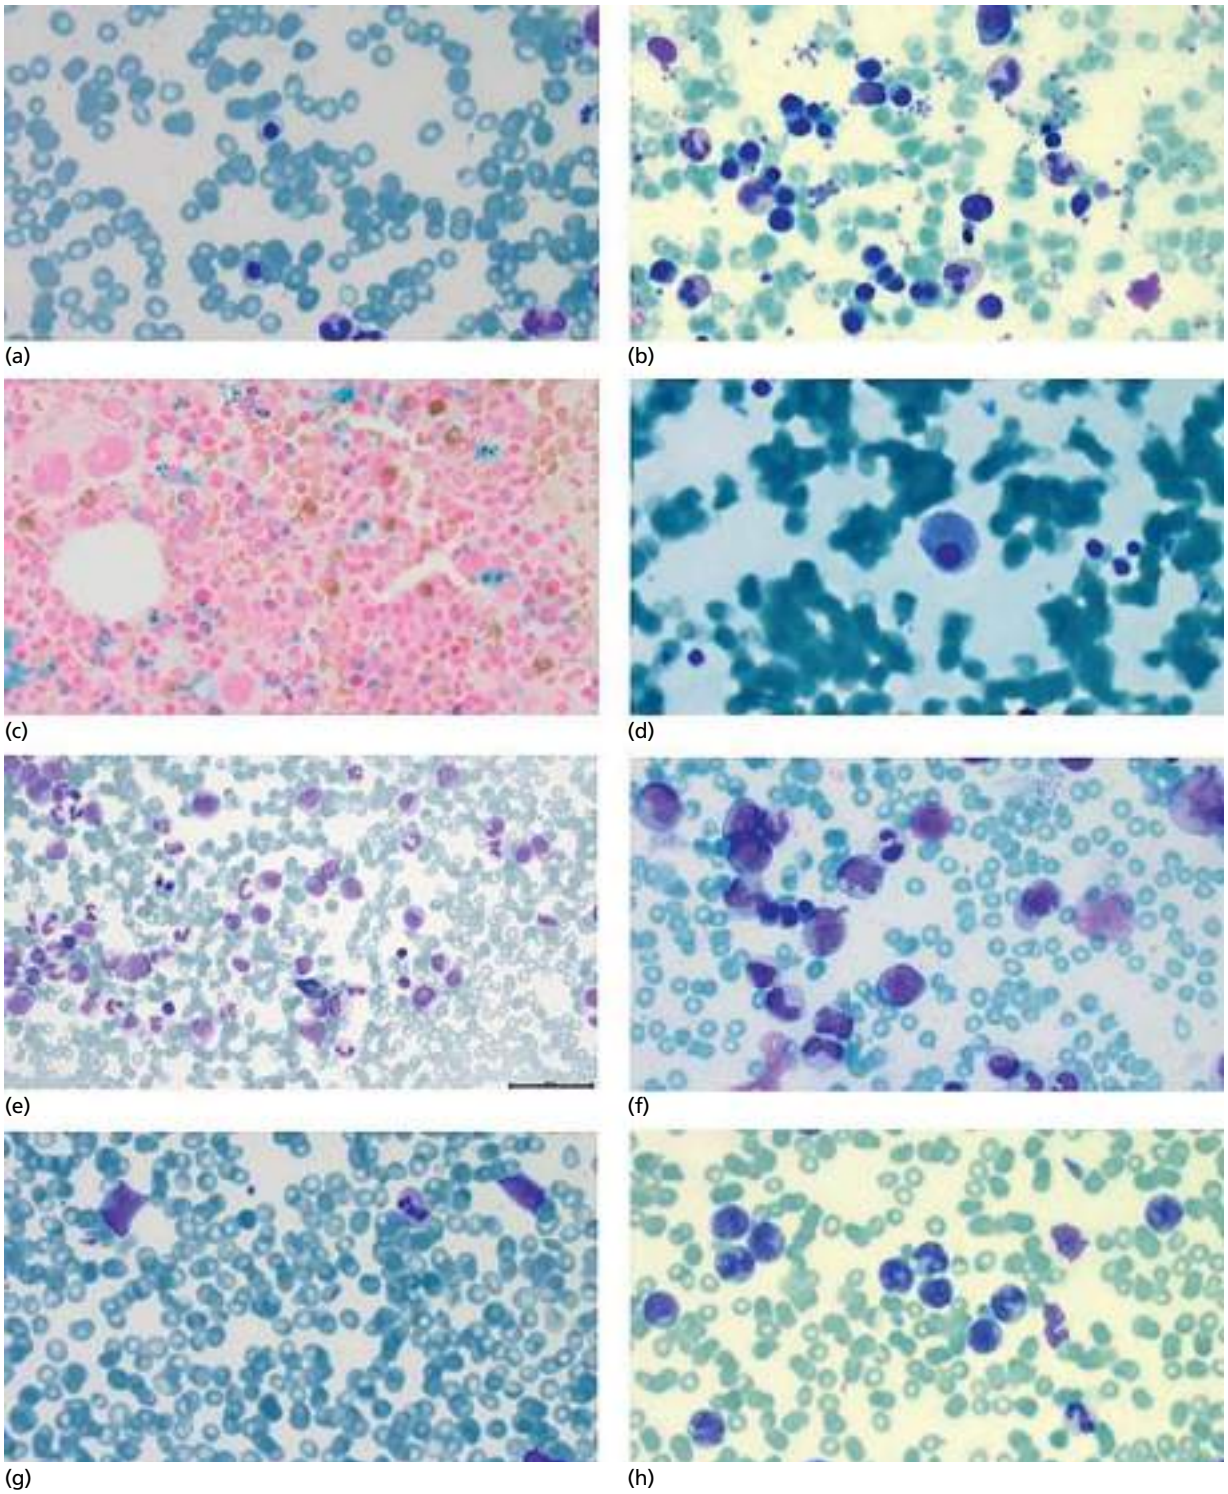

Figure 34.4 Morphology, (a) erythroid dysplasia with vacuolised erythroblasts. (b) bone marrow smears with dysplastic erythropoiesis, bilobed nuclei and irregular nuclear contours. (c) iron stain showing ring sideroblasts. (d) dysplastic monolobed megakaryocyte. (e) dysplastic neutrophils with pseudo-Pelger nuclei and hypogranulated cytoplasm. (f) myeloblasts and promonocytes in CMML, also note dysplastic neutrophils. (g) bone marrow smears from RAEB with two myeloblasts and one neutrophil granulocyte. (h) bone marrow smears with promonocytes and mature monocytes in CMML (Source: From professor Birgitta Sander, Dept of Pathology, Karolinska University Hospital and Karolinska Institutet.)

present. Megakaryopoiesis is commonly dysplastic, of which the most specific feature is the micromegakaryocyte, which is typically the size of a myeloblast with an ill-defined or blebbed outline and a single monolobulated nucleus (Figure 34.4). Other megakaryocytes may exhibit hypolobulation or contain multiple disparate nuclei due to aberrant maturation. In the 5q– syndrome, there are often increased numbers of megakaryocytes that vary in size and contain large non-lobulated nuclei.

A bone marrow trephine biopsy with histological analysis is mandatory in suspected cases of MDS, according to WHO 2022, as histology is necessary to correctly assess bone marrow architecture, cellularity, fibrosis and stromal aberrations like infiltration of metastatic solid tumours, or aberrant vascularisation. Cytological evidence of dysplasia can be found in all lineages but is most easily detected in the erythroid precursors. Abnormal clustering of megakaryocytes is often seen, as are micromegakaryocytes that can be more easily detected by immunohistochemical staining with CD61 (Figure 34.5). The finding of of abnormal localisation of immature precursors (ALIPs) may indicate an increased risk for leukaemic transformation. ALIPs are aggregates (3–5 cells) or clusters (>5 cells) of myeloblasts, usually localised in the central portion of the bone marrow away from vascular and endosteal surfaces of trabeculae.

Reticulin staining should be performed to assess fibrosis that may be mild (grade 1) or more severe, grade 2 or 3 (Figure 34.5). The presence of reticulin is often helpful in differentiating hypoplastic MDS from aplastic anaemia. In fibrotic MDS, splenomegaly is commonly absent or mild. MDS with increased blasts and fibrosis is recognised as a distinct entity in WHO 2022. In some cases, an increase in mast cells may be present, and a tryptase stain may be useful to exclude the presence of an additional systemic mastocytosis disease, especially in CMML where systemic mastocytosis may be found in around 5% of cases (Figure 34.5).

A minimal staining panel include Haematoxylin and Eosin, Giemsa, Gomori's silver stain, iron stain and immune histochemistry for CD34, p53, CD61 and glycophorin A (GPA) (Figure 34.5). In addition, staining for epithelial tumour markers may be used to exclude cytopenia caused by metastatic carcinoma. Other malignant differential diagnoses to MDS encompass MPN, acute leukaemia, aplastic anaemia, LGL, hairy cell leukaemia and congenital dyserythropoietic anaemia.

Flow cytometry

Flow cytometry immune phenotyping is recommended but not mandatory and can confirm dysplasia in peripheral blood or fresh bone marrow within 2 days of sampling. The myeloid compartment should be assessed with regard to increase of aberrant progenitors, asynchrony of myeloid differentiation antigens, decreased side scatter of granulocytes, aberrant lineage marker expression on immature or maturing cells, and in the erythroid compartment altered CD36 and or CD71 expression on nucleated cells. For CMML, immune phenotyping in peripheral blood may be useful in discriminating reactive

monocytosis from CMML, with the percentage of classical monocytes (CD14+/CD16-) being increased in CMML.

Haemoglobin electrophoresis may be performed to detect HbH that is elevated in the rare form of acquired HbH disease, and HbF that is elevated and an adverse prognostic marker in JMML.

Autoantibodies may be assessed and are frequently present in CMML, in up to 50% of cases. Serum electrophoresis is part of routine diagnostic workup to assess inflammation and presence of paraprotein.

Cytogenetic abnormalities

Cytogenetic analysis is mandatory in the diagnostic workup and remains a cornerstone in all prognostic scores. In general, at least 20 metaphases should be assessed. Clonal cytogenetic abnormalities occur in about 50% of patients with MDS and 20–50% of MDS/MPN. The most common cytogenetic abnormality in MDS is del(5q) occurring in around 15% of cases of MDS and 3% of MDS/MPN. Del(5q) isolated or in combination with one other abnormality excluding chromosome 7, and blast count <5% is called 5q- syndrome (described above). Trisomy 8, monosomy 7 or del(7q), del(20q) and -Y are the most frequent cytogenetic aberrations both in MDS and MDS/MPN. In therapy-related MDS, aberrancies of chromosome 7 are found in up to 50% of cases.

Detection of some cytogenetic abnormalities are presumptive of MDS if accompanied by cytopenia, even in the absence of morphological dysplasia. These include unbalanced aberrations such as monosomy 7 (−7), del 7q), −5, del(5q), isochromosome 17q i(17q), t(17p), 13, or del(13q), del(11q), del(12p), t(12p), del(9q), idic(X)(q13) and the more rare balanced translocations t(11;16)(q23;p13.3), t(3;21)(q26.2;q22.1), t(1;3)(p36.3;q21.2), t(2;11)(p21;q23), inv(3)(q21q26.2) and t(6;9)(p23;q34).

By contrast, the presence of trisomy 8, −Y or del(20q) require morphological evidence of dysplasia to establish the MDS or MDS/MPN diagnosis. Complex karyotype with three or more aberrancies is highly associated to adverse prognosis, as are chromosome 7 aberrancies ((−7), de(l7q)), and trisomy 8 for MDS/MPN, whereas −Y is consistent with a favourable prognosis. Tables 34.5 and 34.6 describe details on prognostic impact of chromosomal aberrations in IPSS-R and CPSS-Mol from cytogenetic aberrancies in MDS and MDS/MPN.

Molecular abnormalities

Understanding the patterns of somatic heterozygous mutations in myeloid malignancies is a rapidly expanding field and will likely bring changes to diagnostic categories as well as to prognostic tools for myeloid disease. *SF3B1* and *TP53* mutations defined disease entities already in the 2022 WHO classification and molecular abnormalities are increasingly incorporated into prognostic scores.

It is well accepted that recurrent acquired somatic mutations defining clonal haematopoiesis (CHIP) are identified in a majority of MDS patients in particular in the MDS/MPN categories. The same mutations occur across myeloid malignancies (Table 34.4). Importantly, several of these mutations occur also in the healthy elderly population, and in CCUS. There are clear differences between disease types, and e.g. CMML is more mutationally homogenous than MDS.

Targeted sequencing panel is recommended to be performed at diagnosis, on bone marrow or peripheral blood. Results are useful both for providing evidence of clonality in unclear cases like separating hypoplastic MDS from aplastic anaemia, and in cases of suspected MDS in case of a normal karyotype. Moreover, it can aid in differentiating MDS from non-clonal cytopenia e.g. in inflammatory conditions. Panel sequencing can also be used to follow disease progression or remission measuring variant allele frequency of the known mutations, to provide prognostic information with regard to type of mutations present, as well as for selecting potential targeted therapy.

While targeted mutational analysis is increasingly used in the MDS workup it is likely that also whole genome sequencing

Table 34.5 IPSS-R prognostic score for MDS.

Prognostic variable	0	0.5	1	1.5	2	3	4
Cytogenetics*	Very good	—	Good	—	Intermediate	Poor	Very poor
BM blast, %	≤2	—	>2%–<5%	—	5–10%	>10%	—
Haemoglobin (g/dL)	≥10	—	8–<10	<8	—	—	—
Platelets × 10^9/L	≥100	50–<100	<50	—	—	—	—
ANC × 10^9/L	≥0.8	<0.8	—	—	—	—	—

* Cytogenetic alterations: −Y and del(11q) are very good, normal, del(5q) and double alterations including del(5a), del(12p), del(20q) are good, del(7q), trisomy 8, trisomy 19, i(17q) and any other single or double independent clone is intermediate, −7, inv(3)/t(3q)/del(3q), double including −7/del(7q) and complex with three abnormalities are poor, and complex of more than 3 abnormalities is very poor. – indicates not applicable. The IPSS-R risk groups are: Very low ≤1.5 points, Low >1.5−3 points, Intermediate >3−4.5 points, High >4.5−6 points, and Very high >6 points, according to Greenberg 2012.

Table 34.6 CPSS molecular risk score for CMML.

Genetic risk score	**0**	**1**	**2**
Cytogenetic risk	low	intermediate	high
ASXL1	unmutated	mutated	–
NRAS	unmutated	mutated	–
RUNX1	unmutated	–	mutated
SETBP1	unmutated	mutated	–

Prognostic variable	**0**	**1**	**2**	**3**
Genetic risk score (see above)	low	Intermediate-1	Intermediate-2	high
BM blast %	<5	≥5	–	–
Leukocyte count $\times 10^9$/L	<13	≥13	–	–
Red blood cell transfusion dependence	no	yes	–	–

The genetic risk is first defined by cytogenetic risk (low risk is normal karyotype and isolated-Y, high risk is trisomy 8 and complex karyotype with three or more aberrancies, and all chromosome 7 abnormalities. All other are intermediate risk), and the presence or absence of *ASXL1*, *NRAS*, *RUNX1*, and *SETBP1* mutations. The genetic risk score is then calculated as low risk (0p), intermediate-1 (1p), intermediate-2 (2p), and high risk (3 or more points). The genetic risk is then incorporated with clinical parameters to a CPSS-Mol risk of low (0p), intermediate-1 (1p), intermediate-2 (2-3p) and high risk (4 or more points).
– indicates not applicable

will develop into a fundamental cornerstone in the diagnostic procedure of myeloid malignancies in the coming years. When sequencing costs and turnaround time decrease, whole genome and whole transcriptome sequencing may with time replace most genetic analyses enabling sensitive readout of chromosomal aberrations as well as mutations, accounting also for loss of heterozygosity.

Prognostic workup

MDS is a haematological malignancy with a varying but mainly poor prognosis. The overall median survival in large population-based registries varies between 12 and 18 months, longer in more recent cohorts due to earlier diagnosis and more patients being subject to disease-modifying treatment. The poor prognosis in most cases of MDS reflects that there are few specific treatment options reflecting the fact that malignancies with origin in the HSC compartment generally are more difficult to target.

International prognostic scoring systems

The first International Prognostic Scoring System (IPSS) was based on seven previously reported patient cohorts and was published in 1997. Based on a larger patient cohort, the cytogenetic scoring system was subsequently refined, more weight was put on the degree of cytopenia, and the percentage of bone marrow blasts was subdivided further (Table 34.5). The IPSS-R divides patients into five categories with median survival times varying between 0.7 and 5.4 years. The IPSS-R has been widely validated and used, including as a basis for enrollment if clinical trials. As with all scoring systems, there are challenges, the most prominent with IPSS-R being the intermediate risk category showing a median survival of 2.7 years and with a relatively large inter-patient variation.

It is important to note that other clinical/pathological prognostic factors not included in IPSS-R can also predict outcomes. For example, numerous studies have confirmed that the presence of a regular transfusion need is associated with a significantly worse outcome both regarding survival and transformation to AML. Another well-described risk factor is bone marrow fibrosis, associated with a worse outcome irrespective of IPSS-R.

IPSS-Molecular (IPSS-M) risk assessment score

Both the type of genetic pathway that is mutated (Figure 34.1) and the total number of mutations in an individual patient have importance for the prognosis in MDS. Commercial target sequencing panels encompassing 50–100 genes will likely be sufficient for clinical diagnostics and prognostics, the larger panels also including some of the most common hereditary alterations.

The novel prognostic scoring IPSS-M includes the variables from IPSS-R, and in addition, the molecular profiles

obtained from the panel sequencing and is from 2023 a cornerstone in national and international MDS guidelines. The IPSS-M divides patients into six risk strata and improve the prognostic precision in particular for patients with <5% marrow blasts and for the IPSS-R low and intermediate categories. Another important lesson derived from IPSS-M is the detrimental risk associated with multi-hit *TP53* mutations. Risk scores for individual patients will be difficult to calculate by hand and will require computer algorithms available on official websites. As for many other diseases 'artificial intelligence' will be one tool for guiding prognostication and optimal patient management however will never replace a competent and empathic haematologist with a general understanding of the patient´s clinical presentation and specific needs.

Prognostic scores for MDS/MPN

The two largest subtypes in this category are CMML and MDS/MPN-NOS. It was earlier shown that the myeloproliferative subtype of CMML has an overall worse outcome than the myelodysplastic subtype. The well-established and widely used CMML-specific CPSS-mol score is based on cytogenetics, peripheral blood counts, blast count and includes four myeloid mutations, *ASXL1*, *SETBP1*, *NRAS* and *RUNX1* with more weight on *RUNX1* mutation (Table 34.6). CPSS-Mol identifies four clearly separated risk groups where the low-risk group has a median survival not reached in the study and an incidence of leukaemic transformation of 0%, and the high risk has an overall survival of 18 months and a 48% risk of leukaemic transformation. IPSS-M can be used for CMML patients with leucocyte count $<12 \times 10^9$/L. For MDS/MPN-NOS, there are currently no specific prognostic scores, and despite MDS/MPN-U patients scoring lower risk points in IPSS-R, the majority will have a poor outcome.

Management and treatment

Good management of MDS is based on careful diagnostic and prognostic procedures, as well as on the patient´s individual comorbidities and preferences. Risk-based therapeutic decision-making generally uses IPSS-R, but will increasingly incorporate mutational profiles and scores also. In addition to disease-specific variables, patient-related factors are essential. Age and comorbidities, naturally, influence the spectrum of available therapies and are incorporated into comorbidity and frailty scores both for MDS and blood cancer in general. Such scores are in particular essential in the decision-making for allogeneic stem cell transplantation. Hence, accounting for both disease- and patient-related factors considerably improves risk stratification and decision-making.

Therapeutic options

Molecularly-guided precision medicine, like tyrosine kinase inhibitors for CML, is still not available for MDS and the development of novel therapeutic compounds with the propensity to markedly alter patient outcome lags behind many other blood cancers. Therapeutic options for patients with MDS vary from supportive care to allogeneic stem cell transplantation (SCT) depending on disease and patient-related risk factors with SCT being the only curative option. As websites such as MDS Europe and National Comprehensive Cancer Network (NCCN) (see reference list for web addresses) and a number of National guidelines are relatively specific about indications and dosing, this will not be detailed in this chapter.

Supportive care

Supportive care is a cornerstone in the management of all patients. Population-based studies show that about 50% of newly diagnosed patients require red blood cell transfusions and that anaemia progresses in the majority of untreated patients. Severe anaemia and transfusion-need are also associated with reduced quality of life and progression-free survival. Clinical studies indicate that QoL not only improves in patients responding to pro-erythroid growth factors, but also that higher transfusion targets are associated with improved QoL. Many guidelines therefore recommend individual transfusion targets tailored according to individual symptoms and comorbidities.

Severe thrombocytopenia with platelet transfusion need becomes more frequent with the course of disease. Consensus-based guidelines agree that platelet transfusions should be governed by trigger platelet count levels during active treatment with chemotherapy and hypomethylating agents (HMA), but mainly based on bleeding symptoms in case of chronic thrombocytopenia. Eltrombopag and romiplostim are licensed for treating severe chronic immune-mediated thrombocytopenia. These compounds have not showed to improve survival in MDS but can be used to raise platelet counts to avoid bleeding symptoms in case of severe chronic thrombocytopenia. Granulocyte-CSF is not licensed for low neutrophil counts associated with MDS but is frequently used as supportive care in case of neutropenia caused by hypomethylating agent treatment, especially after recurrent infectious events.

Iron chelation

Transfusion dependence leading to iron overload can have a negative impact on patient outcome. It is well-known from studies of thalassemia patients that severe iron overload starting in childhood significantly impairs organ function and shortens the life span. However, the exact degree of iron overload influencing outcome in adult MDS patients is not known. Based on

retrospective analyses iron chelation therapy (ICT) has been suggested to improve the outcome of lower-risk MDS patients. Only one prospective randomised phase III placebo-controlled study has been performed showing improved event-free survival in the deferasirox group with events defined as death, transformation and cardiac or hepatic abnormalities. The study design prevented evaluation of the effect on overall survival. A pragmatic view adopted by most guidelines is that iron chelation is indicated in lower-risk MDS with a permanent transfusion need but with otherwise favourable outcome, and in patients eligible for allogeneic stem cell transplantation. The drugs used for iron chelation are currently deferasirox (oral), deferioxamine (intravenous via infusion pump) and deferiprone (oral).

Haemopoietic growth factors

Erythropoiesis-stimulating agents (ESAs) constitute since long standard treatment for the anaemia of lower-risk MDS. ESAs improve haemoglobin levels and thereby QoL in at least 50% of treated patients and provided overdose and supranormal haemoglobin levels are avoided, no severe adverse events or increased risk for disease progression have been reported. Importantly, a recent large prospective registry study showed that ESA treatment significantly prolongs the time to first transfusion, if started prior to a permanent transfusion dependency. This led to an important change in the European guidelines now recommending treatment at the onset of symptomatic anaemia. If a patient responding to ESA relapses with anaemia, this is usually not associated with disease progression and the biological reasons for treatment failure are poorly understood. However, the addition of low-dose Granulocyte-CSF to erythropoietin may restore the response rate to ESA, as shown by several randomised phase II trials. The synergistic effect is particularly seen in MDS-RS and related to the anti-apoptotic effects of G-CSF on mitochondria-mediated apoptosis.

Immunosuppression

Treatment with immunosuppressive agents such as antithymocyte globulin (ATG) and Cyclosporin A may improve the cytopenia in a small proportion of patients, usually in the setting of hypoplastic MDS. There are few large prospective studies, most of them with short follow-up times, and each study has used different inclusion criteria and IST regimens. In a large meta-analysis of 570 patients with a median age of 62 years, 80% of patients had IPSS scores low or intermediate-1, the complete remission and red blood cell transfusion independence rates were 12.5 and 33%, respectively, and the progression rate to AML 8.6% per patient-year. Immunosuppressive therapy has not been confidently evaluated in relation to mutational profiles. Both European and US guidelines identify a group of younger lower-risk MDS patients with hypo- or normoplastic bone marrow and normal karyotype with the exception of trisomy 8, who may respond to immunosuppressive therapy.

Lenalidomide

Lenalidomide is licensed for lower-risk MDS with deletion 5q. Initial phase II studies showed a high probability of abrogated transfusion need in these patients as well as reversal of the del(5q) abnormality. This effect was confirmed in a Phase III randomised placebo-controlled trial, demonstrating around 50% erythroid responses and a significant proportion of partial or complete cytogenetic responses. However, lenalidomide is not a curative treatment, the median response duration is around 2 years with a clear risk of molecular and disease progression in relapsing patients. About 20% of patients with lower-risk del(5q) MDS carry *TP53* mutated subclones and as *TP53* mutated cells are insensitive to lenalidomide, treatment can lead to clonal selection with subsequent disease progression. These data led to recommendation in the NCCN and MDS-Europe MDS guidelines to treat symptomatically anaemic del(5q) MDS patients who are refractory or ineligible to erythropoiesis-stimulating agents with lenalidomide and to avoid treatment in case of *TP53* mutations.

Luspatercept

MDS-RS have been shown to display increased levels of the transforming growth factor beta (TGFβ) superfamily inhibitors in erythroid cells and plasma. Luspatercept, a recombinant fusion protein, is thought to trap TGFβ ligands and reduce SMAD2 and SMAD3 signalling, and enhance erythroid maturation and has in a recent Phase III trial been shown to increase haemoglobin levels and reduce transfusion need in MDS-RS patients, refractory or ineligible for erythropoiesis stimulating agents. Hence, luspatercept was recently licensed for use in this category and subsequent studies are ongoing to delineate its role in the therapeutic arsenal.

Hypomethylating agents

Early studies performed in the 1990s indicated clinical activity with low toxicity when used in low doses for MDS patients, and subsequently two large, randomised phase III studies were conducted. The American CALGB9221 included patients with all subtypes of MDS and showed improved overall response rate and progression-free survival in the azacitidine arm. The second randomised study, AZA-001, was designed to demonstrate a possible difference in overall survival and included patients with higher risk MDS (IPSS int-2 and high) and CMML. The median overall survival for the azacitidine-treated patients was 24.5 versus 15 months for patients assigned to the control arm consisting of either supportive care, intensive chemotherapy or low-dose cytarabine. Subgroup analyses comparing azacitidine

and the control arm demonstrated a survival benefit for azacitidine compared with low-dose cytarabine and with supportive care. There was also a survival benefit for azacitidine compared with ICT (9 months), however not significant probably due to the low number of patients in this group. Azacitidine is approved in Europe for treatment of higher-risk MDS (IPSS int-2 and high) and in the US for treatment of all MDS subgroups.

There are phase-II studies indicating a clinical effect with limited toxicity also in lower-risk MDS although the clinical benefit and the risks for this population are still unclear and no studies have hitherto provided evidence for prolonged survival.

Much effort has been given to produce clinical scores predicting response and survival after start of azacitidine treatment. Neither models based on clinical data nor clinical data in combination with gene mutations have been able to predict outcome in a robust way. Recent data have shown higher response rate for patients with *TP53* mutations. The response duration for these patients is, however, short and survival is not prolonged. By contrast, patients with *DDX41* mutations often exhibit long-lasting responses.

Based on the AZA001 study, azacitidine is licensed for CMML. The response rate for CMML patients is around 40%, but it was not until recently a large retrospective study could demonstrate a beneficial role for azacitidine in CMML. Decitabine has been evaluated in two controlled studies using the standard dose 20 mg/m^2 for 5 days. Both studies demonstrated a higher response rate (around 30%) compared to the control arm consisting of supportive care, but no survival advantage. The studies are comparable in safety and efficacy to those using azacitidine albeit lacking the Phase III data demonstrated with azacitidine. An interesting study reported high response rate for *TP53*-mutated AML patients treated with a 10-day decitabine regimen instead of the standard 5-day protocol, although with short response durations.

Intensive chemotherapy

The rate of complete remission achieved with intensive chemotherapy (e.g. cytarabine + daunorubicin) is around 50%. Patients with adverse cytogenetics, in particular those with complex karyotype, respond less well than patients with normal cytogenetics. However, cure or long-term survival of MDS with intensive chemotherapy is very rare, as chemotherapy targets cycling cells and will not target the frequently resting MDS stem cells.

Since the advent of hypomethylating agents, the use of intensive chemotherapy has decreased substantially. Intensive chemotherapy can be used to induce remission prior to allogeneic stem cell transplantation in patients with a highly proliferative disease with bone marrow blasts >10% either upfront or after hypomethylating agent failure. A clinical benefit of intensive chemotherapy for patients who are not candidates for allogeneic stem cell transplant has not been demonstrated

Other chemotherapeutic agents

For proliferative MDS/MPN and CMML, hydroxcarbamide is frequently used to reduce leucocytosis. Hydroxycarbamide may be combined with HMA treatment. For MDS/MPN with inflammation, immunomodulating agents like cyclosporin A, interferon, and more recently ruxolitinib have been empirically used. There is some support from clinical studies for ruxolitinib in combination with HMA in the MDS/MPN group including CMML.

Allogeneic stem cell transplantation

Allogeneic stem cell transplantation (SCT) is the only therapeutic modality that leads to long-term disease control and cure in MDS. MDS is the second most common indication for SCT. The risk of severe complications is high and SCT is generally limited to fit patients up to around 70–75 years of age. In historical data, long-term survival rates of between 25 and 45% have been reported with non-relapse mortality and relapse occurring in approximately a third of the patients. More recent studies indicate improved outcome with long-term survival exceeding 50%.

Optimal timing for performing allogeneic SCT is of crucial importance. Patients with lower-risk MDS have a higher cure rate with both lower non-relapse mortality as well as lower relapse rate compared to higher-risk patients. However, lower-risk patients may have a long life-expectancy without allogeneic stem cell transplantation. The recommendation is to transplant higher-risk MDS patients upfront, and lower-risk patients at signs of progression.

Chromosomal aberrations have a large impact on relapse risk. Relapse-free survival at 5 years in the five IPSS-R cytogenetic risk groups have been reported to span between 10 and 42%. Moreover, emerging data identifies patients with *TP53*- and the *RAS*-pathway mutations as having a particularly high risk of relapse. Another important factor for the risk of relapse is disease status at the time of performing SCT where patients in remission have lower risk of relapse. Cytoreductive treatment e.g. hypomethylating agent or intensive chemotherapy is usually given for patients with a more proliferative disease or increased blasts. If such treatment changes outcome after SCT is, however, still unclear. Retrospective studies have demonstrated similar outcomes for treated and untreated patients before SCT but selection bias might contribute to these results.

Patients can be transplanted using either a reduced intensity conditioning protocol associated with higher risk of relapse but lower risk of non-relapse mortality, or a myeloablative conditioning protocol with lower risk of relapse but higher risk of non-relapse mortality. Retrospective studies have shown similar long-term overall survival.

Patients that relapse after allogeneic SCT have a poor prognosis; however, donor lymphocyte infusions and hypomethylating agent treatment may reverse the relapse in a small proportion of patients.

For MDS, there are no validated minimal residual disease markers available in MDS that can be used for initiating pre-emptive treatment. Emerging data suggest that NGS and other molecular techniques could be used to guide treatment post-SCT.

Novel therapeutic options

The BCL2 antagonist venetoclax has synergistic effects with Azacitidine in AML where it has shown to prolong survival in elderly patients not fit for intensive chemotherapy, compared to Azacitidine as monotherapy. The experience in MDS is still limited, but similar to AML, venetoclax in combination with azacitidine may be effective in reducing marrow blasts. In contrast to AML however, MDS patients seem to have more haematological toxicity with deep and prolonged cytopenia. Recent data indicate that venetoclax is not effective in patients carrying TP53 or RAS pathway mutations.

IDH1 and IDH2 inhibitors have documented clinical effects on relapsed/refractory AML carrying *IDH1/2* mutations. Several prospective studies evaluating the effect in combination with standard therapy are ongoing. Data on MDS is limited but small studies indicate an effect also in MDS. Studies on the combination of IDH1/2 inhibitors with Azacitidine are ongoing. Treatment with IDH1/2 inhibitors result in improved differentiation of the haematopoiesis and can induce a differentiation syndrome.

Eprenetapopt (APR-246) has been shown to restore tumour-suppressor function in mutant p53 cells and also to induce cell death in various cancer types. A recent study evaluated the effect of e. in *TP53* mutated MDS and AML, but failed to show a significant effect on overall survival.

With the present development of classification and prognostic systems, prospective clinical trials should be guided by molecular features rather than the present WHO categories of MDS or AML, which would facilitate access to new treatment for patients.

Future directions

MDS remains one of the more complex haematological malignancies – and one of the most difficult to treat due to the stemness of the initiating tumour cell. The development over the last decade reflects a transition from purely clinical and morphological criteria for diagnosis to a system encompassing also detailed understanding of both germline and somatic genetic abnormalities. Precision diagnostics is already in use and online tools will be an essential part of future prognostic decision-making. The relative paucity of novel therapeutic breakthroughs is presently challenged by extensive research aiming to develop precision therapy for different clinical and molecular subgroups of patients. In the end, the treating haematologist will have to encompass all this new knowledge, and the patient's general condition and personal preferences into well-functioning personalised medicine.

Introduction

For the purposes of this chapter, the term myeloproliferative neoplasms (MPNs) will refer to clonal disorders of haemopoiesis that lead to an increase in the numbers of one or more mature myeloid cell progeny. The chronic myeloid leukaemias would fit this definition and share pathogenetic features with some of the MPNs, but have, historically (since the discovery of the Philadelphia chromosome), been studied separately from the MPNs and are described in Chapter 33. The myelodysplastic syndromes (MDS) can also, in a minority of cases, fit our working definition of MPN, in being associated with increased numbers of mature cell progeny, but dysplasia is a major feature and with the exception of overlap syndromes (MDS/MPN) these are classified separately by the WHO (Chapter 34) and recent international consensus criteria (ICC).

This chapter will focus on the classical MPNs: polycythaemia (rubra) vera (PV), essential thrombocythaemia (ET) and primary myelofibrosis (PMF). They share clinical, morphological and molecular features and can transform, in their course, into one another. They are clonal disorders of the pluripotent haemopoietic stem cell and have, to varying degrees, the potential to transform into acute myeloid leukaemia (AML). Secondary (non-clonal) polycythaemias and thrombocytoses will also be discussed in this chapter, as they often enter the differential diagnosis of their clonal counterparts. In addition, some of the less common MPNs will be described, the clonal eosinophilic syndromes, chronic neutrophilic leukaemia (CNL) and a group of entities which are not classified as MPN by the WHO, mastocytosis.

The molecular biology of the myeloproliferative neoplasms

Mutations in *JAK2*, *CALR* and *MPL* in PV, ET and PMF

A relationship between PV, ET and PMF was originally suggested by William Dameshek in 1951, but it was not until 2005 that a molecular basis for this was identified: an acquired activating mutation in the gene for the cytoplasmic tyrosine kinase JAK2. With sensitive detection techniques, the *JAK2 V617F* mutation is detectable in over 95% of patients with PV, and 50–60% of those with ET or PMF. JAK2 acts downstream of several cell-surface receptors including those for erythropoietin and thrombopoietin (Figure 35.1). Upon binding of a ligand such as EPO to its receptor, JAK2 becomes phosphorylated and in turn phosphorylates downstream targets, most important of which are the STATs (signal transducers and activators of transcription). PI3K and MAPK pathways are also activated and JAK2 has some direct nuclear effects through chromatin modification. Valine 617 is located in the JH2 domain of JAK2,

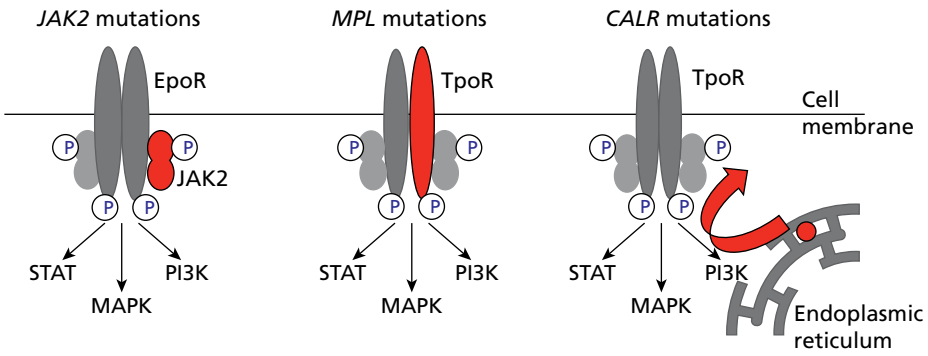

Figure 35.1 Illustration of common driver mutations in ET, PV and PMF.

which acts to repress its kinase activity. The *V617F* mutation leads to increased and constitutive kinase activity, confers cytokine independence and can cause erythrocytosis and/or thrombocytosis in mouse models.

The *JAK2 V617F* mutation is homozygous in a proportion of patients with PV and PMF, but this is uncommon in ET. The presence and size of a homozygous clone is one of the number of factors that determine how a different specific disease phenotype can arise in the context of the same pathogenic mutation. Other factors determining phenotype include any additional mutations that are acquired alongside *JAK2 V617F* and in what order they arise, as well as germline genetic background, gender and body iron stores.

Subsequent to the identification of *JAK2 V617F*, mutations in exon 12 of the *JAK2* gene were detected in almost all patients with *JAK2 V617F*-negative PV. Many different mutations have been reported, usually small in-frame insertions or deletions, but all seem to affect the pseudokinase domain, again leading to constitutive activation of the JAK2 kinase. Compared to PV patients with the *V617F* mutation, those carrying exon 12 mutations have similar rates of thrombosis, disease progression and survival. However, they tend to have a more isolated erythrocytosis, with less frequent thrombocytosis and leucocytosis, and exon 12 mutations are also not found in ET. These differences have been proposed to reflect differential interaction of the JAK2 mutant proteins with specific cytokine receptors.

Activating point mutations in the thrombopoietin receptor gene, *MPL*, were identified in 2006 and are found in 5–10% of patients with ET and PMF, but not in PV. Similar to *JAK2* V617F, these confer cytokine independence and can cause an MPN phenotype in mouse models, but *MPL*-mutant disease is characterised by thrombocytosis and/or marrow fibrosis without erythrocytosis, reflecting activation of pathways limited to the thrombopoietin receptor, compared to *JAK2*-mutant disease.

Mutations in the calreticulin (*CALR*) gene were identified in 2013 and are found in 25–35% of patients with ET and PMF, but not in PV. CALR protein is found within the endoplasmic reticulum (ER) and the frameshift mutations found in MPNs are all predicted to result in a novel C-terminal protein sequence, the commonest being a 52-bp deletion ('type 1') or 5-bp insertion ('type 2'). The two mutation types are found with similar frequencies in ET, while type 1 mutations are much commoner than type 2 mutations in PMF and in this context carry a more favourable prognosis than other mutations. Mutant CALR protein interacts with the thrombopoietin receptor (MPL) within the ER, leading to altered traffic of MPL to the cell surface and activation of downstream signalling pathways (Figure 35.1), explaining the phenotypic similarities with *MPL*-mutant disease.

Additional mutations in PV, ET and PMF

Mutations in *JAK2, CALR* and *MPL* are considered fairly specific to the classical MPN phenotype, although *JAK2 V617F*, in particular, has been reported in small numbers of patients with MDS, MDS/MPN and AML, together with a higher prevalence in MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T). In addition, mutations in other cancer driver genes are found in over half of patients with MPN. The commonest mutations are in *TET2* (10–15% of MPN patients), *ASXL1* (5–10%) and *DNMT3A* (5–10%), with a lower prevalence in splicing regulators (*SRSF2, SF3B1, U2AF1, ZRSR2*) and other regulators of chromatin structure, epigenetic functions and cellular signalling (e.g. *EZH2, IDH1, IDH2, CBL, KRAS, NRAS, STAG2, TP53*). These mutations may act through a variety of cellular mechanisms to increase the selective fitness of a haematopoietic stem cell clone harbouring a *JAK2, CALR* or *MPL* mutation, rather than driving the specific myeloproliferative phenotype. Consistent with this, these mutations are commonly found in other myeloid malignancies such as MDS and AML and some are also prevalent in age-related clonal haematopoiesis in individuals with normal blood counts (e.g. *DNMT3A, TET2, ASXL1*), although interestingly *JAK2 V617F* can also be found in the absence of blood count abnormalities in up to 3–5% of the population, depending on sensitivity of the techniques used.

These additional mutations are commoner in myelofibrosis and blast phase compared to PV and ET and some are known to carry a poorer prognostic risk (e.g. *EZH2, IDH1, IDH2, SRSF2* and *ASXL1* mutations in PMF). Biallelic *TP53* mutations are

associated with leukaemic transformation and identify a disease category with particularly unfavourable outlook.

Germline predispositions to MPNs

Although *JAK2 V617F* or exon 12, *CALR* and *MPL* mutations are acquired, several germline factors have been found to alter the risk of development of an MPN. The most important is a specific *JAK2* haplotype on chromosome 9 ('46/1'), which is present in a quarter of the population. This haplotype is enriched in patients with MPNs and *JAK2* mutations occur preferentially on the 46/1 haplotype allele. The latter observation raises the possibility that this haplotype could be more susceptible to acquisition of mutations, although an alternative explanation for the association is that mutant clones arising in patients with the haplotype have a greater proliferative advantage. Interestingly, the haplotype is associated with *JAK2* exon 12-mutant MPNs and also *MPL*-mutant disease in some studies. A number of single nucleotide polymorphisms (SNPs) in other genes (e.g. *TERT*, *TET2, SH2B3, MECOM, CHEK2, ATM, PINT, GFI1B*) have also been associated with MPNs, sometimes with varying effects between diseases; for example, a SNP between the *HBS1L* and *MYB* genes is enriched in *CALR*- and *MPL*-mutated MPNs and *JAK2*-mutated ET.

First-degree relatives of patients with MPN have a five to seven fold increased risk of developing an MPN (of any type), and familial clusters of cases are reported but account for less than 5% of cases. These families typically show incomplete penetrance, often with mixed phenotypes within a family and with the usual pattern of acquired *JAK2 V617F, CALR, MPL* and additional mutations found in sporadic cases. In most families, the predisposing allele has not been identified, but a small number of rare germline variants have been shown to contribute to such familial clusters, including structural variants at the *TCL1A/ATG2B/GSKIP* locus and *RBBP6* mutations.

Systemic mastocytosis

Mastocytosis represents an expansion of neoplastic mast cells in various tissues and is associated in the vast majority of patients with an activating mutation in the *KIT* gene, encoding the tyrosine kinase receptor for stem cell factor (SCF). The Asp816Val (*D816V*) mutation leads to ligand-independent phosphorylation of c-Kit and a consequent clonal expansion of mast cells and can be identified in the peripheral blood or bone marrow of up to 90% of patients with systemic mastocytosis (SM). A minority of patients who lack *KIT D816V* have been shown to harbour an alternative mutation either in the Asp816 codon (*D816F/H/I/Y*) or other codons (e.g. *D820G, N822K*). In other patients, the *D816V* mutation may be present but not detectable with standard assays because of a very low mast cell burden and/or suboptimal tissue sampling, and high-sensitivity assays should be available for diagnostic purposes.

Indolent and smouldering SM are primarily driven by mutated KIT, while more advanced forms of the disease (aggressive SM, SM with an associated haematological neoplasm (SM-AHN), and mast cell leukaemia) are very often associated with additional myeloid driver mutations such as in *TET2*, *SRSF2*, *ASXL1*, *RUNX1*, *JAK2*, *NRAS*, *KRAS, CBL* and *EZH2*. Additional mutations are associated with a less favourable prognosis, particularly those in *SRSF2, ASXL1* and *RUNX1*. The KIT mutation is variably detectable in the AHN cellular component, more often in chronic myelomonocytic leukaemia (CMML) than in MPN or AML.

Clonal eosinophilias

The WHO classification of tumours of haematopoietic and lymphoid tissues now includes a specific chapter for neoplasms associated with eosinophilia and recurrent rearrangements affecting genes including *PDGFRA, PDGFRB, FGFR1, FLT3* and *JAK*2. These fusions result in constitutive activation of the associated tyrosine kinase and can be associated with a variety of clinical presentations that are important to recognise because of potential implications for therapy. A *PDGFRA* rearrangement most often results from a cryptic deletion at 4q12, leading to a *FIP1L1::PDGFRA* fusion. The commonest *PDGFRB* rearrangement, t(5;12)(q31~33;p12), results in an *ETV6::PDGFRB* fusion gene but many variants have been reported and *FGFR1* rearrangements result from a variety of translocations affecting the *FGFR1* gene at 8p11. The *PCM1::JAK2* fusion currently defines an additional category in the WHO classification and other rarer fusions affecting *JAK*2 (*ETV6::JAK2, BCR::JAK2*) are also included; some cases, but not all, are associated with eosinophilia.

Eosinophilia can also occur in SM and in association with *JAK2* V617F or other rare gene rearrangements that cause tyrosine kinase activation (e.g. *ETV::ABL1*, *ETV6::FLT3*). More recently, an activating mutation in the *STAT5B* gene (*STAT5 N642H*) which was previously recognised in lymphoproliferative disorders was identified in a minority (1.6%) of patients investigated for eosinophilia. Lastly, novel recurrent acquired mutations have been reported in *JAK2* exon 13 (*Leu583-Ala586DelInsSer/Gln/Pro*) in a small number of patients with eosinophilia. These mutations also result in constitutive JAK2 activation and some patients showed a concomitant PV phenotype.

Chronic neutrophilic leukaemia

Chronic neutrophilic leukaemia (CNL) is a rare disease characterised by expansion of mature neutrophils in the blood and bone marrow granulocytic hyperplasia without dysplasia. In 2013, mutations in the gene for the colony-stimulating factor 3 receptor, *CSF3R*, were identified in patients with CNL. There are two classes of mutation with somewhat different

biochemical effects: membrane-proximal mutations, most commonly T618I, cause ligand-independent JAK-STAT signalling, while truncation mutations affecting the cytoplasmic tail cause dysregulation of SRC family and TNK2 kinases. Although *CSF3R* mutations were initially described in the MDS/MPN atypical CML, other studies have suggested that *CSF3R* mutations are fairly specific for CNL and can be detected in most patients. Other mutations reported in CNL include those in *SETBP1, ASXL1, SRSF2* and *TET2*.

Erythrocytosis/polycythaemia

Erythrocytosis

A true erythrocytosis is present when there is an absolute increase in the total body red cell volume or mass which is defined as an increase in red cell mass greater than 125% of predicted for sex and body mass. This is reflected in a raised haemoglobin (Hb) or haematocrit (Hct) although these are not entirely accurate and formal measurement of red cell mass is required to prove a true erythrocytosis is present. Without an increase in red cell mass, a reduced plasma volume may lead to an apparent erythrocytosis where there appears to be an erythrocytosis but this is only a reflection of the reduced plasma volume. The requirement for red cell mass testing was formally dropped in the recently revised WHO criteria for PV but it remains a useful test in some circumstances.

An erythrocytosis can be primary where there is an intrinsic defect in the erythroid compartment leading to increased red cell production or secondary where erythropoietin (EPO) production drives red cell production. An erythrocytosis can be congenital or have an acquired causation. Following investigation there remains a group for whom no cause for the erythrocytosis is identified termed idiopathic erythrocytosis (see Table 35.1)

Table 35.1 Causes of an erythrocytosis.

Primary (abnormality within erythroid compartment)
- Congenital
  - *EPOR* gene mutation
  - Mutations within *SH2B3*
- Acquired
  - Polycythaemia vera

Secondary (erythropoietin driven)
- Congenital
  - Mutation in genes in Oxygen sensing pathway: *PHD2*, *VHL* or *HIF2A* mutations
  - *EPO* gene gain-of-function mutation
  - Abnormal haemoglobin with increased oxygen affinity
  - Methaemoglobinaemia
  - *BPMG* mutation leading to reduced 2,3-bisphosphoglycerate
  - *PEIZO*1 mutations
  - *SLC30A10* mutations with hypermanganesemia
- Acquired
  - Hypoxia driven: high altitude, chronic lung disease, right-to-left cardiopulmonary vascular shunts (cyanotic congenital heart disease), carbon monoxide poisoning, smokers, hypoventilation syndromes including sleep apnoea
  - Local hypoxia :Renal artery stenosis, end-stage renal disease, hydronephrosis, renal cysts (polycystic kidney disease), following kidney transplantation
  - Pathological EPO production: Tumours – cerebellar haemangioma, meningioma, parathyroid carcinoma/adenomas, hepatocellular carcinoma, renal cell carcinoma, pheochromocytoma, uterine leiomyomas
  - Exogenous EPO: drug-associated erythropoietin and androgens
  - Associated with a monoclonal gammopathy (TEMPI, Clarkson's syndrome)

Idiopathic erythrocytosis (cause unknown)

Polycythaemia vera

The commonest acquired primary erythrocytosis is polycythaemia vera (PV). In this disorder, there is an acquired clone which drives an expansion in the total red cell mass, although accompanying elevations in the platelet and/or neutrophil counts are relatively common. The first description of PV was by Vaquez in 1892. In 1903, Osler published the first series of patients, identifying salient clinical features and setting PV apart from other erythrocytoses. Considerable information has been gathered about PV since the work of these pioneers, much of it due to the work of the Polycythaemia Vera Study Group (PVSG), which was set up in 1967 with the aim of optimising diagnosis and management of PV. The discovery of the V617F mutation in the pseudokinase domain of the tyrosine kinase *JAK2* in 2005 in nearly all cases of PV, was a major advance delineating the clonal nature of the disease.

Pathophysiology

PV is a stem cell disorder classically characterised by hyperplasia of all three myeloid cell lineages. The first line of evidence in support of the stem cell origin of PV came in the form of clonality studies. Using X-chromosome inactivation patterns (XCIPs) in the mid-1970s Fialkow and colleagues showed that neutrophils, erythrocytes and platelets originated from the same clone.

Erythropoiesis in PV is autonomous and does not rely on erythropoietin (EPO). Therefore, the levels of this cytokine are typically reduced in PV patients. PV progenitor cells, unlike normal ones, can survive *in vitro* and give rise to erythroid colonies (BFU-E) in the absence of added EPO (endogenous erythroid colonies, EECs). PV erythroid progenitors show an increased sensitivity to EPO and to several other growth

factors, including insulin-like growth factor-1, thrombopoietin, interleukin-3 and granulocyte/monocyte colony-stimulating factor.

When sensitive methods are used for the detection of the *JAK2* V617F mutation, over 95% of PV patients are positive. Mutations elsewhere in *JAK2* have been described in most of the V617F-negative patients who have PV by strict diagnostic criteria. These mutations cluster in exon 12 and can be of several different types, but all seem to affect the pseudokinase domain, leading to constitutive activation of the JAK2 kinase.

Diagnostic criteria

The diagnosis of PV requires the identification of features in support of this diagnosis, and the exclusion of other erythrocytoses (Table 35.1). The original diagnostic criteria were formulated by the PVSG in the 1970s. Criteria for PV have been refined over time as more is known about the pathophysiology. The current WHO criteria were published in 2022 and set Hb and Hct limits, the presence of an acquired clone and distinctive bone marrow trephine appearances. The British Society of Haematology (BSH) has reviewed the evidence and defined guidelines for making a diagnosis of PV, both are shown in Table 35.2.

Most patients can now be diagnosed on the basis of a raised haematocrit (>0.52 for men and >0.48 for women using BSH criteria) together with the presence of the *JAK2* V617F mutation. It is also important to note that the *V617F* mutation has been identified in a small proportion of other haematological malignancies (e.g. AML, chronic myelomonocytic leukaemia and MDS). However, none of these disorders is associated with a raised red cell mass and clinical distinction from PV is rarely an issue.

The role of bone marrow biopsy in the evaluation of PV remains controversial. It is required for WHO diagnostic criteria but this is predicated on the issue that a bone marrow biopsy can reliably distinguish PV from other MPNs such as ET. The WHO does suggest that 'bone marrow biopsy may not be required in patients with sustained absolute erythrocytosis if major criterion 3 and minor criterion are present but initial myelofibrosis can only be detected by bone marrow biopsy'. On that basis, a bone marrow biopsy may be useful as a baseline investigation for later comparison in younger patients with the disorder, or if there are atypical clinical and laboratory features at presentation. Hb and Hct limits in the current WHO criteria are lower and within the normal range. These are based on

Table 35.2 Diagnostic criteria for polycythaemia vera.

WHO criteria (2022)	BSH criteria
Major criteria	*JAK2-positive polycythaemia vera (requires both criteria)*
1 Elevated haemoglobin concentration (>165 g/L in men;160 g/L in women)or elevated haematocrit (>49% in men; 48% in women)	**1** High haematocrit (>0.52 in men, >0.48 in women) OR raised red cell mass (>25% above predicted)
2 Bone marrow biopsy showing age-adjusted hypercellularity with trilineage growth (panmyelosis) including prominent erythroid, granulocytic and megakaryocytic proliferation with pleomorphic, mature megakaryocytes	**2** Mutation in *JAK2*
3 Presence of *JAK2*V617F or *JAK2* exon 12 mutation	
Minor criterion	
Subnormal serum erythropoietin level	*JAK2-negative polycythaemia vera (requires A1-A4 plus another A or two B* criteria)
The diagnosis on PV requires either all three major or the first two major plus the minor criterion (*JAK2* negative PV)	**A1** Raised red cell mass (>25% above predicted) OR haematocrit ≥0.60 in men, ≥0.56 in women
	A2 Absence of mutation in *JAK2*
	A3 No cause of secondary erythrocytosis
	A4 Bone marrow histology consistent with PV
	A5 Palpable splenomegaly
	A6 Presence of an acquired genetic abnormality (excluding *BCR::ABL1*) in the haematopoietic cells
	B1 Thrombocytosis (platelet count $>450\times10^9$/L)
	B2 Neutrophil leucocytosis (neutrophil count $>10\times10^9$/L in non-smokers, $\geq12.5\times10^9$/L in smokers)
	B3 Radiological evidence of splenomegaly
	B4 Low serum erythropoietin

defined levels to separate PV, ET and iron-deficient PV rather than reflecting an actual erythrocytosis.

A few patients with clinical PV are negative for the V617F mutation. Molecular testing for *JAK2* exon 12 mutations should be undertaken in this group as above. Rarely, patients are negative for both V617F and exon 12 *JAK2* mutations. In these patients, the diagnosis of PV can be made if the other criteria set out in Table 35.2 are met (WHO first 2 major and the minor criteria). However, this group of truly *JAK2*-negative PV is very rare and repeat testing for *JAK*2 V617F on a bone marrow sample, and/or every few years on a blood sample should also be considered in these patients.

Epidemiology

Combined annual incidence of PV is reported to be around 0.84 per 100,000 of the population, with a slight male predominance. The median age at onset is 55–60 years and although incidence increases with age, PV can occur at any age, rarely, in childhood.

Clinical features

Symptoms

Many patients are asymptomatic at presentation; however, a range of symptoms are associated with PV either at presentation or later in the course of the disease. General symptoms such as tiredness are described. Sluggish cerebral blood flow secondary to the increased haematocrit is thought to underlie features such as headaches, drowsiness, insomnia, amnesia, tinnitus, vertigo, chorea and even depression. Transient visual disturbances also occur.

Pruritus occurs in about one-quarter of PV patients and in some, it may be severe and even associated with suicidal ideation. It is characteristically aquagenic, precipitated by warm baths and can be associated with erythema, swelling or even pain. Pruritus is often relieved by controlling the haematocrit, but its aetiology remains elusive. Basophilia, hyperhistaminaemia and iron deficiency may be factors.

Signs

Many skin changes are seen in PV. Plethora (Figure 35.2), dilated conjunctival vessels and rosacea-like facial skin changes are not uncommon at presentation. Brown discolouration of the skin, erythromelalgia and, rarely, Sweet's syndrome may be seen.

Hypertension is probably more common in patients with PV, as is hyperuricaemia, with gout seen in about 5% of cases. Palpable splenomegaly is seen in 30–50% of cases of PV. It is unclear if its presence affects prognosis, but it may be associated with an increased risk of progression to myelofibrosis.

Complications

Thromboembolic events

Untreated PV patients run a greatly increased risk of thrombosis, which can be arterial, venous or microvascular. The increased haematocrit leads to an increased blood viscosity, rheological abnormalities and abnormal platelet–endothelial contact. Additionally, procoagulant changes in platelets (e.g. decreased response to prostaglandin D_2), thrombocytosis and pre-existing vascular disease can all be involved in increased thrombotic risk.

Figure 35.2 Typical appearance in a patient with PV.

Arterial occlusions can lead to myocardial infarcts, strokes, transient ischaemic attacks, amaurosis, scotomata and mesenteric and limb ischaemia (Figure 35.3). Less commonly, microvascular occlusions affecting the extremities and erythromelalgia can occur. In the venous circulation, unusual sites, such as the splanchnic vessels can be involved. As a result, mesenteric, splenic and hepatoportal thromboses are recognised as presenting features of PV. This propensity to venous thrombosis in atypical sites is particularly strongly correlated with the presence of the *JAK2* V617F mutation, and indeed patients presenting with otherwise unexplained splanchnic vein thrombosis (SVT) will often be found to have the mutation, even in the absence of an overt MPN. Superficial thrombophlebitis, conventional deep venous thromboses and pulmonary emboli are also seen. Much morbidity and mortality in PV is due to thrombotic events. Arterial thrombosis is more common than venous thromboembolism (VTE). Acute thrombotic events should be managed according to current guidelines with low molecular weight heparin (LMWH) the first choice of treatment followed by vitamin K antagonists. Direct oral anticoagulants are increasingly used even though there is little data for their use in MPNs. Introduction or optimisation of cytoreductive therapy is required to maximise blood count control.

Primary and secondary prevention should include screening for and control of cardiovascular risk factors. In unprovoked VTE, indefinite anticoagulation is recommended for secondary prevention as the underlying clonal disease remains present.

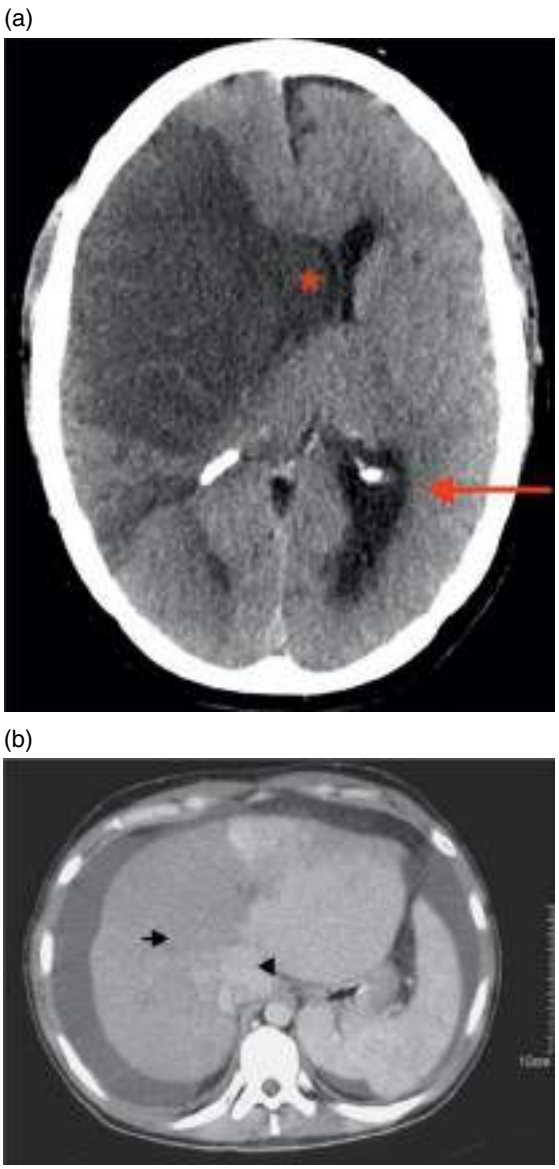

Figure 35.3 (a) Acute cerebral infarction. A 57-year-old male presented 5 days earlier with acute onset of left-sided weakness. Unenhanced CT demonstrates a large acute right middle cerebral territory infarction involving the right frontal and parietal lobes, insula and basal ganglia (asterisk — head of the right caudate nucleus). There is swelling of the infarcted brain tissue with loss of grey-white differentiation. Associated mass effect has resulted in midline shift and acute hydrocephalus of the left lateral ventricle (evidenced by dilatation of the left occipital horn, arrow (Source: Courtesy of Dr Francis Scott). (b) Polycythaemia vera presenting with the Budd–Chiari syndrome in a 28-year-old female; contrast-enhanced computerised tomography showing reduced enhancement of the right lobe of the liver (arrow) with characteristic sparing of the caudate lobe (arrowhead). On this occasion, the left lobe was also relatively spared. Marked ascites and a bulky spleen are also seen (Source: Courtesy of Dr Edmund Godfrey).

There seems to be a predilection for thrombosis in certain sites in MPN. Splanchnic vein thrombosis (SVT) involves thrombosis of the hepatic, portal, superior mesenteric and splenic veins singly or in combination. Hepatic vein thrombosis (Budd Chiari Syndrome) is commoner than portal-mesenteric axis venous thrombosis in PV and the incidence of SVT during the course of PV varies from 0.8 to 7.8%. SVT is commoner in young females. The *JAK*2 V617F mutation seems to confer a particular susceptibility. LMWH in the acute phase should be instituted unless contraindicated, with thrombolysis and stenting interventions to recanalise vessels collaborating with interventional radiology, hepatology and other colleagues. Recurrence rates are high and long-term anticoagulation is required. Cytoreduction to control blood counts with interferon is usually the first-line agent in young people. Adoption of therapeutic targets lower than the normal range may be a useful therapeutic strategy.

Cerebral vein thrombosis occurs in about 1% of MPN patients and a third of patients suffer recurrence despite anticoagulation and cytoreduction. Recurrence often involves SVT. These patients should also be treated with long-term anticoagulation and cytoreduction.

Myelofibrosis

Progression to myelofibrosis, post-PV myelofibrosis (PPV-MF) occurs in around 10–20% of PV cases 15 years from diagnosis. This figure is approximate, not least because different studies have used distinct criteria to define myelofibrotic transformation. Transformation often occurs gradually over many years, is thought to reflect accumulation of additional mutations and is associated with an increased risk of conversion to leukaemia. The management of these patients is similar to that of PMF.

Leukaemia transformation

This is the most catastrophic complication of PV, but the risk of developing acute leukaemia in PV patients treated only with venesection is thought to be small in the short term (1–3%). This risk, however, increases dramatically (more than 10-fold) when radioactive phosphorus (^{32}P), chlorambucil or irradiation are used as treatment. The median time interval between first starting such therapy and developing acute leukaemia is 5–8 years. Interestingly, in about one-third of patients transforming to acute leukaemia from a preceding *JAK2*-positive MPN, the leukaemia is *JAK2*-negative. Recent long-term studies suggest that the risk of myelodysplasia (MDS) or AML in PV patients treated with hydroxycarbamide, is approximately 20% at 20 years, although it is not clear whether this represents an effect of the drug or part of the natural history of the disease.

Prognosis and risk stratification

In the first half of the twentieth century, entirely untreated PV had a dismal prognosis, with a 50% survival of less than 2 years,

deaths being due to thromboembolic events. However, adequately treated PV now has a longer natural history with a life expectancy of over 11 years, which, bearing in mind that the average age of onset is 60–65 years represents a modest reduction in actual life expectancy. Factors predictive of poorer prognosis and increased complication rates in PV include *JAK2* mutation burden and white cell count at diagnosis, both factors probably serving as surrogate markers of disease activity.

On the basis of the biological factors, patients are classified as high or low risk for thromboembolic complications. The BSH defines high risk as age ≥65 years and/or prior PV-associated thrombotic history and this is the group that will primarily be considered for cytoreductive therapy.

Treatment

Treatment in PV is aimed at reduction of the thrombotic and haemorrhagic risk. Minimisation of the symptomatology and complications and minimisation of the risk of transformation to myelofibrosis and acute leukaemia are other aims to be considered.

The mainstay of treatment for low-risk PV is regular venesection in patients who can tolerate it. However, some 'low risk' patients may be considered higher risk in the presence of cardiovascular risk factors, elevated white blood count, extreme thrombocytosis or haematocrit uncontrolled by venesection and this group may need to be considered for cytoreductive therapy. A target haematocrit of ≤0.45 is used, following the demonstration that in patients with PV, higher haematocrit targets are associated with a significantly increased risk of thrombosis. This has been confirmed in a randomised controlled trial, CYTO-PV. Venesection has little impact on the haematocrit in the short term: the purpose of regular venesection is to induce iron deficiency, such that the haematocrit remains chronically below the target threshold of 0.45. Thus, typical venesection regimens start with phlebotomy every 2–3 weeks until the haematocrit is controlled, and thereafter phlebotomy is generally needed every 1–3 months, depending upon factors such as dietary iron intake and erythropoietic activity. Low-dose aspirin (75–100 mg daily) reduces thrombotic complications in PV and should be used in all PV patients without contraindications to this drug. Its use is supported by a randomised study (ECLAP).

High-risk patients are recommended for cytoreductive therapy. It is also recommended for patients unable to undergo venesection and in some low-risk patients with marked thrombocytosis, leucocytosis or intractable symptoms. The first-line management option of the high-risk PV patient is either hydroxycarbamide or a pegylated interferon, depending on patient and physician choice. The second line option is usually the drug not chosen for first-line use. Ruxolitinib is a second-line option for those intolerant or resistant to hydroxycarbamide. Third-line options are busulphan, ^{32}P, pipobroman or anagrelide in those where control of the platelet count is difficult.

Hydroxycarbamide (hydroxyurea) is the most commonly used drug; it is orally bioavailable and generally very well tolerated, and it will reduce both the haematocrit, leucocyte count and platelet count. The commonest complications are leucopenia or thrombocytopenia, which are dose-dependent and can usually be avoided by close monitoring of the blood count when the drug is first introduced. In susceptible patients, it can cause photosensitivity, painful leg ulcers and gastrointestinal side effects. Other important cutaneous toxicities of hydroxycarbamide include increased risk of sun-induced squamous skin lesions, these may be both cancerous and precancerous, and pigmentation can also occur. Patients should be warned about these effects and counselled about sun exposure. Hydroxycarbamide is also genotoxic and as a radiomimetic, it should be stopped during radiotherapy. The usual dose is 0.5–2 g daily.

It has been suggested that hydroxycarbamide may increase the inherent leukaemogenic risk associated with PV. This concern is largely based on studies involving small numbers of patients or patients who have also required other cytotoxic agents (and may therefore represent a subgroup with more aggressive disease). At present, there is no convincing data to show that hydroxycarbamide, when used as a single agent, significantly increases the risk of leukaemia, although a small effect cannot be excluded. The only available comparator studies have shown that the comparator treatments (e.g. pipobroman) are more leukaemogenic. Studies of hydroxycarbamide in sickle cell disease are reassuring, with long follow-up. However, sickle cell disease is not an acquired clonal disease with an inherent tendency to leukaemic transformation, so while this data is reassuring it is not directly transferable to MPN patient populations.

Interferons (IFN) are effective in controlling both the platelet/leucocyte count and the haematocrit and may induce impressive reductions in the burden of V617F-positive cells in the blood. Pegylated forms are now in widespread use with pegylated IFN-α-2a (PEG-α-2a) showing complete responses in high percentages of patients and some complete molecular remissions. Peg-α-2b has also been shown to be effective in controlling disease and proline-PEG-α-2b (Ropeginterferon) has demonstrated haematological and molecular responses in the PROUD-PV studies. This drug is now licensed for the treatment of PV. Pegylated IFNs are more costly and have to be administered by the subcutaneous route. There is a significant associated side-effect profile (including fatigue, flu-like symptoms, depression and autoimmune phenomena). They are, however, non-cytotoxic and are therefore an option in younger patients, those who are reluctant to take other cytotoxic agents and in pregnancy. Doses vary depending on the product used.

Ruxolitinib has been shown to be effective in the treatment of PV and has been approved for PV patients resistant or intolerant to hydroxycarbamide. It is very effective in the treatment of side effects such as itch in some patients. The UK MAJIC study showed that ruxolitinib was superior to other available therapies in this patient group with improved blood count control,

event-free survival and molecular responses in ruxolitinib-treated patients. This study also demonstrated a strong correlation between molecular response (50% reduction) in *JAK2 V617F* mutant allele fraction and better overall, progression-free and thrombosis-free survival.

Busulfan is sometimes used in elderly patients or if other treatments are not tolerated. It is convenient as it need only be administered intermittently but may increase the risk of leukaemia. The usual dosage is 25–75 mg as a single dose every 2–3 months, or 2–4 mg daily for 7–14 days repeated every 4 weeks until the target blood count is reached. ^{32}P is a similar option if available. It is administered by single injection in patients who can manage the radioactivity risk post-injection. It can be repeated every 1–2 years in recurrence. However, it does increase the long-term risk of leukaemia.

Anagrelide can be useful in controlling the platelet count and can be combined with hydroxycarbamide allowing lower doses of both agents. Approximately 10% of patients are completely refractory to anagrelide. The usual dose is 1–2 mg daily, but occasional patients may require doses of up to 8 mg daily. Its side effects are mainly secondary to its inotropic and vasodilatory properties (e.g. headaches, palpitations and fluid retention) although marked anaemia may also occur. Anagrelide is currently only approved in Europe for patients with ET and as second-line therapy.

Pruritus often improves with control of the haematocrit, but paroxetine, antihistamines and aspirin (in some cases) can help. There are also reports that psoralen-UV light therapy and IFN are of use. The JAK1/2 inhibitor ruxolitinib can be particularly beneficial in intractable cases.

Other causes of erythrocytosis

All disorders with an increased red cell mass which are not due to a clonal proliferation of haemopoietic progenitors are included under this heading of erythrocytosis and are classified as in Table 35.1. A group of patients do not fall into any of these categories and are given the diagnosis of idiopathic erythrocytosis. The clinical management of many of these syndromes is not well defined.

Congenital erythrocytosis

A congenital or familial erythrocytosis can be present in young patients and/or those with a family history. A number of genetic lesions can give rise to this situation. The main primary congenital erythrocytosis is due to mutations in the *erythropoietin receptor (EPOR)*. These mutations lead usually to a C-terminal truncation of the EpoR protein which is no longer down regulated and is therefore active without the addition of EPO to the receptor.

The oxygen-sensing pathway (Figure 35.4) is responsible for the maintenance of oxygen homeostasis in the cell. A number of proteins, prolyl hydroxylases (PHD), von Hippel–Lindau (VHL) and hypoxia-inducible factors (HIF) are involved in the pathway.

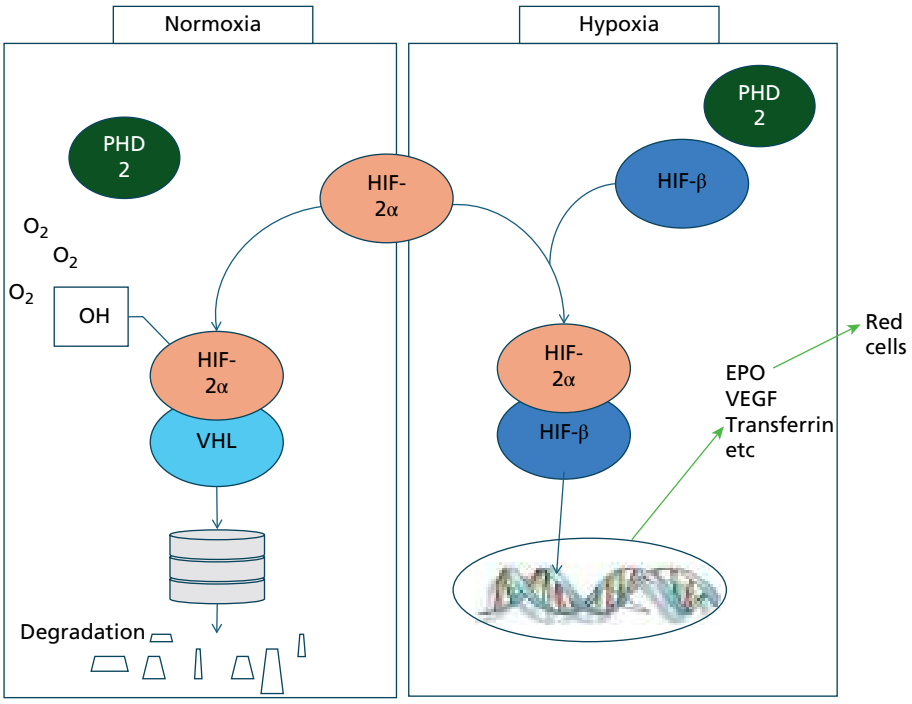

Figure 35.4 Schematic representation of the oxygen sensing pathway. EPO, Erythropoietin; HIF, Hypoxia-inducible factors; O_2, oxygen; OH, hydroxyl; PHD, Prolyl hydroxylase; VEGF, Vascular endothelial growth factor; VHL, von Hippel–Lindau.

PHD proteins have an absolute requirement for oxygen and in normal oxygen conditions hydroxylate HIF-α. Following this, VHL associates with HIF-β and is degraded in the proteasome. However, in hypoxic conditions, this does not occur. Instead, HIF-α accumulates and associates with HIF-β. A stable HIF complex is formed which translocates to the nucleus binding to promoters and enhancers of a series of genes. This leads to transcription of genes and protein production including production of EPO. Mutations in the genes in the oxygen-sensing pathway could lead to abnormal protein production which is not degraded in states of normal oxygen tension but remains as if in a state of hypoxia. Mutations of *VHL*, *PHD2* and *HIF2A* have been described causing secondary erythrocytosis.

The first mutation found in the oxygen sensing pathway was in *VHL* and was linked to erythrocytosis in the Chuvashia in the upper Volga region of Russia where there were a large number of cases. All affected cases had a homozygous mutation C598T. This has been described in other populations and compound heterozygote VHL mutations have also been seen. Autosomal dominant pedigrees with mutations in the *PHD2* and *HIF-2A* genes have been described with erythrocytosis.

There are a number of other inherited conditions which can lead to a secondary erythrocytosis: (i) An extended kindred with a mutation in the *EPO* gene itself which leads to increased translation and production of EPO has been discovered. (ii) High-affinity haemoglobins release less oxygen for a given oxygen partial pressure and may thus give rise to tissue hypoxia. This leads to an EPO-driven erythrocytosis. The pathognomonic anomaly is a left shift in the oxygen dissociation curve. There are over 90 haemoglobin variants with an increased affinity for oxygen, all dominantly inherited. Most are due to mutations in β-globin, with a small number due to mutations in α-globin. (iii) Abnormalities in red cell metabolism that lead to a reduction in intraerythrocytic 2, 3-BPG. The best characterised defect is a mutant 2, 3-BPG mutation. (iv) Hereditary methaemoglobinaemias can be due to haemoglobin mutations involving amino acids around the haem pocket (haemoglobin M disease), or secondary to enzymatic deficiencies that interfere with the generation of NADH, which is required for day-to-day methaemoglobin reduction (namely NADH reductase and cytochrome *b*5 reductase). With the chronic nature of the methaemoglobinaemia in these disorders, secondary erythrocytosis can develop. (v) Another gene recently associated with erythrocytosis is the *PIEZO1* (Piezo type mechanosensitive ion channel component 1) gene encoding for the protein, a mechanosensitive ion channel, which translates a mechanical stimulus into calcium influx. Gain-of-function mutations have been described in hereditary xerocytosis and in some cases, erythrocytosis is associated.

Management of congenital erythrocytosis

There is a sparse evidence base to guide management of the rare group of patients with congenital erythrocytosis. Low-dose aspirin is proven to reduce the incidence of thromboembolic events in acquired MPNs. As such, it seems logical to give this to those with congenital erythrocytosis in whom there is no contraindication to aspirin. Venesection would be the logical therapeutic intervention to reduce the Hct and by implication the viscosity. However, this may not be of benefit as the altered physiology due to the mutations may require a higher Hb for satisfactory oxygen supply to tissues. Venesection is only suggested if a decrease in Hb is associated with improvement in symptoms. Inhibitors of the JAK/STAT pathway and PHD2 and HIF2a may have a role in inhibition of specific defective proteins in the future.

Acquired secondary erythrocytosis

Erythrocytosis: hypoxia driven

Systemic hypoxia for a variety of reasons will lead to an EPO drive and an attempt at a corrective erythrocytosis. Lung disease including chronic obstructive pulmonary disease (COPD) and syndromes such as obstructive sleep apnoea and hypoventilation due to muscle weakness or paralysis, chronic carbon monoxide poisoning, smokers, high altitude and cyanotic heart disease can all lead to states of chronic systemic hypoxia and thus be associated with secondary erythrocytosis. Local hypoxia as in lesions in the kidney leading to a local oxygen deficit and therefore EPO production by the kidney can produce a secondary erythrocytosis. This includes renal artery stenosis and renal cysts, following renal transplantation and other renal disease.

Abnormal EPO production

EPO can be produced pathologically by a variety of tumours (see Table 35.1) where the abnormal EPO secreted by the tumour drives erythrocytosis. The other source of EPO is when there is an exogenous supply. This can either be by the administration of EPO itself or androgens which stimulate EPO release.

Idiopathic erythrocytosis

In a small proportion of patients with erythrocytosis, the criteria for the diagnosis of PV are not met and no other aetiology for the raised red cell mass can be identified. With the advent of increasingly sophisticated diagnostic tests and the identification of the molecular lesions in many inherited forms of erythrocytosis, idiopathic erythrocytosis is becoming a rare entity. Guidelines suggest aspirin if no contraindication and venesection in selected cases with the HCT target tailored to the thrombotic history and risk factors.

Reactive thrombocytosis

Thrombocytosis is most commonly reactive and secondary to increased levels of circulating cytokines that stimulate thrombopoiesis. Inflammatory, vasculitic and allergic disorders,

acute and chronic infections, malignancies, haemolysis, iron deficiency and blood loss can all lead to an increased platelet count (Table 35.3). Reactive thrombocytosis can sometimes be marked and, occasionally, the platelet count can be greater than 1000×10^9/L. Initial assessment of thrombocytosis should include comprehensive history and examination, iron studies and inflammatory markers. As a minimum a chest radiograph is recommended in patients aged over 40 years and other investigations should be considered according to clinical assessment.

Essential thrombocythaemia

Following exclusion of reactive causes of thrombocytosis, and in the absence of other blood count abnormalities that would suggest an alternative myeloid neoplasm such as chronic myeloid leukaemia (Table 35.3), patients with a persistent thrombocytosis greater than 450×10^9/L should be assessed for ET.

Table 35.3 Causes of thrombocytosis.

Reactive
- Iron deficiency
- Blood loss (acute or chronic)
- Hyposplenism/splenectomy
- Surgery
- Acute bacterial infection
  - Pneumonia, septicaemia, meningitis, diverticular abscess, etc.
- Chronic inflammation
  - Vasculitides
  - Inflammatory bowel disease
  - Connective tissue disorders
  - Rheumatoid arthritis
  - Chronic infections
- Non-myeloid malignancies
- Rebound thrombocytosis
  - Following treatment of immune thrombocytopenic purpura
  - Recovery from chemotherapy
- Drugs
  - Vincristine

Clonal myeloid disorders
- Myeloproliferative neoplasms
  - Essential thrombocythaemia
  - Polycythaemia vera
  - Primary myelofibrosis
  - Chronic myeloid leukaemia
- Myelodysplastic/myeloproliferative neoplasms
  - MDS/MPN with ring sideroblasts and thrombocytosis
- Myelodysplastic syndromes
  - MDS with isolated del(5q)

Diagnosis

A mutation in *JAK2* (*V617F*, 50–60%), *CALR* (25–30%) or *MPL* (~5%) can be detected in 85–90% of patients with ET and testing for these variants, which can be performed on peripheral blood, is a first-line investigation for an unexplained thrombocytosis. A bone marrow biopsy typically shows megakaryocytic expansion with increased large or giant forms showing abundant, mature cytoplasm and hyperlobulated nuclei (Figure 35.5). WHO criteria (Table 35.4) mandate the use of a bone marrow biopsy at diagnosis to confirm the features of ET and to distinguish it from prefibrotic myelofibrosis. The alternative criteria proposed by the BSH allow a diagnosis of ET to be made in the presence of an appropriate pathogenic mutation, if other myeloid malignancies can be excluded using other clinical and laboratory criteria (Table 35.4), although a bone marrow biopsy remains a recommended investigation in patients likely to have a long disease history or in the presence of atypical features (e.g. splanchnic thrombosis). In patients with uncomplicated ET, cytogenetic or comprehensive genomic profiling studies are not required since additional abnormalities do not change management recommendations.

In 10–15% of patients with ET, no mutation in *JAK2, CALR* or *MPN* is detectable. Patients lacking these mutations with a persistent, significant and unexplained thrombocytosis require a bone marrow biopsy for further assessment, including for alternative diagnoses. Confirmatory histology is mandatory to make a diagnosis of ET in these cases, although there can be substantial inter-observer variability in the interpretation of histological criteria for MPNs and in patients with mild or moderate thrombocytosis and no confirmatory molecular marker,

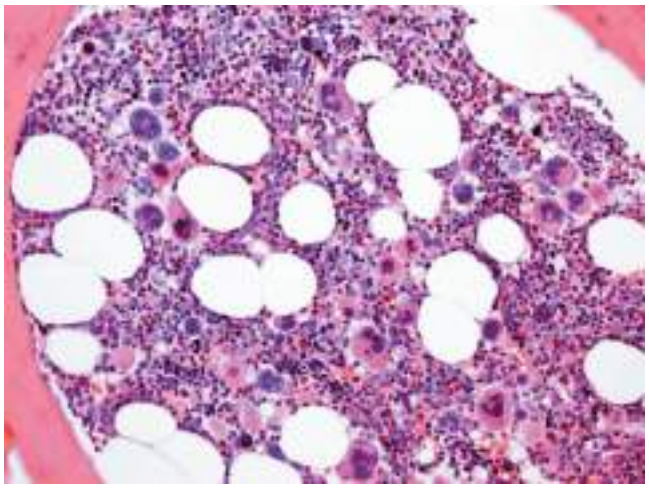

Figure 35.5 Bone marrow trephine section (haematoxylin and eosin, H&E) from a 60-year-old man with essential thrombocythaemia. Note the hypercellularity and marked increase in megakaryocyte numbers, consisting largely of clusters of mature, multilobated forms.

Table 35.4 Diagnostic criteria for essential thrombocythaemia proposed by the British Society of Haematology and World Health Organization.

BSH (2014 modification of 2010 criteria)		WHO 2022	
A1	Sustained platelet count $\geq 450 \times 10^9$/L	Major criteria	**1** Platelet count $\geq 450 \times 10^9$/L
A2	Presence of an acquired pathogenic mutation (e.g. *JAK2, CALR* or *MPL*)		**2** BM biopsy showing proliferation mainly of the megakaryocyte lineage with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei. No significant left-shift of neutrophil granulopoiesis or erythropoiesis and very rarely minor (grade 1) increase in reticulin fibres
A3	No other myeloid malignancy, especially PV, PMF, CML or MDS		**3** Not meeting criteria for *BCR::ABL1*$^+$ CML, PV, PMF, MDS or other myeloid neoplasms
A4	No reactive cause for thrombocytosis and normal iron stores		**4** Presence of *JAK2, CALR* or *MPL* mutation
A5	Bone marrow aspirate and trephine biopsy showing increased megakaryocyte numbers displaying a spectrum of morphology with predominant large megakaryocytes with hyperlobated nuclei and abundant cytoplasm. Reticulin is generally not increased (grades 0–2/4 or grade 0/3)	Minor criteria	Presence of a clonal marker or absence of evidence for reactive thrombocytosis
Diagnosis requires A1–A3 or A1 + A3–A5		Diagnosis requires all four major criteria or first 3 major and one minor criteria	

a confident histological diagnosis can be challenging. Although more extensive profiling of panels of myeloid genes using next-generation sequencing (NGS) can be considered, many cases of ET, particularly young patients, have no detectable recurrent genomic abnormalities when tested with such panels. The aetiology of the thrombocytosis in such patients is unclear, and it remains possible that a proportion may have a non-clonal disorder contributed to by polygenic factors. *BCR::ABL*1 analysis should be performed to exclude CML and cytogenetic studies and/or NGS panels should be considered in patients in whom appearances suggest an alternative clonal disorder such as MDS/MPN.

Epidemiology of ET

The annual incidence of ET is similar to that of PV at around 1.5–2.0 cases per 100,000 of the population. The median age at onset is 55–60 years, with a small second peak in women of reproductive age and, although it can occur at any age, it is rare in childhood.

Clinical features

Over half of patients are asymptomatic at diagnosis. Less commonly, patients may present with headaches or other microvascular symptoms such as erythromelalgia, or with vascular (thrombotic or haemorrhagic) complications. Splenomegaly is present in a minority of patients at diagnosis and is rarely more than mild. Progressive enlargement of the spleen during the course of ET should raise suspicion of evolving myelofibrosis.

In comparison to *JAK2*-negative patients, patients with *JAK2*-mutant ET show some clinical features resembling PV, including increased haemoglobin levels, neutrophil counts, bone marrow erythropoiesis and granulopoiesis, lower platelet counts, mean corpuscular volume, serum erythropoietin and ferritin. Compared to *JAK2*-mutant ET, patients with a *MPL* mutation present with a more isolated thrombocytosis and less hypercellular bone marrow, whereas those with a *CALR* mutation have lower haemoglobins and higher platelet counts.

Vascular complications and risk stratification

As with PV, thrombotic complications are the main cause of morbidity and mortality in ET. Thromboses are present in around 15–20% of patients at presentation and may be arterial or venous. The range of clinical syndromes is similar to PV, but the frequency of splanchnic thromboses is probably lower and strongly correlated with presence of the *JAK2 V617F* mutation. Bleeding is less common and less well-studied than thrombosis in ET but can be dramatic. Although alterations of platelet function have been described in MPNs, this investigation is unable to predict haemorrhagic risk. Bleeding is, however, more common in patients with a marked thrombocytosis (e.g. platelet count $>1000 \times 10^9$/L) and, in at least some cases, this is due to

Table 35.5 Revised IPSET-thrombosis risk stratification system.

Risk category	Variables
Very low	No thrombosis history + age ≤60 years + *JAK2*-unmutated
Low	No thrombosis history + age ≤60 years + *JAK2*-mutated
Intermediate	No thrombosis + age >60 years + *JAK2* unmutated
High	Thrombosis history (any age/genotype) or age >60 + *JAK2*-mutated

(*Source:* Adapted from Barbui T, Vannucchi AM, Buxhofer-Ausch et al. (2015) Practice-relevant revision of IPSET-thrombosis based on 1019 patients with WHO-defined essential thrombocythemia. *Blood Cancer J.* 5(11):e369.

an acquired von Willebrand syndrome, with a decrease in circulating high-molecular-weight multimers caused by adsorption to the surface of the excessive platelets. Testing for acquired von Willebrand syndrome is not routinely recommended but should be considered in patients with atypical bleeding or in planning major surgery in patients with an uncontrolled thrombocytosis.

A number of risk factors are associated with an increase in the risk of thrombosis in patients with ET. Patients aged over 60 years or with a previous history of thromboembolic events have consistently been shown to have an increased risk of future thrombosis and all such patients should be considered high-risk and offered cytoreductive therapy to reduce the platelet count. In addition, the *JAK2 V617F* mutation has been shown to independently increase the risk of vascular events and has now been incorporated into the revised IPSET-thrombosis score (Table 35.5) for risk stratification. Other risk factors for thrombosis reported in ET include the more standard cardiovascular risk factors (diabetes, hypertension and cigarette smoking), white cell count at diagnosis and reticulin levels at diagnosis, although these are not usually used in isolation for individual treatment decisions.

The risk of major haemorrhage in ET has also been associated with a high white cell count and more significantly with a high platelet count. This is the rationale for the recommendation that patients with a marked thrombocytosis ($>1500 \times 10^9$/L) receive treatment to reduce the platelet count, even if young.

Disease transformation

Polycythaemic transformation occurs in less than 1–2% of patients over 10 years and is seen exclusively in *JAK2*-mutant ET. Transformation to post-ET myelofibrosis is a well-recognised complication but its frequently insidious onset and the reluctance to serially study bone marrow trephine biopsies has hampered attempts to define its nature and frequency. From the available data, myelofibrotic transformation occurs in less than 10% of patients and may be commoner in *MPL*-mutant patients and those with a *CALR* type 1 mutation. The risk also increases with age and in those with higher white cell counts, lower haemoglobin and higher bone marrow reticulin grade at diagnosis. More recently, a group of 'adverse' risk mutations (*SH2B3*, *IDH2*, *SF3B1*, *U2AF1*, *EZH2*, *TP53)* have been have been described in ET, associated with less favourable myelofibrosis-free, leukaemia-free or overall survival.

Transformation to MDS or AML occurs in less than 5% of patients. In addition to adverse risk mutations, the presence of cytogenetic abnormalities and previous treatment with alkylating agents also increase this risk, although approximately a quarter of patients who develop AML have never received any cytoreduction. Approximately 3% of patients treated with hydroxycarbamide alone develop MDS or AML if followed for a median time of 8 years. As with PV, there are no data that demonstrate that hydroxycarbamide as a single agent significantly increases the risk of leukaemia, but a small effect cannot be excluded.

Treatment

Patients are stratified according to their risk of vascular complications, with those aged over 60 or with a previous history of vascular events being considered at 'high risk' of thrombosis and those with a platelet count $>1500 \times 10^9$/L also warranting cytoreductive therapy in view of haemorrhagic risk. Screening and strict management of other cardiovascular risk factors are also mandatory and use of the combined oral contraceptive pill should be discouraged.

High-risk patients

All high-risk patients are recommended to receive low-dose aspirin. This is an extrapolation of data from the ECLAP study in PV and there are no equivalent prospective data in ET. Aspirin can also improve microvascular symptoms such as erythromelalgia and headaches.

In high-risk patients, control of the platelet count with hydroxycarbamide was shown to reduce thrombotic events compared to no cytoreductive therapy in a randomised trial. The MRC high-risk PT-1 trial compared treatment with hydroxycarbamide plus low-dose aspirin to anagrelide plus low-dose aspirin. Patients receiving anagrelide plus aspirin were significantly more likely to reach the composite primary endpoint (arterial thrombosis, venous thrombosis or major haemorrhage) and more likely to discontinue their allocated treatment. Compared to hydroxycarbamide plus aspirin, treatment with anagrelide plus aspirin was associated with a significantly increased rate of arterial thrombosis, major haemorrhage and myelofibrotic transformation, but a decreased rate of VTE. These results have established hydroxycarbamide plus aspirin as first-line therapy for most high-risk patients. Anagrelide is a useful second-line agent; a subsequent smaller study (the ANAHYDRET trial) reported non-inferiority between

hydroxycarbamide and anagrelide in patients with ET, as strictly defined by the WHO-diagnostic criteria, but was underpowered to see the differences observed in the PT1 study.

Pegylated IFN-alfa can achieve good control of the platelet count in ET, although side effects may be more problematic than with hydroxycarbamide. It has not been studied as widely in ET as in PV, although the recent randomised MPDRC-112 study showed equivalence of hydroxycarbamide and pegylated IFN-alfa in PV and ET patients with increased rates of molecular remission with interferon. It is not yet known whether the molecular responses observed in some patients with ET, as in PV, will translate into reduced rates of important long-term outcomes such as thrombosis and disease transformation. IFNs remain a very useful option in the management of ET in pregnancy and are increasingly used as a first-line treatment option in younger patients.

Busulfan can achieve good control of the platelet count but is only used in patients with limited life expectancy because of concerns over its long-term leukaemogenic potential. This is true for other alkylating agents and for radioactive phosphorus (^{32}P). More recently the JAK inhibitor ruxolitinib has been assessed in patients resistant to or intolerant of hydroxycarbamide but did not achieve better rates of haematological response than alternative best available therapy. A number of agents acting through novel mechanisms including epigenetic regulation and telomere biology are currently under investigation in clinical trials.

The optimal platelet count target is not known in ET, particularly since platelet count does not correlate with risk of thrombotic events. In patients with 'high-risk' factors the aim is typically to achieve a platelet count in the normal range, although a more moderate target (e.g. $<600\times10^9$/L) may be appropriate in patients who do not have evidence of very high vascular risk and in whom first-line therapy is not fully tolerated or effective. In younger patients for whom the only indication for therapy was a marked thrombocytosis, a more relaxed platelet target can be considered.

Low-risk patients

All patients with ET were previously recommended to take low-dose aspirin. However, more recent retrospective data in low-risk disease suggested that while use of antiplatelet agents was associated with a lower rate of thrombotic events in *JAK2*-mutant patients, a higher rate of bleeding was seen in *CALR*-mutant disease. Current recommendations remain to use aspirin in *JAK2*-mutant disease, but it should be used with caution in those with a marked thrombocytosis ($>1000\,L\times10^9$/L) and is now typically omitted in young, *CALR*-mutant patients without cardiovascular risk factors.

The 'intermediate-risk' PT-1 trial randomised patients aged 40–59 years and without high-risk features to hydroxycarbamide plus aspirin or aspirin alone and found no difference in either the incidence of vascular events or the rate of progression to myelofibrosis or leukaemia (note that this was a different definition of 'intermediate risk' to the IPSET-thrombosis risk system discussed above). Routine use of cytoreduction in patients lacking high-risk factors is therefore not recommended, but may occasionally be considered for severe symptoms such as headaches, with target of symptom control rather than a particular platelet count.

Prognosis

Few studies have directly addressed survival in ET and these have reached variable conclusions about life expectancy compared to the general population. A recent multicentre study showed a median survival of 19.8 years (32.7 years if diagnosed younger than 60 years), which was worse than the age- and sex-matched population but superior to PV.

Management of pregnancy

ET is the MPN encountered most frequently in women of childbearing age, hence the most data exists for this compared to other MPN. In pregnancy, the commonest complication of ET is first-trimester miscarriage, which occurs in up to 30% of pregnancies and is thought to reflect placental microinfarcts and insufficiency. Other less frequent complications include intrauterine death, growth retardation, premature delivery and pre-eclampsia and risks of maternal thrombosis and haemorrhage are also higher than in normal pregnancy. Nonetheless, a successful outcome (live birth) is achieved in around 70% of cases with MPNs.

Management recommendations for ET in pregnancy include use of low-dose aspirin in patients who are pregnant or planning a pregnancy, in the absence of contraindications, and at minimum a period (e.g. 6 weeks) of thromboprophylaxis with LMWH post-partum when the risk of VTE is highest. Pregnancies deemed at 'high risk' (Table 35.6) should be considered for therapy with a combination of IFN, aspirin and low-molecular-weight heparin. Hydroxycarbamide and anagrelide should not be used on account of their teratogenic potential. Fetal growth and successful placentation should be closely monitored and therapies adjusted accordingly. The blood count may rise dramatically in the postpartum period. Hydroxycarbamide and anagrelide are contraindicated during breast-feeding; interferon-alfa is also excreted in breast milk but is unlikely to be absorbed intact by the baby and there are reports of successful breast-feeding while the mother was receiving IFN. Management for PV and PMF are similar, the main difference for PV being the need to ensure the Hct remains in the middle of the gestation-appropriate range (i.e. 0.45 is too high for women beyond the first trimester of pregnancy).

Uncommon causes of thrombocytosis

Aside from ET, PV and PMF, a number of other haematological malignancies can be associated with thrombocytosis. Chronic

Table 35.6 Criteria for high-risk pregnancy in myeloproliferative neoplasms (MPN).

*Sustained rise in platelet count rising to above 1500 × 10^9/L**
Previous venous or arterial thrombosis
*Previous haemorrhage attributed to MPN**
Previous pregnancy complication:
- ≥1 unexplained deaths of a morphologically normal fetus ≥10 weeks of gestation.
- ≥1 premature delivery of a morphologically normal fetus <34 weeks gestation due to:
  - **i** Severe pre-eclampsia or eclampsia defined according to standard definitions.
  - **ii** Recognised features of placental insufficiency.
- ≥3 unexplained consecutive miscarriages <10 weeks gestation, with maternal and paternal factors (anatomic, hormonal or chromosomal abnormalities) excluded.
- Otherwise unexplained intrauterine growth retardation.
- Significant antepartum or postpartum haemorrhage requiring transfusion.

Abnormal uterine artery Dopplers at 20 weeks (mean pulsatility index >1.4)

* These would represent indications for interferon only rather than interferon plus low molecular weight heparin.

myeloid leukaemia (CML) occasionally presents as an isolated thrombocytosis. MDS and MDS/MPN are generally associated with cytopenias and do not commonly present with thrombocytosis, but exceptions are MDS/MPN with ring sideroblasts and thrombocytosis and MDS with isolated del(5q), the latter being associated with thrombocytosis in one third to one-half of patients. These entities will be diagnosed on bone marrow morphology together with supplementary molecular or cytogenetic tests.

Rare cases of hereditary thrombocytosis have been described due to germline mutations in the *MPL, JAK2* and *THPO* genes. These variants are different to the germline variants which predispose to classical MPNs and account for clusters of cases within families, described above. For *MPL*, certain individual mutations (e.g. *S505N*) have been described to occur as either acquired or germline variants. *JAK2 V617F* has not been described in the germline, but a germline *JAK2 V617I* mutation was described in a family with hereditary thrombocytosis.

Prefibrotic myelofibrosis

The WHO 2016 and subsequent 2022 criteria included an entity called prefibrotic myelofibrosis (diagnostic criteria are shown in Table 35.7). The optimum management of this condition which often presents in a similar manner to ET but is said to have a worse prognosis with higher rates of thrombosis and myelofibrosis transformation has yet to be fully defined.

Table 35.7 Diagnostic criteria of prefibrotic myelofibrosis.

Prefibrotic myelofibrosis	
All three major and one minor criterion must be met	
Major criteria	Typical megakaryocyte changes accompanied by ≤grade 1 fibrosis
	Presence of *JAK2*, *CALR* or *MPL* mutations or presence of other clonal markers, or absence of evidence for reactive BM fibrosis (see Table 35.12)
	Not meeting WHO criteria for other myeloid neoplasms
Minor criteria	Anaemia not otherwise specified
	Leucocytosis ≥11 × 10^9/L
	Splenomegaly detected clinically and/or by imaging
	Increased lactate dehydrogenase
	A leucoerythroblastic blood smear

(*Source:* With permission of WHO 2022/World Health Organization).

Primary myelofibrosis

Primary myelofibrosis (PMF) is a more aggressive condition than ET, PV or pre-MF which is progressive and frequently profoundly affects quality of life for affected patients. As discussed earlier, patients with ET, PV or pre-MF are all at risk of transformation to myelofibrosis which may be known as post-ET-MF or post-PV MF. The management of patients at this stage is the same as for those with PMF with the exception of the use of prognostic scores which can perform differently in this setting. Analogous to the concept of chronic and accelerated phases in CML, it seems likely that PMF represents the presentation in accelerated phase of a previously undiagnosed MPN. Consistent with this concept, patients with PMF harbour more mutations, have more cytogenetic abnormalities and display an increased risk of leukaemic transformation

Epidemiology

The estimated annual incidence of PMF is around 0.5–1.5 per 100,000 of the population, with most patients diagnosed in the sixth decade and roughly equal involvement of the two sexes. Up to a third of patients are asymptomatic at diagnosis and many of these are discovered after unrelated blood tests show modest abnormalities, such as anaemia and thrombocytopenia. Splenomegaly is common, progressive and often massive (Figure 35.6).

Figure 35.6 Massive splenomegaly in a 53-year-old man with an 8-year history of primary myelofibrosis (PMF).

Diagnosis

A diagnosis of PMF is achieved by following established criteria which use a combination of clinical and laboratory features (Tables 35.8 and 35.9). As with all MPN, the diagnosis should be reviewed and a management plan made in the context of a multi-disciplinary format.

Laboratory features

A leucoerythroblastic blood film and the presence of red cell abnormalities in particular tear drop poikilocytes (Figure 35.7) are key diagnostic features in PMF. Mild to moderate anaemia is

Table 35.8 Diagnostic criteria for PMF.

Primary myelofibrosis (overtly fibrotic)	
All three major and one minor criterion must be met	
Major criteria	Typical megakaryocyte changes accompanied by ≥grade 2 fibrosis
	Presence of *JAK2*, *CALR* or *MPL* mutations or presence of other clonal markers, or absence of evidence for reactive BM fibrosis (see Table 35.10)
	Not meeting WHO criteria for other myeloid neoplasms
Minor criteria	Anaemia not otherwise specified
	Leucocytosis $\geq 11 \times 10^9$/L
	Splenomegaly detected clinically and/or by imaging
	Increased lactate dehydrogenase
	A leucoerythroblastic blood smear (Figure 35.7)

Table 35.9 Diagnostic criteria for post PV or post ET MF.

WHO (2022) diagnostic criteria for post PV MF	
Required criteria	Prior documentation of WHO-defined PV
	Bone marrow fibrosis ≥grade 2
Additional criteria 2 required	Anaemia or loss of need for phlebotomy/ cytoreductive treatment
	A leucoerythroblastic blood smear (Figure 35.7)
	Increasing splenomegaly
	Development of constitutional symptoms
WHO (2022) diagnostic criteria for Post ET MF	
Required criteria	Prior documentation of WHO defined ET
	Bone marrow fibrosis ≥grade 2
Additional criteria 2 required	Anaemia and a ≥20 g/L fall in haemoglobin level
	A leucoerythroblastic blood smear (Figure 35.7)
	Increasing splenomegaly
	Development of constitutional symptoms
	Increased serum lactate dehydrogenase

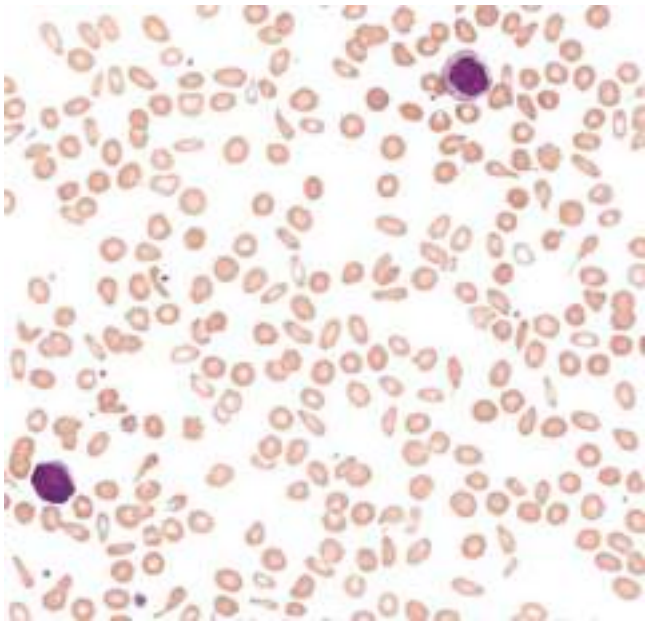

Figure 35.7 Peripheral blood film in PMF, showing a blast, an abnormal myelocyte, teardrop red cells and marked anisopoikilocytosis.

Table 35.10 Differential diagnosis of marrow fibrosis.

Haematological malignancies	*Drugs/toxins*
Primary myelofibrosis	Benzene
Chronic myeloid leukaemia	Thorotrast
Acute myelofibrosis (AML M7)	Irradiation
Myelodysplasia	*Bone disease*
Myeloma	Paget disease
Hairy-cell leukaemia	Osteopetrosis
Non-Hodgkin lymphoma	*Inflammatory diseases*
Hyperparathyroidism	Systemic sclerosis
Hodgkin disease	Systemic lupus
Hypoparathyroidism	*Other*
Systemic mastocytosis	Grey platelet syndrome
Metastatic carcinoma	TAFRO syndrome
Infections	
Tuberculosis	
Leishmaniasis	

found in most patients at presentation and worsens as myelofibrosis progresses. The anaemia is in large part due to reduced erythropoiesis but may be compounded by hypersplenism, bleeding and iron or folate deficiency. Acquired HbH disease is a rare complication. Platelet counts are raised in up to one-half of the cases at presentation and can be associated with thrombotic complications. However, progressive thrombocytopenia is a frequent occurrence and becomes increasingly troublesome as the disease progresses. Dysmegakaryopoiesis and abnormal platelet function further add to the risk of haemorrhagic complications.

Extramedullary haemopoiesis

The spleen is the commonest site of extramedullary haemopoiesis in PMF. The liver is also usually involved and this can lead to significant hepatomegaly. Unusual sites can sometimes be affected, leading to haemopoietic tumours surrounded by a capsule of connective tissue. Such sites include lymph nodes, central nervous system, skin, pericardium, peritoneum, pleura, ovaries, kidneys, adrenals, gastrointestinal tract and lungs. Many such cases remain asymptomatic, but involvement of the central nervous system can be a cause of serious morbidity. Treatment with agents such as ruxolitinib, radiotherapy or surgery, when required, almost always leads to resolution of these masses.

Systemic symptoms

A hypermetabolic state presenting with fevers, anorexia, weight loss and night sweats develops in many cases of PMF, sometimes early on in the disease. Other symptoms are often present in particular fatigue, bone pain and spleen-related symptoms such as pain and early satiety. The presence of specific symptoms – weight loss, night sweats and fever are prognostically significant. It is generally recommended that symptoms should be assessed using a specific score such as the MPN-symptom assessment form (MPN-SAF) or MPN-10 (Figure 35.8).

Bone marrow

Attempts at bone marrow aspiration often yield a dry-tap or a haemodilute sample, making aspirate morphology of limited diagnostic value. Sufficient material can often be obtained from either bone marrow or peripheral blood to assess the karyotype, which can help exclude diagnoses such as CML. Other chromosomal abnormalities may be found in up to 60% of cases, as detailed above. Abnormalities of chromosomes 5 and 7 are usually found in patients with prior exposure to genotoxic agents and are associated with a poor prognosis.

Bone marrow trephine biopsy is essential to make a diagnosis of PMF. Initial stages are characterised by an increase in bone marrow cellularity in association with a disorganisation of marrow architecture and the presence of abnormal large megakaryocytes often occurring in clusters (Figure 35.9). Bone marrow fibrosis becomes increasingly dominant and progressively replaces haemopoiesis. Intrasinusoidal haemopoiesis can sometimes be seen at this stage (Figure 35.9). The degree of fibrosis is best demonstrated using silver impregnation, which stains reticulin fibres (see Figure 35.10). Collagen fibres are best demonstrated using a trichrome stain. The degree of fibrosis can be graded from 0 to 4 (Bauermeister) or MF-0 to 3 (EU consensus) according to severity. In a minority of cases of advanced PMF, osteosclerosis ensues, with thickening of the trabecula and extensive deposition of osteoid. Such changes may be evident on plain radiography and MRI imaging.

Prognosis

Historically the median survival for patients with PMF was regarded as 3–5 years, but the range is very wide; ruxolitinib and improvements in general care have improved this in recent years. The most widely used algorithms to determine prognosis are shown in Table 35.11 and are the International Prognostic Score System (IPSS) and Dynamic (D)IPSS or DIPSS-plus. Increasingly molecular markers are having an impact upon prognosis, and have been included in newer prognostic scores such as MIPPS70, MIPSS70+ and GIPSS, Table 35.12 and for Post ET or Post PV MF the MYSEC score Table 35.13.

GIPSS, genetically-inspired prognostic scoring system, Survival quotes are for all age groups; HMR, high molecular risk mutations include *ASXL1, SRSF2, EZH2, IDH1, IDH2*

Fill out the form below to track the burden of your symptoms.

Symptom: 1 to 10, 0 if absent and 10 being worst imaginable

Please rate your fatigue (weariness, tiredness) by circling the one number that best describes your WORST level of fatigue during the past 24 hours

Fatigue										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

Circle the one number that describes how much difficulty you have had with each of the following symptoms during the past week

Filling up quickly when you eat (early satiety)										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

Abdominal discomfort										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

Inactivity										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

Problems with concentration - compared to before my diagnosis										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

Night sweats										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

Itching (pruritus)										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

Bone pain (diffuse, not joint pain or arthritis)										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

Fever (> 37.8°C or 100°F)										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(DAILY)

Unintentional weight loss last 6 months										
0	1	2	3	4	5	6	7	8	9	10
(ABSENT)										(WORST IMAGINABLE)

To help you get a clear overall picture of how you are feeling, you can add up all your scores to calculate your Total Symptom Score. **Total:** ☐

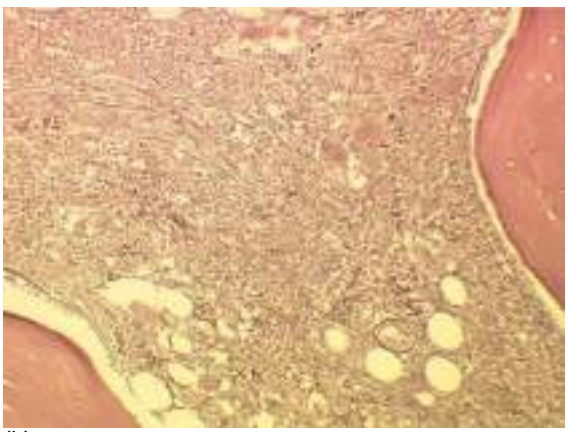
(a)



(b)

Figure 35.10 Bone marrow trephine sections from a patient with early-stage PMF. The H&E stain (a) shows hypercellularity, disorganised architecture, increase in megakaryocyte numbers and prominent sinusoids. The silver stain (b) also shows a marked increase in reticulin fibres.

and for GIPSS and MIPSS70+ version 2.0 *U2AF1Q157*; MIPSS70, mutation-enhanced international prognostic system for transplant-age patients (age ≤70 years); MIPSS70+ version 2.0 and karyotype enhanced international prognostic system; VHR, very high-risk karyotype (single/multiple abnormalities of −7, inv(3)/3q21, i(17q), 12p−/12p11.2, 11q−/11q23 and autosomal trisomies (e.g., +21, +19) other than +8 or +9).

Treatment

The only curative treatment for PMF is allogeneic stem cell transplantation, but this is only appropriate for a small proportion of patients who are fit enough, and have a suitable donor. In the remaining cases, therapy remains supportive and aimed at alleviating symptoms. The development of JAK inhibitors, initially ruxolitinib and the more recently approved fedratinib and momelotinib have radically altered the therapeutic algorithm for the management of PMF. Treatment is generally focused upon specific features of the disease (Table 35.14 below).

The control of symptoms and splenomegaly with JAK inhibitors such as ruxolitinib (a JAK1 and JAK2 inhibitor) and the more recently approved fedratinb (a JAK2 inhibitor) has enabled significant treatment advances for patients with PMF linked with improved quality of life and in some cases survival. These drugs, however, do not cure the disease or induce molecular remissions. Both may worsen anaemia and thrombocytopenia which may require discontinuation or the addition of other therapies. There is more real-world experience with ruxolitinib which has highlighted immunosuppressive effects leading to opportunistic infections, non-melanoma skin cancers and its positive use in inflammatory conditions such as graft versus host disease. Abrupt withdrawal of ruxolitinib is not recommended as this can lead to rapid return of splenomegaly and symptoms. There is insufficient experience with fedratinib to comment regarding immunosuppression or withdrawal but concerns with regard to Wernicke's encephalopathy have been raised with this drug and thiamine levels should be carefully monitored.

Anaemia is a common problem, and it is important to exclude another underlying cause in particular bleeding from varices due to portal hypertension. A variety of agents can be used. Human recombinant erythropoietin has shown promise in small clinical studies of anaemia in PMF, usually where endogenous Epo levels are below 250–500 IU. Momelotinib, an inhibitor of JAK2, JAK2 and ACVR1, has recently been approved and can improve anaemia in some patients. Alternatively, androgens (such as danazol), corticosteroids or immunomodulatory agents such as thalidomide may be used. Lenalidomide has been evaluated in MF but is generally recommended for the rare patients who have MF and a 5q− cytogenetic abnormality. Splenectomy may also have a residual

role for transfusion-dependent anaemia. Splenic irradiation is an alternative to splenectomy in some cases and it can significantly reduce splenic size, albeit transiently. This procedure is not without complications, as it can lead to life-threatening cytopenias. Radiotherapy can also be useful for treating pockets of extramedullary haemopoiesis involving vital organs or bodily cavities.

Thrombocytopenia is a significant challenge in the setting of PMF and options are similar to those for anaemia with the exception of ESA, splenectomy is unlikely to be successful in that setting.

Cytoreductive therapy such as hydroxycarbamide or interferon can be useful in the management of some aspects of PMF, such as leucocytosis, constitutional symptoms and troublesome thrombocytosis.

Table 35.11 Risk stratification for PMF patients.

IPSS prognostic score				
Prognostic variable	*0*	*1*		
Age in years	≤65	>65		
WBC count × 10^9/L	≤25	>25		
Haemoglobin g/L		<100		
Peripheral blast %	<1	>1		
Constitutional symptoms	No	Yes		
Risk assignment: Low = 0; Intermediate 1 = 1; Intermediate 2 = 2; High = 3+ Median survivals are 135, 95, 48 and 27 months, respectively				
DIPSS prognostic score				
	0	*1*	*2*	
Age in years	≤65	>65		
WBC count × 10^9/L	≤25	>25		
Haemoglobin g/L			<100	
Peripheral blast %	<1	>1		
Constitutional symptoms	No	Yes		
Risk assignment: Low = 0; Intermediate 1 = 1 or 2; Intermediate 2 = 3 or 4; High = 5 or 6 Median survival: not reached, 14.2, 4 and 1.5 years, respectively				
DIPSS plus prognostic score				
Points from DIPSS	*0*	*1*	*2*	*3*
DIPSS prognostic group points	Low risk 0	Intermediate 1 risk 1	Intermediate 2 risk 2	High risk 3
To the DIPSS prognostic group add one point each for:				
Platelet count × 10^9/L		<100		
Red cell transfusion required	No	Yes		
Unfavourable karyotype*	No	Yes		
Risk assignment number of points: Low = 0; Intermediate 1 = 1; Intermediate 2 = 2 or 3; High = 4 to 6 Corresponding median survival estimates: 185, 78, 35 and 16 months				

* Unfavourable karyotype includes +8, −7/7q−, i(17q), inv(3), −5/5q−, 12p−. 11q23 rearrangements and complex karyotypes.

Table 35.12 Newer prognostic models in primary myelofibrosis incorporating newer molecular and cytogenetic data.

	MIPSS70 (3 tiered)		MIPSS70+ version 2.0 (5 tiered)		GIPSS (4 tiered)

Constitutional symptoms/	Ruxolitinib*
Quality of life	Fedratinib*
	Momelotinib*
Improved survival	Allogeneic stem cell transplant
	Ruxolitinib*
	? Fedratinib*

* Other JAK inhibitors such as pacritinib are in advanced development.

Mastocytosis

Mastocytosis comprises a heterogeneous group of rare haematological neoplasms characterised by the accumulation of clonal mast cells in the skin or extracutaneous organs. As discussed earlier more than 90% of patients with mastocytosis will harbour the *C-KIT* D816V mutation. Paediatric mast-cell disease overall has a good prognosis and will not be discussed here. Approximately 1:10,000 people worldwide are estimated to have mastocytosis. In 2017 and subsequently in the 2022 update, the World Health Organization (WHO) created a separate category for mastocytosis with three broad subtypes: cutaneous mastocytosis (CM), SM and an extremely rare variant mast cell sarcoma (see Figure 35.11 and Table 35.15 for classification of mastocytosis and diagnostic criteria). The WHO 2022 classification introduced a new disease category of bone marrow mastocytosis (absence of skin lesions and basal serum tryptase below 125 ng/mL).

The majority of patients have CM; the rarer condition SM is diagnosed when extracutaneous organs such as bone marrow, liver, spleen, lymph nodes and gastrointestinal tract are involved. SM is further subdivided into non-advanced or advanced diseases. Advanced systemic mastocytosis (AdvSM) comprises patients with aggressive SM, SM with an associated haematological neoplasm (SM-AHN, up to 70% of AdvSM) and mast cell leukaemia. In patients with SM-AHN the concomitant haematological neoplasms are usually myeloid, the most prevalent being CMML, MDS, MPNs and AML. In this group, additional mutations in *ASXL1*, *SRSF2*, *TET2*, *RUNX1* or *RAS* may be seen. The prognosis in these patients is unfavourable and is usually dictated by the prognosis of the AHN.

Investigations

Clinical features of mastocytosis can be highly suggestive of the disease, but diagnosis usually requires histological and biochemical confirmation. Routine investigations should include a full blood count, liver function tests, bone profile and a serum tryptase. Tests for histamine metabolites in 24-hour urine specimens are probably no more useful than measurements of serum tryptase. A genetic variable that may influence tryptase levels and symptom profile is Hereditary alpha Tryptasemia (HαT), an autosomal dominant trait defined by an increased copy number of the *TPSAB1* gene encoding alpha tryptase.

Bone marrow aspiration and trephine biopsy allow assessment of bone marrow involvement. Mast-cell aggregates can be visualised on conventional haematoxylin and eosin-stained sections (Figures 35.12 and 35.13). Immunochemistry using mast cell tryptase antibodies (MCT) and CD2, CD25 are important. Flow cytometry to look for expression of CD2 and CD25 in bone marrow mast cells may be useful, as this phenotype is not seen in normal mast cells. Quantitative PCR methods should be used to detect *C-KIT* mutations in bone marrow or peripheral blood as NGS is not sensitive enough to detect low disease burden. NGS for the detection of the presence of additional mutations is useful for predicting prognosis.

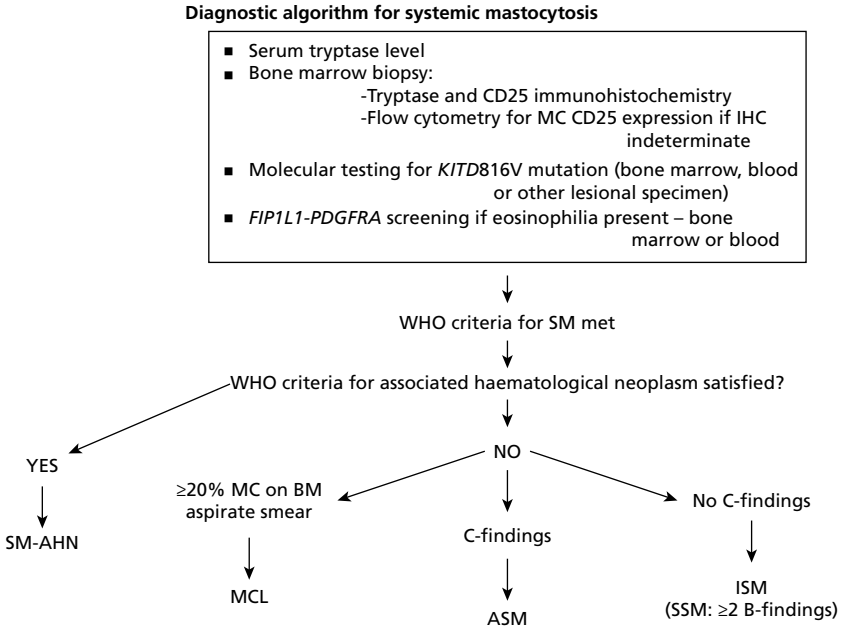

Figure 35.11 Diagnostic algorithm for systemic mastocytosis. ASM, aggressive systemic mastocytosis; IHC, immunohistochemistry; ISM, indolent systemic mastocytosis; MC, mast cell; SM, systemic mastocytosis SM-AHM MCL mast cell leukaemia; SSM, smouldering systemic mastocytosis.

Table 35.15 World Health Organization (WHO 2022) classification and criteria for diagnosis of systemic mastocytosis.

Classification

Cutaneous mastocytosis

Urticaria pigmentosa/maculopapular cutaneous mastocytosis (UP/MPCM) with monomorphic or polymorphic subtypes
Diffuse cutaneous mastocytosis (DCM)
Cutaneous mastocytoma (isolated or multilocalised)

Systemic mastocytosis

Bone marrow mastocytosis (BMM)
Indolent systemic mastocytosis (ISM)
Smouldering mastocytosis (SSM)
Aggressive systemic mastocytosis (ASM)
Systemic mastocytosis with an associated haematologic neoplasm (SM-AHN)
Mast cell leukaemia (MCL)

Mast cell sarcoma

Diagnostic criteria for systemic mastocytosis

The diagnosis of SM can be made when the major criterion and one minor criterion or at least three minor criteria are present

Major criterion

Multifocal, dense infiltrates of mast cells (≥15 mast cells in aggregates) detected in sections of bone marrow and/or other extracutaneous organs

Minor criteria

a >25% of all mast cells are atypical on bone marrow smears or are spindle-shaped in dense and diffuse mast cell infiltrates in sections of bone marrow/other extracutaneous organ(s).
b Detection of an activating point mutation in *KIT* in bone marrow, blood or other extracutaneous organ.
c Mast cells in bone marrow, blood or another extracutaneous organ(s) aberrantly express one or more of the following antigens: CD2, CD25, CD30.
d Serum total tryptase persistently exceeds 20 ng/mL (unless there is an associated myeloid neoplasm, in which case this parameter is not valid). In the case of a known Hereditary α-Tryptasemia, the tryptase level should be adjusted.

'B' findings

1 High mast cell burden shown on BM biopsy: >30% infiltration of cellularity by mast cells (focal, dense aggregates) and/or serum total tryptase level > 200 ng/mL and/or KIT D816V VAF ≥10% in bone marrow or peripheral blood leucocytes.
2 Signs of dysplasia or myeloproliferation, in non-mast cell lineage(s), but insufficient criteria for definitive diagnosis of an associated haematological neoplasm (AHN), with normal or only slightly abnormal blood counts.
3 Hepatomegaly without impairment of liver function, palpable splenomegaly without hypersplenism, and/or lymphadenopathy on palpation or imaging.

'C' findings

1 Bone marrow dysfunction caused by neoplastic mast cell infiltration, manifested by ≥1 cytopenia(s) (ANC $<1.0 \times 10^9$/L, Hb<100 g/L and/or platelet count $<100 \times 10^9$/L).
2 Palpable hepatomegaly with impairment of liver function, ascites and/or portal hypertension.
3 Skeletal involvement with large osteolytic lesions with/without pathological fractures or bone pain (pathological fractures caused by osteoporosis do not qualify as a 'C' finding.
4 Palpable splenomegaly with hypersplenism.
5 Malabsorption with hypoalbuminaemia and/or weight loss due to gastrointestinal mast cell infiltrates.

ANC, absolute neutrophil count; Hb, haemoglobin; ng, nanograms; ml, millilitre; l, litre; VAF, variant allele frequency.

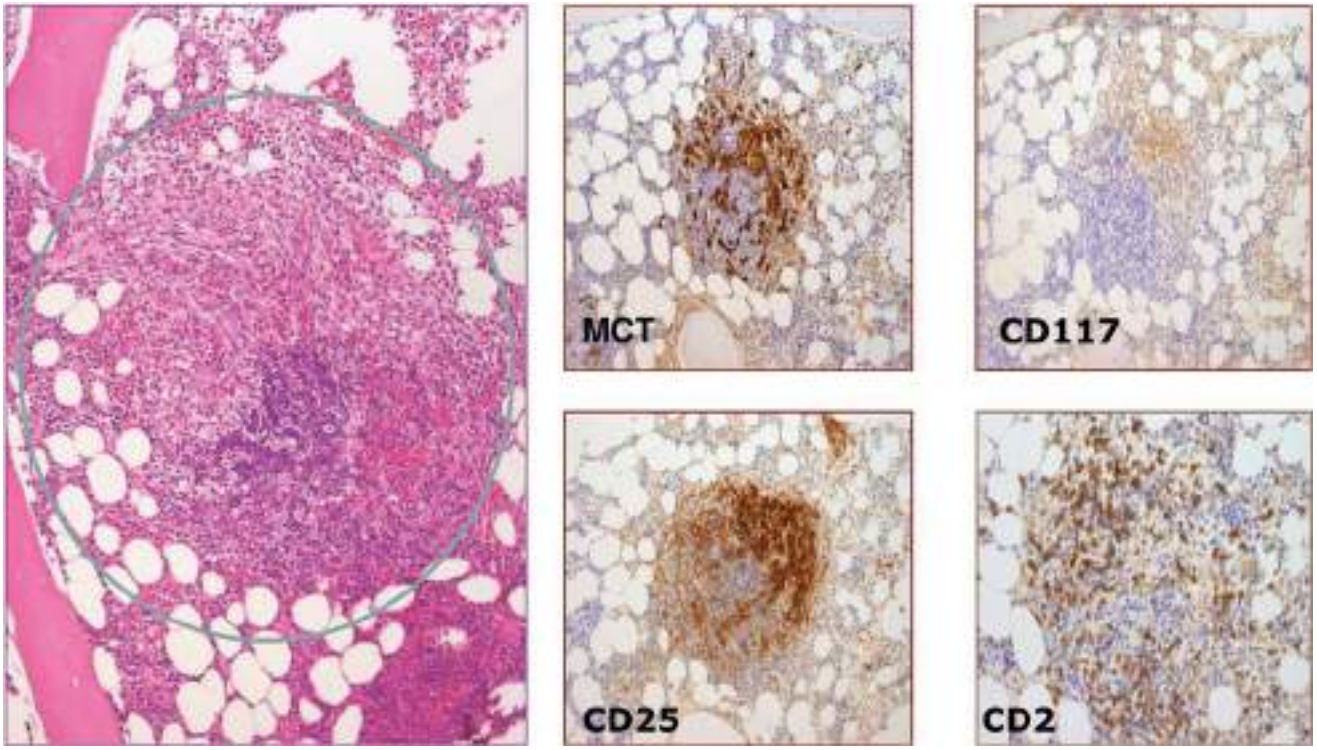

Figure 35.12 Systemic mastocytosis involving the bone marrow (H&E). Malignant whorls of rounded and spindle-shaped mast cells are seen infiltrating the bone marrow in a paratrabecular distribution (circle). Expression of CD2, CD25 and mast cell tryptase is seen (Source: Reproduced with permission from Dr Deepti Radia).

Abdominal ultrasound or computerised tomography should be performed to look for hepatosplenomegaly and lymphadenopathy. Plain radiography and bone densitometry can be used to look for bone involvement and osteoporosis. Endoscopies with biopsies or liver biopsies can be useful if gut or liver involvement is suspected.

Clinical features of systemic mastocytosis

Cutaneous manifestations

Maculopapular cutaneous mastocytosis is the usual presenting feature in children and adults with isolated mastocytosis. Yellowish–brown lesions, usually macular and sometimes papular, appear in a patchy distribution. Less commonly, there is diffuse involvement of the skin, which becomes thickened and darker brown (Figure 35.14). Pruritus is common, as is flushing, and some cases develop haemorrhagic bullous disease. Wealing of lesions upon rubbing is known as Darier's sign.

Constitutional features

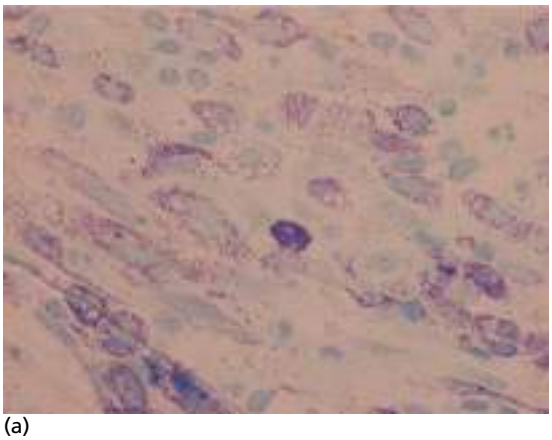
Symptoms due to mast cell mediator release vary amongst mastocytosis patients. Episodes of flushing, angioedema or even anaphylaxis, with or without any specific triggers can occur. Gastrointestinal symptoms include abdominal pain, diarrhoea, nausea, vomiting with gastritis and peptic ulceration occurring due to hyperhistaminaemia. Severe cases may develop malabsorption. Osteoporosis is well recognised and can sometimes lead to pathological fractures. Fever, fatigue and weight loss can sometimes ensue and may result from the release of cytokines such as tumour necrosis factor-α (TNF-α) and IL-1.

Systemic disease

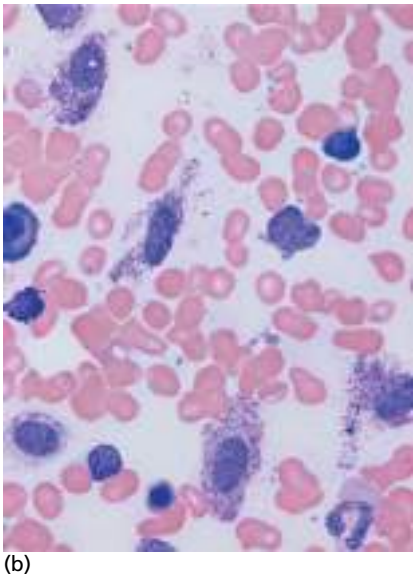
Peripheral blood cytopenias occur due to mast-cell infiltration of the bone marrow and splenomegaly. Hepatosplenomegaly is more common in cases associated with another clonal haematological disorder. Symptoms of organ failure due to infiltration are characteristic of advanced systemic mastocytosis.

Treatment

Despite significant advances in the understanding of its pathophysiology, no curative treatment exists for mastocytosis (aside from the very rare patients who are eligible for



(a)



(b)

Figure 35.13 Toluidine blue stain of bone marrow aspirate (a) and trephine biopsy section (b) in systemic mastocytosis. Abnormal spindle-shaped mast cells containing metachromatic granules are seen.

allogeneic stem cell transplant), the management of which remains symptomatic.

There are three main components to the management of mastocytosis:

1 Avoidance of factors that can trigger mediator release from mast cells.

2 Symptomatic management due to mediator release: acute and chronic.

3 Reduction of the mast cell burden/organ infiltration.

Avoidance of triggers

Avoidance of triggers of mast-cell mediator release is primarily an exercise in patient education. Severe reactions due to systemic mast-cell mediator release are difficult to predict in patients with

Figure 35.14 Female with diffuse maculopapular cutaneous mastocytosis: patient has given signed consent for photograph to be used for educational purposes.

mastocytosis and do not correlate well with disease category, mast-cell burden or severity of other symptoms. All patients and relevant healthcare workers should be warned of particular triggers, including general anaesthesia, contrast radiography and insect stings. Known mast-cell activators such as morphine and dextran should only be used with caution. Patients, regardless of whether they have had previous anaphylaxis or not, should carry injectable adrenaline and they, their family and friends should be instructed in its intramuscular administration. Local mediator release in cutaneous mastocytosis can be moderated by avoidance of triggering factors such as friction and heat.

Symptomatic management of mediator release

Acute systemic mast-cell mediator release should be treated in much the same way as other forms of anaphylaxis. Treatment with adrenaline and intravenous fluids should be started as soon as possible, with early involvement of intensive care specialists in severe cases. A short course of corticosteroids may be required. Antihistamines (H_1 and H_2 blockers) should be introduced and continued long term if the episode was particularly severe or recurrent.

Symptoms of chronic mediator release are the commonest clinical problem in mastocytosis. Symptomatic cutaneous disease should be managed with the help of a dermatologist. Treatments include H_1 and H_2 blockers, topical corticosteroids and PUVA for severe disease. Non-life-threatening systemic symptoms such as flushing, abdominal pain and diarrhoea should be treated with H_1 and H_2 blockers, mast cell stabilisers e.g. sodium cromoglycate and corticosteroids. Inhibitors of prostaglandin synthesis, such as aspirin and non-steroidal anti-inflammatory drugs, can also be useful. Aspirin should always be started with caution as it can initially lead to acute mediator release. Gastrointestinal disease usually responds to mast-cell stabilisers such as sodium chromoglycate. Leucotriene antagonists may also be useful. Peptic ulcer and reflux disease should be treated with proton pump inhibitors. Osteoporosis should be treated with bisphosphonates and may be prevented with bisphosphonates or calcium and vitamin D supplementation. Bone density should be recorded and monitored according to the severity of osteoporosis. Tricyclic anti-depressants are useful in neuropathic pain. Radiotherapy can help with severe localised pain.

Cytoreductive therapies

Patients with ISM who are still symptomatic despite maximal anti-mediator treatments and those with AdvSM should be considered for cytoreductive or targeted treatments. IFN-α, usually given in combination with oral corticosteroids, and cladribine has been found to result in partial remissions in some patients but can cause severe myelosuppression with risk of infections.

Tyrosine kinase inhibitors (TKIs) demonstrate efficacy in patients with AdvSM, imatinib in *C-KIT* negative patients or with unknown mutational status and patients with well-differentiated SM variant with *F522C* transmembrane mutation/wild type *KIT*. Midostaurin, an oral multi-kinase inhibitor of wild-type *KIT* and *D816V* mutation as well as *FLT*3, *PGRFR*α/β and2 has been approved for patients with AdvSM in 2017 by the FDA and EMA demonstrating decreases in mast cell burden, reduction in spleen size, bone marrow mast cell burden with improved symptom scores. The FDA recently approved avapritinib (June 2021), an oral-directed C-KIT D816V inhibitor for patients with AdvSM. Significant reductions were seen in mast cell burden, clearance of mast cell aggregates and reduction in C-KIT allele burden becoming undetectable in some patients with this agent.

Finally allogeneic bone marrow transplantation is an option for those patients with a suitable donor and more so with the promising results shown in the clearance of mast cells with the new TKIs. Treatment of any associated haematological disorder should be undertaken as appropriate for that disorder and the overall prognosis is usually that of the latter.

Eosinophilia

An eosinophilia can be present in a range of conditions, and for the most part, does not itself cause harm to the patient. However, eosinophilia can be a marker of underlying disease which requires treatment and rarely in the form of hypereosinophilic syndrome (HES) which will cause tissue damage. The approach to the investigation and management of this manifestation is complex and outlined below (Table 35.16).

Table 35.16 Suggested evaluation of a patient with persistent eosinophilia, following a thorough history and examination.

In all cases of eosinophilia:
- Full blood count and blood film
- Routine biochemical tests including renal and liver function tests, bone profile, lactate dehydrogenase
- Erythrocyte sedimentation rate and/or C-reactive protein
- Vitamin B_{12} assay

In patients who are otherwise well with mild to moderate eosinophilia between 0·5 and $1{\cdot}5 \times 10^9$/L, further testing may not be indicated

Patients with systemic symptoms or those with persistent eosinophilia (at least $1{\cdot}5 \times 10^9$/L), with or without suspected organ damage, should be investigated for possible secondary causes with the following:

How to test for organ damage:
Cardiac assessment:

Chest radiography, electrocardiogram, echocardiogram, serum troponin T. If there is a suspicion of cardiac involvement discuss with cardiologist see Figure 35.15

Pulmonary assessment:
Pulmonary function tests including spirometry, O_2 saturation and transfer factor of the lung for carbon monoxide (TLCO)

Thrombotic event:
An unprovoked thromboembolic event is regarded as a manifestation of tissue damage

(*Continued*)

Table 35.16 (*Continued*)

For those with a suspected clonal eosinophilia
- See algorithm in Figure 35.16 below including molecular tests and serum tryptase

In those with a suspected allergic aetiology:
- Serum total immunoglobulin E (IgE)
- Allergen-specific IgE tests
- Skin-prick testing for specific allergies

In those with a suspected non-allergic dermatological cause:
- Skin biopsy

In those with a suspected infectious cause:
- Fresh stool microscopy for ova, cysts and parasites
- Serological tests for suspected parasitic infections e.g. strongyloidiasis, schistosomiasis, filariasis, toxocariasis where appropriate
- Consider the need to test for human immunodeficiency virus (HIV) or human lymphotropic virus 1 (HTLV-1) in patients with probable opportunistic infections

In those with a suspected gastrointestinal cause:
- Upper gastrointestinal endoscopy, small bowel endoscopy and/or colonoscopy/sigmoidoscopy
- Serum amylase
- Serology for coeliac disease-related autoantibodies (anti-tissue transglutaminase)

In those with a suspected connective tissue disorder
- Antinuclear activity (ANA) or anti-double stranded DNA (dsDNA) antibodies
- Antibodies to cyclic citrullinated peptide (CCP)

In those with a suspected vasculitis:
- Antineutrophil cytoplasmic antibodies (ANCA)
- Serology for hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV), cytomegalovirus (CMV) and parvovirus B19

In those with suspected respiratory disease:
- Appropriate imaging
- Bronchoscopy with bronchoalveolar lavage/endobronchial ultrasonography

In those with a suspected lymphoma, non-haematological malignancy or T-cell driven eosinophilia:
- Appropriate imaging and tissue biopsy
- Peripheral blood T-cell immunophenotyping and T-cell receptor gene rearrangement studies

Miscellaneous:
- Tests for athero-embolic disease
- Immunoglobulins and C1 esterase levels

Figure 35.15 Cardiac magnetic resonance imaging scan in a 65-year-old man with HES, showing a rim of subendocardial fibrosis (arrow).

A suggested testing algorithm for clonal eosinophilia is shown in Figure 35.16. In a non-urgent situation, it is prudent to do the least invasive tests first with peripheral blood analysis for *FIP1L1::PDGFRA* and serum tryptase where an underlying mast cell condition is considered.

Management of eosinophilia

In the absence of a clear cause with no associated end-organ damage after careful evaluation the best course is likely to be monitoring only. For eosinophilia secondary to a known cause, then treatment relates to the underlying cause. If it is necessary to treat the eosinophilia in addition to the underlying cause then high doses of corticosteroids are helpful. It is important to consider adding the anti-parasitic ivermectin. The remainder of

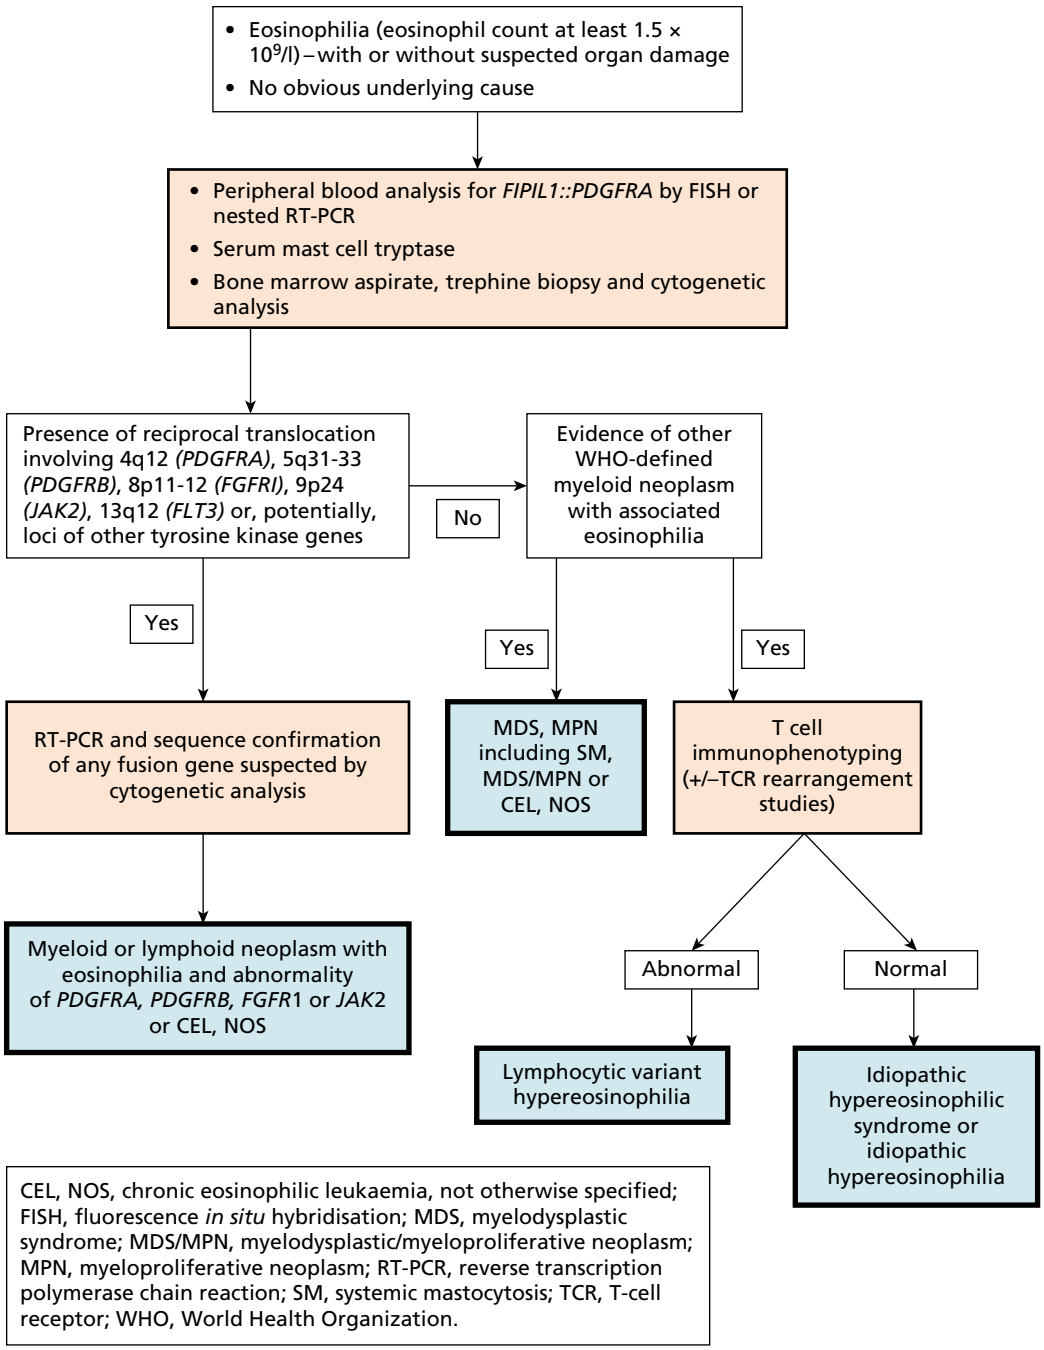


Figure 35.16 Suggested algorithm for suspected clonal eosinophilia (Source: Butt *et al.* 2017/John Wiley & Sons).

this section is devoted to discussing the management of eosinophilia related to haematological causes and hypereosinophilic syndrome. For all of these conditions stem cell transplantation should be considered for those patients with refractory disease or progressive organ damage.

Treatment of clonal eosinophilia

For those patients with an identified targetable abnormality an appropriate drug should be selected. The best-described abnormality is clonal eosinophilia with *FIP1L1::PDGFRA* (which can rarely also present with acute leukaemia). These

patients are frequently male and should be treated with low-dose imatinib. Specialist advice should be sought and monitoring of clonal burden will facilitate personalised therapy. For some patients, there is an emerging literature suggesting it is possible to stop the imatinib after some years of treatment. This is a field where variants and targets are expanding. Other examples include *PDGFRB* rearrangement or *ETV6::ABL1* fusion whom should receive imatinib. *ETV6::FLT3* fusion should be considered for sunitinib or sorafenib therapy. Those with *JAK2* rearrangement should be considered for ruxolitinib therapy. Recently for the rare patients with 8p11 or *FGFR* rearrangements pemigatinib has shown dramatic responses. It is recommended that patients with other haematological neoplasms including AML with clonal eosinophilia should have treatment directed at management of the neoplasm. If there is organ damage or dysfunction relating to the eosinophilia, treatment with corticosteroids should also be given.

Chronic eosinophilic leukaemia (CEL NOS)

CEL, NOS is *BCR::ABL1*-negative without detectable clonal markers known to be associated with eosinophilia and an eosinophil count of at least $1{\cdot}5 \times 10^9$/L. As distinct from AML-Eo, blast cells must be increased but less than 20% in both the peripheral blood and bone marrow. Overall CEL, NOS is recognised to be a rare and aggressive disorder associated with a median survival of 20 months and a high rate of acute transformation.

Treatment of lymphocytic variant of hypereosinophilic syndrome

Patients with the lymphocytic variant of hypereosinophilic syndrome (HES) can be managed in the same manner as idiopathic HES once an underlying lymphoma has been excluded.

Treatment of idiopathic hypereosinophilia and idiopathic hypereosinophilic syndrome (HES)

Idiopathic hypereosinophilic syndrome is defined by the presence of an eosinophilia, absence of an identified cause and detectable tissue damage typically including the heart, lungs, skin, nervous system, GI tract and thrombosis. In the absence of detectable tissue damage the diagnosis is idiopathic hypereosinophilia which for the most part does not require treatment.

Patients with idiopathic HES requiring treatment should be treated in the first instance with corticosteroids, high doses may be required. For those HES patients who either do not respond adequately to corticosteroids, or who either require prolonged corticosteroid therapy or are intolerant of corticosteroids other agents should be considered but these are patients who should be discussed with a specialist centre. A short trial (4–6 weeks) of any of the following could be considered: imatinib, immunomodulatory agents (interferon alpha, ciclosporin or azathioprine), myelosuppressive therapy (hydroxycarbamide) and finally alemtuzumab. Note should be made of the efficacy of monoclonal antibody therapy for example with mepolizumab (anti-interleukin 5).

Chronic neutrophilic leukaemia

Chronic neutrophilia is most commonly secondary, for example to chronic infections, inflammation or malignancy, with mildly elevated counts also found in smokers or corticosteroid use. Clonal causes include chronic myeloid leukaemia and the WHO 2022-defined condition MDS/MPN with neutrophilia (formerly 'atypical CML'), both of which are associated with left shift in the peripheral blood, and CNL, characterised by expansion of predominantly mature neutrophils.

Clinical features

CNL is a rare neoplasm whose true incidence is unknown, particularly when strict diagnostic criteria are applied. Median age at diagnosis is approximately 66 years. Patients may present with constitutional symptoms, splenomegaly and, in some cases, anaemia or thrombocytopenia in addition to the neutrophilia. The blood film shows an increase in segmented neutrophils and bands (Figure 35.17), the bone marrow is hypercellular with marked granulocytic expansion and without dysplasia or increased blasts, and there is no peripheral monocytosis. Diagnostic criteria (Table 35.17) now include the presence of a *CSF3R* mutation and if absent, the diagnosis should be made with care and secondary causes fully excluded.

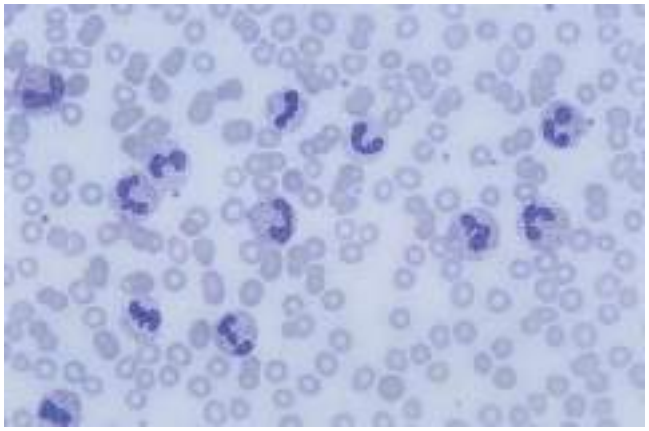

Figure 35.17 Abundance of mature neutrophils and band forms in a blood film from a patient with chronic neutrophilic leukaemia.

Table 35.17 Diagnostic criteria for chronic neutrophilic leukaemia from the World Health Organization (2022).

1	Peripheral blood white cell count $\geq 25 \times 10^9$/L
	Segmented neutrophils + band forms ≥80% of white blood cells
	Neutrophil precursors (promyelocytes, myelocytes, metamyelocytes) <10% of white blood cells
	Myeloblasts rarely seen
	Monocytes count <10% of peripheral blood leucocytes and not meeting criteria for CMML
	No dysgranulopoiesis
2	Hypercellular bone marrow
	Neutrophil granulocytes increased in percentage and number
	Neutrophil maturation appears normal
	Myeloblasts <5% of nucleated cells
3	Not meeting criteria for *BCR::ABL1*+ CML, PV, ET or PMF
4	No rearrangement of *PDGFRA*, *PDGFRB* or *FGFR1* or *PCM1::JAK2*
5	Presence of *CSF3R* T618I or other activating *CSF3R* mutation
or	
In the absence of a *CSF3R* mutation, persistent neutrophilia (≥3 months), splenomegaly and no identifiable cause of reactive neutrophilia (including absence of plasma cell neoplasm) or, if present, demonstration of clonality of myeloid cells by cytogenetic/molecular studies.	

Treatment

No therapies have been shown to improve survival, with the exception of allogeneic stem cell transplantation which is appropriate for the small minority of younger patients. Hydroxycarbamide has been used most frequently; other options include interferon, hypomethylating agents and busulphan. Responses to ruxolitinib have been reported in some patients with the *CSF3R T618I* mutation, although patients with a compound mutation (co-existing truncation mutation) are likely to be resistant.

Prognosis

Median survival of CNL is approximately 2 years, with a proportion of patients transforming to AML. *ASXL1* mutations confer an adverse prognosis. However, it is important to remember that this entity like many of those described in this chapter is very uncommon and further data is required to understand likely outcomes for patients and optimise treatment approaches.

CHAPTER 36

Macrophages, dendritic cells and histiocytic disorders

36

Matthew Collin, Venetia Bigley and Chris Bacon

Translational and Clinical Research Institute, Newcastle University, Newcastle upon Tyne, UK

Origin and classification

Overview

Macrophages and DC are myeloid cells that play fundamental roles in tissue homeostasis, immunoregulation and host defence. They are found in nearly all healthy tissues where they maintain a state of immune tolerance. Resident macrophages are also known as histiocytes – literally 'tissue cells' – a term that usefully distinguishes them from monocyte-derived cells that enter from the blood. During inflammation, monocyte-derived cells are recruited to tissues, massively augmenting the population of macrophages. DC migrate to draining lymph nodes to prime naïve T cells and direct immune responses. Both lineages contribute to the afferent phase of an immune response by elaborating chemokines, cytokines and other mediators to attract leukocytes from the bloodstream. While DC play a primary role as professional antigen-presenting cells in the lymph nodes, inflammatory monocyte-derived cells are also able to present antigen to primed T cells, modulating and amplifying local immune responses. Recruited inflammatory monocytes differentiate into a range of activated macrophage phenotypes with important effector roles in the phagocytosis and killing of pathogens, recognition of tumours, efferocytosis of apoptotic and dead cells and resolution of inflammation.

A modern view of macrophage and dendritic cell ontogeny

Recent developments have taken our understanding of macrophages and DC far beyond the mononuclear phagocyte system in which macrophages and DC are derived from monocytes emanating from the bone marrow.

Macrophages

Mammalian haematopoiesis develops through successive waves beginning extra-embryonically in the yolk sac blood islands whence primitive macrophages migrate through the pre-vascular embryo and establish themselves in most tissues including the brain and epidermis (Figure 36.1a). A wave of fetal liver monocytes then enters the tissues significantly augmenting the population of resident macrophages, with the exception of microglia, now isolated by the blood–brain barrier. At least in animal models, microglia remain exclusively yolk sac-derived for life and together with most other populations including Langerhans cells, Kupffer cells and alveolar macrophages, form stable and self-renewing populations into adulthood. Other macrophage populations in the gut, skin and interstitial tissues continue to recruit from the monocyte pool derived from definitive haematopoietic stem cells (HSC) via chemokine receptor CCR2 which binds the monocyte chemoattractant proteins, CCL2, CCL8 and CCL16.

Righthand side whole-mount immunofluorescence of human dermis showing DC, macrophages and T cells in a perivascular sheath. (Source: Image courtesy of Xiao Wang).

Dendritic cells

Dendritic cells are now known to have an independent haematopoietic origin to monocytes and macrophages. The lineage boundary only becomes blurred when inflammatory monocytes become potent antigen-presenting cells corresponding to the classic monocyte-derived DC-derived in vitro with GM-CSF and IL-4. DC traffic continuously through tissues to the draining lymph nodes where they survive for a few weeks at most. At the onset of inflammation, DC undergo functional maturation with increased expression of MHC class II, co-stimulatory molecules (CD80, CD83 and CD86) and the chemokine receptor CCR7 that directs their homing to lymph nodes along CCL19 and CCL21

chemokine gradients. Migratory DCs from inflamed tissues transport antigen to T cell areas of the lymph node to initiate immune responses.

Monocyte and DC haematopoiesis

In both human and mouse systems, it is possible to identify discrete pathways of haematopoiesis for monocytes and DC. Haematopoiesis is now conceived as a collection of discrete trajectories primed early in development, rather than a sequence of bifurcating fate decisions (Figure 36.1b). Precursors such as the granulocyte-monocyte precursor (GMP) are not discrete homogenous populations but regions of phenotype parameter space containing related lineage trajectories. As lineages develop they gradually become more distinct, until it is possible to separate them into mature cell phenotypes. The textbook dichotomy, splitting haematopoiesis into lymphoid and myeloid lineages, has been revised; it is now thought that all mononuclear cells emerge from a common lympho-myeloid trunk (lymphoid-primed multipotent progenitors; LMPP). Thus, it is no longer surprising that DC appear to differentiate from progenitor fractions bearing both lymphoid and myeloid markers.

Classification of macrophages and dendritic cells

Immune cell lineages are highly diversified to provide a wide range of finely tuned responses. Macrophages are geographically specialised by transcriptional programmes specific to different tissue niches. Within each tissue, the specialised populations of microglia, Langerhans cells, alveolar macrophages and Kupffer cells are complemented by neuronal and vascular-associated resident macrophages and transient populations of monocyte-derived macrophages. The classification of mammalian DC is now well established. Two major classes exist, myeloid DC, bearing CD33, CD13, CD11b and CD11c in common with monocytes, and plasmacytoid DC which lack these antigens but express the naïve T cell marker CD45RA and high levels of the IL-3 receptor CD123. Myeloid DC comprise three subsets DC1, DC2 and DC3. DC1 (previously known as cDC1 for conventional DC1) expresses the lectin CLEC9A for apoptotic cell uptake and the unique chemokine receptor XCR1. DC1 is characterised as cross-presenting DC critical for responses to virus-infected cells, intracellular pathogens and tumours. DC2 and DC3 are closely related and were previously known collectively as cDC2. These DC correspond to the 'indeterminate cell' that inhabits interstitial tissues, expressing lower CD1a than LC and no Langerin. They both express CD1c, CD2 and FcεR1 and are more abundant than DC1 in blood and tissues. DC2 express some antigens found on DC1, such as BTLA, while DC3 share monocyte antigens including CD14 and CD163. DC3 have greater expression of inflammatory gene modules and are selectively expanded in inflammatory and autoimmune diseases. Both are capable of presenting antigens to T cells. By transcriptional analysis DC can be aligned along a lymphoid-myeloid axis in the order: pDC; DC1; DC2; DC3 (Figure 36.1).

Monocyte and dendritic cell deficiency

It is well known that inborn errors of haematopoiesis can lead to cellular deficiency such as anaemia, neutropenia or thrombocytopenia. Recently, a number of constitutive genetic defects have been described that lead to the loss of monocytes and DC and comprise a class of primary immunonodeficiency. Heterozygous *GATA2* mutation truncates the entire lymphomyeloid branch of haematopoiesis causing a severe loss of DC, monocytes, B and NK cells associated with susceptibility to mycobacterial infection, papilloma virus-driven malignancy and pulmonary alveolar proteinosis. Acquired *ASXL1* mutation and monosomy 7 are common leading to myelodysplasia and acute myeloid leukaemia. *IRF8* is a critical gene regulating monocyte and DC production in an exquisitely dose-dependent manner. In biallelic deficiency of *IRF8*, there is severe monocytopenia, loss of DC and an excess of neutrophils. Less severe defects ablate only DC development causing an excess of monocytes or DC3. Ikaros (*IKZF1*) mutation also affects the balance of haematopoietic output between pDC and DC1. Recently human Flt3 Ligand *(FLT3LG)* mutation has also been described as a cause of DC deficiency. The presence of Langerhans cells and some tissue monocytes in these disorders demonstrates their independence from the bone marrow in humans.

The histiocytic neoplasms

Overview

Classification

The histiocytic neoplasms are a group of rare and complex disorders classified by the Histiocyte Society into five clinicopathological groups: L, C, R, M and H (Table 36.1). These groups do not map to WHO classification or ICD codes and in the near future, more rigorous genetic profiling will doubtless instigate another revision. This chapter will describe the major clinically recognisable disorders known to arise from acquired genetic aberrations of mitogen-activated protein kinase (MAPK) and PI3K–AKT pathways: Langerhans cell histiocytosis (LCH); Erdheim Chester Disease (ECD) Juvenile Xanthogranuloma (JXG) and Rosai Dorfman Destombes Disease (RDD). Haemophagocytic lymphohistiocytosis (HLH) is a completely distinct clinical and pathological process that will be described separately.

Molecular and cellular aetiology

In 2010, the oncogenic driver $BRAF^{V600E}$ was identified in about two-thirds of cases of LCH, revolutionising the field of

Table 36.1 Classification of the histiocytic disorders.

histiocytosis. This remains the most prevalent mutation overall but has been joined by a wide catalogue of hits to the MAPK pathway including *BRAF* indels and fusions, *MAP2K1* (MEK) mutations, common oncogenic mutations of *NRAS* and *KRAS* and most recently, mutation of the M-CSF receptor gene *CSF1R*. Some cases, especially of RDD, may yet turn out to be reactive phenomena, but it remains likely that all classic manifestations of these conditions are driven by somatic mutation. New potential driver mutations are still being documented. *ALK* translocations, most frequently *KIF5B-ALK,* define a new pathological entity of ALK+ histiocytosis. *ETV3-NCOA2* translocation has been documented as the driver of indeterminate cell histiocytosis.

MAPK pathway activation

The MAPK mutations driving histiocytic neoplasms beautifully underscore the role of M-CSF in promoting macrophage and DC development and neatly parallel mutation of the JAK/STAT signalling pathway driving conventional myeloproliferative neoplasms (MPN) (Figure 36.2a). Unlike conventional MPN, however, MAPK pathway activation, confers little proliferative advantage on HSC and is only found at very low frequency in HSCs even in multisystem disease. In single-system disease, mutation is localised exclusively to the peripheral tissues. Lesions progress through the accumulation of neoplastic histiocytes with relatively low proliferative potential. Histiocytic neoplasms do not typically progress to myeloid

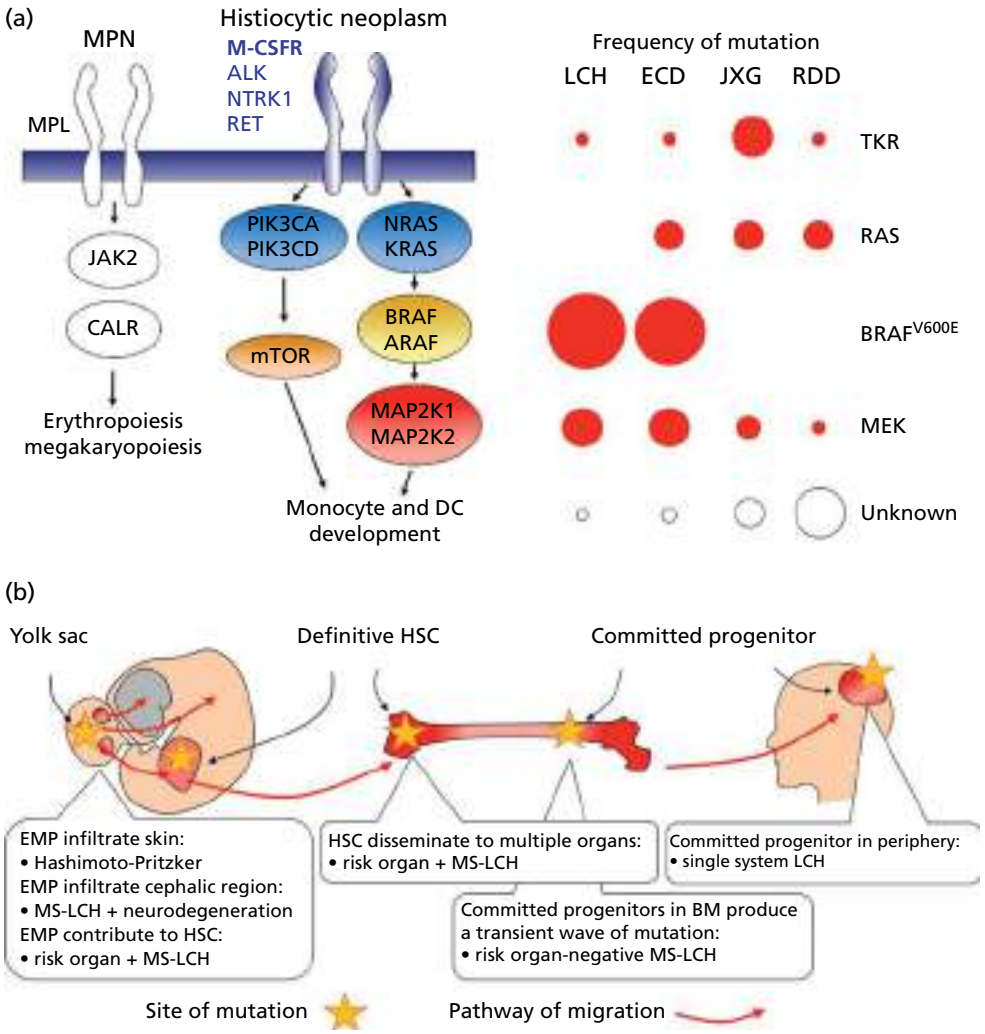

Figure 36.2 (a) Schematic comparing signal transduction activation in myeloproliferative neoplasms (MPN) and MAPK pathway activation in histiocytic neoplasms. Most commonly mutated proteins are labelled in bold. Red circles depict the relative frequency of mutation at each level in the pathway in each histiocytic neoplasm. (Source: Data redrawn from Durham, 2019). (b) Multistage model of LCH pathogenesis depicting how mutation arising at different stages of haematopoiesis might influence the clinical spectrum of disease. The involvement of early myeloid progenitors (EMP) in LCH is entirely speculative based on mouse models. HSC are known to be involved in risk organ-positive multi-system (MS)-LCH but not in most instances of risk-organ-negative or single system-LCH.

malignancy but conversely, may evolve as a subclone of clonal haematopoiesis and myelodysplasia.

Second hits

Second hits may explain the peculiar tissue tropism of many histiocytic neoplasms. LCH localises to the skin folds in infants, dental alveolar bone in adults and lungs in smokers, which are all sites of inflammation. ECD and xanthomatous histiocytic disorders have predilection for skin, internal adipose tissue and vasculature where lipid metabolism may produce pro-inflammatory mediators. Critically, the MAPK pathway is a rheostat for response to inflammation at the convergence of somatic mutation and exogenous stimuli. In keeping with this, case-control studies have reported that neonatal infection was associated with an increased risk of multi-system LCH (OR 2.8–3.8).

Genetic analysis

Genetic analysis has become an important new tool in the diagnosis, prognosis and treatment of these complex pathologies. In localised disease, mutation is often confined to the lesion but in multi-system LCH and advanced ECD, mutation is usually accessible from myeloid cells and cell-free DNA in the blood. The detection of mutation in the blood is therefore of potential value in staging and prognosis. The identity of the mutated gene

is also relevant. In paediatric LCH, *BRAF*^{V600E} is present in 90% of infants with multi-system LCH and is associated with an increased risk of relapse and neurodegeneration. *BRAF* mutation is also more prevalent in certain subgroups of ECD. The discovery of a molecular aetiology has had profound implications for therapy since many drugs are available targeted to *BRAF* and *MEK*, owing to the prevalence of *BRAF* mutation in melanoma and other cancers.

Langerhans cell histiocytosis

LCH epidemiology

The population incidence of LCH in the UK is 1.5 per million person-years ranging from 11.9 in infants <1 year old to 1.0 in those >15 years. An equal number of children and adults are diagnosed each year. North America, France and Sweden, report similar incidences in children ranging between 2.6 and 8.9 new cases per million. Social deprivation is associated with an increased risk of LCH independent of smoking which is the primary trigger for pulmonary LCH.

LCH pathophysiology

LCH is characterised by intense inflammatory lesions containing neoplastic histiocytes expressing S100, CD1a and langerin (CD207, a C-type lectin) admixed with a background of eosinophils, macrophages, multinucleated giant cells and T cells (Figure 36.3). Bone lesions with this morphology are synonymous with 'eosinophilic granuloma'. In other sites, notably the bone marrow liver and brain, LCH cells are rare. LCH-associated neurodegeneration is typically a gliotic process involving T cells. By electron microscopy, LCH cells contain Birbeck granules, unique endosomal structures found

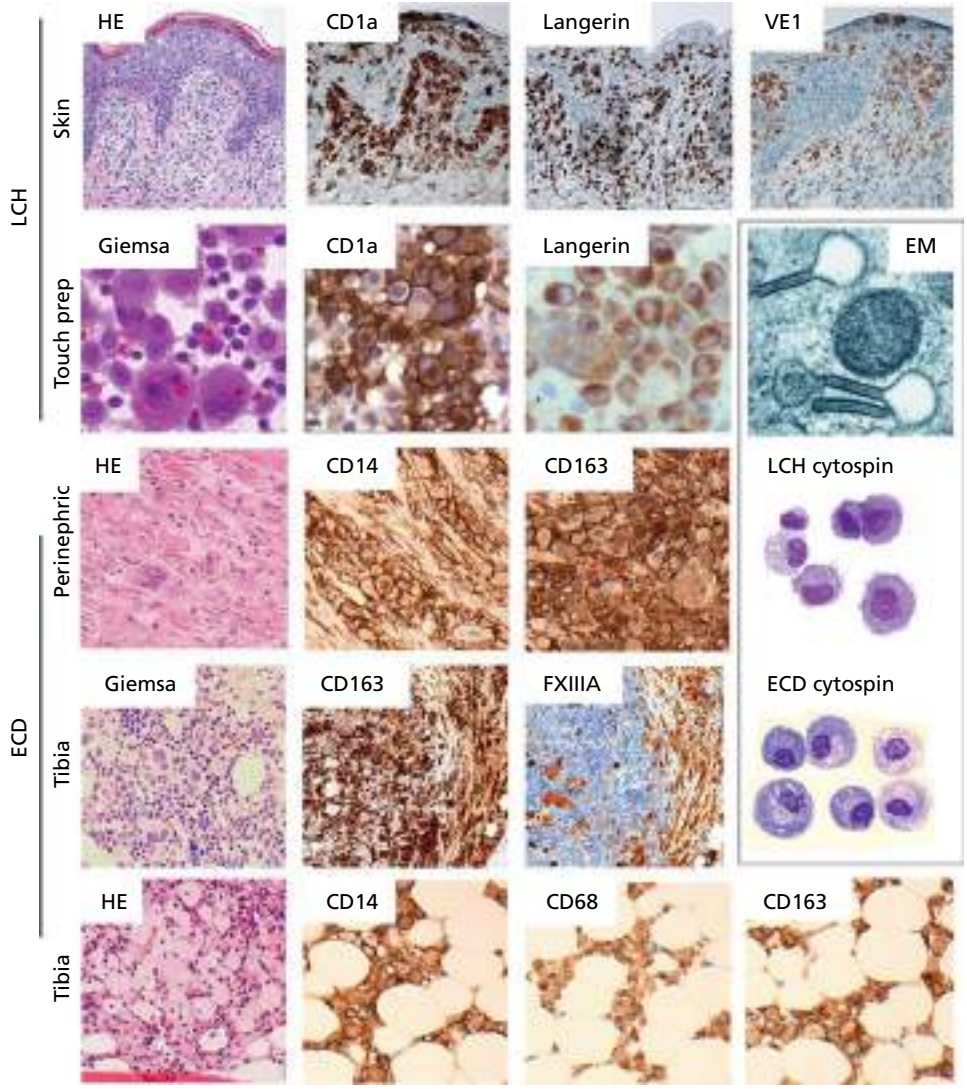

Figure 36.3 Histology, touch prep images and electron microscopy. (Source: Courtesy of Marian Malone).

in Langerhans cells. By gene expression, LCH cells are relatively immature and express a high level of PDL-1, holding T cells in an anergic state. This is reflected in their relatively bland pale-staining cytoplasm and the famous 'coffee bean' nucleus containing folded but open chromatin. LCH can cause a wide range of pathology from single lesions to disseminated high-risk disease (Figure 36.2b). Single system disease appears to arise either locally through mutation of Langerhans cells or tissue macrophages, with self-renewal capacity, or from the bone marrow through mutation of committed progenitors producing a transient wave of abnormal haematopoiesis. In multi-system disease, somatic mutation is detectable in HSC, consistent with disseminated disease and the propensity for relapse after treatment. DC2, DC3 and monocytes all harbour *BRAF* mutation and are able to differentiate into high langerin-expressing cells with Birbeck granules, *in-vitro*. A third possibility is that mutations could arise prenatally in early yolk sac or fetal liver myeloid progenitors and seed the microglia of the brain, cutaneous Langerhans cells and HSC. This mechanism has been proposed for congenital self-healing LCH (Hashimoto–Pritzker disease), infantile multisystem LCH and LCH-related neurodegeneration. Congenital mosaicism amongst histiocytes might explain regional cephalic disease involving the scalp, cranio-facial bones, posterior pituitary and neurodegeneration.

LCH clinical presentation

The clinical presentation of LCH is extremely variable potentially involving many different organs (Figure 36.4). A simple staging system distinguishes between single-system disease which is usually confined to either skin, bone or lungs (in adults) and multisystem disease which can be severe when it involves the bone marrow, liver and spleen. These sites are therefore known as 'risk organs' leading to the designation risk organ positive (RO+) LCH. RO+ multi-system LCH occurs almost exclusively in infants and young children and matches the historical syndrome of Letterer Siwe disease. The major acute consequences are fever, cytopenia, intrahepatic jaundice and liver failure. These elements, together with organomegaly, area of skin involvement, lymphadenopathy, bone and soft tissue lesions have been compiled into a disease activity score (DAS). RO+ multi-system LCH may be amplified by secondary HLH, considerably increasing the therapeutic challenge. Prior to molecularly targeted therapy, RO+ multi-system LCH incurred a mortality of 10% and a high risk of late effects including neurodegeneration. This type of presentation is not described in adults and cytopenia or severe systemic illness should prompt a thorough investigation for Erdheim Chester disease concomitant myelodysplasia or other myeloid malignancy.

Risk organ negative (RO−) multisystem LCH has many potential variants of two or more organs. The classic triad of exophthalmos, ulcerating skull lesions and diabetes insipidus has been recognised for many decades as Hand Schuller Christian disease, also described as 'chronic multifocal LCH'. The lytic skull lesions are contiguous with soft tissue inflammation and painful skin ulceration. Lesions may extend to the mastoid and auditory canal, maxilla and mandible presenting as ear discharge and floating teeth. LCH is thus an important rare differential of otitis externa and periodontitis. Involvement of facial bones, base of skull and posterior pituitary have well-recognised associations with neurodegeneration. Lesions at the base of skull are known as 'special sites' for the risk of neurodegeneration, leading to more intensive treatment regimens in children.

Single-system bone LCH has a predilection for the axial skeleton and may be unifocal or multifocal. Eosinophilic granuloma of a vertebral body can present with a sudden onset of back pain and vertebra plana. Skin rashes frequent the skin folds and are typically erosive, itchy and very painful but provide an easy biopsy site. Their appearance can be misleading and overlap with nappy rash in infants or eczema and sebbhorreic dermatitis in older children and adults.

Pulmonary LCH occurs in two completely different clinical settings: neonates, with severe single organ respiratory failure or as part of RO+ multisystem LCH; and adolescents and adults who smoke, where it is mostly single system but can have multisystem extrapulmonary manifestations. Presenting features are breathlessness, chest pain and pneumothorax. Radiology reveals cysts at the apices, which may be very large, with widespread nodules and interstitial inflammation typically sparing the lung bases. A radiological diagnosis is usually reached without biopsy.

LCH can infiltrate the posterior pituitary, present as mass lesions and cause a devastating neurodegenerative syndrome. Pituitary stalk inflammation, swelling or small masses are frequently seen with recent diabetes insipidus. Mass lesions can cause headache, visual disturbance and gross derangement of satiety, memory and executive function. Hyperphagia is an uncommon presentation of hypothalamic lesions that, with memory loss, can prove unmanageable and ultimately fatal. Neurodegeneration is suspected when educational performance declines and difficult behaviours appear, especially with the onset of gait disturbance, clumsiness, dysarthria and dysphagia indicative of cerebellar dysfunction. More than half of patients with diabetes insipidus or craniofacial bone disease develop high T2-weighted signal in the cerebellum within 3 years, and one-quarter of these (about 15% overall) suffer irreversible neurological decline.

LCH diagnosis

Several recent guidelines describe the diagnosis and management of LCH in detail (see further reading). A thorough clinical history and examination are required to document the extent of disease. Bone pain, dental health, ear discharge, polyuria and polydipsia, skin rash, breathlessness and neurological symptoms are all important features. The extent of skin involvement, bone tenderness, chest signs, organomegaly, lymphadenopathy, jaundice, ascites and bruising should be noted. A full blood workup is usually indicated to exclude cytopenia, liver dysfunction, endocrine

abnormalities and hyperinflammation/HLH. Plain radiography is helpful for sites of bone pain. Most patients warrant at least one PET-CT to fully document sites of disease although skull lesions can be difficult to visualise adjacent to the brain, and PET avidity may be relatively low for older bone lesions and liver involvement. MRI of the head is useful to document pituitary stalk and posterior bright spot together as a baseline for neurodegeneration. Clinical evaluation includes lung function, water deprivation for suspected diabetes insipidus, ataxia rating, mental state including memory and depression scores. Pathological diagnosis

is usually reached by skin or bone biopsy; occasionally, lymph node, gut, liver or lung biopsy is necessary. Bone marrow examination is indicated with pancytopenia and is essential for defining RO+ status. A full molecular evaluation should be undertaken involving a rapid and sensitive PCR-based test for *BRAF*^{V600E}. In wild-type cases, DNA sequencing should be undertaken for other MAPK pathway mutations or deletions and RNA should be analysed for gene fusion. These investigations are increasingly useful for confirmation of difficult pathology and inform the decision for targeted therapy in refractory disease.

LCH management

International treatment protocols, devised over the last 40 years, deliver risk-adjusted therapy to patients with LCH. Unifocal bone LCH often resolves after biopsy or with intra-lesional corticosteroid. Wide excision or resection should be avoided, as severe defects often regenerate and unnecessary grafts and prostheses often lead to severe chronic pain. Post-inflammatory pain is common and may respond to indometacin or bisophosphonates. In adults, fractionated radiotherapy in the range 10-20Gy is highly effective and can be useful for critical, painful or inaccessible bone lesions, although it is seldom used for children owing to growth arrest of the involved field. Skin disease often responds to topical immunomodulation by corticosteroids or adjuvants.

The mainstay of frontline systemic therapy for multi-system LCH in children is vinblastine and prednisolone, although RO+ disease has a high relapse rate. Salvage with cytarabine, cladribine or clofarabine is required for nearly half of RO+ infants, initially exposed to vinblastine. Cytarabine and cladribine are also useful for older adults with multifocal bone disease, pulmonary LCH or multisystem LCH who do not tolerate vinblastine and prednisolone well. Etoposide is active in LCH but rarely used owing to the risk of t-AML.

Maintenance plays an important role in treating LCH. Daily 6-mercaptopurine and weekly methotrexate are used for 12–24 months in paediatric protocols and for adults. Azathioprine or 6-mercaptopurine has also been widely used for skin disease in adults. Hydroxycarbamide is known to suppress chronic relapsing skeletal and cutaneous disease.

MAPK inhibitors have revolutionised salvage for children and adults with the highest risk of disease who fail conventional chemotherapy. Most experience has been obtained with vemurafenib (targeted to *BRAF*^{V600E}), dabrafenib (*BRAF*), cobimetinib and trametinib (MEK inhibitors). For patients with BRAF mutation, a combination of *BRAF* and MEK inhibitors may be used. If *BRAF* is wild-type or the genotype is unknown then MEK inhibition is usually effective. An important limitation is that it is difficult to withdraw therapy without brisk relapses. Sustained MAPK inhibitor therapy is not without difficulty owing to the many idiosyncratic toxicities of these drugs and unknown long-term consequences.

Pulmonary LCH requires absolute abstinence from smoking or may progress to end-stage respiratory failure requiring lung transplantation. Systemic treatment with vinblastine and prednisolone, cytarabine or cladribine is effective in progressive disease or with concurrent extra-pulmonary involvement, although cytoreductive treatment is very challenging to deliver in the face of declining lung function. MAPK inhibitors are yet to be widely used but may play a key role in patients with severe compromise unable to tolerate chemotherapy.

Neurodegeneration was considered an irreversible and ultimately fatal complication of LCH, before the advent of MAPK inhibitors. There was evidence that cytarabine or intravenous immunoglobulin could modify progression but neither was associated with dramatic improvement as has been documented with inhibitor therapy.

Fortunately, in children, overall survival is good and only patients with RO+ disease are at risk of death (up to 5%). However, late effects and permanent disability are common in patients treated for multi-system disease. Children face multiple challenges of normal development and educational achievement that have long-lasting consequences. In adulthood, chronic skeletal pain, respiratory compromise, anxiety and depression are commonplace and difficult to manage. The burden of morbidity in older adults is starkly illustrated by their poor survival of less than 40% at 5 years.

Erdheim Chester disease

Erdheim Chester disease epidemiology

ECD is the most clinically important 'non-Langerhans' histiocytic neoplasm. It is about half as frequent as LCH with an estimated annual population incidence of 0.5 per million, a mean age at diagnosis of 55 years and male preponderance of 3:1.

ECD pathophysiology

ECD is characterised by inflammatory, fibrotic lesions containing xanthomatous (fat-laden) foamy macrophages expressing typical macrophage markers: CD68, CD14, CD163 and variable factor XIIIA (Figure 36.3). Touton giant cells are often but not invariably found. ECD, JXG and other xanthomas are referred to as 'non-Langerhans' histiocytosis because the abnormal histiocytes are negative for LCH markers, S100, CD1a and langerin. Critically for the pathologist, ECD macrophages have no specific neoplastic phenotype and it is not possible to separate ECD from many other xanthomatous and non-neoplastic disorders. The cellular background is also highly variable and may be mimicked by a wide range of pathology. The common molecular aetiology of histiocytic neoplasia is underscored by the overlap between pathological LCH and ECD in about 10% of patients and the observation that LCH lesions evolve with time to become more fibrotic and 'ECD-like'. A distinct entity overlapping with Rosai Dorfman disease has also been described.

In simple terms, ECD and LCH are respectively macrophage-biassed and DC-biassed evolutions of a shared neoplastic process. Mutations are concentrated in monocytes and myeloid DC

similarly to multi-system LCH but the relationships between abundance of alleles, stage of disease and response to therapy are less well established. About half of ECD is caused by *BRAF*^{V600E}; the remainder is more skewed to *RAS*, *PIK3CA* mutations and gene fusions than LCH (Figure 36.2). Clonal haematopoiesis may be a modifier that increases macrophage bias and explains the greater incidence in older males. Neoplastic macrophages infiltrate lipid-rich sites where interstitial macrophages are likely to be bone marrow-derived, producing many bizarre but characteristic pathologies.

ECD clinical presentation

ECD causes unique syndromes with highly specific features that should not be missed (Figure 36.5). About 90% of patients have long bone osteosclerosis that is painful in 38%. Appearances are often but not invariably dramatic and

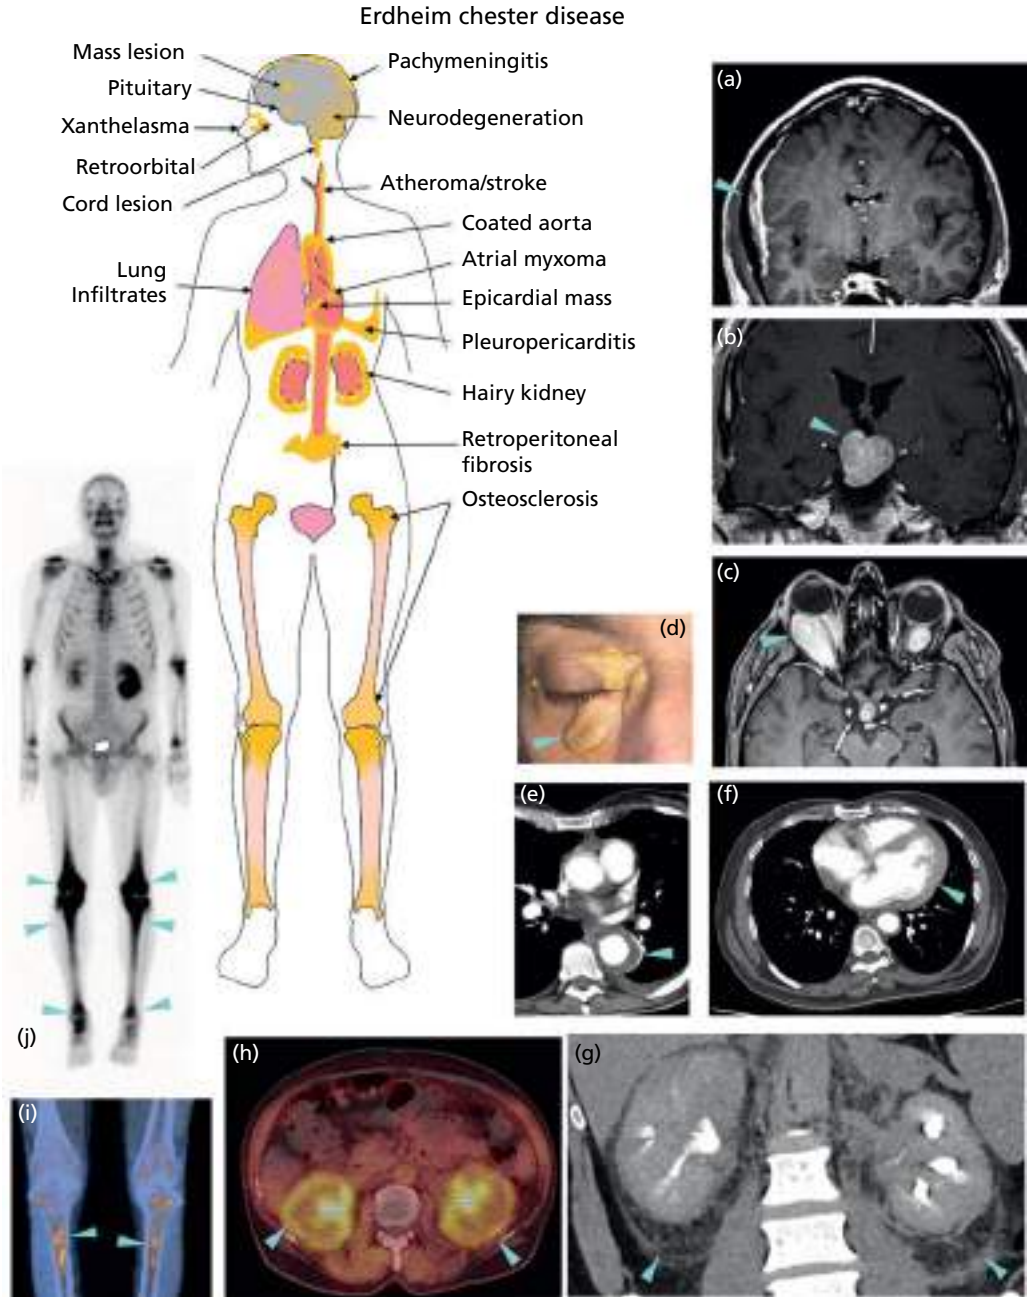

Figure 36.5 Clockwise from top right: (a) Pachymeningitis (dural thickening). (b) Suprachiasmatic mass. (c) Retro-orbital infiltration. (d) Xanthelasma. (Source: Courtesy of Ian Park). (e) Coated descending aorta. (f) Pericardial inflammation. (g) Perinephric inflammation (hairy kidney). (h) Hairy kidney PET-CT. (i) Long bone osteosclerosis PET-CT. (j) Long bone osteosclerosis bone scintigraphy.

symmetrical on PET-CT or bone scintigraphy. A minority of patients present with classic peri-orbital xanthomata. Inflammation of the peri-renal fat results in 'hairy kidney' on CT and retroperitoneal fibrosis presenting with obstructive nephropathy may cause irreversible ureteric obstruction. Aortitis may be diagnosed appearing as a 'coated aorta', a prominent sheathing of the adventitia, on CT. This is highly morbid causing stroke, coronary, renal and mesenteric ischaemia and infarction. The serosal surfaces may become thickened and inflamed causing pericardial and pleural effusions. Atrial myxoma, myocardial infiltration and epicardial inflammatory masses can lead to valvular obstruction, heart block and tamponade. Retro-orbital xanthoma with somatic mutation may trigger a diagnosis of ECD. In the CNS, diabetes insipidus is common, affecting about half of patients. Mass lesions may occur almost anywhere including the spine but dural thickening or pachymeningitis is a classic finding and may be confused with subdural haematoma. Scattered small lesions may occur in the cortex, periventricular white matter, brainstem, pons and cerebellum resulting in significant neurological deficits. Endocrine dysfunction and autoimmunity are common complications and patients frequently have fever and constitutional symptoms with leukocytosis, monocytosis and raised inflammatory markers. A staging system has not been agreed for ECD but it is clear that skeletal, cutaneous and peri-nephric infiltration are relatively low risk while cardiovascular and neurological involvement may be life-threatening. An urgent approach is also required to prevent loss of sight and irreversible ureteric obstruction.

ECD diagnosis

ECD is a clinical and radiological diagnosis supported by consistent pathology that excludes any other diagnosis. Recent series indicate an unacceptable mean delay of 2.7 years between the presentation and diagnosis of ECD, which should be a differential in a huge range of imaging abnormalities. Guidelines for diagnosis and management are now well described (see further reading). ECD should be considered in the differential of any adult presenting with xanthelasma, diabetes insipidus, bilateral osteosclerosis, retro-orbital inflammation, retroperitoneal mass or fibrosis, aortitis, pericarditis, atrial myxoma, atypical lung lesions, perinephric inflammation and unusual CNS lesions. A full blood work should document baseline leukocytosis, inflammatory markers and lipids toexclude cytopenias, autoimmunity, liver dysfunction and endocrine abnormalities. Immunoglobulins should be measured including IgG4 for potential overlap with Rosai Dorfman and IgG4 disease. Full body PET-CT should be performed to include the knees and ankles, MRI brain and gated cardiac CT or MRI are also essential for initial staging. High-resolution CT of the chest and dedicated vascular examinations may also be required. There should be a low threshold to examine the bone marrow and a myeloid NGS panel should be sent from blood or bone marrow to exclude myelodysplasia or myeloproliferative neoplasm. The best site for biopsy is superficial xanthelasmata which are accessible and cellular, followed by proximal tibia and perirenal biopsy although these are usually more fibrotic. Inflammatory masses in the retro-orbital space, dura, pericardium and other sites also provide very good material for genetics if the diagnosis is suspected. Sensitive PCR-based $BRAF^{V600E}$ testing should be performed on unfixed material, followed by DNA sequencing for other MAPK pathway mutations or deletions and RNA sequencing for gene fusion.

ECD management

ECD may respond to corticosteroids and chemotherapy but lesions are much less sensitive than LCH. Low-dose methotrexate and interferon alpha have supporting evidence. Anakinra, infliximab and tocilizumab may also be useful to suppress inflammatory cytokines but their use is not widespread. Sirolimus also is reported to have activity. Anything more advanced than cutaneous, skeletal and low-grade retroperitoneal and vascular disease should be treated with MAPK inhibitors. These can be life-saving in advanced cardiorespiratory compromise, vascular and CNS disease. Case series evidence supports vemurafenib or dabrafenib for *BRAF*-mutated disease and cobimetinib or trametinib for *BRAF* wild-type or uncharacterised genetics. Typically, 25–50% of the recommended dosing used in melanoma, effects rapid clinical improvement with tolerable side effects. Unlike melanoma, resistance is extremely rare and partial or intermittent dosing often circumvents toxicity. Dual agents are especially effective in $BRAF^{V600E}$ mutation and intermittent high dose pulses are recommended for achieving therapeutic levels in CNS disease. Similar to LCH, it has been difficult to withdraw treatment without rapid relapses. Neurological and psychological symptoms are reported by 92% of patients and specialist care is desirable. Five-year survival in specialist centres with access to inhibitors is 80%.

Juvenile Xanthogranuloma

The incidence of JXG is estimated at 1 per million children, about four-fold lower than LCH. It causes mostly solitary cutaneous lesions in infants, one-third presenting at birth and some in association with neurofibromatosis type 1. In fewer than 10% of cases, xanthomata may also occur in the liver, spleen, lung, soft tissues, eye, heart and CNS. The bone marrow may be infiltrated and there is a 20-fold increased risk of JMML. JXG is indistinguishable from ECD at the microscopic level, containing foamy macrophages with typical markers (CD68, CD14, CD163 and factor XIIIA) (Figure 36.6a). It has recently been shown that JXG is specifically associated with mutations in the receptor

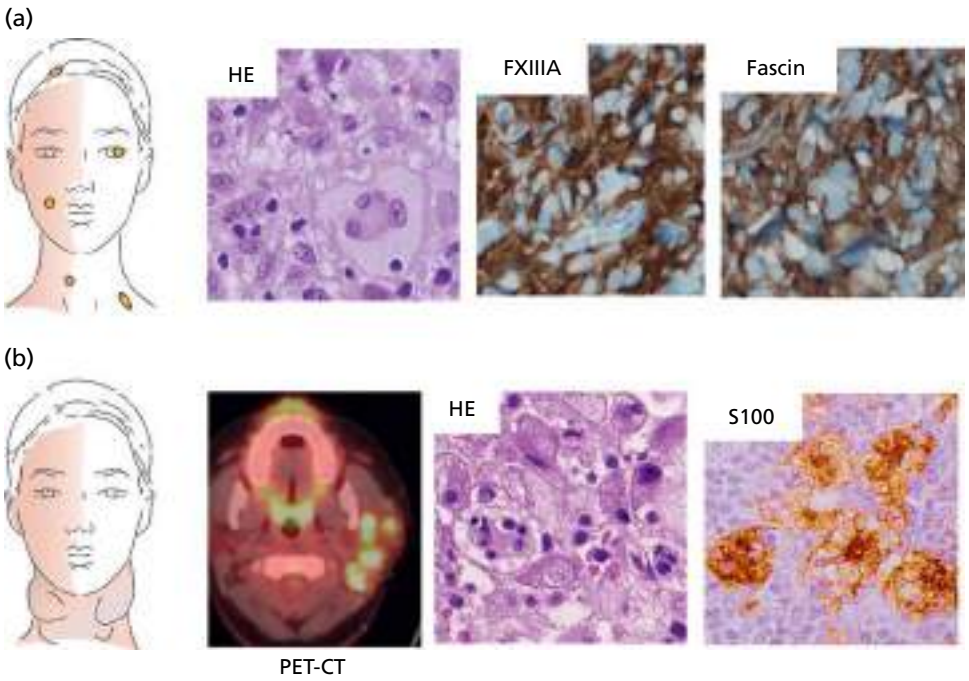

Figure 36.6 (a) The main features of JXG showing from left to right: superficial xanthogranulomata sometimes affecting the eye, foam cells and high expression of FXIIIA and fascin. (b) The main features of classical RDD showing from left to right: massive cervical lymphadenopathy and cells engaging in emperipopolesis (engulfment of viable cells) with S100 expression.

tyrosine kinase, *M-CSFR*. Lesions often spontaneously involute or respond to local therapy with surgery or cryotherapy. Systemic therapy may be required with prednisolone, vinblastine or methotrexate. Cytarabine and clofarbine have been used for more aggressive disease compromising the liver, trachea or CNS. MAPK inhibitors are likely to be highly efficacious but experience is limited.

Adult xanthogranulomas

Several rare macrophage-type histiocytic disorders are found in the C group (cutaneous) according to the Histiocyte Society classification. Somatic mutations have not been found yet.

Rosai Dorfman Destombes disease

Rosai Dorman Destombes Disease is a rare histiocytosis occurring in <1 per million population, first described by the French pathologist Destombes. The classic presentation, sinus histiocytosis with massive lymphadenopathy (SHML), describes very large painless cervical nodes that resolve spontaneously or with a short course of corticosteroids. This occurs mostly in children and young adults with a mean age of 21. About half of RDD cases are extranodal in subcutaneous tissue, exocrine glands, bone, orbits, pleural cavity, lungs and CNS. Sinus histiocytes have the phenotype of more recent monocyte derivatives and express S100 in addition to macrophage antigens CD68, CD163 (Figure 36.6b). They characteristically show emperipolesis or engulfment of other cells such as lymphocytes and granulocytes. RDD-like pathology may be reactive in SLE, JIA, IgG4 disease and lymphoma and *MAPK* mutations have only been reported in about half of cases (Chakraborty *et al*. 2021). RDD pathology is also seen in germline mutation of the *SLC29A3* gene which perturbs M-CSF receptor signalling and is manifest as Faisalabad histiocytosis and H syndrome. Single lesions rarely present clinically significant problems regardless of their true aetiology. Corticosteroids, vinca alkaloids, 6-mercaptopurine, methotrexate, cladribine, thalidomide and sirolimus have their advocates but radiotherapy has little efficacy. MEK inhibitors are effective when a mutation is discovered.

Malignant histiocytosis

Langerhans cell sarcoma and histiocytic sarcoma are acute histiocytic lesions with a high mitotic index and grave prognosis. They are probably best treated with radical local excision although recent reports suggest some may have targetable *MAPK* mutations. Follicular dendritic cell sarcoma is also high risk and difficult to cure. It is not haematological but mesenchymal in origin and benefits from a multi-disciplinary approach involving a sarcoma oncologist.

Hyperinflammation and haemophagocytic lymphohistiocytosis

Pathophysiology

In the steady state, tissue macrophages play a major role in maintaining immunological quiescence. A long-lived resident population engages in efferocytosis, the non-immune phagocytosis of dead cells, and a transient population of monocyte-derived cell patrols, probably leaving via the lymphatics. The full effector function of the macrophage is only unleashed when activated NK cells and T cells elaborate interferon-gamma (IFNγ). Originally described as 'Macrophage Activation Factor', IFNγ is the soluble mediator that effects immunity to viruses, mycobacteria, leishmania and other intracellular pathogens. Activated macrophages, in turn, promote adaptive immunity by releasing IL-1, IL-18 and IL-6. This feedback loop provides the ultimate cellular immune response against pathogens but is a potentially lethal force when unchecked (Figure 36.7). The grave illness caused by this phenomenon is described as Macrophage Activation Syndrome (MAS), corresponding to the pathological observation of haemophagocytic lymphohistiocytosis (HLH). More recently these have both been described as 'hyperinflammation'. HLH, the more familiar term in haematology, will be used here.

The HLH spectrum: primary and secondary

HLH is always multifactorial and attributable to an inflammatory trigger on a susceptible genetic background, sometimes compounded by acquired immune dysregulation. The two extremes of this spectrum have been characterised as 'primary' where inherited gene disorders cause a neonatal illness, triggered only by leaving the sterile environment of the uterus and 'secondary' where genetic susceptibility has not been identified but acquired immune dysregulation or potent inflammatory triggers are apparent (Figure 36.7). HLH becomes a risk in genetic or acquired loss of cytotoxic effector function because when cytotoxicity fails, pathogens and inflammatory triggers persist, driving a feed-forward loop of lympho-histiocytic activation and a state of hyperinflammation. The cytotoxic granule defects causing primary HLH are well defined and include severe phenotypes associated with mutation in *PRF1*, *UNC13D*, *STX11*, *STXBP2*, *RAB27A* or *LYST*. In general, less severe defects present later and older children and young adults display an increasingly diverse genetic background. In principle, almost any genetic primary immune disorder can predispose to HLH either through immunodeficiency and failure to deal with common viral triggers such as EBV and CMV or immune dysregulation manifest as auto-inflammation. EBV susceptibility in X-linked lymphoproliferative disorder (due to *SH2D1A* or *XIAP* mutation) and T cell defects in *ITK116*, *CD27* and *MAGT1* all predispose to HLH as do the lysosomal syndromes Griscelli and Chédiak–Higashi, and the inflammasome disorders arising from *CDC42* or *NLRC4* mutation.

Triggers of HLH are many and varied. Almost any virus, including COVID-19, is implicated. Herpesviruses EBV and CMV are common, mycobacteria, leishmania. Immune disorders associated with a significant risk of HLH are juvenile idiopathic arthritis and adult-onset Still's disease, Crohn's disease treated with azathioprine and haematopoietic stem cell transplantation. Malignancy is another significant trigger of HLH, especially lymphoproliferative disorders including PTLD, myelodysplasia, LCH and solid malignancy.

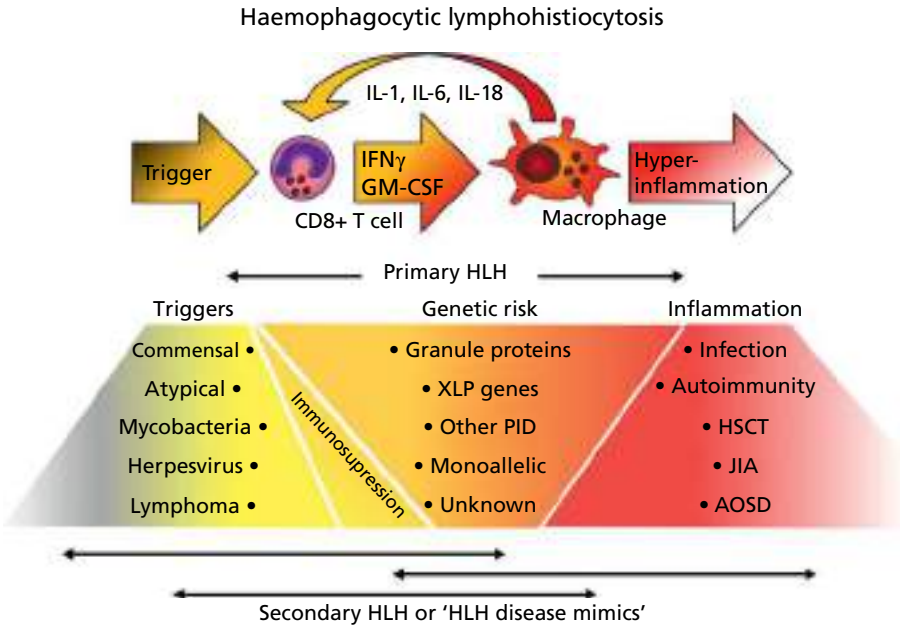

Figure 36.7 A schematic showing the main cellular circuit and risk factors predisposing to HLH. A given horizontal distance is required to reach a threshold of HLH, whether this is genetic in primary HLH or largely driven by acquired factors in secondary HLH syndromes, also described as 'HLH disease mimics'. (Source: Adapted from Jordan *et al.* 2019).

HLH epidemiology

The annual incidence of HLH is reported at about 1–2 per million, with the highest rate in infants <1 year of 10–20 per million. In the UK, the incidence has recently been estimated from electronic health records at 2 per million overall, with a rate of 14.6 per million in infants <1 year, decreasing to 0.8 in 15–44 year-olds and rising to 2.2 per million in >75 year-olds. These data also show much better one-year survival in children (77%) compared with older adults (30%).

HLH presentation and diagnosis

One of the most common misconceptions about diagnosing HLH is that it must be proven by the presence of haemophagocytosis on a bone marrow aspirate. This is only one criterion that may occur rapidly and subsequently vanish with the blood count. The classic triad of refractory fever, progressive cytopenia and organomegaly should prompt a rapid clinical and laboratory assessment for hyperinflammation. Two clinical scoring systems are in use: a paediatric score from the HLH2004 trial where >5/8 categorical variables trigger diagnosis and the HScore, a more sophisticated weighted score of nine staged variables (Table 36.2). The HScore was initially devised for adults but performs equally well in children and has the distinct advantage that all the parameters are routinely available, facilitating rapid diagnosis and monitoring. Both scores incorporate fever, organomegaly, cytopenia, fibrinogen, lipids, liver enzymes and ferritin. HLH 2004 criteria also include measurements of cytotoxic granule release and soluble CD25 (IL-2 receptor) but guidelines advise that pursuit of these results should not delay diagnosis. In adults, they play almost no role although the ratio of sCD25:ferritin may be useful for identifying lymphoma-associated HLH. The HScore is also marginally superior to the HLH 2004 criteria in critically ill patients. Important clinical features that influence the course of the illness include cytopenia, sepsis, liver failure and neurological dysfunction. Isolated CNS HLH is particularly challenging. A multi-disciplinary approach is beneficial, especially in adults who may have a range of comorbidities and potential triggers.

Management of primary HLH in infants

HLH in neonates and infants has a strong genetic component, often already recognised as familial and rapidly ascertainable by germline DNA sequencing in de novo cases. Infection and malignancy should also be rigorously excluded by viral PCR, cultures, PET-CT and bone marrow examination. Immunosuppressive treatment is urgently required, often as a bridge to allogeneic stem cell transplantation in severe phenotypes associated with cytotoxic granule defects. The HLH 2004 protocol is based on induction with dexamethasone, IVIg, ciclosporin and pulsed etoposide. Intrathecal treatment is given for CNS disease. Although this approach was life-saving when first introduced, the

mortality of primary HLH has not improved in the last decade and newer cytokine-based approaches are evolving, including emapalumab (IFNγ), tocilizumab (IL-6) anakinra (IL-1) and JAK inhibition. Cytokine-based approaches are proven to be effective but universal access is currently ensnared by regulation. ATG or alemtuzumab are also useful as a preconditioning step to achieve transplantation in refractory patients. Allogeneic transplantation is indicated for mutation in *PRF1*, *UNC13D*, *STX11*, *STXBP2*, *RAB27A*, *LYST* or *SH2D1A* but is not straightforward since reduced intensity conditioning is associated with partial chimerism and graft failure.

Management of HLH in older children and adults

Significant triggers are required to initiate HLH in older children and adults. Prompt investigation of viral infection or reactivation, bacterial infection, other pathogens, autoimmunity and lymphoproliferative disorders should be initiated with viral PCR, cultures, autoantibody titres, PET-CT and bone marrow examination. Flow cytometry of blood bone marrow and even splenic aspirate maybe required to detect intravascular or splenic lymphoma. MRI brain and CSF examination are indicated with even mild neurological impairment. EBV and CMV should be treated with rituximab and ganciclovir, respectively. Broad-spectrum antibiotics, antifungals and even empiric mycobacterial treatment are warranted, pending culture results. Successful treatment will often resolve HLH eventually but parallel suppression of hyperinflammation should not be delayed. While the HLH 2004 approach is tolerated and widely used in older children, it often fails in adults reported. A dismal median survival of 3.2 months and overall survival of 35% have been reported partly because highly immunosuppressive and cytoreductive therapy are hazardous in the face of serious infection and mask the diagnosis of lymphoma, a major trigger. Important lessons have been learned from the use of anakinra by rheumatologists treating MAS in patients with autoimmune disease. It is possible to avoid etoposide and to minimise steroid exposure in most patients. Suppression of IFNγ with emapalumab, IL-6 with tocilizumab and JAK-STAT signalling with ruxolitinib or baricitinib are also proving successful in early phase studies. As in primary HLH, alemtuzumab is a potent salvage agent but commits the patient to allogeneic transplantation.

Conclusion

The macrophage and DC systems have unique developmental pathways and roles in host defence that set them apart from other components of the human haematological system. Deficiency, neoplasm and hyperactivation lead to a wide spectrum of pathology formerly known as 'histiocytosis'. New developments in molecular pathology are having profound effects on diagnosis and management.

CHAPTER 37

Stem cell transplantation

37

Charles Craddock[1] and Ronjon Chakraverty[2]

[1] Centre for Clinical Haematology, Queen Elizabeth Hospital, Birmingham, UK
[2] MRC Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, UK

Introduction

The first haematopoietic stem cell transplants were performed in 1957. Although clinical outcomes were dismal initially, the vision of clinical pioneers, such Don Thomas, led to the demonstration more than a decade later that transplantation of bone marrow from HLA-matched siblings had the capacity to deliver long-term disease-free survival in a small proportion of patients with refractory leukaemia. Despite continued widespread scepticism, slow but steady progress continued to be made in the development of more effective forms of graft-versus-host-disease prophylaxis; coupled with advances in supportive care, the immediate toxicity and long-term morbidity of transplantation significantly reduced during the 1970s. At about the same time, transplantation of cryopreserved autologous bone marrow was shown to be a curative procedure in a proportion of patients with relapsed Hodgkin lymphoma. Although allogeneic transplantation was initially limited to patients with an HLA-matched sibling donor, the pioneering work of the Anthony Nolan and other nascent donor registries across the world demonstrated that it was possible to use HLA-matched unrelated donors as an alternative stem cell source in patients lacking a suitable sibling donor. More recently, the advent of reduced intensity conditioning regimens coupled with the growth of unrelated donor registries worldwide and the successful utilisation of cord blood cells and, more recently, haploidentical donors has dramatically increased access to transplant for patients with haematological malignancies, bone marrow failure and haemoglobinopathies.

Immunological basis of stem cell transplantation

The major complications of allogeneic SCT are caused by the immunological responses triggered by the infusion of donor haemopoietic progenitors and lymphocytes into an immunosuppressed host. These can take the form of either a host-versus-graft (HVG) or a donor-derived graft-versus-host (GVH) response. Clinically, the HVG response can result in graft rejection, while a GVH response may manifest itself as either graft-versus-host disease (GVHD) or a graft-versus-leukaemia (GVL) reaction (Chakraverty and Teshima 2021). It is now possible to blunt the HVG reaction by optimising the immunosuppressive properties of the conditioning regimen and consequently, graft rejection is rare in most clinical settings. In contrast, GVHD and disease relapse remain the major complications of allogeneic stem cell transplantation, and novel approaches that permit the induction of a GVL effect without inducing GVHD-related host injury are required. Conversely, autologous SCT is a relatively unremarkable immunological event in which such allogeneic responses are absent.

The human leucocyte antigen system

The human leucocyte antigen (*HLA*) genes are located within the major histocompatibility complex (MHC) on the short arm of chromosome 6 (6p21.3) (Figure 37.1) (Cornaby *et al.* 2021). *HLA* class I genes encode polypeptides expressed as cell-surface

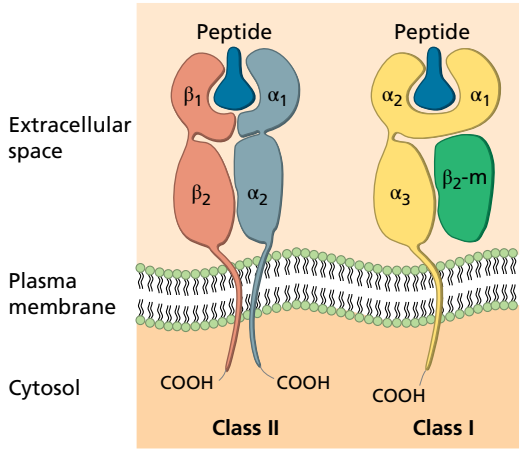

Figure 37.1 Diagrammatic representation of HLA class I and II molecules showing protein domains and bound peptide.

transmembrane glycoproteins in complex with a soluble protein, β_2-microglobulin. The three classical class I proteins, HLA-A, HLA-B and HLA-C are expressed on virtually all nucleated cells and also on platelets. HLA class II molecules possess a similar structure to HLA class I molecules and are composed of two MHC-encoded polypeptide chains (α and β). The three HLA class II molecules, HLA-DR, HLA-DQ and HLA-DP, have a restricted tissue distribution; they are mainly expressed on antigen-presenting cells such as B cells, dendritic cells and macrophages, but can be expressed on other cells in the context of inflammation.

Both class I and II HLA molecules share a similar structure of four extra-membranous domains. The two most membrane-distal domains of HLA class I (α1 and α2) and HLA class II (α1 and β1) contain a cleft available for binding of small peptides. Thus, both class I and class II proteins can be considered trimolecular proteins consisting of three subunits: HLA heavy chain, β_2 -microglobulin and peptide form class I molecules, and HLA α-and β-chains and peptide form class II molecules. The binding of peptides is key to the functions of the classical HLA molecules. The source of peptides and the binding procedure differ for the two classes of molecules. HLA class I molecules are assembled within the endoplasmic reticulum (ER), where chaperone proteins mediate the association with β_2 -microglobulin and peptide. Peptides are derived from endogenous molecules (e.g. self or viral proteins) by cytosolic degradation within the proteasome, a multicatalytic protein complex, before being actively transported into the ER. Once the HLA class I trimolecular complex is formed, the molecule leaves the ER and traffics to the cell surface via the Golgi apparatus. The formation of a peptide-bound HLA class II molecule is distinct in several ways. Both α-and β-chains are directed to the ER, where they first associate with the transmembrane invariant chain. The invariant chain blocks binding of ER-resident peptides and instead directs the class II molecule via the Golgi apparatus to endosomal vesicles. Peptides contained in the endosome are derived from the processing of exogenous proteins (e.g. derived from microbes or dead cells). Within the endosome, the invariant chain is cleaved in a series of steps and specific peptide binding is catalysed by HLA-DM before the HLA class II–peptide complex is transported to the cell surface.

T cells and natural killer (NK) cells both possess receptors that recognise and interact with HLA molecules (see also Chapter 4). T cells expressing the CD4 molecule recognise HLA class II molecules and T cells expressing CD8 recognise HLA class I molecules. The specificity of interaction is determined during development of T cells within the thymus, such that circulating T cells should not interact with HLA molecules presenting peptides derived from normally expressed 'self' proteins. However, the presentation of 'non-self' peptides, for example peptides derived from viral or bacterial proteins initiate activation signals mediated by the T-cell receptor and coreceptors, resulting in the generation of an immune response against the cells expressing the target HLA protein–peptide complex. NK cells express a highly diverse repertoire of receptors, including killer-cell immunoglobulin-like receptors (KIRs) that elicit either activation or inhibitory signals. Interaction between an NK cell and a target cell is influenced by the interaction between certain HLA class I molecules on the target cell (e.g. HLA-B and C) and KIRs on the NK cell. Interactions between an HLA class I molecule and a corresponding KIR may result in a negative signal that outweighs any activation signals; thus, the NK cell will not attack the target cell. However, if a cell has lost expression of HLA molecules as a result of malignancy or viral infection, the absence of the inhibitory signal may result in activation signals being dominant and allow NK cell-mediated attack on the target cell.

The outstanding feature of the *HLA* genes is their extensive polymorphism (www.ebi.ac.uk/imgt/hla/). At each of the genes, there are multiple possible variant alleles and the majority of this variation occurs within regions encoding the peptide binding domains. Because different HLA proteins bind peptides with different sequences, one of the functions of *HLA* polymorphism is to allow the presentation of numerous different peptides to the immune system. As there are six antigen-presenting 'classical' HLA molecules (HLA-A, -B, -C, -DR, -DQ, -DP) and most individuals are heterozygous for these loci, potentially each individual has 12 different HLA molecules, each of which can bind thousands of different peptides. Evolution of *HLA* polymorphism occurred as a result of selective pressure imposed by geography, climate and infectious pathogens so that the repertoire of HLA alleles varies between different populations.

Detection of HLA polymorphisms is performed using DNA methods, including PCR with sequence-specific primers or sequence-specific oligonucleotide probes; however, these approaches are being rapidly superseded by high-throughput, low-cost automatic next-generation sequencing technologies.

Each HLA allele is given a unique numerical designation. For example, for the allele *HLA-A* 02:101:01:02N,* the gene name *HLA-A* is followed by an asterisk (*) and then a series of four fields separated by colons (:). The first field indicates the allele group (02), which often corresponds to the broad serological antigen encoded by the allele. The second field (101) indicates the subtype, a number assigned in the order in which the DNA sequences were determined. Alleles whose numbers differ in the first two fields must differ in one or more nucleotide substitutions that change the amino acid sequence of the encoded protein. The third field is used to name alleles that differ only by synonymous nucleotide substitutions (also called silent or non-coding). The fourth field is used to name alleles that differ in either intron or 3′ or 5′ regions of the gene. Lastly, an allele may have a suffix indicating aberrant expression; for example *N* indicates that it is a null allele with no protein being expressed, *L* indicates low cell-surface expression and *S* indicates that the molecule is expressed only in a soluble form.

HLA matching for transplantation

The frequency of T cells capable of reacting against a foreign antigen is of the order of 1 in 10–100,000. However, if cells from two *HLA* disparate individuals are mixed, the frequency of responding (or 'alloreactive') cells can be as high as 1–10%. Excessive alloreactivity occurring after allogeneic SCT can result in graft failure or GVHD. To reduce alloreactivity following allogeneic SCT, it is necessary to define the *HLA* type of donor and recipient. The degree of *HLA* matching informs not only the choice of donor, but also the selection of conditioning protocol and format for GVHD prevention.

In situations where the donor is genetically identical to the recipient (syngeneic transplantation), graft rejection or significant GVHD are not observed. For patients undergoing allogeneic transplantation using an HLA-identical sibling donor, there is still a significant risk of GVHD as a result of polymorphisms outside the HLA system; these generate so-called 'minor' histocompatibility antigens that are presented as processed peptides in the context of 'self' HLA molecules. For any individual donor and recipient pair, there will be several thousand non-synonymous mismatches in coding SNPs, although only a minority will generate peptides that can bind to HLA with high affinity. Although naïve T cells reactive to mismatched minor antigens can induce GVHD, previous exposure to minor antigens may increase this risk. For example, male patients will possess antigens encoded by Y chromosome genes that are absent in females (HY antigens). Female donors, specifically multiparous individuals who have had male infants, may have been primed against HY antigens and as a consequence have circulating memory T cells that recognise male patient cells expressing these proteins. This is likely to underlie the increased risk of GVHD in male recipients of female grafts.

The chances of a sibling being HLA-identical to a patient is theoretically one in four and, taking into account the size of most families, about a third of patients will have an HLA-identical sibling donor. Another source of HLA-matched donors is the various volunteer donor registries (such as the Antony Nolan Registry and the US National Marrow Donor Program) that exist throughout the world and that have accrued over 40 million donors (Karpova *et al.* 2019). The likelihood of finding an optimal donor matched for *HLA-A, HLA-B*, *HLA-C* and *HLA-DRB1* alleles is about 75% amongst whites of European descent, but significantly lower for other ethnic groups. Although single HLA mismatches can be reasonably well tolerated clinically, greater degrees of mismatch are associated with increased rates of graft rejection or GVHD. Certain *HLA* mismatches may be 'permissive' so that they do not result in a worse transplant outcome. For example, a subset of permissive mismatches at *HLA-DPB1* (a locus not usually considered in matching with unrelated donors) may actually be associated with an improved outcome because of a lower risk of disease relapse, although this is not a consistent finding across all studies. Newer transplant strategies (e.g. use of post-transplant cyclophosphamide [PTCy] or abatacept) may permit unrelated donor grafts with even greater degrees of *HLA*-mismatch to be tolerated.

Additional options include *HLA*-mismatched related (usually haplo-identical) or umbilical cord blood donors. Cord blood maybe a useful option because recipients tolerate a greater degree of *HLA* mismatching than is possible with adult grafts, most likely reflecting the reduced alloreactivity of fetal T cells. Cord blood units mismatched for one or two HLA loci are available for the majority (>80%) of adult patients. The main limiting factor is the relative lack of cord blood donations with sufficient numbers of HSCs to ensure engraftment, especially for larger adults. This deficiency could be overcome by using dual cord transplants, where ultimately long-lived haematopoiesis is derived from one of the cord units. Although comparative trial data do not yet suggest an advantage over cord blood, related haplo-identical donors are increasingly used based upon updated GVHD prevention and ease of procurement. *In vivo* purging of alloreactive T cells using PTCy, or alternatively using methods to completely deplete T cells from the graft are both effective at reducing the risk of GVHD. In some situations, a haplo-identical donor may be chosen over a single HLA antigen-mismatched unrelated donor, for example under conditions where the former donor can offer greater protection against CMV infection. Where HLA-mismatched donors are used, it is important to screen recipients for antibodies that react to mismatched donor HLA antigens, as this can be linked to a higher risk of graft rejection. For both cord and haploidentical SCT, there is growing interest in other factors that influence outcomes. For example, the risks of transplantation may also be influenced by the complex interaction between mismatching at HLA class

I and the repertoire of activating or inhibitory *KIR* genes inherited by the donor. Furthermore, there is also evidence that recipients of cord or haploidentical grafts may be less prone to develop GVHD if they possess a haplotype that is absent in the donor, but is shared with the donor's mother; in this scenario, *in utero* exposure to non-inherited maternal antigens (NIMAs) is postulated to induce tolerance of donor T cells.

Acute graft-versus-host disease

Acute GVHD is a complex immunological disorder in which donor T cells initiate tissue damage consequent upon recognition of recipient antigens not expressed in the donor. The recipient is unable to reject the donor T cells because of the immunosuppressive effects of conditioning therapy. Chemotherapy-or radiation-induced tissue damage leads to the release of proinflammatory cytokines and altered chemokine or adhesion molecule expression. These changes impact on the developing alloreactive T-cell response, leading to further cytokine dysregulation and enhanced trafficking of cellular effectors to the organs targeted in GVHD.

Initiation of GVHD (Figure 37.2) requires presentation of host antigens to donor T cells, although there appears to be considerable redundancy in the type of antigen-presenting cells involved. In pre-clinical models, $CD8^+$ T cells and $CD4^+$ T cells differ in terms of whether they require priming by professional antigen-presenting cells; in the latter case, upregulation of HLA Class II in inflamed peripheral tissue cells, for example in the gut, may be sufficient to trigger a response. Conditioning-related tissue injury leads to the release of damage-associated molecular patterns (DAMPs, e.g. uric acid and ATP) or exposure to pathogen-associated molecular patterns (PAMPs, resulting from entry of microbes across damaged epithelia). Recognition of DAMPs or PAMPs by cell-surface or intracellular pattern-recognition receptors induces the release of proinflammatory cytokines, such as interleukin (IL)-1β. Enhanced expression of HLA and costimulatory (e.g. B-7 family) molecules upon host cells promotes their priming capacity. Primed donor T cells rapidly undergo proliferation and develop a multitude of effector functions, including the capacity to generate proinflammatory cytokines (e.g. TNF-α, interferon-γ and IL-17) or the upregulation of cytotoxic machinery (e.g. perforin/granzyme B). The primed effector T cells then traffic in large numbers to epithelial target cells and recruit other cellular effectors such as neutrophils, macrophages and NK cells, which in concert cause further damage.

Epidermal stem cells in the skin and crypt-associated stem cells in the gut are particularly sensitive to immune injury; the consequent loss of epithelial regenerative capacity at these sites exacerbates disease. In parallel, damage to specialised intestinal epithelial cells, for example Paneth cells that produce anti-microbial peptides, can lead to major shifts in the overall composition and diversity of the gut microbiome. In a feed-forward loop, overgrowth of particular pathogenic bacterial species can lead to further loss of epithelial integrity, for example by reducing the concentrations of microbial metabolites that have a gut-protective functions. Other factors such as use of broad-spectrum antibiotics or reduced enteral nutrition may also impact on these processes and increase the risk of gut injury.

Chronic graft-versus-host disease

Chronic GVHD is a disorder associated with continuing host injury, profound immunodeficiency and autoimmunity. One of the key features is fibrosis which is a consequence of maladaptive repair following initial acute tissue injury. For example, in the skin and lung, pro-inflammatory Th17 cells induce recruitment of monocytes that differentiate into pathogenic macrophages producing TGF-β, which in turn drives local myoblast differentiation. Myofibroblasts deposit excess collagen that drives organ dysfunction (e.g. bronchiolitis obliterans, sclerodematous-like skin changes). The thymic stroma is also a target of GVHD; this may lead to reduced naive T cell output as well as impaired negative selection of autoreactive T cells which have the potential to damage peripheral tissues. Damage to lymph node stroma may also impair T-cell homeostasis and disrupt peripheral tolerance mechanisms (e.g. reducing Treg survival or function, or failure to delete autoreactive T cells). These findings may help to explain why individuals with chronic GVHD develop simultaneous features of immunodeficiency (infections) and autoimmunity (e.g. immune cytopenias, sclerodermatous change). Host-reactive $CD4^+$ T cells (e.g. follicular helper T cells) might provide helper functions for B cells leading to the production of allo- or auto-antibodies which may provoke macrophage activation and further reinforce the fibrotic process. Accordingly, some patients with chronic GVHD may respond to anti-B-cell monoclonal antibody therapy or imatinib.

Graft-versus-leukaemia effect

The importance of an immunologically mediated GVL effect in contributing to the curative effect of allogeneic SCT is supported by the observations that T-cell depletion (TCD) increases the risk of relapse and that patients who develop GVHD have a lower risk of disease relapse. Conclusive evidence was provided by the demonstration that infusion of donor lymphocytes can produce durable remissions in patients who have relapsed after allogeneic SCT. It has subsequently been shown that donor lymphocyte infusion (DLI) is a remarkably effective salvage therapy in chronic myeloid leukaemia (CML), with more than 80% of patients achieving a sustained molecular remission. Durable responses can also be achieved in patients transplanted for indolent lymphoma and Hodgkin lymphoma, with responses

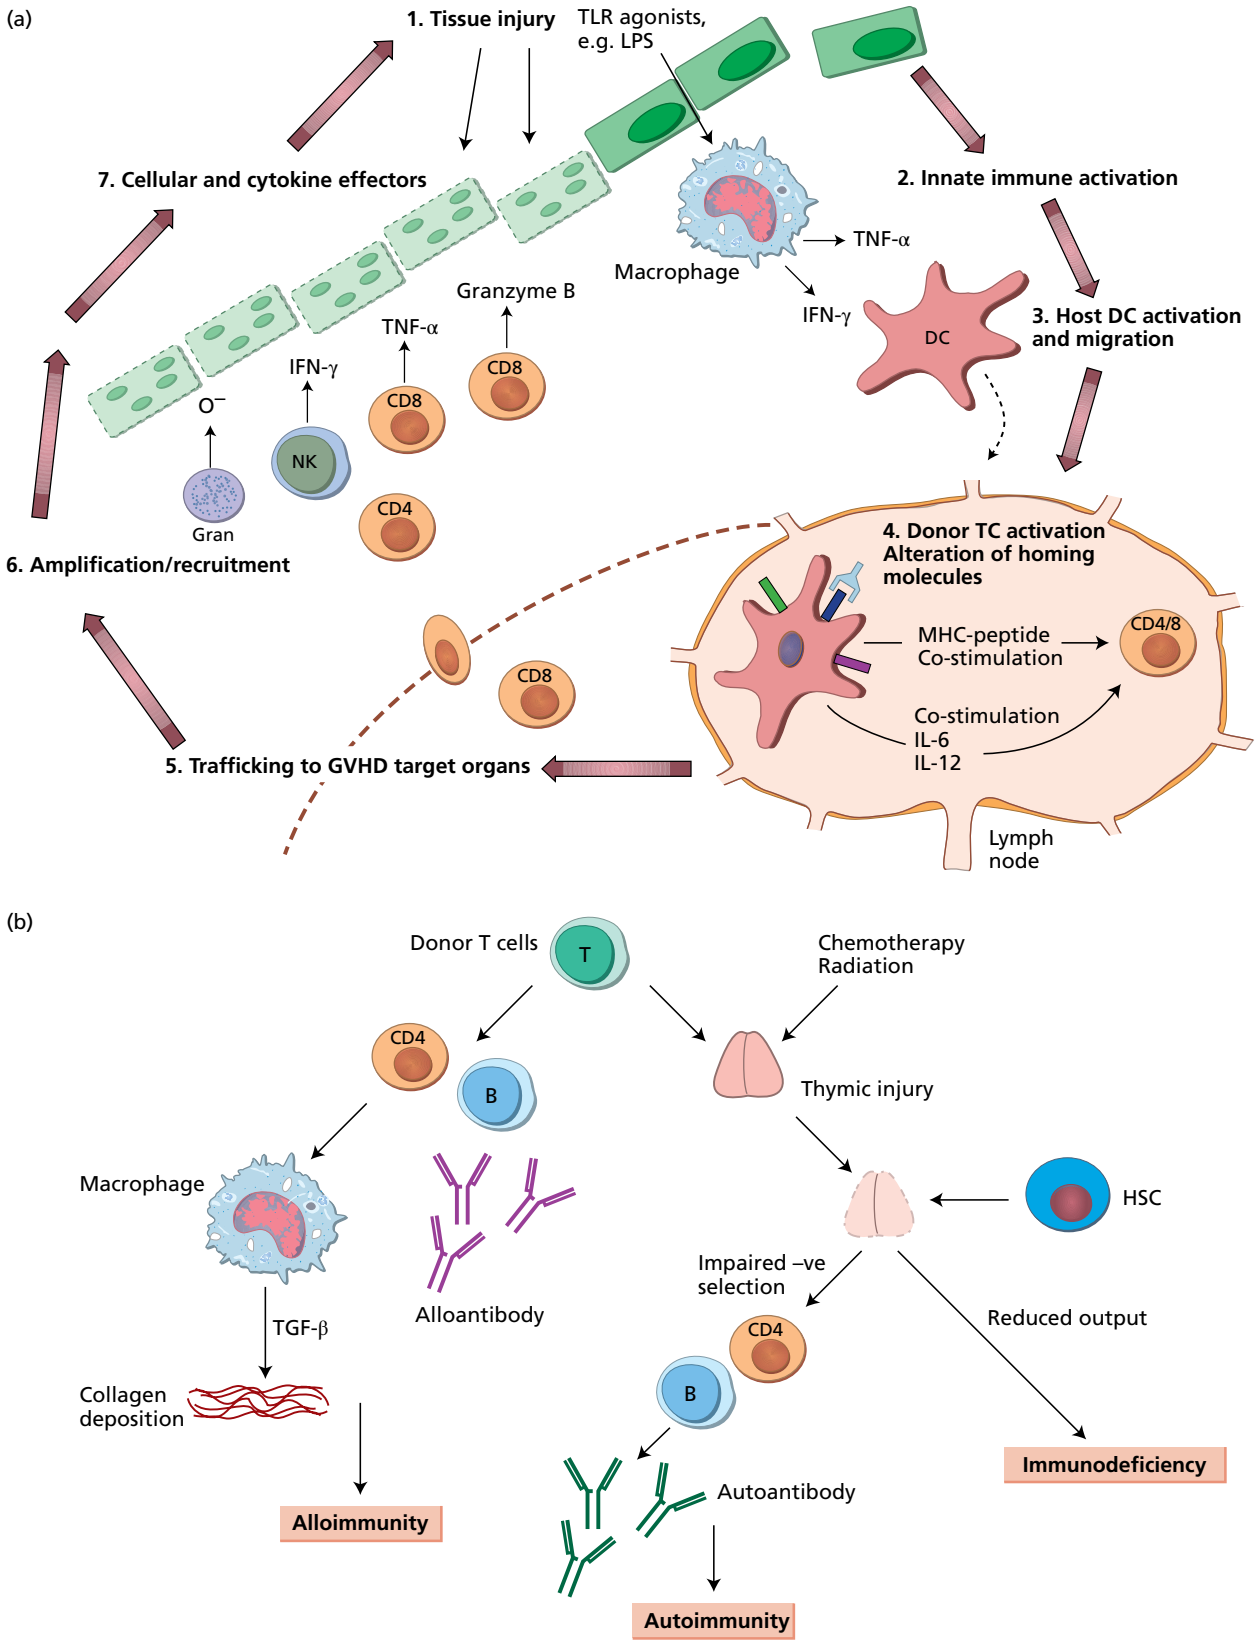

Figure 37.2 Pathophysiology of acute GVHD (a) and chronic GVHD (b). See text for explanation of abbreviations.

being observed less commonly in patients with aggressive lymphoma, myeloma or acute leukaemias. As would be predicted, DLI can be complicated by the development of GVHD, although the risk of this life-threatening complication is reduced if the lymphocytes are infused following a significant delay (>12 months) after transplantation or by using an escalating dose schedule rather than a single 'bulk' infusion. For the most part, the antigens recognised in a GVL reaction overlap with those recognised during GVHD. Clinical separation of GVL and GVHD may reflect increased sensitivity of normal or malignant haemopoietic tissue to an emerging GVH reaction compared with epithelial cells. Selective expression of antigenic targets of a GVH reaction on haemopoietic tissues (e.g. the minor H antigen HA-1, proteinase 3 or WT1) or leukaemic blasts (e.g. the product of the mutated *NPM1* gene in AML) may also underlie the development of a GVL reaction in the absence of GVHD. This concept forms the basis of novel strategies to deliver a GVL effect without a concomitant risk of GVHD, such as peptide vaccination, or gene transfer of T-cell receptors (TCRs) or chimeric antigen receptors (CARs) specific for leukaemic antigens.

Immune reconstitution

Allogeneic SCT is followed by a prolonged period of cellular and humoral immunodeficiency, while donor-derived immune recovery occurs. Reconstitution of an immune response after transplantation can be evaluated in the clinic by monitoring the absolute numbers of T (CD4, CD8), B and NK cells. NK cell numbers recover most rapidly while other subsets (especially $CD4^+$ T cells and B cells) recover more slowly. In patients who have received a TCD graft, T-cell recovery is substantially delayed. Analysis of thymic function after transplantation can be evaluated by measuring the episomal DNA excision circles of the TCR δ locus deleted during recombination of the TCR in functional αβ T cells (known as TREC, for T-cell receptor excision DNA circles). TREC levels are low for the first 6 months following transplantation and recover thereafter. As a consequence, the recovering T-cell repertoire is initially limited and mostly dependent on peripheral expansion of donor memory T cells. Thymic function is reduced in adults and may be further compromised by the effects of chemoradiotherapy and GVHD. Significant HLA mismatching between donor and recipient may also lead to 'holes' within the T-cell repertoire due to perturbations in thymic selection. These defects reflect a failure of donor-derived thymic emigrants to interact with peptides presented in the context of 'foreign' host HLA molecules. Quantitative B-cell deficiency is present in virtually all patients in the first months after transplantation and may persist for a number of years post-transplantation as a consequence of reductions in the number of marrow B-cell precursors, particularly in patients with chronic GVHD. This defect in B-cell production has multifactorial causes, including damage to the bone marrow stroma, the deleterious effect of inflammatory cytokines and the lymphocytic effects of glucocorticoid therapy. The source of stem cells also influences the kinetics of immune reconstitution. Thus, peripheral blood stem cell (PBSC) grafts, which contain higher numbers of haemopoietic progenitors and mature T cells, are associated with more rapid immune reconstitution than bone marrow grafts. Cord blood transplantation may be affected by poor immune reconstitution in adults since the number of haemopoietic progenitors is often limited and the transferred T cells are naive. Thus, patients are at heightened risk of re-activation of cytomegalovirus (CMV) or Epstein–Barr virus (EBV).

Stem cell mobilisation

Biology of stem cell mobilisation

The ability of both cytokines and chemotherapy to mobilise HSC from the bone marrow into the peripheral blood has transformed clinical practice such that mobilised peripheral blood stem cells (PBSC) are now the most widely used stem cell source in both autograft and allograft recipients. The localisation of haemopoietic stem and progenitor cells within the bone marrow cavity is mediated through the binding of a range of adhesion molecules, including CXCR4 and VLA4, with their cognate ligands on bone marrow stroma. Administration of haemopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) disrupts the adhesion of progenitors to the bone marrow stroma, resulting in their mobilisation into the peripheral blood in large numbers. Antagonists to CXCR4, such as plerixafor, significantly augment G-CSF-mediated stem cell mobilisation and this has transformed mobilisation options in candidates for an autologous transplant in whom low levels of stem cell mobilisation can be predicted. Importantly there is also now substantial interest in the development of novel stem cell mobilisation strategies in order to optimise the delivery of genetically manipulated HPC (Karpova *et al.* 2019).

Stem cell mobilisation in clinical practice

In patients undergoing autologous SCT, administration of G-CSF as monotherapy represents the commonest method of stem cell mobilisation although G-CSF in conjunction with salvage chemotherapy remains an important mobilisation strategy in certain patient subgroups. G-CSF can be administered as an outpatient and, in one commonly used schedule, patients receive four daily subcutaneous injections of G-CSF, with stem cell harvesting scheduled for day 5 and 6. G-CSF at a dose of 5–10 μg/kg/day is typically reasonably well tolerated although commonly associated with myalgia, bone pain and headache which are usually easily managed with symptomatic therapy including paracetamol. Splenic rupture has been reported as a very rare

occurrence in patients undergoing G-CSF-stimulated HPC mobilisation and it is wise to advise patients to report any unexpected abdominal or pleuritic pain during the period of G-CSF administration. Using G-CSF-based mobilisation strategies, a minimum target cell dose of 2×10^6 $CD34^+$ cells/kg is achieved in more than 80% of patients. In patients who fail to mobilise the target number of $CD34^+$ cells, the CXCR4 antagonist plerixafor can be successfully combined with G-CSF and this advance now permits mobilisation of the required numbers of PBSC in more than 95% of autograft candidates. Initially used in patients who had previously failed to mobilise in response to G-CSF alone or G-CSF/chemotherapy, plerixafor can now be pre-emptively administered in patients undergoing G-CSF mobilisation who can be predicted to be poor mobilisers on the basis of low numbers of circulating $CD34^+$ cells in the peripheral blood on the first day of leukapheresis (Figure 37.3). In the small minority of eligible patients with relapsed lymphoma who fail to mobilise adequate numbers of PBSCs using combined G-CSF/plerixafor administration, alternative consolidation strategies such as allogeneic transplantation should be considered

G-CSF-mobilised PBSCs also represent the commonest stem cell source in patients undergoing allogeneic SCT. The apparent safety of G-CSF doses in the range routinely used for autologous stem cell mobilisation (10–15 μg/kg for 4–6 days) has resulted in its adoption as the standard approach for stem cell mobilisation in sibling and, increasingly, adult unrelated donors. The options of both PBSC donation and bone marrow harvest, as well as any expressed preference of the transplant centre, are discussed with volunteer unrelated donors. Donors who elect to receive G-CSF also need to be aware of the 2–3% chance that an additional bone marrow harvest will be required if G-CSF fails to mobilise sufficient PBSC. Initial concerns that G-CSF may predispose to the subsequent development of secondary haematological malignancies in normal donors have not been substantiated. The effects of G-CSF on the fetus are not completely understood and all female donors of childbearing age should have a negative pregnancy test prior to its administration.

Choice of stem cell source and dose

Autologous transplantation

In autologous transplant recipients, the use of PBSC as a stem cell source is associated with accelerated neutrophil and platelet engraftment compared with those observed using harvested bone marrow; coupled with their ease of procurement, this means that PBSC are almost universally used of as the stem cell source in autograft recipients. The minimum stem cell dose in autologous transplants is 2×10^6 $CD34^+$ cells/kg. Although increasing the number of $CD34^+$ cells transplanted hastens neutrophil and platelet engraftment, there is little evidence that transplantation of more than 5×10^6 $CD34^+$ cells/kg is beneficial and there remain concerns, largely unsubstantiated, that higher stem cell doses may be associated with an increased risk of tumour contamination. In patients transplanted for myeloma, many centres aim to harvest a minimum of 4×10^6 CD34-positive cells/kg, using G-CSF alone or in combination with plerixafor, in order that sufficient cells are available for the option of a tandem transplant, or second autograft at the time of relapse.

Sibling and unrelated donor transplantation

PBSCs are the most frequently used stem cell source for patients undergoing a sibling allograft and are increasingly used in unrelated donor transplant recipients. Transplantation of PBSCs results in earlier neutrophil and platelet engraftment, which may reduce transplant-related mortality (TRM), particularly in patients with advanced leukaemia. In patients transplanted using a reduced intensity conditioning (RIC) regimen, PBSC are the preferred stem cell source. In patients transplanted using a myeloablative conditioning regimen (MAC), there are randomised

data demonstrating equivalence of survival in patients undergoing transplantation from a matched unrelated donor transplanted using PBSC or bone marrow as the stem cell source. There were no differences in the rates of acute GVHD or disease relapse. Of note, however, while the rates of primary graft failure in patients transplanted using PBSC were lower, more chronic GVHD was reported although whether these observations apply in patients receiving TCD as GVHD prophylaxis is unclear. Despite these observations, and perhaps because of the more widespread adoption of *in vivo* TCD in GVHD prophylaxis, the use of PBSC as the preferred stem cell source in patients transplanted for haematological malignancies continues to increase. Importantly, in patients transplanted for aplastic anaemia, where prevention of chronic GVHD is a key consideration, and in paediatric transplants, bone marrow remains the preferred stem cell source in many centres.

Cell dose is an important factor determining outcome after both matched sibling and unrelated donor transplants, likely consequent on accelerated immune reconstitution in recipients of a higher stem cell dose. The lowest acceptable stem cell dose to secure engraftment in recipients of a PBSC allograft is considered to be 2×10^6 CD34-positive cells/kg (2×10^8 mononuclear cells/kg if bone marrow is being used), although in practice the great majority of patients transplanted with a PBSC graft containing in excess of 1×10^6 CD34-positive cells/kg will still engraft. Since outcome is improved with higher doses of CD34-positive cells, most centres aim for a dose in the region of 4×10^6 CD34-positive cells/kg. In patients transplanted from an HLA-identical sibling using a T-replete myeloablative regimen, there is some evidence that the incidence of chronic GVHD is increased if the stem cell dose exceeds 8×10^6 CD34-positive cells/kg. In this setting, it may therefore be reasonable to have a target dose of $4–8\times10^6$ CD34-positive cells/kg. However, there is no evidence, as yet, that there should be an upper limit on cell dose in patients transplanted using an RIC regimen or if the graft is T-cell depleted.

Haploidentical stem cell transplantation

The last decade has seen a dramatic increase in the number of children and adults transplanted using a haploidentical donor. Historically, the degree of patient-donor HLA disparity associated with the use of a haploidentical donor resulted in prohibitive rates of graft failure and severe GVHD. Initial approaches used stringent *ex vivo* TCD coupled with an intensely immunosuppressive conditioning regimen and transplantation of high 'mega' doses of CD34-positive cells to overcome these barriers. While encouraging results were reported from selected centres, an unacceptably high incidence of viral infections and complex post-transplant morbidities prevented this approach being widely adopted. More recently, two approaches have proved effective at reducing the risk of graft failure and acute GVHD. The administration of PTCy, which results in the *in vivo* depletion or anergy of alloreactive host and donor T cells in patients transplanted using an unmanipulated bone marrow or PBSC results in high rates of neutrophil and platelet engraftment while simultaneously reducing the risk of severe acute and chronic GVHD in recipients of transplants from both mismatched unrelated and haploidentical donor. Although the extent to which PTCy abrogates a GVL effect remains uncertain, particularly in recipients of a RIC regimen, this innovative GVHD prophylaxis strategy has transformed the deliverability of haplo-identical transplants and resulted in a rapid increase in the number of such procedures delivered worldwide (Fuchs *et al*. 2021). Importantly, the PTCy platform also appears a very promising GVHD prophylaxis strategy in recipients of mismatched unrelated donor transplants potentially increasing transplant accessibility for patients from ethnic minorities (Shaw *et al*. 2021). An alternative approach, which yields particularly encouraging results in children, uses *ex vivo* CD3+/CD19+ or alternatively αβ TCD and represents an important alternative approach to haploidentical transplantation, particularly in the paediatric setting.

Cord blood transplantation

UCB remains a valuable stem cell source in paediatric and adult transplantation. Underpinning its importance is the observation that comparable degrees of HLA disparity result in lower rates of severe GVHD after a cord blood transplant than would be expected using a mismatched unrelated donor. This has important implications in terms of increasing donor options in patients with uncommon HLA types for whom a suitably matched unrelated donor cannot be readily identified. A major limitation to the more widespread use of UCB transplantation (UCBT) has been delayed or failed engraftment, which used to be a common problem, particularly in adult recipients. The two most important factors determining the likelihood of neutrophil and platelet engraftment after UCBT are nucleated cell dose and HLA disparity. More recently, it has been shown that transplantation of two UCB units, harvested from separate donors, increases the speed of engraftment and is associated with a decreased risk of primary graft failure. Consequently, results approaching those achievable using a well-matched adult unrelated donor are now routinely observed in patients with high-risk leukaemia after a double UCB transplantation performed using UCB units that meet well-defined cell dose and matching criteria. Immune reconstitution is markedly delayed after UCBT and viral infections (particularly CMV, HHV 6 and adenovirus) contribute to the significant infectious-related TRM although the advent of improved supportive care strategies, notably the use of letermovir (a CMV DNA terminase complex inhibitor) may reduce this risk. The development of novel conditioning regimens, which deliver high rates of durable engraftment, coupled to the modest toxicity UCBT, means that this modality is often the preferred approach in both children and adults,

particularly when performed in transplant centres with sustained expertise in UCBT delivery (Barker *et al.* 2020). Continued progress in the development of *ex vivo* stem cell expansion protocols promises to further increase the number of patients who will benefit from cord blood transplants.

Conditioning regimens: basic principles

The combination of drugs and radiotherapy administered prior to stem cell infusion is termed the 'conditioning' or 'preparative' regimen. In autologous SCT, where there is no alloreactive response, the sole purpose of the conditioning regimen is disease eradication. The most common conditioning regimens used in autologous transplantation use alkylating agents, alone or in combination, and other chemotherapeutic drugs.

In the setting of allogeneic SCT, the conditioning regimen serves two purposes: immunosuppression designed to abrogate an HVG reaction, thereby preventing graft rejection, and dose escalation of chemoradiotherapy in order to de-bulk and potentially eradicate host malignant disease. Total body irradiation (TBI) and high-dose cyclophosphamide have been the most commonly used immunosuppressive modalities in allogeneic transplantation but these are increasingly being either supplanted or complemented by fludarabine and other purine analogues such as clofarabine as outlined below. Of note, the advent of fludarabine-based regimes coupled with the increased use of PBSC as a stem cell source has played an important part in the recent reduction in rates of primary graft failure, particularly in recipients of alternative donor transplants. Historically, conditioning regimens resulted in irreversible myeloablation. Increasing recognition of the potency of the GVL effect, coupled with awareness that the toxicity and attendant TRM of MAC regimens precluded their routine deployment in patients older than 50–55 years led to the development of less intensive conditioning regimens, tolerable in older patients and which rely on a GVL effect as the dominant anti-tumour activity. Associated with a substantially reduced TRM, both non-myeloablative (NMA) (which result in only transient cytopenias) and RIC regimens (which result in significant cytopenias but use dose-reduced chemotherapy schedules) permit allogeneic transplants to be safely performed in patients who would previously been judged ineligible on the grounds of age or comorbidity (Gagelmann and Kroger 2021). The remarkable success of RIC and NMA regimens in reducing early transplant toxicity has resulted in a dramatic increase in the number of allografts performed worldwide and has transformed treatment options for many patients with AML, MDS, ALL and relapsed lymphoma in whom conventional chemotherapy would be unlikely to deliver long-term disease-free survival. Although RIC regimens are associated with a higher rate of disease relapse than would be observed using a MAC regimen, this deficiency is at least partially offset by a marked reduction in early and late TRM. The results of prospective randomised studies comparing outcomes after specific MAC and RIC regimens will be essential in order to assist personalisation of conditioning regimen selection in specific disease settings but are already proving of value in diseases such as AML as outlined below.

Conditioning regimens in autologous SCT

Conditioning regimens in autologous SCT are designed with dose intensification in mind and are limited principally by extramedullary toxicity. High-dose melphalan (200 mg/m^2) is the standard conditioning regimen in myeloma autografts. A randomised comparison between a TBI-containing regimen and high-dose melphalan alone demonstrated that no benefit was associated with the use of TBI. BEAM (carmustine, etoposide, cytarabine, melphalan) is widely used in patients with lymphoma although the BCNU is frequently substituted for lomustine (LEAM) or, in some centres, bendamustine (benda-EAM) albeit the latter demonstrating an increased risk of nephrotoxicity. In patients with relapsed CNS lymphoma, thiotepa-based preparative regimens play an important role. Autologous transplants are indicated in certain patients with AML, principally those with APML in second CR, but sometimes also in patients with AML associated with a CBF abnormality who lack an allogeneic donor, and both busulfan/cyclophosphamide and cyclophosphamide/TBI are effective preparative regimens in this setting. A number of other drug combinations incorporating melphalan, busulfan and thiotepa are used in solid tumours. The major extramedullary toxicities of these regimens are mucositis and gastrointestinal toxicity. Disappointingly, there are few prospective randomised data on which to base the choice of conditioning regimen in autologous SCT.

Myeloablative conditioning regimens in allogeneic SCT

Traditionally, the most widely utilised MAC regimens used in allogeneic SCT employed combinations of cyclophosphamide (Cy) and either TBI or busulfan (Bu). These are now increasingly being supplanted by fludarabine (Flu) based combinations, typically Flu/BU or Flu/Cy.

TBI/cyclophosphamide

The use of high-dose Cy and myeloablative doses of TBI (collectively referred to as Cy/TBI) remains a commonly used MAC regimens in patients allografted for acute lymphoblastic leukaemia (ALL) but is now less commonly employed in patients with AML. Cy is an alkylating agent that, when administered in the doses routinely used in myeloablative conditioning regimens (typically 120 mg/kg), has both immunosuppressive and anti-leukaemic properties. It is a pro-drug that must be metabolised by the cytochrome P450 system in the liver to produce metabolically active derivatives (principally

phosphoramide mustard) which exert their cytotoxic activity through the production of inter-strand DNA links. The two major complications of Cy at the doses employed in allogeneic transplantation are haemorrhagic cystitis and cardiac toxicity. Haemorrhagic cystitis results from the toxic effects of a Cy metabolite, acrolein, on the uroepithelium and can be reduced by use of sodium 2-mercaptoethanesulfonate (MESNA), while cardiac toxicity is rare at doses of cyclophosphamide below 150 mg/kg.

TBI has dual immunosuppressive and anti-leukaemic properties when administered in myeloablative doses (typically 12–14.4 Gy). Radiobiological principles predict that the toxicity of TBI can be reduced by either decreasing the overall dose of radiation or, as is now common, by giving it in fractionated form over a number of days (e.g. 14.4 Gy divided into eight fractions over 4 days). The degree of immunosuppression produced by TBI-containing regimens is related to the total dose of irradiation delivered. The use of higher TBI doses is therefore an effective method of optimising engraftment in myeloablative allografts where there is use of TCD or an alternative donor and consequently an increased risk of graft failure. Haematological malignancies are highly radiosensitive and the risk of disease relapse is reduced if a higher dose of TBI is used, although this benefit is blunted by increased transplant toxicity (see below). Early complications associated with the use of TBI include nausea, vomiting, diarrhoea and parotitis, which can usually be managed symptomatically. Increased doses of TBI are also associated with pneumonitis and veno-occlusive disease (VOD) of the liver, both of which may be life-threatening. Long-term complications include cataract formation, hypothyroidism, infertility and, in children, growth retardation. In patients undergoing a sibling allograft for ALL, etoposide is often substituted for cyclophosphamide and a TBI/etoposide regimen has been reported to be associated with improved outcome.

Busulfan/cyclophosphamide

Busulfan/cyclophosphamide (Bu/Cy) is a well-established MAC regimen which has the practical advantage of not requiring the presence of irradiation facilities on site. Bu is an alkylating agent with potent activity against leukaemic progenitors and is a core component of both allogeneic and some autologous transplant regimens. Historically, Bu has only been available as an oral preparation, used at a dose of 14–16 mg/kg delivered 6-hourly over a period of 4 days. In this formulation, VOD and pulmonary and central nervous system (CNS) toxicity represent major complications. The pharmacokinetics of oral Bu are highly variable because it undergoes first-pass metabolism in the liver and there is therefore substantial interpatient variability in plasma drug levels using a standard dosing schedule. Because the incidence of VOD is closely correlated with higher plasma Bu levels and patients with low Bu levels also have an increased risk of relapse, oral preparations of this drug are far from ideal. The successful development of an intravenous formulation of Bu, characterised by more predictable pharmacokinetics, has substantially improved the tolerability and efficacy of Bu-based MAC (the typical dose of intravenous Bu in MAC regimens is 12.8 mg/kg) and RIC (the typical dose of intravenous Bu in RIC regimens ranges from 6.4 to 9.6 mg/kg) regimens and has largely replaced oral Bu use. It should be remembered that both oral and intravenous Bu preparations require the use of prophylactic anticonvulsants to prevent seizures when used at high dose.

Fludarabine/busulfan and other novel MAC regimens

Flu augments alkylator-induced cell killing *in vitro* and regimens combining Flu are active and well tolerated although often associated with a significant degree of mucositis which often requires opiates for management. Flu in combination with myeloablative doses of Bu (FB4) is now established as an important new MAC regimen. In AML, a randomised comparison of FB4 and BuCy in patients allografted using a matched sibling or unrelated donor demonstrated superiority of outcomes in the FB4 arm with respect to 1-year TRM (reduced from 17 to 8% in the Flu/Bu4 arm) and equivalent overall survival (Rambaldi *et al*. 2015). This has resulted in its widespread adoption by many transplant centres as a preferred MAC regimen in younger fit patients allografted for AML.

Thiotepa is a new alkylating agent which is commonly combined with Bu and Flu in the TBuF regimen as a MAC regimen for patients undergoing a haploidentical transplant. The utility of a TBuF regimen in recipients of allografts from sibling or adult unrelated donors is currently being evaluated in prospective randomised trials. Treosulfan is an additional alkylating agent that shows promise as a component of both MAC and RIC regimens in patients allografted for myeloid disorders and shows particular promise in combination with BU as a novel RIC regimen (Beelen *et al*. 2020).

The increased HLA disparity and high rates of primary graft failure in UCBT make it critical to optimise the immunosuppressive properties of the preparative regimen. In adults undergoing transplantation using a myeloablative regimen, engraftment rates in the region of 90–95% can be achieved by the addition of Flu to a Cy/TBI regimen, providing an adequate stem cell inoculum is used. More recently, highly promising results have been achieved using an 'intermediate intensity' conditioning regimen consisting of Flu, Cy, Thiotepa and 400 cGy TBI (Barker *et al*. 2020).

GVHD prophylaxis strategies in recipients of a MAC allograft

Post-transplant immunosuppression using a calcineurin inhibitor (ciclosporin or tacrolimus) and methotrexate remains a widely used GVHD prophylaxis regimen in patients undergoing

a MAC sibling or unrelated donor transplant. Rates of chronic extensive GVHD using such an approach are in the region of 30 and 66% for recipients of T-replete sibling and unrelated donor transplants, respectively. TCD is an additional, and highly effective method of reducing the risk of both acute and chronic GVHD in patients transplanted using a calcineurin inhibitor-based prophylaxis regimen. TCD in this setting can be achieved either by manipulating the stem cell inoculum *ex vivo* (e.g. by manipulating the graft using immunomagnetic beads to enrich for CD34+ cells or remove T cells) or by the *in vivo* administration of T-cell-depleting antibodies such as anti-thymocyte globulin (ATG) or alemtuzumab (a humanised monoclonal antibody that recognises CD52). Although a highly effective method of GVHD prophylaxis, TCD is associated with an increased risk of relapse and graft failure and delayed immune reconstitution, increasing the risk of post-transplant infections such as CMV and EBV. A number of recent randomised studies, although not all, have confirmed the ability of *in vivo* ATG to reduce the risk of both acute and chronic GVHD without increasing relapse risk in recipients of a matched unrelated donor transplant resulting in its widespread adoption in many European centres. In contrast, there are no compelling randomised data supporting the use of *ex vivo* TCD although a number of centres still use this approach in combination with a markedly intensified TBI-based MAC regimen. PTCy, initially developed in the setting of haploidentical transplantation, has also recently shown promise in patients transplanted using an HLA-matched sibling or unrelated donor. A number of other agents, including abatacept and JAK inhibitors, are under investigation as novel GVHD prophylaxis regimens.

In patients transplanted using a ciclosporin-based GVHD prophylaxis regimen, there is evidence that the intensity of post-transplant immunosuppression is an important predictor of relapse and post-transplant outcome. Great attention should therefore be paid to meticulous monitoring of ciclosporin (and by extension tacrolimus) levels in the post-transplant period and both the degree of post-transplant immunosuppression and its duration patient should be personalised according to an individual patient's predicted risk of relapse. Thus, it may be desirable to avoid the use of TCD in patients with advanced leukaemia in whom the risk of relapse is high. In contrast, patients with a low risk of disease recurrence, such as aplastic anaemia, may benefit from a more intensive GVHD prophylaxis regimen.

Reduced-intensity conditioning regimens in malignant and non-malignant disease

Reduced-intensity regimens which incorporate either Flu or low-dose (200 cGy) TBI as a core immunosuppressive component reliably deliver durable donor stem cell engraftment and are associated with a markedly reduced toxicity profile, particularly in older patients or those with significant comorbidities. The recent demonstration that the risk of relapse after a RIC allograft is both reduced in the presence of chronic GVHD and correlates with the intensity of post-transplant immunosuppression confirms that these transplant platforms also have the capacity to exert a potent GVL effect. However, disease relapse and GVHD remain major causes of morbidity and mortality after RIC allografts and despite a proliferation of differing regimens, there are few randomised data to inform the choice of the optimal RIC regimen.

Low-dose (200 cGy) TBI-based regimens

Pioneering work in a canine model by Storb's group demonstrated that durable engraftment could be achieved with an NMA conditioning regimen that used immunosuppressive doses of TBI (200–450 cGy) in conjunction with post-transplant immunosuppression in the form of ciclosporin and mycophenolate mofetil. Combined administration of Flu and low-dose TBI (200 cGy) reliably achieves high rates of engraftment and full donor chimerism with a substantially reduced TRM, compared with myeloablative preparative regimens in patients with a range of haematologic malignancies up to (and on occasions beyond) the age of 70. The main causes of treatment failure using this regimen include a substantial risk of chronic GVHD and disease relapse, particularly in patients with advanced haematologic malignancies. Up to 66% of patients experience chronic extensive GVHD, the management of which is often very challenging, especially in elderly and more frail patients.

Fludarabine-based RIC regimens

The most commonly used RIC regimens all incorporate an immuosuppressive Flu backbone administered in combination with a range of myelosuppressive drugs including Bu, melphalan, treosulfan and Cy. In common with NMA regimens, RIC regimens deliver long-term disease-free survival in patients with both myeloid and lymphoid malignancies and are associated with markedly reduced immediate transplant toxicity. Commonly used RIC regimens in AML/MDS include Flu in combination with Bu (FB2), melphalan (Flu/Mel) and treosulfan (Flu/Treo). In patients allografted for AML, an early randomised comparison of two of the most widely used NMA/RIC regimens demonstrated equivalent survival in patients transplanted in CR1 using either a FB2 or low-dose TBI regimen (Blaise *et al.* 2013). Of interest, the low-dose TBI regimen was associated with a markedly reduced 100-day transplant-related mortality but this benefit was blunted by an increased risk of disease relapse. Encouraging results have been reported in a randomised trial utilising a Flu/Treo RIC regimen which merit confirmation (Beelen *et al.* 2020). More recently, a UK study demonstrated no benefit of a sequential Flu-amsacrine-cytarabine-Bu regimen compared with FB2

(Craddock *et al*. 2021). On the basis of these data, it is not possible currently to recommend an optimal RIC regimen in older patients with AML. The accelerated delivery of prospective randomised trials, with embedded genomic and MRD assessments which compare specific RIC regimens through trial networks such as the US BMT CTN and UK IMPACT initiatives is important if patient outcomes in this and other transplant settings are to be optimised. Initial RIC regimens utilised a T-replete stem cell inoculum and were associated with a significant risk of severe acute and chronic GVHD. As outlined below *in vivo* TCD using either ATG or alemtuzumab is now a widely incorporated as a highly effective form of GVHD prophylaxis in patients transplanted using a Flu-based RIC regimen.

Conditioning regimens in non-malignant diseases

In non-malignant disorders, such as aplastic anaemia, Cy alone can be used as a conditioning regimen and is sufficiently immunosuppressive to permit engraftment of allogeneic stem cells, provided an adequate stem cell inoculum is transplanted. Addition of Flu is increasingly used in conjunction with Bu coupled with alemtuzumab or ATG in patients with sickle cell disease and thalassaemia.

Strategies for GVHD prophylaxis in RIC regimens

Until recently, two contrasting approaches were used for GVHD prophylaxis in patients undergoing a RIC allograft. The first uses combinations of a calcineurin inhibitor (ciclosporin or tacrolimus) and methotrexate or mycophenolate mofetil (MMF) as the sole form of GVHD in patients transplanted using a T-replete stem cell inoculum. Methotrexate is commonly omitted and replaced by either MMF or sirolimus (an MTOR inhibitor). The alternative approach uses ciclosporin alone in combination with either ATG or alemtuzumab as *in vivo* TCD. Supporters of such a TCD approach argue that the incidence of acute, and particularly chronic, GVHD is otherwise unacceptably high, particularly in older patients transplanted using an unrelated donor. It can also be argued that this strategy generates an effective platform for the subsequent delivery of DLI with less GVHD-related toxicity. They point to the effectiveness of ATG and alemtuzumab in reducing the risk of GVHD while at the same time securing high rates of durable donor engraftment. Those favouring a T-replete strategy highlight the risks of TCD citing a potential abrogation of a GVL effect, which it is argued may increase the risk of relapse, as well as delayed immune reconstitution and an attendant increased risk of viral, particularly CMV, infection. Recently, the BMT CTN 1703 trial has shown that PTCy improves clinical outcomes when compared to a standard T-replete strategy after RIC HLA-matched transplants. PTCy is also now being compared to TCD in prospective randomised controlled trials. The optimal form of GVHD prophylaxis used in an individual patient will depend on a number of factors including stem cell source, the type of RIC regimen used, the underlying disease biology and presence of co-morbidiies.

Clinical management of patients undergoing stem cell transplantation

The use of PBSCs coupled with improved supportive care has decreased the 100-day TRM of autologous transplantation to 1–3% in most centres. The morbidity and mortality of allogeneic SCT have also continued to fall over the last two decades, but although the 100-day TRM after either a RIC or MAC allograft can be as low as 3–6%, the 1-year TRM remains substantially higher and in the region of 15–25%, depending on patient age and comorbidities, donor type, disease status and stem cell source. This progress reflects advances in supportive care and, in patients undergoing an unrelated donor transplant, more accurate tissue typing. Despite these improvements, organ toxicity, acute GVHD and infections consequent on delayed immune reconstitution still represent major causes of morbidity and mortality in the first few months after allogeneic transplantation (Figure 37.4). In addition, chronic GVHD remains an increasing issue for patients and transplant services alike, with the increasing use of mismatched unrelated and cord blood donors. The long-term complications of allogeneic transplantation, which can significantly compromise a patient's quality of life, are also increasingly recognised and have led to the introduction of specific late-effects clinics where multidisciplinary input from transplant physicians, specialist nurses, endocrinologists, gynaecologists, ophthalmologists and psychologists can be provided (Hashmi *et al*. 2018).

Practicalities of stem cell infusion and blood product support

Stem cell products are infused in the same way as other blood products except for the fact that online blood filters should not be used. Stem cell products must not be irradiated. They may either be infused once collected or, in the case of cryopreserved products, be infused immediately after being unfrozen, at the patient's bedside. The most common side-effect of the cryopreservative (dimethyl sulfoxide, DMSO) is nausea, but since it is excreted by the lungs, a garlic-like odour is also observed for 2–3 days after stem cell infusion. Damage to red blood cells releases free haemoglobin, which can precipitate acute renal failure, and thus patients should be adequately hydrated prior to stem cell infusion and for the following hours. In all patients, urine output must be monitored closely.

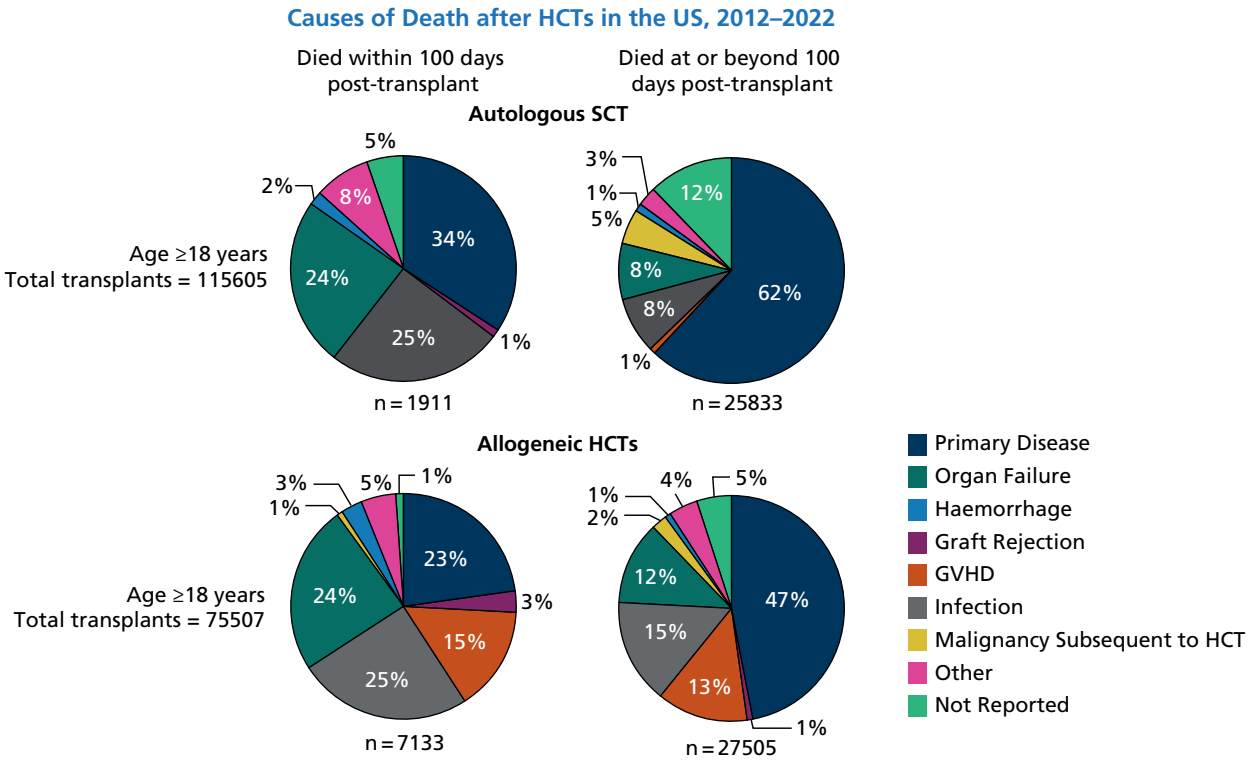

Figure 37.4 Causes of death after stem cell transplantation in (a) autologous and unrelated donor transplants in 2018 (Source: Courtesy of the International Bone Marrow Transplant Registry.)

Patients will require red cell and platelet support during the immediate post-transplant period. In allograft recipients, particularly UCBT and patients receiving myelotoxic drugs such as ganciclovir, platelet transfusion may be required for a number of months after transplantation. All cellular blood products should be irradiated (25 Gy) prior to administration in order to prevent transfusion-related GVHD (see Chapter 19). This should be commenced 6 weeks prior to transplant (and 7 days prior to stem cell collection in the case of autologous transplantation) and is continued for 3 months after an autologous transplant (or 6 months if TBI was used) or indefinitely for allogeneic transplants. In patients undergoing allogeneic SCT where there is a major ABO incompatibility between donor and recipient (e.g. a group O recipient receiving group A bone marrow), the a bone marrow graft must be depleted of red cells prior to administration. When PBSCs are being transplanted, red blood cells are usually effectively depleted during leukapheresis, although on occasions the stem cell product may need to be administered over two days. Measurement of anti-A or anti-B titres, as appropriate, is mandated in all patients undergoing an allogeneic transplant associated with a major ABO incompatibility. The subsequent choice of blood group for platelets or red cells depends on the precise nature of the ABO incompatibility, the time from transplant and the results of blood grouping. For example, if the donor is group A and the recipient is group B, red cells with blood group O would be used until the patient began to type as blood group A, whereas group AB platelets (lacking anti-A and anti-B) would be infused. Delayed erythroid engraftment or haemolysis caused by continuing synthesis of isohaemagglutinins by host lymphocytes may occur several weeks after stem cell infusion and is associated with the presence of a positive direct antiglobulin test and anti-donor red cell antibodies in serum or red cell eluates.

Early complications of allogeneic stem cell transplantation (days 0–90)

Graft failure

Although there are no agreed definitions, primary graft failure will be the most likely cause in the event a patient fails to achieve a neutrophil recovery within 4 weeks of transplant. Risk factors include transplantation of a low CD34+ cell or bone marrow mononuclear cell dose, increased donor–host HLA disparity, the presence of anti-donor HLA antibodies and the deployment of TCD, particularly using *ex vivo* depletion technologies. The mortality of primary graft failure is in excess of 50% and it should be suspected in any who fail to demonstrate evidence of neutrophil engraftment by day +21. Use of PTCy may delay engraftment compared to other protocols and this needs to be considered when deciding on intervention.

The key investigations include an urgent bone marrow aspirate and trephine and chimerism studies. Graft rejection is likely in patients with no morphological evidence of engraftment or leukaemia (as demonstrated by a good-quality trephine biopsy) and an absence of donor chimerism; these patients require a second transplant from an alternative donor, preferably using G-CSF-mobilised PBSC, after administration of a second conditioning regimen incorporating fludarabine with or without low-dose TBI designed to maximise host immunosuppression. When donor cells are identified by chimerism studies, this will imply poor graft function without rejection. Under these circumstances, rescue of graft function can be achieved by a CD34-selected stem cell infusion without any additional conditioning.

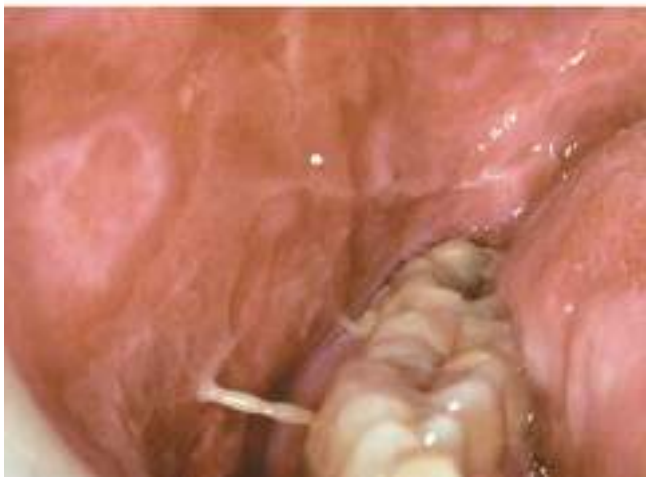
Secondary graft failure leads to one or more cytopenias after initial donor engraftment in the absence of disease relapse. It is rare in sibling allografts and occurs predominantly in recipients of mismatched (including haplo-identical) or unrelated donor transplants. The aetiology of secondary graft failure is often complex, but causes that need to be considered include late graft rejection (rare), major ABO incompatibility, drugs (particularly ganciclovir and, on rare occasions, cotrimoxazole), viral infection (CMV, HHV-6 and parvovirus B19) and, rarely, hypersplenism. Secondary graft failure is associated with significant mortality related to infection and must be investigated urgently with a bone marrow aspirate and trephine, urgent chimerism studies and virological assessment to exclude parvovirus B19 or human herpesvirus (HHV)-6 infection. In patients with a hypocellular marrow and evidence of donor cells on chimerism, a second infusion of CD34-positive selected PBSC can be used and leads to responses in about 2 in 3 patients. Additional measures could include use of growth factors or thrombopoietin mimetics. For single red cell or platelet cytopenias, the possibility of immune haemolytic anaemia or immune thrombocytopenia should also be considered.

Acute graft-versus-host disease

Acute pattern GVHD usually occurs within the first 3 months following transplant, often at or near the time of engraftment, and is characterised by the presence of rash, diarrhoea or (less commonly) abnormal liver function tests. Depending on the conditioning regimen and GVHD prophylaxis employed, between 20 and 70% of patients will develop this disorder. Acute pattern GVHD occurring after 3 months, with no features of chronic GVHD, is also increasingly recognised in patients receiving RIC transplants, often following withdrawal of immunosuppression. Risk factors for the development of acute GVHD include increased recipient age, unrelated or HLA-mismatched donor transplantation and the use of a female donor. Children have a lower risk of acute GVHD and recipients of UCBT may have a lower incidence of GVHD compared with adult bone marrow transplantation with similar degrees of HLA disparity.

Skin GVHD typically presents as a maculopapular rash involving the face, neck, palms and soles, but may extend to involve the whole body (Figure 37.5). In the worst cases, it progresses to erythroderma, with bullae formation and painful blistering. Histology shows apoptosis at the base of dermal crypts, dyskeratosis and evidence of lymphocytes in a perivascular distribution or adjacent to dyskeratotic keratinocytes. Gastrointestinal involvement presents

(a)



(b)

Figure 37.5 Acute skin GVHD: (a) acute cutaneous GVHD; (b) chronic oral GVHD.

with nausea, vomiting, secretory diarrhoea and/or abdominal pain. In more advanced forms, severe abdominal pain and distension associated with voluminous, occasionally bloody, diarrhoea may occur. Gastric, antral and rectal biopsies have a high diagnostic yield, with diagnostic features including the presence of apoptotic cells in the base of crypts and a lymphocytic infiltrate. A well-defined manifestation of upper gut GVHD is the development of anorexia and nausea, both of which usually resolve rapidly if treated with lower dose methylprednisolone (0.5–1 mg/kg). A rising bilirubin and raised alkaline phosphatase are the initial features of liver GVHD, which typically develops later than skin or gut GVHD. Liver histology is diagnostic and demonstrates a portal tract lymphocytic infiltration, peri-cholangitis and bile duct loss.

Accurate and early diagnosis of acute GVHD is essential for effective management of this potentially life-threatening disorder. Where possible, diagnostic biopsies should be taken to both confirm the presence of intestinal or liver GVHD and assist in the exclusion of other aetiologies. It is also important to stage GVHD accurately and the revised criteria devised by the Mount Sinai Acute GVHD International Consortium are widely recommended (Table 37.1). This staging system is a reliable indicator of prognosis and guides the intensity of treatment required. To aid assessment and standardisation, acute GvHD scores can be calculated using an eGvHD App (www.uzleuven.be/egvhd). It is possible that peripheral blood biomarkers of tissue injury (e.g. ST2 or Reg3a) will be used in the future to determine prognosis and guide treatment. Grade 2–4 acute GVHD should be treated with high-dose methylprednisolone (typically 2 mg/kg daily), which is tapered according to response. In the setting of limited skin GVHD and upper gut GVHD, topical or oral steroids (e.g. prednisolone 0.5–1 mg/kg) coupled with optimisation of ciclosporin levels may be sufficient to control symptoms. Approximately 70% of patients will improve significantly with oral or intravenous corticosteroid therapy, but a number will either fail to respond or relapse when immunosuppression is tapered. Failure to respond to 5–7 days of intravenous corticosteroid therapy or failure to taper dosing without disease progression defines steroid-resistant and steroid-dependent acute GVHD, and these patients require the use of second-line therapy. The current standard of care for second-line therapy is the JAK1/2 inhibitor, Ruxolitinib, which is superior to other approaches. Dosing is lower than used for myelofibrosis (10 mg bd), but lower doses may be required in patients with co-existent cytopenias or end-organ dysfunction. Even with the use of ruxolitinib, steroid-refractory acute GVHD has a poor prognosis, with a high non-relapse mortality, which is consequent predominantly on infectious complications. Currently, robust evidence supporting efficacy of third-line

Table 37.1 Acute GVHD scoring – MAGIC criteria (a) clinical staging; (b) clinical grading.

Stage	Skin (active erythema only)	Liver (bilirubin)	Upper GI	Lower GI (stool output/day)
0	No active (erythematous) GVHD rash	<34 micromol/L (or <2 mg/dL)	No or intermittent nausea or vomiting or anorexia	<500 mL/day or <3 episodes/day
1	Maculopapular rash <25% of body surface area (BSA)	34–50 micromol/L (or 2–3 mg/dL)	Persistent nausea or vomiting or anorexia	500–999 mL/day or 3–4 episodes/day
2	Maculopapular rash 25–50% of BSA	51–102 micromol/L (or 3.1–6 mg/dL)		1000–1500 mL/day or 5–7 episodes/day
3	Maculopapular rash >50% of BSA	103–255 micromol/L (or 6.1–15 mg/dL)		>1500 mL/day or >7 episodes/day
4	Generalised erythroderma (>50% BSA) plus bullous formation and desquamation >5% BSA	>255 micromol/L (or >15 mg/dL)		Severe abdominal pain with or without ileus, or grossly bloody stool (regardless of stool volume).

Overall clinical grade (based upon most severe target organ involvement)
Grade 0: No stage 1–4 of any organ
Grade I: Stage 1–2 skin without liver, upper GI or lower GI involvement
Grade II: Stage 3 rash and/or stage 1 liver and/or stage 1 upper GI and/or stage 1 lower GI
Grade III: Stage 2–3 liver and/or stage 2–3 lower GI, with stage 0–3 skin and/or stage 0–1 upper GI
Grade IV: Stage 4 skin, liver or lower GI involvement, with stage 0–1 upper GI

treatments is lacking and wherever possible, such patients should be offered clinical trials. Patients with acute severe GVHD often require intensive supportive measures, including replacement of gastrointestinal losses, parenteral nutrition, pain control and infectious prophylaxis. Maintenance of enteral nutrition should be maintained wherever possible to prevent gut dysbiosis that has the potential to worsen intestinal GVHD.

Infectious complications

Bacterial, fungal, protozoal and viral infections are a major cause of morbidity and mortality after allogeneic transplantation (see also Chapter 55). Host factors include neutropenia, post-transplant immunosuppression and acute or chronic GVHD requiring steroid therapy. Numerous additional factors contribute to delayed immune reconstitution after an allograft and include thymic atrophy in adults, the use of TCD and a suboptimal stem cell inoculum. Infectious complications are a particular challenge after UCBT. The temporal pattern of infectious complications after allogeneic SCT is shown in Figure 37.6. In contrast, autologous transplantation is associated with significantly fewer infective episodes which are predominantly confined to neutropenia-related bacterial and fungal infections in the immediate post-transplant period.

Considerable progress has been made in the prevention and treatment of infectious complications after allogeneic SCT. All patients should be nursed in single rooms, preferably with laminar airflow or high-efficiency particulate air filtration. Data from prospective randomised trials supports the use of triazole antifungals, such as fluconazole 100–400 mg daily, as an effective means of reducing *Candida* infection. Aciclovir (200–400 mg up to 4 times daily) is usually administered to prevent herpes simplex virus (HSV) re-activation. Quinolone antibiotics (e.g. ciprofloxacin 500 mg twice daily) are used by some units to reduce the risk of severe Gram-negative infections, although the evidence supporting this measure is inconclusive and practice should be guided by advice from local microbiologists concerning the prevalence and sensitivity of drug-resistant organisms. Patients should promptly receive cotrimoxazole (e.g. 480 mg twice daily 3 times per week) prophylaxis at the time of neutrophil engraftment (neutrophils $>1.0\times10^9$/L) to prevent *Pneumocystis jirovecii* infection. Importantly, cotrimoxazole also provides effective prophylaxis against infection with Toxoplasma gondii. If a patient demonstrates a convincing allergy to cotrimoxazole, dapsone or atovaquone may be considered as substitutes for cotrimoxazole. Cotrimoxazole is typically discontinued once patients have completed immunosuppression and reconstituted a lymphocyte count of >1.0 × 109/L. It is also important to remember to restart cotrimoxazole prophylaxis in allograft patients in whom immunosuppressive therapy is restarted.

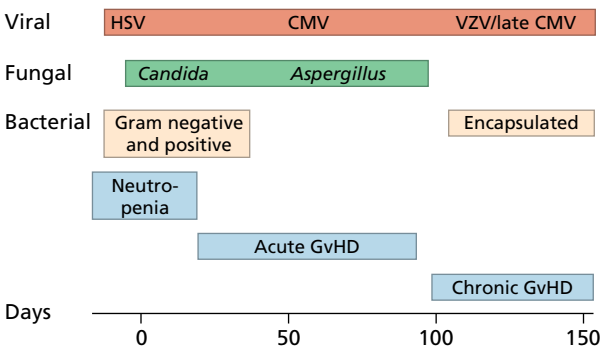


Figure 37.6 Temporal pattern of infectious complications after allogeneic stem cell transplantation.

Allogeneic transplants, particularly recipients of TBI-containing regimens, continue to be at long-term risk from infections caused by encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* and require lifelong prophylaxis with penicillin (250 mg twice daily) or erythromycin (250 mg twice daily) if allergic to penicillin. Antibody titres to diseases for which childhood vaccination is performed decline after SCT. Re-vaccination to bacterial organisms which are targeted by childhood immunisations is therefore recommended, particularly in allograft recipients, and most centres commence such a programme 6–12 months after transplantation.

Herpesvirus infection: CMV, HSV, varicella zoster and HHV-6

Human CMV is a ubiquitous herpesvirus present in up to 60% of the general population, which re-activates after allogeneic SCT in seropositive recipients or those transplanted from a seropositive donor, giving rise to either asymptomatic infection or, less commonly, end-organ damage (CMV disease). Patients at the highest risk of CMV re-activation are seropositive recipients, especially those who have a seronegative donor, or who receive TCD or unrelated donor grafts, and patients who develop GVHD requiring steroid therapy. Previous studies from the EBMT have demonstrated improved transplant outcome in CMV-positive recipients transplanted from a CMV-positive donor, and CMV status remains an important consideration in the choice of an optimal volunteer unrelated donor. In the absence of effective pharmacological prophylaxis, such as can now be provided by letermovir, CMV re-activation occurs in 40–80% of at-risk patients and can result in end-organ damage, typically CMV pneumonitis, but also less commonly upper gastrointestinal ulceration or colitis, hepatitis and retinitis. All at-risk patients should receive weekly monitoring for evidence of CMV infection using a polymerase chain reaction (PCR)-based detection strategy. Until recently, pre-emptive therapy with intravenous ganciclovir, a nucleoside analogue that inhibits viral thymidine kinase, or its oral prodrug valganciclovir was the routine approach to management of asymptomatic CMV infection. While these approaches are effective in reducing the risk of early CMV disease, late CMV infection (beyond 100 days post-transplant)

remains a significant problem, and the use of both ganciclovir and valganciclovir (especially in the immediate post-transplant period) is associated with significant neutropenia and thrombocytopenia. The recent randomised controlled trial demonstrating that prophylactic letermovir, a CMV terminase complex inhibitor, substantially reduces the risk of CMV infection post-transplant and is well tolerated, has transformed prophylactic strategies in patients at risk of CMV infection after an allogeneic stem cell transplant (Marty *et al.* 2017). Letermovir prophylaxis, typically from the time of engraftment to 100 days post-transplant is now routine in at-risk patients, although it is still important to screen such patients for CMV infection until day +100 post-transplant. Late CMV infection after cessation of letermovir may also occur, particularly in patients receiving immunosuppressive therapy for chronic GVHD and prolonged lymphopenia. Primary infection of seronegative patients may occur as a result of the infusion of stem cell or blood products from a CMV-positive donor but is rare. For this reason, seronegative transplant recipients should receive CMV-negative or leucodepleted blood products to limit the possibility of primary infection.

The incidence of CMV pneumonitis after allogeneic transplantation has very substantially reduced since the advent of effective screening and letermovir prophylaxis but remains an important component of the differential diagnosis in patients with post-transplant pneumonitis. It occurs in patients with evidence of CMV reactivation within the first 100 days after transplantation and typically presents with dyspnoea, hypoxaemia and pulmonary infiltrates. Ganciclovir and foscarnet are often ineffective in patients with established CMV pneumonitis. However, recent studies have demonstrated significant activity of cidofovir, which is now considered in some units to be first-line treatment in all patients with CMV pneumonitis. Cidofovir is nephrotoxic but can usually be safely administered if attention is paid to adequate hydration and other nephrotoxic drugs, particularly foscarnet, are discontinued. The role of high-titre CMV immunoglobulin in the treatment of CMV pneumonitis remains unclear, although it is still widely used.

Other members of the herpesvirus family have the potential to cause significant morbidity after allogeneic SCT. The incidence of HSV, which used to be very common in the first 30 days after SCT, has been very substantially reduced by the use of prophylactic aciclovir. Re-activation of varicella zoster virus (VZV) occurs in up to 50% of at-risk patients after allogeneic SCT and typically presents as shingles with severe pain and a dermatomal vesicular eruption. Less commonly, VZV re-activation presents with atypical pain (headache or undiagnosed abdominal pain) in the absence of a rash. The risk of shingles in allograft recipients is substantially reduced by the use of prophylactic acyclovir (e.g. 400 mg b.d) which is typically continued until after patients have received inactivated VZV vaccine (Shingrix) in the post-transplant period. Prompt treatment of shingles or atypical VZV re-activation with high-dose intravenous aciclovir is essential after allogeneic SCT both to reduce the risk of dissemination but also to reduce the severity of post-herpetic neuralgia. HHV-6 is also increasingly being reported in patients receiving TCD allografts or cord blood transplant and typically presents with features of an encephalitis, classically with a psychiatric component including hallucinations, and or hepatitis.

Fungal infections

Fungal infections remain an important complication after both autologous and allogeneic SCT. A high index of clinical suspicion is therefore required in transplant patients, particularly allografts, and most units administer systemic antifungal therapy early in the management of neutropenic fever. Risk factors for the development of fungal infection include prolonged neutropenia after SCT, the use of high-dose corticosteroids for treatment of GVHD and a history of prior fungal infection.

Effective strategies exist for the prophylaxis and treatment of infection with yeasts (*Candida* spp.) and increasingly moulds such as *Aspergillus* spp. *Candida* infections typical manifest as oral thrush and less commonly as oesophageal candidiasis. Hepatosplenic candidiasis is seen occasionally, presenting with high spiking fevers at the time of engraftment in association with abnormal liver function tests. Ultrasound or computed tomography (CT) of the liver and spleen will confirm the diagnosis. Prophylactic use of fluconazole (100–400 mg daily) has proved effective in reducing the incidence of both superficial and invasive candidiasis. Patients who develop either hepatosplenic candidiasis or candidaemia should be treated with systemic antifungals, usually liposomal amphotericin or an echinocandin such as caspofungin. All indwelling catheters must be removed. Emergence of fluconazole-resistant *Candida* species such as *Candida kruseii* or *Candida glabrata* is of concern, and sensitivity data must be requested in any patient with *Candida* infection.

Aspergillus infections usually present prior to or shortly after engraftment. The most common manifestation is as invasive pulmonary aspergillosis (IPA), which typically presents with an antibiotic-resistant fever, a significantly raised C-reactive protein, and abnormal chest radiography or high-resolution CT, often in the absence of respiratory symptoms. Rarely invasive *Aspergillus* infections can present with cerebral or hepatic disease. Accurate diagnosis of *Aspergillus* infections remains problematic since spores are only rarely cultured from lavage fluid or infected tissues and the sensitivity and specificity of other currently available diagnostic techniques is low. Galactomannan detection assays and aspergillus PCR are of value in supporting a diagnosis of *Aspergillus* infection in patients with typical clinical features but all too often results of these sophisticated diagnostic assays are not available in a timely manner and therapeutic decision-making is based on clinical and radiographic features. Operationally, the most

helpful test in deciding whether IPA is a clinical possibility is high-resolution CT of the chest, which should be obtained in all patients with a neutropenic fever that has persisted for more than 72 hours. While the characteristic radiographic features of peripheral nodular shadows, with or without evidence of cavitation or a 'halo' sign, may take weeks to develop, the presence of any significant pulmonary infiltrate substantially increases the likelihood of *Aspergillus* infection and is an indication for the consideration of treatment doses of liposomal amphotericin or a broad-spectrum azole, usually voriconazole. Importantly, the likelihood of IPA in a patient with a normal chest on high-resolution CT is low. Improved antifungal prophylaxis and treatment now make it possible to contemplate allogeneic transplantation in patients with a previous proven or suspected invasive fungal infection. Risk factors for recrudescence of fungal disease in this setting include a short period (<6 weeks) of antifungal treatment prior to transplant, the use of bone marrow or UCB as opposed to PBSCs, occurrence of >grade 2 acute GVHD, and CMV re-activation. Azoles, typically voriconazole, posaconazole and isovuconazole and liposomal Amphotericin B preparations remain mainstays of treatment of probable or proven *Aspergillus* infections post-transplant. While prophylactic strategies in patients undergoing allogeneic transplantation differ, there is good evidence that posaconzole prophylaxis reduces the risk of invasive fungal infections in patients receiving steroid therapy for severe GVHD disease.

Organ toxicity

Gastrointestinal toxicity

Mucositis is frequently observed in patients transplanted using a MAC regimen but is less common in patients transplanted using a RIC regimen. Symptoms of oral pain and pain on swallowing typically develop in the first few days after stem cell infusion and peak approximately 8 days post-transplant. The severity of mucositis is closely correlated with the intensity of the conditioning regimen, the use of higher doses of fractionated TBI and the inclusion of methotrexate as a component of the GVHD prophylaxis regimen. Patients with severe mucositis should receive adequate (often opiate) analgesia and be monitored for evidence of airway obstruction. In patients who develop symptoms of severe oesophagitis, the possibility of superadded infection with *Candida albicans* or HSV must be considered, the latter typically being associated with intractable vomiting.

Diarrhoea and/or abdominal pain are common manifestations of conditioning toxicity. Alternative causes of diarrhoea in the first 4 weeks after transplantation include enteritis due to *Clostridium difficile*, adenovirus, rotavirus, norovirus or CMV infection, acute GVHD and pancreatitis. VZV re-activation can occasionally present with severe abdominal pain, often in association with markedly deranged liver function tests sometimes days in advance of, or even in the absence of, the development of classic vesicles. It is particularly important to exclude a diagnosis of lower gut GVHD in patients who develop diarrhoea within the first 100 days post-transplant. While exclusion of infectious causes, particularly *Clostridium difficile* infection, is extremely important it is sometimes necessary to admit patients so that intravenous methylprednisolone (2 mg/kg) can be started and a sigmoidoscopy and diagnostic biopsy obtained after a short period of observation before the results of stool cultures are available.

Liver toxicity

Abnormalities in liver function tests are commonly observed after allogeneic SCT and causes include VOD, drugs, infectious complications, cholelithiasis, acute GVHD and transfusional iron overload (Table 37.2). VOD is a clinical syndrome characterised by a triad of hyperbilirubinaemia (bilirubin >34 μmol/L), weight gain (>5% over baseline) and painful hepatomegaly. It is associated with evidence of damage to sinusoidal endothelial cells and hepatocytes and subsequent damage to the central veins in zone 3 of the hepatic acinus. In severe cases, hepatic venular occlusion and widespread zonal disruption may lead to portal hypertension, hepatorenal syndrome, multiorgan failure and death. Risk factors for the development of VOD include the use of conditioning regimens containing Bu or higher doses of TBI, pretransplant abnormalities of liver function tests, previous abdominal irradiation and recent exposure to the anti-CD33 and anti-CD22 monoclonal antibodies gemtuzumab ozogamicin (Mylotarg) and inotuzumab ozogamicin respectively. A diagnosis of VOD is most commonly made on clinical criteria. Hepatic Doppler studies demonstrating evidence of reversal of portal flow support the diagnosis. Definitive diagnosis requires trans-jugular venous liver biopsy, which has significant morbidity in the early post-transplant period and is

Table 37.2 Causes of abnormal liver function tests after allogeneic SCT.

Precipitant	Clinical presentation
Veno-occlusive disease	Hyperbilirubinaemia associated with weight gain, ascites and painful hepatomegaly
Drugs	Ciclosporin (hyperbilirubinaemia), azole antifungals (raised AST/ALT)
Haemolysis	Fall in Hb associated with unconjugated hyperbilirubinaemia and positive Coombs test
Biliary obstruction	Dilated biliary tree associated with gallbladder 'sludge' or cholelithiasis
Infection	Viral hepatitis, fungal infection (disseminated aspergillosis or candidiasis), cholangitis lenta (progressive development of obstructive picture occurring days after an episode of sepsis)

therefore often avoided. It is important to exclude other causes of hyperbilirubinaemia, particularly ciclosporin toxicity (which can present with a very similar clinical picture), haemolysis (typically consequent on donor–recipient ABO mismatch or transplantation-associated microangiopathic haemolytic anaemia) and the hepatitis of sepsis (cholangitis lenta). Defibrotide (25 mg/kg/day in 4 divided doses) should be commenced in conjunction with meticulous fluid balance, judicious use of diuretics and, where necessary, haemofiltration, in patients with a likely diagnosis of VOD. Because of the clinical similarities between VOD and ciclosporin toxicity, it is wise to discontinue ciclosporin for at least 48 hours in any patient in whom a diagnosis of VOD is suspected and it is surprising how often hyperbilrubinemia responds to this simple manoeuver.

Renal toxicity

The importance of the daily monitoring of weight, fluid balance and renal function in the effective management of patients after SCT cannot be overestimated. Impairment of renal function is frequently observed after allogeneic SCT unless careful attention is paid to fluid balance and the nephrotoxic potential of drugs commonly used during SCT, especially ciclosporin, amphotericin, aminoglycosides and loop diuretics. Ciclosporin-related renal toxicity is usually easily reversible by temporary omission and dose reduction. Occasionally, ciclosporin toxicity manifests itself as a microangiopathic haemolytic anaemia (MAHA), with features of thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome. Withdrawal of the drug is mandatory. There is no convincing evidence that plasmapheresis is beneficial. Introduction of an alternative immunosuppressive regimen (typically mycophenolate mofetil) in conjunction with oral corticosteroid is required in patients who develop ciclosporin-induced MAHA.

Pulmonary infections and non-infectious complications

A range of pulmonary infections occur after allogeneic SCT. In the first month after transplantation, bacterial and fungal pneumonias are common. CMV, respiratory syncytial virus, influenza and parainfluenza are important causes of pneumonitis and typically occur in the first 90 days after transplantation. *Pneumocystis* pneumonia and *Toxoplasma* infection are still seen occasionally in the first few months after transplantation in patients who do not receive, or who are not compliant with, cotrimoxazole prophylaxis.

Non-infectious pulmonary complications occurring after allogeneic transplantation can be reversible, but demand prompt diagnosis if treatment is to be effective. Pulmonary oedema consequent on either increased capillary hydrostatic pressure caused by fluid overload or increased capillary permeability due to irradiation or sepsis is frequently seen in the post-transplant period. Idiopathic pneumonia syndrome, defined as diffuse lung injury occurring after SCT for which no infectious or non-infectious aetiology can be identified, typically occurs 30–50 days after transplantation. The classic presentation includes dyspnoea, non-productive cough, hypoxaemia and non-lobar infiltrates on chest radiography and can progress rapidly to acute respiratory distress syndrome. Treatment is supportive but frequently unsatisfactory, and steroids have little effect on outcome. Diffuse alveolar haemorrhage is seen predominantly in patients undergoing autologous SCT, but can also be seen in allogeneic recipients. This complication usually occurs within the first 2–3 weeks of transplantation and presents with dyspnoea, non-productive cough and hypoxaemia. Radiographic changes include interstitial or alveolar shadowing. Definitive diagnosis requires bronchoscopy, which shows fresh blood on repeated lavage. Early recognition of this disorder is essential since early intervention with high-dose steroids may significantly improve survival.

Post-transplant lymphoproliferative disease

Post-transplant lymphoproliferative disease (PTLD) includes a spectrum of EBV-driven B-cell hyperproliferative states that range from polyclonal benign proliferations to life-threatening neoplastic disease. Most cases of PTLD involve EBV-seropositive donors and present with lymphadenopathy and fever. In contrast to the PTLDs that develop following solid organ transplantation, the majority of cases after SCT are of donor origin and arise as a result of inadequate T-cell control of proliferation of EBV-infected B cells. Risk factors for the development of PTLD include TCD, particularly the use of ATG and alemtuzumab, and increased HLA disparity. Weekly PCR quantitation of EBV viraemia is indicated in patients undergoing allogeneic transplantation that incorporates ATG or alemtuzumab and in all UCBT procedures until 100 days post-transplant. Patients with a rising EBV load may be managed by a reduction in immunosuppression and/or treated with pre-emptive anti-CD20 monoclonal antibody (rituximab), although the triggers for intervention differ between centres. In patients with a documented PTLD, early treatment with rituximab and, where possible, cessation of immunosuppressive therapy is the key to treatment. DLI using EBV-specific cytotoxic T lymphocytes has also been used with effect. Chemotherapy in patients with rituximab-resistant PTLD is rarely of value.

Intensive care support

The likelihood of developing organ failure requiring admission to the intensive therapy unit (ITU) after SCT varies widely according to stem cell source (autologous versus allogeneic), the intensity of the conditioning regimen and the presence of pre-transplant comorbidities. While recent studies suggest a reduction in the proportion of transplant recipients requiring ITU admission, it remains the case that approximately 10% of allografted patients, and in some institutions significantly more, will require ITU admission at some stage during their treatment.

Analysis of outcomes in patients admitted to ITU has identified factors determining survival at varying stages after transplantation, allowing rational decisions about the likelihood of benefit of sustained intensive care in patients with multiorgan failure. Further sophistication in defining who will benefit from admission to ITU has been provided by the application of scoring systems. These include the Acute Physiology and Chronic Health Evaluation (APACHE) II and III mortality prediction models and Simplified Acute Physiology Score (SAPS) prognostic systems. Application of these scores prior to admission to ITU and, where appropriate, after a 72-hour period on ITU is helpful in identifying patients who will benefit from institution or continuation of intensive support. A number of studies have indicated that the development of progressive organ failure or the presence of multiorgan failure 72 hours after admission to ITU predicts an extremely poor outcome. The careful integration of these data into discussion with relatives and, where possible, patients can spare many the indignity of prolonged and futile intervention.

Late complications of allogeneic stem cell transplantation (beyond day 100)

As the results of allogeneic SCT have improved, its long-term complications have come to be better recognised. Chronic GVHD, secondary malignancies and growth and fertility disorders represent an increasingly important cause of morbidity in patients who have been cured of their underlying disease (Battiwalla *et al.* 2017).

Chronic GVHD

Chronic GVHD refers to a complex syndrome usually occurring more than 3 months following allogeneic transplantation and is its commonest long-term complication. There is increasing recognition that the onset of chronic GVHD onset can be variable and also that patients may present features of both acute and chronic GVHD (often referred to as overlap syndrome). Registry data show that chronic GVHD occurs in approximately one-third of patients undergoing T-replete transplants from *HLA*-identical siblings, rising to two-thirds of patients receiving T-replete grafts from unrelated donors. Chronic GVHD is the major factor that patients report impairs their quality-of-life in the longer term. Risk factors for the development of chronic GVHD include increased recipient age, the use of PBSCs as opposed to bone marrow as the stem cell source, transplantation from an unrelated or *HLA*-mismatched donor, the use of a T-replete stem cell inoculum and the presence of prior acute GVHD. Chronic GVHD may develop directly from acute GVHD (progressive), after the resolution of an episode of acute GVHD (quiescent), or *de novo* in patients with no history of chronic GVHD. The clinical manifestations are characterised by features of both immunodeficiency and concurrent inflammation (Figure 37.7). Patients with progressive-type onset, extensive skin involvement, thrombocytopenia or bronchiolitis obliterans have a particularly poor prognosis. The NIH scoring system based on the number of organs involved and the severity within each affected organ is the current accepted standard. To aid assessment and standardisation, chronic GvHD scores can be calculated using an eGvHD App (www.uzleuven.be/egvhd).

Current treatment involves immunosuppression with ciclosporin or prednisolone prior to the institution of a gradual reduction in responding patients. In patients, who fail to respond or who show steroid dependency, the second-line therapies include Belumosudil (a ROCK inhibitor) or Ruxolitinib. It should be noted that only a small minority of patients receiving these second-line drugs show complete remissions and there continues to be an unmet need for better therapies. Extracorporeal photopheresis can be beneficial in patients with sclerodermatous involvement but appears to be less effective in patients with visceral disease. Wherever possible, refractory patients should be offered clinical trials.

Secondary malignancies

The incidence of solid tumours in recipients of allogeneic SCT is increased compared with control populations and includes a higher rate of skin or buccal cavity squamous cell carcinoma and melanoma. In the largest study to date, the cumulative

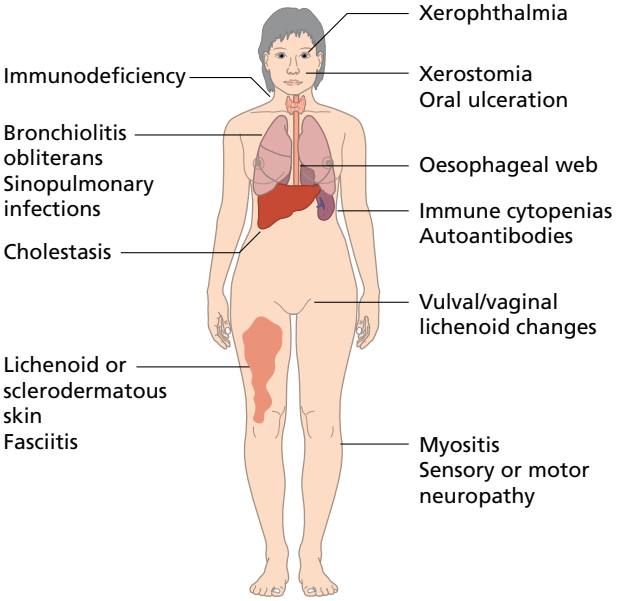

Figure 37.7 Clinical manifestations of chronic GVHD.

incidence of all solid tumours was 2.2% at 10 years and 6.7% at 15 years, although the latter figure may represent an overestimate. Risk factors for the development of secondary malignancies include the use of TBI in the conditioning regimen and the presence of chronic GVHD.

Growth, puberty and fertility

Retarded growth is seen predominantly in children who receive transplants at a younger age (<10 years) and in those who have received irradiation, particularly cranial irradiation. Growth retardation is multifactorial and although growth hormone levels may be diminished as a consequence of hypothalamic or pituitary irradiation, this does not entirely account for the observed reduction in height. Gonadal failure (both testicular and ovarian) is a common consequence of myeloablative conditioning regimens, particularly those that contain TBI or Bu. While prepubertal females receiving Cy alone (as for transplantation in severe aplastic anaemia) have a high probability of experiencing a normal puberty, most receiving other preparative regimens will fail to regain normal ovarian function and will require sex hormone replacement therapy for the induction of puberty. Thereafter sex hormone replacement is indicated to maintain the menstrual cycle and normal bone turnover/mineralisation, but the optimal duration of therapy and the potential long-term risks of hormone replacement therapy in this setting are unknown. Although about 10% of women who receive TBI-containing regimens may have some recovery of gonadal function, the overall incidence of pregnancy is very low. The advent of RIC raises the prospect that some women may remain fertile after transplantation and in this case prior therapies and age will be additional factors determining fertility. Where possible, the need for cryopreservation of sperm in males or oocyte/ovarian tissue cryopreservation in females should be considered at diagnosis before chemotherapy and transplantation..

Complications of autologous SCT

The morbidity and mortality of autologous SCT are much lower than that observed in allogeneic transplantation. The major toxicities relate to immediate or delayed organ failure caused by the conditioning regimen or complications consequent on neutropenia or thrombocytopenia (Table 37.3). The commonest infectious complications are bacterial and fungal and occur in the main in the first 28 days after transplantation. Late complications are rare, but include pulmonary fibrosis in patients who have received Bu and carmustine, and gonadal failure in recipients of TBI or busulfan-containing regimens. Female recipients of BEAM chemotherapy may recover some gonadal function. The development of myelodysplasia is a well-recognised late complication, particularly in patients transplanted using a TBI-based regimen. It appears that prior chemotherapy is an important factor in the development of MDS or AML since the leukaemia-associated cytogenetic abnormality, most commonly involving chromosome 5 or 7, is frequently detected in the infused stem cell inoculum.

Table 37.3 Immediate complications of autologous SCT.

Organ	Complications
Lung	Diffuse alveolar haemorrhage, interstitial pneumonitis especially in recipients of bleomycin/carmustine-and TBI-containing regimens
Gastrointestinal	Mucositis, nausea, diarrhoea
Hepatic	Asymptomatic elevation of bilirubin or AST, veno-occlusive disease (especially recipients of busulfan-containing regimens)
Renal	Prerenal acute renal failure, renal toxicity (nephrotoxic antibiotics), interstitial nephritis
Cardiac	Arrhythmias, cardiac failure (cyclophosphamide)

The evolving role of RIC transplant regimens-which patients should still receive a MAC regimen?

Outcomes in patients after allogeneic stem cell transplantation have improved steadily over recent decades. While considerable progress has been made in reducing transplant-related mortality, largely attributable to the advent of RIC regimens and improvements in supportive care and a reduced risk of severe GVHD consequent upon improvements in tissue typing, there has been little progress in reducing the risk of disease relapse which continues to represent the major cause of transplant failure. The risk of disease relapse is determined by a number of factors including disease biology and status at the time of transplant as well as the intensity of the conditioning regimen. Specifically, in patients allografted for AML, pre-transplant MRD status is an important predictor of relapse risk post-transplant (Hourigan *et al.* 2020; Craddock *et al.* 2021).

It is increasingly recognised that the intensity of the conditioning regimen (MAC versus RIC) is an important determinant of transplant outcome. Large registry studies show that the use of a RIC regimen is associated with a lower TRM but that this benefit is potentially offset by an increased risk of disease relapse. Nonetheless, these retrospective studies raised the important question of whether such RIC regimens should be adopted as the standard conditioning regimen in all patients regardless of age. A number of prospective randomised studies have been addressed this important question in patients with

AML/MDS. To date, randomised data suggest the use of a MAC regimen is particularly important in fit adults with AML in CR1 who are MRD positive and there are no compelling data against using a MAC regimen in fit younger adults regardless of pre-transplant MRD status. At the same time, it is clear that in patients over 50, with some exceptions, the use of a MAC regimen can be associated with excessive toxicity and such patients should be transplanted using a RIC regimen. There is no evidence that delaying transplantation to permit the delivery of further courses of intensive chemotherapy in patients in CR1 who are MRD positive is of benefit. Rather strategies with the potential to reduce the risk of relapse, particularly in patients transplanted using a RIC regimen, are required. Importantly, there is emerging evidence that in patients transplanted for lymphoid diseases such as ALL or Hodgkin lymphoma there may be advantages associated with the use of a RIC regimen in younger patients. Underpinning all decisions concerning the use of either a MAC or RIC regimen is a meticulous assessment of patient fitness. The last decade has seen considerable progress in the development of scoring systems that permit the relatively accurate prediction of TRM after allogeneic transplantation. While the degree of patient–donor HLA mismatch and stem cell source are important determinants of TRM, it is becoming increasingly clear that patient comorbidities are a critical determinant of outcome (Sorror *et al*. 2014). The haemopoietic cell transplant comorbidity index (HCT-CI) incorporates a range of patient-specific variables and predicts outcome after both MAC and RIC allografts. Thus, decisions concerning whether to proceed to an allogeneic transplant are increasingly viewed as a patient-specific appraisal of the predicted reduction in relapse risk if patients are allografted compared with the predicted TRM on the basis of the calculated HCT-CI, stem cell source and donor–patient HLA disparity.

Indications for transplantation

SCT is now an essential constituent of the treatment strategy for many haematological malignancies. In the case of autologous transplantation, current practice has been informed by the results of randomised controlled trials and registry studies comparing the outcome of transplanted patients with those who have received standard treatment. Improvements in the efficacy of first- and second-line treatments in lymphoma coupled with the development of CAR-T cell therapy mean that the role of autologous SCT is evolving rapidly and national guidelines are likely to change. Similarly, the treatment landscape in myeloma has become more complex with the advent of new therapies but autologous transplantation remains, at present at least, the standard of care for patients who respond to first-line therapy. Generation of prospective randomised trial data to inform the optimal role of allogeneic transplantation in both lymphoid and myeloid diseases has proved more challenging for a number of issues. Obstacles not only include randomisation biases introduced because of the perceptions of either physicians or patients, but also the very real problem that the allograft arm may include a smaller proportion of patients with high-risk disease, given the propensity of such patients to relapse before they reach transplantation. The only effective approach that allows these biases to be removed has been the use of a 'donor versus no-donor' analysis, which exploits the availability of an HLA-identical sibling donor as a form of biological randomisation. However, such an approach is hard to apply in rarer diseases and when most patients potentially have access to an alternative stem cell donor. Consequently, despite the development of novel statistical methodologies such as the Mantel–Byer analysis, many of the recommendations concerning the role of allogeneic transplantation in specific diseases will continue to be based on registry data or phase II studies. Prospective randomised trials are urgently needed in allogeneic SCT patients in order to improve transplant outcomes and generation of such robust datasets is necessary in order to inform key therapeutic areas such as conditioning regimen choice, design of GVHD prophylaxis regimens and the generation of innovative strategies with the potential to reduce the risk or relapse post-transplant.

With the aim of providing a robust framework for patient selection for both autologous and allogeneic transplantation, the EBMT publishes a regularly updated summary of indications for transplantation based on currently available data (Table 37.4), which is widely used to inform clinical practice (20). This categorises specific diseases according to whether autologous or allogeneic. SCT is accepted as standard therapy, is a promising treatment modality requiring further evaluation, or is not indicated.

Thanks to the rapid expansion of unrelated donor registries, over 40 million unrelated donors are now registered worldwide. As a result, it is possible to identify a suitable donor in more than 75% of whites of European descent, although this figure is much lower in other ethnic groups. Preferably the donor should be matched for *HLA A, B, C; DRB1* and *DQB1* (10/10). Initial results with unrelated donor transplantation were associated with a high TRM and an increased incidence of severe GVHD. In the last decade there has been a marked improvement in outcome of unrelated donor SCT because of the availability of high-resolution molecular typing at class I and II loci of the HLA complex. As yet, we lack sufficiently robust information to allow us to identify whether specific allelic mismatches are of particular clinical significance. Although the recent growth in the size of unrelated donor registries internationally has increased the availability of volunteer unrelated donors, their unrepresentative ethnic composition limits the availability of donors for ethnic minorities. In addition, lack of availability of a potential donor (e.g. through being lost to contact) remains a significant problem and affects some minority populations

Table 37.4 Indications for SCT.

disproportionately. Consequently, the timely identification of a suitable alternative donor remains a challenge for a significant number of patients, particularly those with high-risk acute leukaemia who require urgent transplantation.

UCB has long been known to be a rich source of haemopoietic progenitors and recent results have demonstrated that high rates of durable engraftment can be achieved in adults, comparable to those achieved in children, providing the cell

dose is optimised. Importantly, it appears that greater degrees of HLA mismatch can be tolerated using UCB than with a volunteer unrelated donor. As a result, it is possible to transplant a cord blood unit mismatched at two or fewer HLA-A, -B or -DRB1 antigens, as long as an adequate cell dose is available. This, coupled with the speed of procurement of UCB units, resulted in the emergence of cord blood as an important alternative stem cell source in both adults and children. Although initial results using UCB in adults were compromised by delayed engraftment and a high rate of primary graft failure, these problems have largely been overcome by ensuring the use of a high total nucleated cell dose or two cord blood units. UCB therefore remains a potentially important stem cell source in adults with high-risk leukaemia lacking a suitable unrelated donor, providing strict matching and cell dose requirements are adhered to, although its precise role needs to be defined in prospective clinical trials.

Historically, haploidentical transplants were associated with unacceptable rates of graft failure and GVHD because of the presence of HLA disparity at all major HLA antigens. Recent studies from groups have shown the feasibility of T-cell-replete haploidentical SCT followed by alloreactive T-cell purging *in vivo* using a strategy of PTCy. Accumulating data have demonstrated encouraging outcomes, both in terms of acceptable transplant toxicity and leukaemia-free survival, in both adults and children transplanted using a haploidentical donor in conjunction with post-transplant cyclophosphamide. Randomised data such as that generated by the recent US BMT CTN network are required however before the role of haploidentical transplantation can be confidently established in patients with high-risk haematological malignancies who have alternative stem cell donors (Fuchs *et al*. 2021).

Prevention and management of disease relapse

Relapse after autologous SCT is caused by either resistance of the underlying haematological malignancy to the conditioning regimen or infusion of contaminating tumour cells at the time of transplantation. While there is trial evidence that a second ASCT can be beneficial in some patients in myeloma, it is likely that this option will need to be re-evaluated in the context of the newer therapeutic approaches available for this disease. Similarly, while patients with lymphoma relapsing after ASCT are often considered for salvage with allograft, other options including CAR-T cells or checkpoint inhibitor drugs are likely to change the therapeutic landscape and treatment algorithms significantly.

Disease relapse remains the commonest cause of treatment failure after allogeneic transplantation and is caused by either resistance of tumour cells to the conditioning regimen or failure of the donor immune system to eradicate residual malignant haemopoiesis. Documented mechanisms for tumour cells evading a GVL effect include downregulation of HLA class II expression on acute myeloid leukaemia blasts or upregulation of co-inhibitory ligands, changes to the tumour microenvironment promoting accumulation of regulatory cell populations (e.g. myeloid suppressor cells or regulatory T cells), the location of residual cells in immune-privileged sites such as the CNS or testes, or loss of T cell 'fitness'.

While it is possible to reduce the risk of disease relapse after an MAC allograft by increasing the intensity of the preparative regimen, this approach has not yet translated into improved overall survival because of the increased TRM associated with a more intense conditioning regimen. In patients transplanted using an RIC regimen, there is limited room for increasing the intensity of the conditioning regimen without increasing transplant toxicity, although this is the subject of ongoing clinical trials including the possible option is the use of targeted radioimmunotherapy as part of the conditioning regimen. Currently, there is more evidence that outcomes can be improved by increasing tolerability and reducing TRM (e.g. through use of different drug combinations or newer drugs such as treosulfan) than by reducing the risk of relapse.

Outside the potential use of new conditioning approaches, reducing relapse requires boosting the GVL effect. Possible measures include limiting post-transplant immunosuppression and correction of mixed T-cell chimerism which is linked to higher rates of relapse, for example in lymphoproliferative disorders. On the basis that it is an indicator of bidirectional tolerance and therefore permissive for disease relapse, the use of pre-emptive donor lymphocyte (DLI) infusions may be used, although definitive evidence that this strategy is effective is being tested in randomised clinical trials. Alternative strategies with the potential to reduce the risk of disease relapse include the administration post-transplant of disease-modifying agents such as tyrosine kinase inhibitors in the setting of AML associated with an *FLT3 ITD* mutation (e.g., sorafenib) or Ph+ leukaemias (e.g., dasatinib) or lenalidomide in patients allografted for multiple myeloma. Post-transplant azacitidine is also being investigated in patients allografted for high-risk AML, given its ability *in vitro* to upregulate tumour antigens and potentially augment a GVL response.

The management of patients who relapse after allogeneic transplantation is complex. In many patients who relapse early after transplant, management should often be palliative, although some patients may want to consider entering early-phase clinical trials. For patients who relapse later or who have indolent disease (e.g. patients with low-grade lymphomas), a DLI or a second transplant could be considered. Two factors determine the use of DLI in clinical practice. Firstly, the ability of DLI to deliver durable remissions is highly dependent on the underlying haematological malignancy. Thus, up to 80% of patients who have relapsed after an allograft for CML will achieve a durable molecular remission with DLI, in contrast to patients transplanted for acute

leukaemia or myeloma, where response rates are much lower. Secondly, additional therapy prior to DLI (e.g. chemotherapy, antibody or small molecule) and acquisition of clinical response, may increase the likelihood of achieving a durable response to DLI. The major complications of DLI are GVHD and less commonly, myelosuppression. Myelosuppression is most commonly observed in patients with overt haematological relapse and may require treatment with G-CSF and occasionally transfusion of donor CD34-positive selected donor PBSCs. In early studies, DLI was administered as a single bulk infusion and was associated with a significant risk of severe GVHD. However, the recognition that use of an escalating schedule of administration substantially reduces the risk of severe GVHD without compromising its efficacy has markedly reduced the toxicity of DLI. The explanation of why early DLI is associated with such a high risk of severe GVHD is unclear, but may relate to more rapid expansion of donor alloreactive T cells in the profoundly lymphopenic environment present in the first few months after transplantation or the residual inflammatory effects of conditioning-induced injury. An alternative approach in patients who relapse late (usually more than 12–18 months post-transplant) is a second allograft using an RIC regimen. Although associated with an increased TRM, a number of studies now show a significant chance of long-term disease-free survival after a second allograft in a significant minority of such patients. Finally, it is increasingly likely that newer approaches such as CAR-T therapy will be employed to salvage patients in certain disease groups. Wherever possible, patients should be offered the option of entering clinical trials.

Future developments in stem cell transplantation

Autologous SCT

Relapse remains the commonest cause of treatment failure in patients after autografting. Most of the drugs contained in preparative regimens are already administered at close to the limit of extramedullary toxicity and there is therefore little room for further dose escalation. Consequently, efforts to reduce relapse rate will depend on either altering the mode of delivery of currently used agents or the development of new forms of chemotherapy or radiotherapy. Many haematological malignancies are highly radiosensitive and there is interest in the possibility of increasing the effective dose of irradiation delivered to the marrow without increasing organ toxicity using radiolabelled immunoconjugates. Early-phase clinical studies using α (^{131}I) or β (^{90}Y) emitters conjugated to haemopoietic antigens, such as CD45 or CD66, demonstrate that such an approach is feasible, and phase II studies in myeloma and lymphoma are ongoing. An alternative strategy is to utilise adjunctive CAR-T cell therapy in patients who relapse after an autograft for myeloma or lymphoma and additional research concerning sequencing of transplant and CAR-T cell therapy is required.

Allogeneic SCT

Major advances in allogeneic transplantation in the past decade include: (i) the introduction of novel GVHD preventative strategies (e.g. PTCy, abatacept) to permit HLA-mismatched transplantation; (ii) the effective use of new drugs to salvage patients with steroid-refractory acute (ruxolitinib) and chronic GVHD (ruxolitinib, belumosudil); (iii) the use of donor CAR-T cells in selected patients who relapse following allo-SCT. There are now a plethora of early phase clinical trials in the arena of GVHD and GVL. In the future, the concept of GVL may become uncoupled from allogenic transplant, and instead used to refer to the use of any donor or 3rd party cell designed to target leukaemia selectively; these therapies will need to provide the breadth and depth of classical GVL while avoiding on- or off-target toxicities.

The breakthrough success of ruxolitinib treatment for GVHD stands as testament to the value of pre-clinical research being translated into clinical trials. It is likely that this drug will be tested in preventative or first-line therapy, alone or in combination with other drugs. In acute GVHD, recombinant IL-22 has been tested in a clinical trial for its capacity to improve epithelial regeneration in the gut. Newer agents such as Hedgehog pathway inhibitors, anti-CSF-1 antibody and pirfenidone are being evaluated for their potential anti-fibrotic actions in chronic GVHD. In the setting of TCD, where the risk of GVHD is low, the emphasis is on minimising the impairment in immune reconstitution and increased infectious complications caused by depletion of donor T cells. One promising approach by which this might be achieved is through the use of 'addbacks' of antigen-specific T cells recognising common post-transplant viral pathogens such as CMV, EBV or adenovirus. Such cells can be generated either by coculturing donor lymphocytes with APCs primed with candidate antigens, followed by expansion, or by early selection on the basis of interferon-γ secretion (a technique termed 'IFN-γ capture'). Alternatively, antigen-specific cells might be selected directly from peripheral blood using immunomagnetic techniques based on labelling of antigen-specific cells using HLA class I–peptide multimers. In order to improve coverage against multiple pathogens, infusion of donor lymphocytes from which alloreactive T cells have been depleted may hasten immune reconstitution without incurring the risk of GVHD normally associated with DLI. 'Allodepletion' strategies being studies include directly removing donor CD8$^+$ T cells from the infusion, *ex vivo* depletion of alloreactive T cells (using immunotoxin against activation markers) following stimulation by recipient APCs, or removal of naïve (CD45RA$^+$) T cells from the graft. There is also substantial interest in the feasibility of transferring naturally occurring or *ex vivo* expanded CD4$^+$ FoxP3$^+$ or IL-10-producing regulatory T cells as

a means of preventing conventional T cells from inducing GVHD. The best approach for isolating and expanding these regulatory populations remains unknown, but the results from early trials have shown promise. At the time of writing, prospective randomised clinical trials have commenced to test the efficacy of CD45RA-depleted grafts or the addback of directly isolated, donor-derived regulatory T cells.

From first principles, reducing the risk of relapse can be achieved by increasing the intensity of the conditioning regimen (ideally without increasing transplant toxicity), administering anti-leukaemic therapies in the post-transplant period or by optimising the GVL effect. Donor T cells that have been expanded selectively to recognise tumour-associated antigens or lineage-restricted minor antigens (e.g. by expanding donor cells in the presence of peptide mixes) may prove effective and have shown feasibility in several trials. Perhaps the most exciting approach under investigation is the gene engineering of T cells to express T cell receptors (TCRs) or CARs specific for tumour-associated antigens. *TCR* gene therapy has the advantage of targeting tumour antigens derived from intracellular proteins but is limited by the need to use receptors that are restricted to particular HLA types, and also by the potential for cross-reactivity with other antigens. Proof-of-concept has already been shown for T cells transduced with a TCR reactive against a tumour-associated antigen (WT-1) in patients with high-risk AML. It is highly likely that the repertoire of TCR available to treat patients will increase rapidly over the next few years. Emerging evidence also supports the use of CAR-T cells in selected patients; these have the advantage that they are not HLA-restricted. For both TCR- and CAR-T therapies, gene editing to remove endogeneous *TCR* and *HLA* genes, raises the prospect of 'off the shelf' therapies from universal donors.

The challenge will be how such therapies can progress from first-in-human trials to prospective, controlled trials that evaluate efficacy and lead to regulatory approval. The complexity and cost of newer therapies, coupled with a high attrition rate when tested at phase I/II level means that most experimental therapies are unlikely to be incorporated into large randomised prospective trials; this could act as a powerful disincentive to the biopharmaceutical industry investment. There is therefore an important need to create collaborative groups including industry that seek to evaluate multiple therapies and to use adaptive trial designs to select winning strategies.

CHAPTER 38

Clonal haematopoiesis

38

Margarete A Fabre and George S Vassiliou

Department of Haematology, Cambridge Stem Cell Institute, University of Cambridge, Cambridge, UK

Introduction

'… if variations useful to any organic being do occur, assuredly individuals thus characterised will have the best chance of being preserved in the struggle for life; and from the strong principle of inheritance they will tend to produce offspring similarly characterised. This principle of preservation, I have called, for the sake of brevity, Natural Selection'. While Charles Darwin set out this theory of evolution in relation to the adaptation of biological organisms over generations, the same fundamental principles apply to the microcosm in which haematopoietic stem cells (HSCs) operate over the lifetime of a single individual.

From the moment a human zygote undergoes its first cell division, its genetic material is susceptible to alteration, such that the DNA sequences of its two daughter cells might not be identical. This process of somatic mutation acquisition continues inexorably through life in all tissues, including in the haematopoietic system. In young individuals, the absolute number of mutations in HSCs is small; diversity in the pool is therefore low and these relatively homogeneous stem cells exist in a rich bone marrow environment. In this setting, the forces of Darwinian selection are weak and many or all of the 50–200,000 HSCs will be equally adept at self-renewal and production of mature blood cell progeny. In contrast, by old age, the passage of time has allowed substantial accumulation of somatic mutations – it is estimated that a typical 70-year-old human harbours up to 70 mutations per protein-coding gene across the HSC population – giving rise to considerable diversity in the stem cell pool. These conditions are ideal for strong natural selection, with functionally variable HSCs now existing in a bone marrow niche altered by ageing. In line with Darwin's theory of evolution by natural selection, the HSCs best suited to the altered niche 'will have the best chance of being preserved in the struggle for life', and their cognate clones will expand relative to those less fit. This relative fitness advantage and subsequent expansion is the defining feature of clonal haematopoiesis (CH).

A historical perspective

Blood cancers are the prototypical examples of CH, with their clonal nature first demonstrated by karyotypic analyses in the 1960s. However, it would be a further two decades before CH was identified in individuals without blood cancer, when skewed X chromosome inactivation patterns were observed in elderly females. In normal embryonic development, one of the two X chromosomes is randomly inactivated in every cell, with approximately half of all early embryonic cells inactivating the paternal X chromosome, and the other half inactivating the maternal X chromosome. Since each cell's X inactivation state is stably maintained across cell divisions, the same balanced allelic ratios of X inactivation might be expected in the HSC pool and circulating progeny. However, investigators did not consistently observe such balance and, instead, some females, particularly older females, displayed skewed X inactivation ratios in blood cells. It was concluded that such skewing resulted from an enlarged clone arising from a single HSC, with consequent overrepresentation of this HSC's X chromosome inactivation pattern (XCIP) in sampled blood cells (Figure 38.1).

Harnessing advances in next-generation sequencing, a series of landmark studies from 2009 onwards steadily characterised

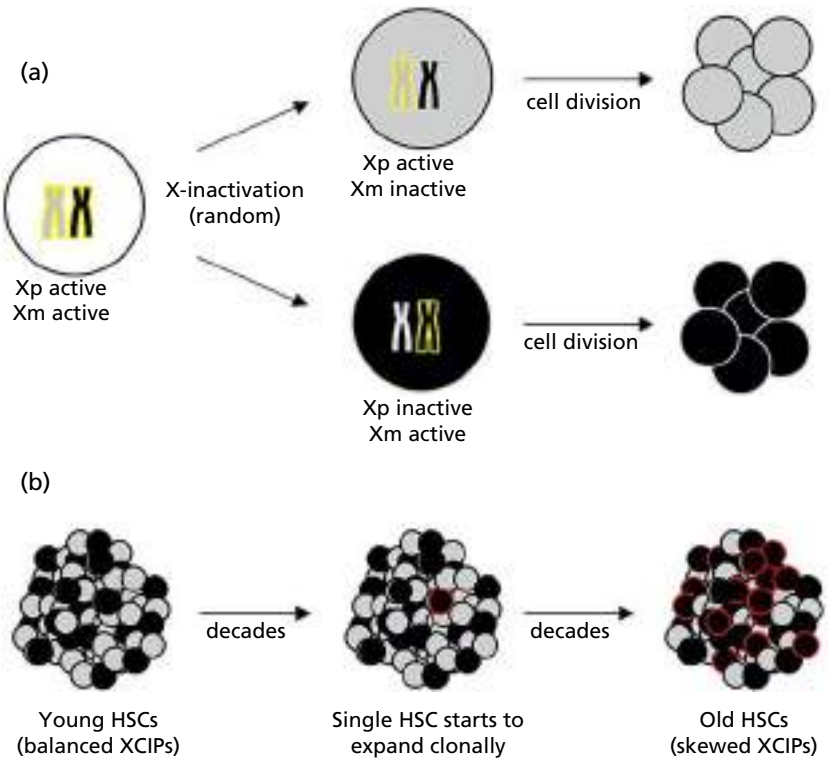

Figure 38.1 Detection of clonality through X-chromosome inactivation patterns (XCIPs). (a) X-inactivation is an epigenetic process that switches off gene expression in one of the two X chromosomes in every cell of the early female embryo. The inactivated X chromosome remains silenced in all cells that descend from the original embryonic cell within which X-inactivation took place. (b) As the process of X-inactivation is random, the ratio of cells bearing an inactive maternal X chromosome versus an inactive paternal X chromosome is expected to be balanced (balanced XCIPs). However, if a single HSC expands clonally *(red circled cell),* the average XCIP in the pool will be skewed towards the pattern of the clonal HSC and its progeny. Xm, maternal X chromosome; Xp, paternal X chromosome; ●, cell with inactive Xp; ●, cell with inactive Xm.

the somatic mutations driving myeloid malignancies. The question that followed was whether these same mutations could drive clonal expansions in individuals without myeloid malignancies. The first affirmation of this emerged in 2012, when mutations in *TET2* (a gene coding for an enzyme that oxidises methylated DNA) were detected in elderly females with skewed XCIPs. Two years later, several large-scale studies that collectively analysed exome or targeted gene sequencing of blood DNA from over 35,000 individuals, verified the phenomenon of CH driven by leukaemia-associated somatic mutations, revealing that it increased in prevalence with advancing age, particularly after the 6th decade of life. Notably, more than 95% of mutations occurred in just 8 driver genes, coding for enzymes involved in DNA methylation (*DNMT3A* and *TET2*) and chromatin regulation (*ASXL1*), proteins involved in cellular growth signalling (*JAK2*) and the DNA damage response (*TP53*, *PPM1D*), and splicing factors (*SF3B1*, *SRSF2*) (Figure 38.2).

Subsequent studies began to uncover additional fundamental characteristics of age-related haematopoietic clonal expansions. Firstly, while the close relationship between age and CH was consistently observed, estimates of the absolute prevalence depended heavily on the sensitivity of the sequencing assay utilised. Indeed, with more sensitive techniques, clonal mutations could be identified in almost all older individuals (Figure 38.3). Secondly, it was noted that expanded blood cell clones did not always harbour recognisable driver mutations and the cause of clonal expansion in these cases could not be determined. Thirdly, some studies identified larger chromosomal alterations as drivers of CH, such as loss of chromosome Y, trisomy 8 and deletions of the long arms of chromosomes 5 and 20. However, these mosaic chromosomal alterations (mCAs) were not as common as clonal haematopoiesis associated with single gene mutations.

Defining clonal haematopoiesis

CH is a clonal phenomenon arising from a multipotent HSC, distinguishing it from other precursor conditions such as monoclonal gammopathy of undetermined significance (MGUS) and monoclonal B-cell lymphocytosis (MBL), which originate

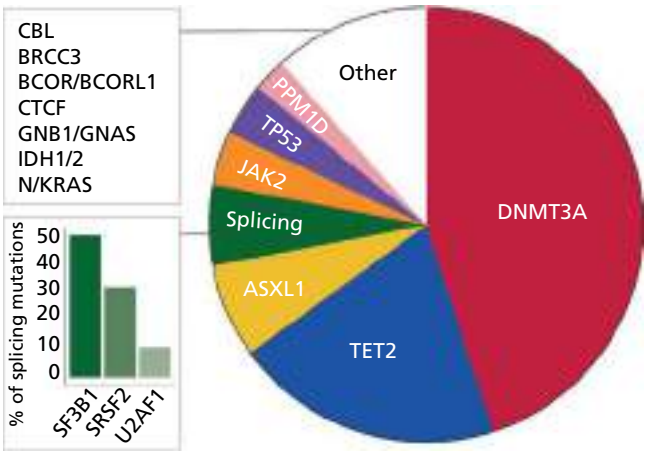

Figure 38.2 Relative prevalence of mutations in different CH driver genes. The proportions depicted here are approximate and derived from large studies of individuals with an average age of ~60 years. Proportions vary between studies, due mainly to differences in age distribution, but also to sequencing technology/depth of coverage. Driver genes in the 'Other' segment are much less commonly found in CH than the individually labelled genes on the pie chart. The list of 'Other' driver genes given in the adjacent box is not exhaustive but includes the more commonly mutated genes in this group.

in lymphoid progenitors. However, the precise definition of CH remains a matter of debate and a series of related descriptors have been coined (Table 38.1). When cytopenias are present, the clinical terms 'idiopathic cytopenia of undetermined significance' (ICUS) and 'clonal cytopenia of undetermined significance' (CCUS) should be used, provided that bone marrow examination is normal, or shows mild abnormalities not sufficient to meet the diagnostic criteria for a myeloid malignancy. These terms are defined in Table 38.1.

The term 'CHIP', referring to CH with driver mutation(s) at a variant allele fraction (VAF) of 2% or greater (corresponding to 4% of cells for heterozygous mutations), has been proposed as a useful category for CH associated with an increased risk of clinical sequelae, such as an increased risk of cardiovascular disease or progression to myeloid neoplasia. This is probably an oversimplification, as smaller clones driven by 'high-risk' genes might also be important to identify. However, since ultrasensitive sequencing can identify tiny CH clones in almost everyone (Figure 38.3b), a pragmatic cut-off based on clone size is useful for inferring likely clinical relevance. In practice, the term 'CHIP' can serve this purpose.

Mechanisms underlying clonal expansion

The process of HSC division results in two daughter cells that follow one of three possible fates: (i) one HSC and one differentiated progenitor, (ii) two differentiated progenitors, or (iii) two HSCs.

Table 38.1 Definitions of CH and related terms.

Term	Description
Clonal Haematopoiesis (CH)	The presence of an expanded clone of blood cells arising from a single HSC.
Clonal Haematopoiesis with a putative driver (CH-PD)*	The presence of an expanded clone of blood cells with an identifiable somatic driver mutation(s), in the absence of blood cytopenias.
Clonal Haematopoiesis with unknown driver (CH-UD)	The presence of an expanded clone of blood cells without an identifiable somatic driver, in the absence of blood cytopenias.
Clonal haematopoiesis of indeterminate potential (CHIP)	The presence of an expanded clone of blood cells with an identifiable somatic driver mutation(s) at a variant allele fraction (VAF) of ⩾2%, in the absence of blood cytopenias.
Clonal cytopenia of undetermined significance (CCUS)	Persistent cytopenia(s) that is not explained by haematologic or non-haematologic conditions and does not meet diagnostic criteria for a myeloid neoplasm, in the presence of CH.
Idiopathic cytopenia of unknown significance (ICUS)	Persistent cytopenia(s) that is not explained by haematologic or non-haematologic conditions and does not meet diagnostic criteria for a myeloid neoplasm, in the absence of CH.

*The putative driver can be a mutation in a single gene or a chromosomal aberration (the latter is also known as 'mosaic chromosomal abnormality').

The first pattern is the most common and maintains a stable number of HSCs, while enabling haematopoiesis to continue. The second pattern leads to HSC loss. The third pattern – symmetric division resulting in two clonal HSCs – leads to HSC gain. An increased propensity to this third fate is a property known as *increased self-renewal*, which is the core characteristic of the persistent clonal expansion defining CH. A sustained increase in self-renewal leads to a steady increase in the number of clonally-derived HSCs (Figure 38.4).

While enhanced self-renewal is a prerequisite for CH, the factors promoting this phenotypic change are complex and can be both *intrinsic* and *extrinsic* to HSCs, with intricate interplay between the two. Ageing is a pervasive factor that impacts both HSCs themselves and the environment in which they reside and is closely linked with the development of CH. The mere passage of time allows for somatic mutations to be acquired and for mutant clones to expand to detectable levels. It is notable that

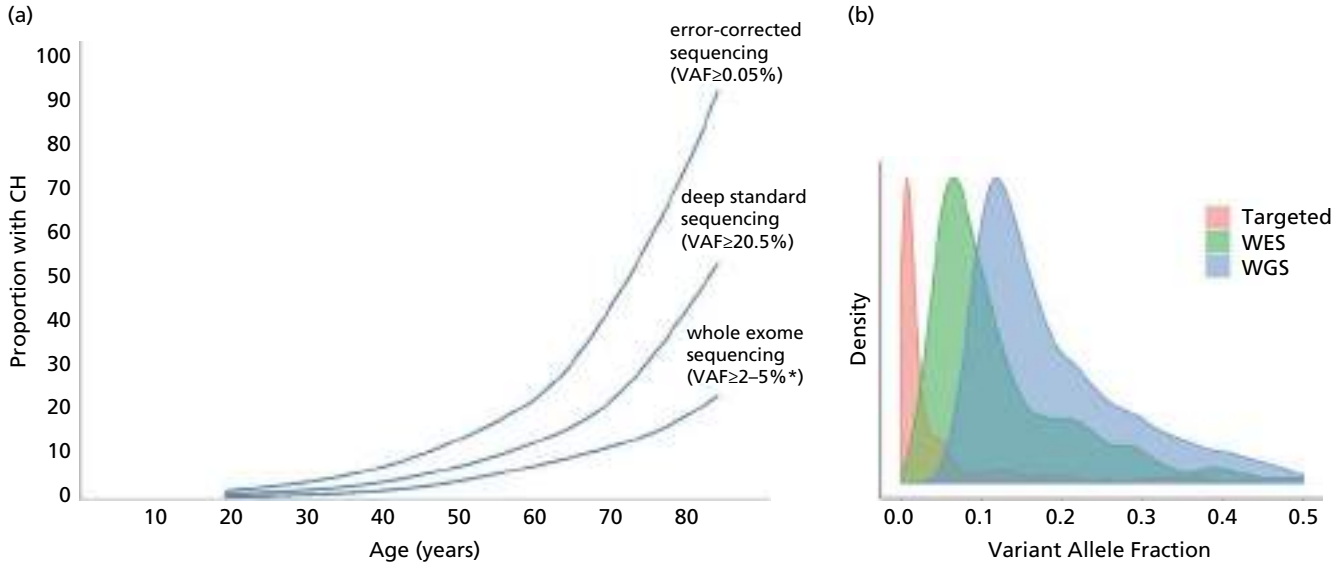

Figure 38.3 CH prevalence and detection in the general population. (a) Different estimates of the age-related prevalence of CH in the general population, according to the sensitivity of the sequencing technology used. *The sensitivity of whole-exome sequencing varies by driver gene due to uneven sequencing depths for different exons/genes. (b) Scaled density plots for Variant Allele Fraction (VAF) of driver mutations detected using different sequencing methods, in descending order of depth of coverage: Targeted sequencing (Abelson *et al*. Nature 2018), Whole exome sequencing (WES) (Jaiswal *et al*. NEJM 2014) and Whole Genome Sequencing (WGS) (Bick *et al*. Nature 2020). This demonstrates that smaller clones (with lower VAFs) can be detected when the depth of sequencing is higher.

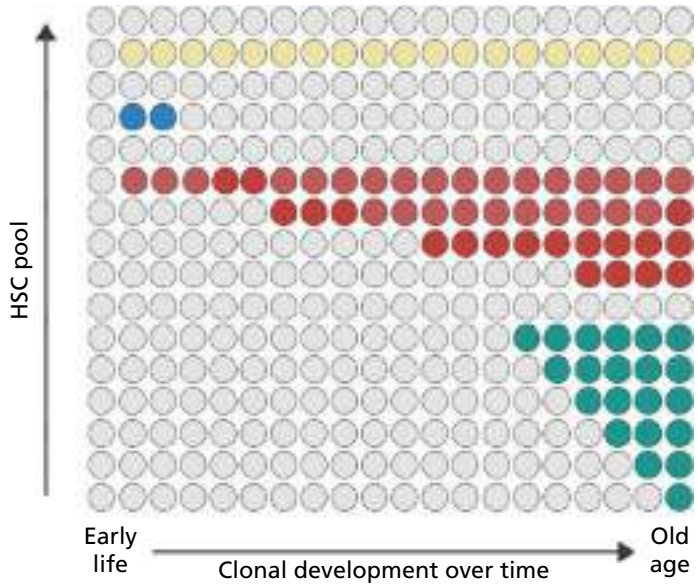

Figure 38.4 Clonal selection and its influence on HSC composition over life. In this schematic, an HSC is represented by a circle, the colour of which reflects its particular mutational status: grey cells carry no somatic driver mutations and other colours depict cells with different mutations. In early life, few somatic mutations have been acquired – in this example, none that drive clonal expansion – and the polyclonal HSC pool is relatively uniform. Over time, HSCs accumulate somatic mutations, which can impact fitness in a number of different ways: (i) Neutral (yellow) – these mutations do not alter fitness and there is no clonal expansion; (ii) Deleterious (blue) – these mutations diminish fitness and affected HSCs are removed from the pool; (iii) Advantageous – these mutations can confer a subtle advantage (red), in which case clonal expansion is slow and might only become evident many decades after mutation acquisition, or stronger advantage (green), when expansion is more rapid. It is important to note that, even amongst mutations that confer a fitness advantage, fixation of the mutant HSC clone in the pool and subsequent expansion is not inevitable, and many clones die out; a clone's chance of persistence is proportional to its fitness. The lifelong process of selection and clonal expansion is universal, and haematopoiesis inevitably becomes oligoclonal by advanced old age.

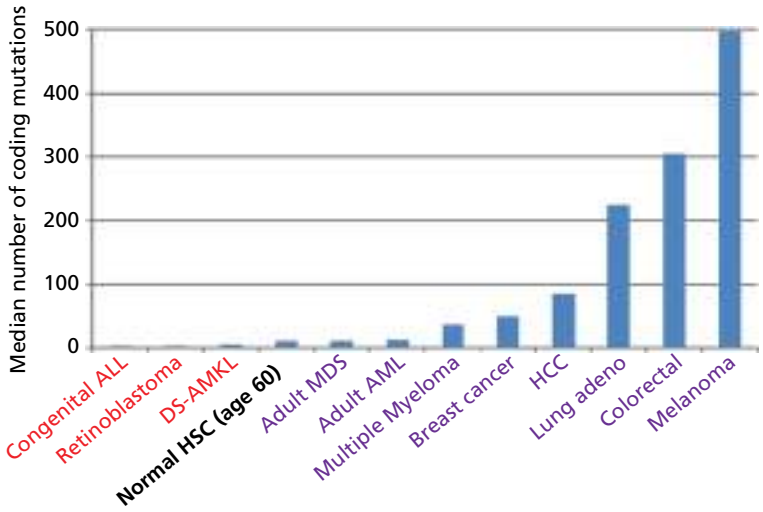

Figure 38.5 Median number of coding mutations in normal-aged HSCs and in different cancer types. In the *x*-axis labelling, paediatric cancers are coloured red, adult cancers are coloured purple and normal HSCs from individuals aged ~60 are in bold type. Notably, the average number of coding mutations in normal-aged HSCs (10) is similar to that in adult AML (10) and MDS (13), and considerably lower than many common adult cancer types. ALL, Acute lymphoblastic leukaemia; DS-AMKL, Down Syndrome-Acute Megakaryoblastic Leukaemia; HSC, haematopoietic stem cell; MDS, Myelodysplastic Syndrome; AML, Acute Myeloid Leukaemia; HCC, Hepatocellular carcinoma.

the number and type of somatic mutations found in an expanded CH clone are similar to those found both in normal-aged HSCs and in myeloid malignancies, indicating that increased mutation rate is not usually a factor in the aetiology of these clonal disorders. This is unlike most of the common adult cancers, where specific mutagens causing larger numbers of mutations are an important factor in disease pathogenesis (Figure 38.5).

However, the influence of ageing on the development of CH goes beyond its simple association with time and mutation acquisition. Most significantly, aged HSCs display cell-intrinsic defects, with altered transcriptional and epigenetic landscapes suggestive of a molecular hardwiring of the ageing process, as well as defects in DNA repair and polarity. These cell-autonomous processes can also be influenced by extrinsic signals and, importantly, the bone marrow microenvironment/niche changes significantly with ageing. Amongst other changes, adipogenesis is favoured over osteogenesis, there is a decline in specialised vascular niches, and the chemical milieu is increasingly inflammatory. In this setting of progressive degeneration of HSCs and their environment, those HSCs that self-renew most effectively will expand relative to their peers, leading to CH. The advantage is often attributable to an identifiable HSC driver mutation, but recent advances suggest that such drivers are not always detected. Apart from ageing, other factors impact clonal expansion more specifically through either cell-intrinsic or cell-extrinsic processes, and these are considered separately below.

Cell-intrinsic contribution to HSC fitness

The genes recurrently mutated in CH broadly fall into three main classes: epigenetic regulators (*DNMT3A*, *TET2*, *ASXL1*), splicing factors (*SF3B1*, *SRSF2*, *U2AF1*) and DNA damage response (DDR) genes (*TP53*, *PPM1D*), with rarer contributions from other epigenetic genes, signalling molecules and haematopoietic transcription factors (e.g. Figure 38.2). An improved understanding of the function of the affected genes can give insights into their role in CH. However, developing appropriate experimental models can be challenging, with the molecular effects of driver mutations often imparting only subtle advantages on host HSCs such that expanding CH clones take decades to become detectable. In addition, any such advantage might only be realised when a mutant HSC resides in a particular environment or context, which might be difficult to recapitulate in the laboratory. Nevertheless, some progress has been made in dissecting the mechanistic role these genes play in driving clonal expansion.

Epigenetic regulators: *DNMT3A* and *TET2*

DNA methylation plays a key role in gene regulation and cellular identity/behaviour, with methylation, particularly at promoters, generally considered a repressive mark. Central to this regulatory process are the enzymes responsible for adding methylation marks, DNA methyltransferases (DNMTs), and the ten-eleven translocation (TET) family, which can remove these marks. While a number of DNMT and TET family members can catalyse these reactions, *DNMT3A* and *TET2* are the genes most commonly mutated in CH and haematological malignancies. Overall, loss of *DNMT3A* function is associated with DNA hypomethylation, while loss of *TET2* function is associated with DNA hypermethylation. Mechanistic studies discussed below have shed some light on the consequences of mutations in these genes, but the question of why they lead to clonal expansion remains largely answered.

Truncating *DNMT3A* mutations occur across the length of the gene, with missense mutations clustering in known structural and functional domains. Importantly, the relative frequency of different DNMT3A mutations in CH is distinct from that observed in myeloid neoplasms (particularly AML), which much more frequently affect the R882 hotspot residue. The distribution of mutations in *TET2* is similar, with missense mutations concentrated in the two conserved regions, and truncating

mutations spread uniformly across the entire gene. However, unlike *DNMT3A*, there are no major mutation hotspots in *TET2*. Mutations in *DNMT3A* and *TET2* are usually heterozygous and lead to loss of protein function. Mouse models carrying loss-of-function mutations in either of these genes display a propensity to develop myeloid malignancies, while their HSCs have a self-renewal advantage over wild-type HSCs, as exemplified by an increased ability to serially form colonies *in vitro* and an ability to outgrow wild type HSCs in competitive transplantation assays *in vivo*.

Why loss of function of either *TET2* or *DNMT3A* has such a profound impact on HSC biology remains elusive. Different mechanisms have been suggested, such as promoter hyper- or hypomethylation leading to changes in the expression of genes that regulate stem cell self-renewal, senescence or proliferation. However, the identity of these genes remains elusive despite extensive research efforts. For example, in both human and mouse cells with *DNMT3A* or *TET2* mutations, there are no marked or consistent gene expression changes and a limited overall correlation between alterations in DNA methylation and changes in expression levels of differentially methylated genes. In addition, these enzymes have complex interactions with other epigenetic regulators, their associated methylation changes might influence 3D genome interactions, and they might play roles independent of methylation. Especially perplexing is the fact that *TET2* and *DNMT3A* have ostensibly opposite biochemical functions, yet mutations in both result in similar phenotypes of enhanced self-renewal, a major conundrum in the field.

Recent longitudinal studies designed to capture the lifelong clonal dynamics of CH have revealed further subtleties. While *TET2* mutations seem able to initiate clonal expansion at any age and exhibit similar growth patterns across life, *DNMT3A*-mutant clones tend to expand faster earlier in life, before decelerating in older age. Why mutations in these genes are associated with different clonal behaviours across life is currently unknown, but the observation is important nevertheless. *Firstly*, it highlights the fact that the ability of these mutations to drive clonal expansion is intimately tied to the cellular and environmental context in which they exist (discussed in more detail later in this chapter). *Secondly*, the disparity in behaviour likely explains why *DNMT3A* is the dominant CH driver gene through the first 6-7 decades of life, only to be 'overtaken' by *TET2* in people aged 75 years or older (Figure 38.6).

Splicing factors: *SF3B1*, *SRSF2* and *U2AF1*

Precursor messenger RNA splicing is a critical step in the post-transcriptional regulation of gene expression, providing substantial expansion of the functional proteome of eukaryotic organisms in relation to the number of genes. The process is executed by the spliceosome, a large and highly dynamic ribonucleoprotein complex. Alternative splicing patterns are tightly regulated but are fluid, changing for example over each 24-hour cycle with the mammalian circadian rhythm, and over a lifetime with advancing age.

Disruption of alternative splicing can be observed in many tumour types, often mediated by mutations in components of the spliceosome. Spliceosome gene mutations are prevalent in myeloid cancers and in CH, and most commonly affect three genes controlling 3′ splicing: *SF3B1*, *SRSF2* and *U2AF1*. Mutations in each of these occur as heterozygous point mutations at specific residues, suggesting gain-of-function alterations. Indeed, mutant *SF3B1* promotes usage of alternative branch points, leading to usage of cryptic 3′ splice sites, and *SRSF2*/*U2AF1* mutations are characterised by alternative exon usage. In addition, mutations in spliceosome genes are generally mutually exclusive with one another, presumably due to redundant effects and/or a limit on cellular tolerance of disrupted spliceosome function. While these biochemical abnormalities lead to aberrant splicing of hundreds of genes, the exact mechanisms by which these mutations lead to clonal expansion remain largely unknown. Extensive analysis has revealed very little overlap between the aberrantly spliced

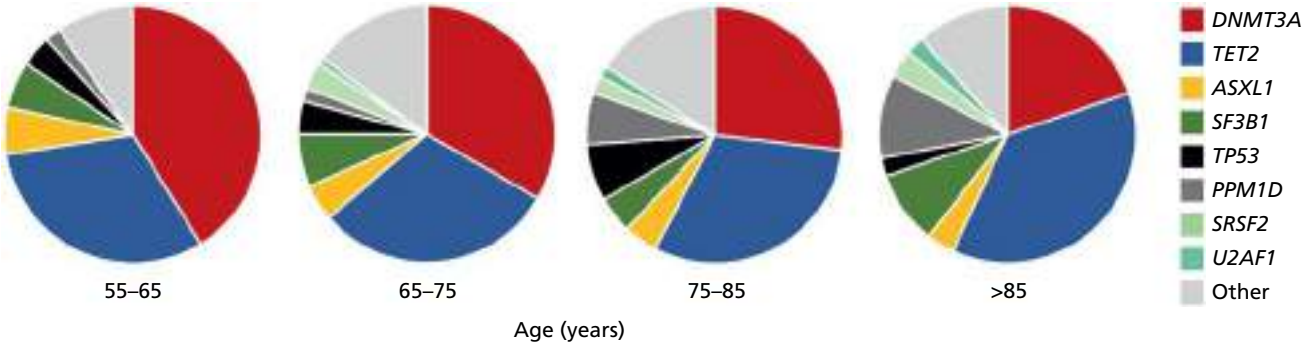

Figure 38.6 Changing spectra of CH-driving mutations with advancing age. *DNMT3A* mutations dominate the landscape of CH in people younger than 60 years old. With advancing age beyond 60 years, *DNMT3A* mutations steadily lose this dominance as *TET2* mutations continue to rise inexorably to become the most common CH drivers beyond the age of ~80 years. Similarly, mutations in splicing factor genes and *PPM1D* become more common in advanced old age (Source: Data from Fabre *et al.* Nature 2022).

target genes associated with different splicing mutations, and the mis-spliced genes are generally not those known to drive cancer. This suggests that the clonal advantage imparted by these mutations might not be explained by any single mis-splicing event, but instead that multiple splicing alterations might cooperatively contribute to clonal expansion. Alternatively, other unknown effects of splicing gene mutations might operate.

The observation that HSCs from mice mutant for *Sf3b1*, *Srsf2* or *U2af1* have a competitive disadvantage *in vivo*, unlike the clonal expansion observed in humans with these mutations, adds further intrigue to the biology. The disparity might be explained by differences in alternative splicing patterns in humans and mice, in part because the intronic sequences identified by mutant splice factors are not well conserved between mice and humans. Another possibility is that splicing gene mutations only drive clonal expansion in a particular context, which could relate to conditions within the mutated HSC or to the environment in which the HSC resides. This possibility is supported by studies showing that splicing gene mutations do not initiate clonal expansion in young individuals and only do so in later life, when they can drive rapid growth. This implies an intimate relationship between these mutations and ageing, but the nature and biology of this interaction remain elusive.

Additional classes of driver mutation

For some other mutant genes, the mechanisms underlying clonal expansion are better understood. For example, activating mutations in *JAK2* that drive 3–4% of CH in most studies, lead to constitutive signalling through growth factor receptors, leading to clonal expansion. In contrast, a number of genes involved in the DNA damage repair (*DDR*) are recurrently mutated in CH, notably *TP53*, *PPM1D* and less often *ATM* and *BRCC3*. *TP53* is a key tumour suppressor in humans and CH driver mutations lead to loss-of-function. *PPM1D* is a negative regulator of the DDR; driver mutations occur almost exclusively in the terminal exon of the gene, truncating the protein to generate a highly stabilised form that attenuates the entire *DDR* (i.e. an effect similar to that of *TP53* loss). *DDR* mutations impart HSCs with a clonal advantage relative to wild-type HSCs, particularly when an individual is exposed to DNA-damaging agents, such as cytotoxic chemotherapy. However, these mutations drive CH quite commonly, including in individuals without known prior exposure to any cytotoxic agent, suggesting that they might confer advantage through additional mechanisms, or that endogenous or agnogenic DNA damage may also exert a selective pressure.

Other drivers of CH remain less extensively studied, and their biology is poorly understood. *ASXL1*, for example, the third most common *CH* driver gene, is a member of the polycomb repressive complex 2 (*PRC2*), which plays a key role in stem cell biology and *Hox* gene regulation. Driver mutations in this gene are always truncating and occur exclusively in the terminal two exons (11 and 12), but the precise way in which the truncated protein leads to clonal advantage is unknown.

In addition to the more recurrently mutated genes driving CH, there is a long tail of less common drivers, including cohesin genes such as *RAD21*, *SMC3* and *STAG2*, G-protein genes such as *GNAS* and *GNB1* and epigenetic regulators such as *BCOR*, *BCORL1*. In fact, it is almost certain that this 'tail' of drivers extends well beyond what has been characterised, with mutations in many other genes conferring a clonal growth advantage which, over decades, can lead to clonal expansion, yet mutations in individual genes are not sufficiently recurrent to be identified in cohorts of the sizes studied to date. This concept is substantiated by studies that used passenger mutations to identify clonal expansions in peripheral blood, in the absence of any identifiable CH drivers. Furthermore, reconstructions of haematopoietic phylogenies of elderly individuals using whole-genome sequencing of single-cell-derived colonies, revealed that the presence of so-called 'unknown-driver' expansions is the norm in old age, with evidence that such expansions have grown under positive selection rather than due to neutral drift.

Finally, somatic acquisition of large chromosomal alterations has also been found to drive CH in some individuals. The commonest such genetic lesion seen in CH is mosaic loss of the Y chromosome (mLOY), with more than 40% of elderly men harbouring clones driven by LOY. Other less common mCAs are also observed and are broadly the same as those found in haematological cancers, such as deletions of 5q, 20q and 17p.

Inherited factors

Germline variation influences the risk of developing CH, the identity of the CH driver mutation and the rate of clonal expansion. A heritable component was initially implied by epidemiological observations, with early reports of CH being more common in men and less common in individuals identifying as Hispanic or East Asian. Initial cohort studies analysing concordance for CH within identical twin pairs did not find a strong inherited predisposition, but more recently genome-wide association studies have revealed a number of risk loci. One set of risk alleles is associated both with CH and with neoplasia in multiple tissues, via dysfunction of genes that maintain genome integrity (e.g. *TERT*, *CHEK2*, *ATM* and *PARP1*). A second set of germline loci is associated with the acquisition of mutations in specific driver genes; for example, the *JAK2* 46/1 haplotype predisposes to the *JAK2* p.V617F mutation via a *cis*-haplotype effect. A third set of risk loci, including, *TCL1A, CD164* and *SMC4*, are linked specifically to CH development, rather than neoplasia more generally. *TCL1A* is particularly interesting because polymorphisms associated with higher *TCL1A* mRNA expression are associated with CH due to mutations in most of the common driver mutations, including *TET2*, *ASXL1*, *SF3B1*, *SRSF2* and *JAK2*. In contrast, polymorphisms associated with low *TCL1A* expression increase the risk of *DNMT3A*-mutant

CH specifically. This reciprocal relationship of *TCL1A* polymorphisms with different CH subtypes suggests that its expression needs to be tightly regulated to prevent clonal expansion.

Characterising the landscape of inherited predisposition remains an active area of research and is important not only for quantifying an individual's risk of CH and its implications in the clinical setting but also for revealing fundamental aspects of the biology and mechanisms of clonal expansion.

Cell-extrinsic contribution to HSC fitness: environmental influences on clone selection

Simple calculations based on the number of HSCs, the size of the genome and the rate of acquisition of somatic mutations, as well as studies using exquisitely sensitive error-corrected sequencing, demonstrate that almost all individuals harbour HSCs with coding mutations in CH driver genes by middle age. However, only in a fraction of individuals do mutant clones expand to levels detectable by standard sequencing techniques. What determines whether such expansion occurs? The identity of the mutation and the timing of its acquisition are important determinants, but do additional extrinsic factors influence whether, or to what degree, a mutation with driver potential stimulates growth? Several lines of evidence suggest that such extrinsic factors do indeed play influential roles.

A clear indication that the environment can determine whether a mutation drives clonal growth or not, comes from the observation that the identities of 'driver' genes vary depending on the context, as illustrated in Figure 38.7. For example, in aplastic anaemia, where autoreactive T cells target and eliminate HSCs, clones with mutations that facilitate immune evasion selectively survive and expand relative to wild-type HSCs. In the very different scenario of genotoxic stress induced by cytotoxic chemotherapy, as discussed above, clones with mutations in DDR genes expand. As these new environments arise, previously neutral mutations now confer a growth advantage, implying that the mutations themselves are not inherently advantageous in isolation, but become so in the presence of particular extrinsic signals/contexts.

A role for non-mutation factors in clonal expansion is also suggested by longitudinal studies showing that clones in different

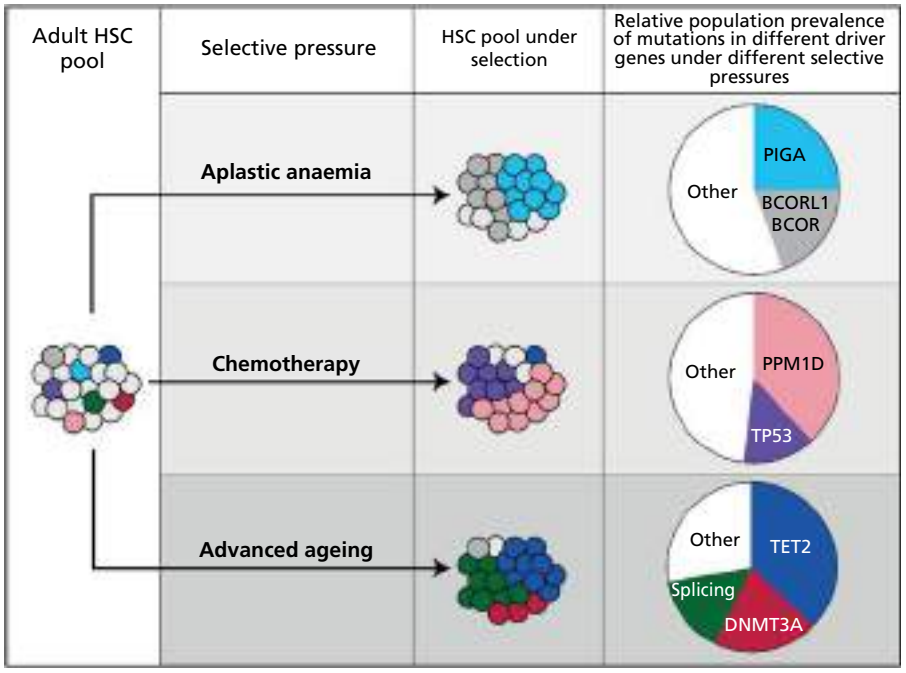

Figure 38.7 Driver gene spectra in different contexts. HSCs acquire somatic mutations inexorably over time, leading to a heterogeneous HSC pool represented by differently coloured cells at the left of the figure. Particular mutations confer a fitness advantage in specific contexts, leading to clonal selection and expansion. In aplastic anaemia (an autoimmune condition), mutations in genes such as *PIGA* allow an HSC to evade immune attack and expand relative to its peers. With exposure to chemotherapy, mutations in DNA-damage-response pathway genes (e.g. *TP53*, *PPM1D*) are selected. In advanced ageing, there is increasing selection for HSCs with mutations in splicing genes and in *TET2* (which 'overtakes' *DNMT3A*, also coloured in the figure for comparison, as the most common driver in this age group). Pie charts on the right of the figure illustrate the relative prevalence of mutations in different driver genes in different contexts.

individuals with identical mutations behave differently over time. Studies in allogeneic sibling transplantation have demonstrated that at least part of the explanation lies outside the mutant cell itself. Here, CH passed from donor to recipient, where the mutant HSC was identical (in all aspects, and not just in the identity of the driver mutation) but now housed in two independent individuals, was found to expand more rapidly in the recipient compared to the donor in most cases. This suggested that some aspect of the transplantation process or the milieu of the recipient bone marrow was particularly conducive to clonal expansion.

In the search for non-cell-autonomous factors influencing clonal growth, much interest has focussed on a potential role for inflammation, a feature of human ageing, particularly in relation to *TET2*-mutant CH. While the long-term function of normal HSCs is perturbed by sustained exposure to proinflammatory cytokines such as tumour necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6), *TET2*-mutant HSCs resist these signals and maintain functional integrity, providing them with a competitive advantage in a chronic inflammatory environment. Furthermore, *TET2* normally functions as a negative regulator of the inflammatory response in myeloid cells, in part by recruiting *HDAC2* to suppress IL-6 production. *TET2* loss-of-function mutations therefore potentially set up a positive feedback loop whereby the mutant myeloid cells secrete more IL-6, further augmenting their relative advantage over wild-type HSCs. Recent evidence suggests that the dependence of *TET2*-mutant clonal expansion on IL-6 inflammatory signals might be partly microbially-mediated, as it only occurred in mice with intestinal dysfunction and bacterial translocation, was reversed by antibiotic treatment and was absent in germ-free mice. Some evidence is also emerging that specific proinflammatory cytokines might induce expansion of CH with particular driver mutations, such as positive selection of *DNMT3A*-mutant clones by interferon-gamma signalling during chronic infection.

Finally, some studies have reported a weak association between smoking and CH, predominantly CH driven by *ASXL1* mutations. Furthermore, large genetic studies using Mendelian randomisation (an unbiased genetic approach for removing confounders) have suggested that smoking is actually a causative risk factor. While it is known that smoking does not induce mutations in HSCs, the reason for the link between smoking and CH remains unclear, although a chronic inflammatory state induced by smoking has been postulated.

Research into non-cell-autonomous influences on CH remains in its infancy but is one with translational potential. It is not currently possible to reverse somatic mutations in clonally expanded HSCs, but it is plausible that extrinsic signals could be altered therapeutically to minimise or negate any advantage conferred by the mutation.

Patterns and determinants of clonal behaviour through life

Pivotal to our understanding of CH, and a key starting point for elucidating underlying mechanisms, is characterising the natural history of clonal behaviour. Until recently, we had almost no insight into the timing of driver mutation acquisition, how/if this relates to the foundation of a mutant clone and how an established clone behaves over time. The first indication that CH driver mutations could be acquired very early in life (in fact, *in utero*), came from two independent studies of human twin pairs in 2020. Across both studies, the twins in each of 3 monozygotic pairs (out of a total of 161 pairs analysed) were found to harbour identical rare somatic driver mutations. It is extremely unlikely that each member of a pair acquired the same mutation independently and by chance. A more plausible explanation is that the somatic mutation occurred just once *in utero*, either prior to twinning or in an HSC whose progeny reached both twins through their shared circulation. The finding that the first step on the path to a clonal phenomenon associated with ageing can be initiated in the earliest stages of life is remarkable. A first glimpse into selection patterns and growth dynamics in CH came later the same year, when population genetic theory was applied to cross-sectional VAF data from ~50,000 individuals to infer the relative fitness of different driver mutations. While this broke new ground, revealing that positive selection, not neutral drift, is the major force shaping CH, the robustness of relative fitness calculations was limited by the study's reliance on two key assumptions: *first*, that a mutation's fitness is constant across time and, *second*, that the propensity for a mutation to found a clone is uniform through life.

These limitations were overcome when lifelong clonal dynamics were studied directly, by (i) tracking clones longitudinally through serial blood VAF measurements, and (ii) reconstructing haematopoietic phylogenies from whole-genome-sequenced single-cell-derived colonies to reconstruct growth trajectories. These analyses revealed that mutations in different driver genes induce characteristic patterns of clonal behaviour throughout life (Figure 38.8). For example, *DNMT3A*-mutant clones preferentially expand early in life and display slower growth in old age (~5% per year). By contrast, splicing gene mutations only initiate clones and drive expansion in old age, when growth is rapid (up to 50% per year for some *SRSF2*-mutant clones). *TET2* displays a more uniform behaviour throughout life, with mutant clones emerging and growing at similar rates (~10% per year) across all ages. Which factors underlie these disparate patterns of lifelong behaviour are unknown, but their elucidation will be critical to our understanding of CH. A further striking observation from longitudinal clonal tracking studies is that, by old age, almost all clones expand at a stable exponential rate over time.

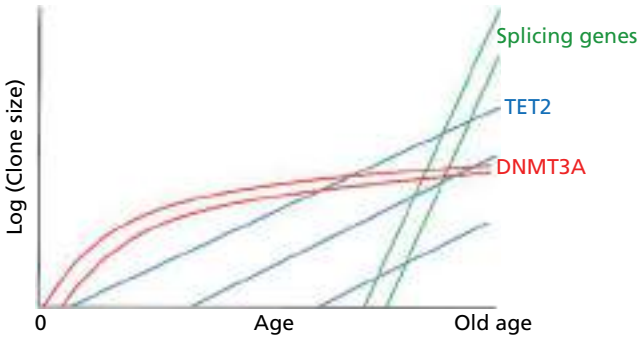

Figure 38.8 Lifelong driver-specific patterns of clonal growth. *DNMT3A*-mutant clones (depicted in red) emerge early in life and expand rapidly, before decelerating and growing slowly in old age. *TET2* mutations (blue) found clones fairly uniformly through life and drive more stable growth across ages. CH driven by splicing gene mutations (green) initiates almost exclusively late in life and exhibits very rapid expansion dynamics.

This constancy is compelling, not only from the biological perspective, but also due to its translational potential, with prediction of future clonal growth in the clinical setting now feasible.

Clonal haematopoiesis and myeloid malignancies

The association between CH and myeloid malignancies, including acute myeloid leukaemia (AML), myelodysplastic syndromes (MDS) and myeloproliferative neoplasms (MPNs), is well documented and unsurprising given the shared mutational landscape. In this context, CH can be viewed as the first step towards malignancy, with the acquisition of additional cooperating mutations responsible for progression. For example, a well-documented pathway to AML is via *NPM1* and/or *FLT3* mutation acquisition in an expanded *DNMT3A*-mutant CH clone. However, co-mutation does not explain all malignant progression; for example, *SF3B1* is the sole identifiable driver gene in one-third of *SF3B1*-mutant MDS cases, and half of all *JAK2*-V617F-mutant MPNs harbour no additional drivers. In these cases, expansion of the single-mutant clone appears to be sufficient to cause disease.

Quantifying and dissecting the risk of malignant progression in people with CH has attracted substantial interest given its potential for use in future leukaemia early-detection/prevention strategies. Studies have shown that individuals at risk of progression to AML can be identified years in advance, as they have larger CH clones and/or harbour mutations in multiple genes or in high-risk genes such as *TP53, SRSF2, U2AF1, IDH1 and IDH2*. An integrated prognostic model incorporating multiple factors could identify approximately 40% of individuals at highest risk with a false positive rate of 1–2%. While helpful, this level of discriminatory power is not sufficient for use in population screening, as large numbers of individuals would be falsely categorised as high-risk. More recently, models have been developed for predicting an individual's risk of developing any myeloid neoplasia (CH risk score, CHRS) or each of the main subtypes (AML, MDS or MPN) separately (MN-Predict). These risk-prediction tools incorporate characteristics of the expanded clone, demographic features and routinely measured complete blood count and biochemical parameters, and quantify malignancy risk years into the future.

Clonal haematopoiesis and non-haematological disease

CH has the potential to lead to diverse organ dysfunction since: (i) clonal selection and function are uncoupled, such that HSCs gain advantage through enhanced self-renewal and survival, even when this adversely affects the quantity and quality of their differentiated progeny, (ii) HSCs are not spatially constrained, so clones can expand to constitute a very large fraction of haematopoiesis and (iii) HSCs give rise to many differentiated immune effector cells, which traffic to every organ/tissue. Indeed, CH is associated with increased mortality, explained predominantly by increased cardiovascular mortality. Several studies have quantified the excess mortality risk in individuals with sizeable CH clones (VAF≥2%) and found it to be 30–40% higher than in individuals without CH. In one study of primarily middle-aged individuals, the risk of coronary heart disease and ischaemic stroke was more than doubled by the presence of CH and was higher in individuals with larger mutant clones. This level of risk was comparable to that conferred by well-known contributors to cardiovascular diseases, such as high LDL-cholesterol levels, smoking and hypertension. Causality was demonstrated in mouse models, with the finding that abnormal pro-inflammatory *TET2*-mutant macrophages accelerated atherosclerosis in susceptible mice. Recent epidemiological evidence suggests that CH is also associated with congestive heart failure, and loss of *TET2* or *DNMT3A* led to worsening heart function in a mouse model of this disease, consistent again with a causal role. A causal link between CH and chronic liver disease has also been proposed (Wong, Embdin, Rogers et al, Nature 2023).

A recent study unexpectedly reported that CH is protective against Alzheimer's dementia and that the degree of protection scales with clone size. Mendelian randomisation analyses and microglial profiling suggested a causal link and it was proposed that mutant, marrow-derived cells might supplement a failing microglial system during ageing. It will be fascinating to see if these observations are confirmed in independent studies and to understand how CH interacts with other neurodegenerative disorders as this area of research broadens.

Other studies have postulated links between CH and other diseases of ageing, such as type 2 diabetes and chronic obstructive pulmonary disease, but causality has not been established. It is

possible that these associations are due either to CH representing a biomarker for advanced biological ageing, or to confounders such as smoking. Specific experimental models will be required for more definitive exploration of these relationships.

A key question is how CH mutations change the molecular biology of immune cells to effect influences on diverse disease types. The importance of *TET2* and *DNMT3A* in restraining inflammatory gene expression in innate immune cells is emerging, with a pro-inflammatory phenotype developing when function is perturbed. While the progressive low-level inflammation associated with ageing might be permissive to mutant clonal growth, it is also possible that CH contributes to this 'inflammaging', or, indeed, that both processes operate in parallel in a cycle of positive feedback. A role for CH genes in the adaptive immune response is also suggested, for example, by *DNMT3A* loss-of-function preventing CD8 T-cell exhaustion in the setting of persistent viral infection. It is also notable that stem cell transplant recipients with haematological cancers who receive donor HSCs from carriers of CH have higher rates of graft-versus-host disease and reduced relapse rates, perhaps due to stronger adaptive immune responses against both normal host tissues and tumour.

Clinical considerations and future perspectives

CH is common, indeed ubiquitous, by old age and is associated with an increased risk of blood cancers and excess mortality from non-malignant diseases. From a basic science perspective, the study of CH is providing fundamental insights into the interactions between ageing, somatic mutation and natural selection, processes that operate across all tissues throughout life. From a clinical perspective, the pervasiveness and implications of CH provoke several important questions and challenges.

First, how should we manage individuals found to have CH 'coincidentally' during investigations for minor or transient haematological abnormalities? In this context, it is reasonable to stratify such individuals by their risk of progression to myeloid malignancy, using predictive tools such as 'MN-Predict' or CHRS. Such tools can help identify higher-risk individuals for close monitoring or entry into clinical studies, taking into account other factors such as comorbidities and life expectancy. A second challenging area is the distinction between CH, CCUS and low-grade MDS, which should involve consideration of morphological findings in the context of the somatic mutations identified. It is possible that the details of classification will evolve as our understanding of the relationships between these clinical states improves. A third important question is how to manage patients found to have CH after chemotherapy or stem cell transplantation for solid or lymphoid cancers. In this context, CH due to high-risk mutations, such as those affecting *TP53*, is more common and probably more strongly associated with progression to secondary myeloid malignancy than sporadic *TP53*-mutant CH. Our ability to predict risk in this context is less developed, but some specialist hospitals are following such patients closely and developing expertise in their management, with specific clinical trials being considered. Another area of debate is the interpretation of persistent CH mutations after treatment for AML. Studies have shown that residual isolated *DNMT3A* mutations after AML therapy do not represent minimal residual disease (MRD) and do not carry a high risk of relapse. The implications of other persistent CH driver mutations, such as *TET2* or *ASXL1,* are less well understood; it is not known if they represent MRD when isolated, or whether they are associated with a higher risk of relapse or development of a new myeloid malignancy.

A final consideration is whether we should screen unselected individuals for CH at scale and, if so, how we should do this. While it is likely that screening will be implemented in some form in future, its utility is currently limited by the lack of therapeutic interventions to reduce or restrain CH. Blockade of downstream inflammatory molecules might be one way to manage associated disorders such as cardiovascular disease, but novel interventions will likely focus on suppressing mutant clones directly, with the potential to prevent progression to myeloid malignancy. Such approaches will likely be tailored to specific driver mutations but will require a much deeper understanding of precisely which factors govern the behaviour of particular mutant clones, and how this relates to myeloid disease. As risk stratification improves and potential therapies are developed, it will be imperative to test these in rigorous clinical trials, ideally in the setting of dedicated CH clinics. Successful implementation of genotype-specific interventions would represent the beginning of a new era of 'precision prevention', in which therapies are tailored to genetically-defined risk groups to prevent potential adverse sequelae.

Introduction

Haemostasis is one of a number of protective processes that have evolved in order to maintain a stable physiology. It interacts with other body defence mechanisms, such as the immune system and the inflammatory response. These links are most clearly seen in ancient species such as the horseshoe crab (*Limulus polyphemus*), where a primitive 'coagulation' pathway is initiated by entry of endotoxin into the haemolymph. Vestiges of these links still exist in humans and may give rise to serious clinical consequences. For example, disseminated intravascular coagulation (DIC) can be initiated by Gram-negative septicaemia. Consequent upon the development of a high-pressure circulatory system, extra components have evolved and have resulted in a complex, highly integrated process in all vertebrates (Figure 39.1). Indeed, analysis of the haemostatic network in bony fish suggests that the network in its entirety evolved over 430 million years ago, prior to the divergence of bony fish from tetrapods.

The high blood pressure generated on the arterial side of the vertebrate circulation requires a powerful, almost instantaneous, but strictly localised procoagulant response in order to minimise blood loss from sites of vascular injury without compromising blood flow generally. Systemic anticoagulant and clot-dissolving components have also evolved to prevent extension of the procoagulant response beyond the vicinity of vascular injury, which would otherwise result in unwanted thrombus formation. The evolved haemostatic system is thus a complex mosaic of activating and inhibitory pathways that integrates its five major components (blood vessels, platelets, coagulation factors, coagulation inhibitors and fibrinolytic elements). In addition, the activated proteases of the coagulation system play an important role in cellular signalling, independent of fibrin generation. This occurs through activation of protease-activated receptors (PARs), a subfamily of seven-transmembrane G-protein-coupled receptors, leading to intra-cellular signalling that results in a plethora of cellular responses.

Overview of haemostasis

In the most simplistic terms, blood coagulation occurs when the enzyme thrombin is generated and proteolyses soluble plasma fibrinogen, forming the insoluble fibrin polymer, or clot. 'Haemostasis' refers more widely to the process whereby blood coagulation is initiated and terminated in a tightly regulated fashion, together with the removal (or fibrinolysis) of the clot as part of vascular remodelling. It is essentially the global process by which vascular integrity and patency are maintained over the whole organism, for its lifetime.

Although it is pedagogically convenient to present the subsystems of haemostasis as if they operate independently, the whole haemostatic mechanism is integrated *in vivo* so that thrombin generation is localised, limited and followed by fibrinolysis and tissue remodelling, which are also localised and limited. Furthermore, thrombin generation is not a simple exponential cascade, as was originally envisaged by Davie and Ratnoff when the 'waterfall' hypothesis was described in the 1950s (Figure 39.2). Rather, it is a complex network of interactions with positive and negative feedback loops. Thus, the effects of

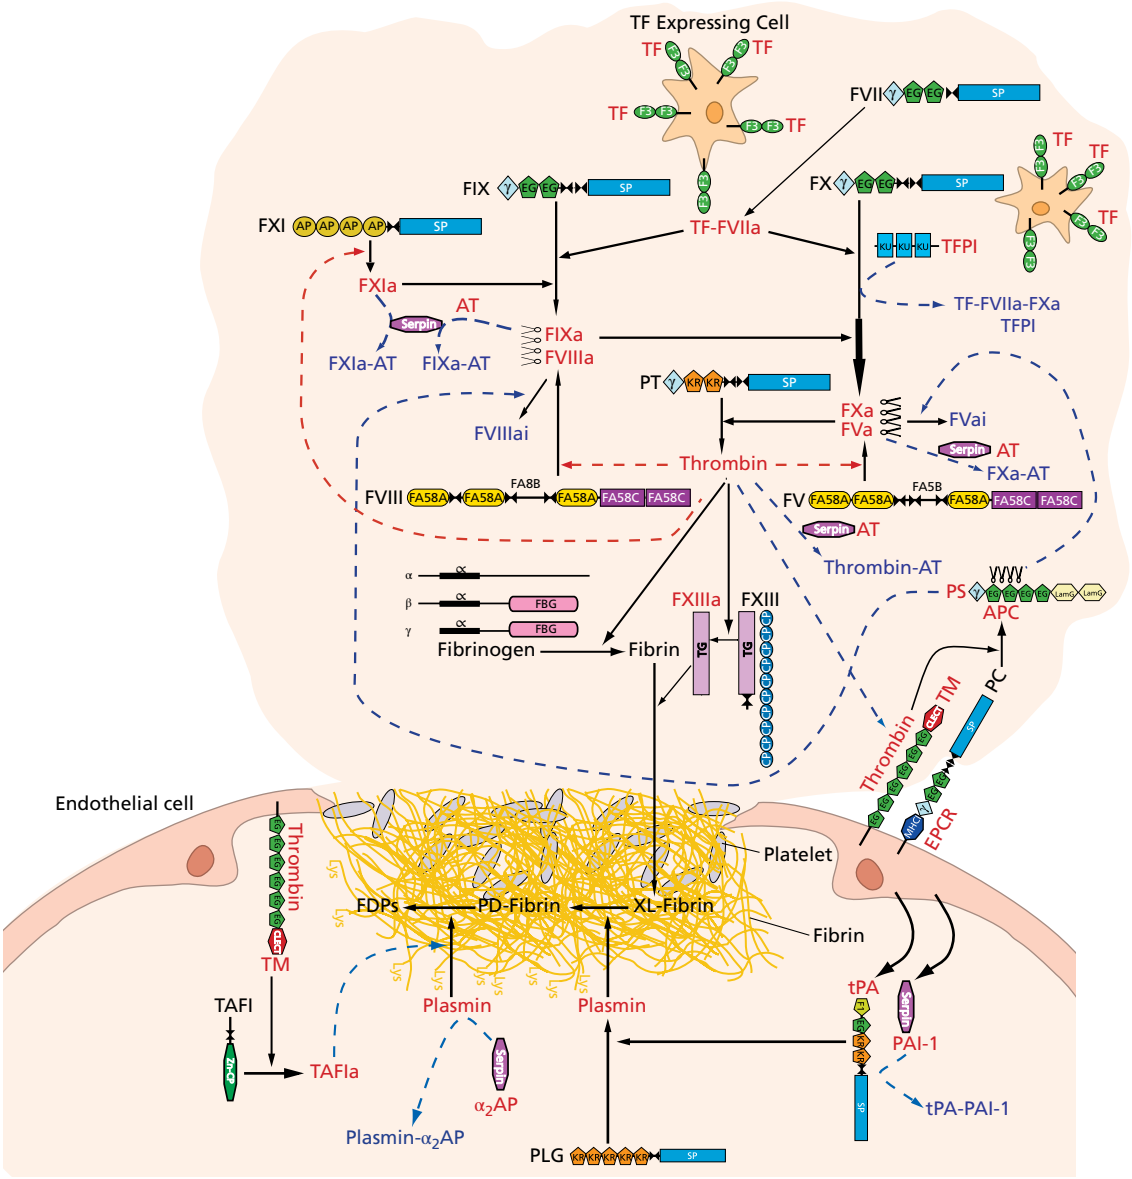

Figure 39.1 The haemostasis network. The network includes elements of coagulation initiation via TF–FVIIa interaction, amplification via the tenase (FVIIIa–FIXa) and prothrombinase (FVa–FXa) complexes, feedback inhibition through specific inhibitors and clot dissolution by fibrinolysis. Modular organisation of proteins is indicated (see Figure 39.8), and all abbreviations are given in the text. Protein names are represented as follows: functionally active proteins, red; inactivated or inhibited proteins, blue; precursors and fibrinogen-derived components, black. Lines and arrows are represented as follows: dashed red lines, positive procoagulant feedback loops; dashed blue lines, negative feedback and inhibitory loops; solid black lines, interactions or processes. Cream boxes indicate assembly of macromolecular complexes on a cellular phospholipid surface. The process of blood coagulation is initiated by the exposure of cells expressing TF to flowing blood. Thrombin generation is propagated by a series of positive feedback loops, leading to fibrin deposition. This process is controlled by a series of negative feedback steps: the initiation complex is inhibited by the formation of the quaternary complex TF–FVIIa–FXa–TFPI, and the active proteases FIXa, FXa and thrombin are inactivated by the serpin AT. In addition, thrombin initiates a negative feedback pathway by activating PC, leading to the inhibition of FVa and FVIIIa by specific proteolytic cleavages. The generation of fibrin leads to activation of the fibrinolytic pathway through binding of tPA, which leads to plasminogen activation and fibrin degradation. This pathway is also subject to inhibition through the binding of the serpins PAI-1 and α_2-antiplasmin (α_2AP) to tPA and plasmin, respectively. All these processes, plus platelet activation, occur simultaneously or with short lag times (Source: McVey and Tuddenham, 2007. Genomics of haemostasis. In: *Genomics and Clinical Medicine* (Kumar, ed.). Reproduced with permission of Oxford University Press.)

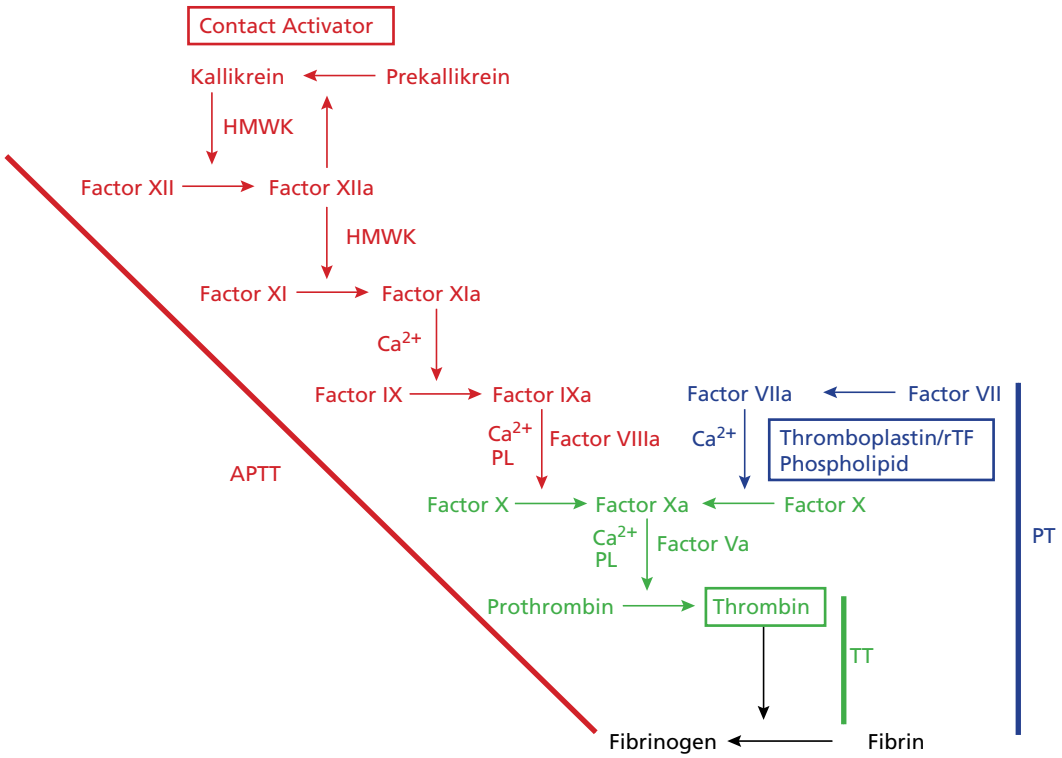

Figure 39.2 The coagulation cascade. The traditional concept of blood coagulation with separate intrinsic (red) and extrinsic (blue) pathways converging on the common pathway (green) with the generation of FXa. The activated partial thromboplastin time (APTT) is initiated by the addition of a contact activator (e.g. kaolin or silica) and calcium and tests for deficiencies in the intrinsic pathway. The prothrombin time (PT) is initiated by addition of thromboplastin (tissue factor), calcium and phospholipids and tests for deficiencies in the extrinsic pathway. The thrombin time (TT) is initiated by addition of thrombin and tests for an inhibitor of thrombin (most commonly heparin) or a problem with fibrin cleavage. HMWK, high-molecular-weight kininogen; PL, phospholipid.

varying the concentration of any component in such a system are not intuitively obvious.

Tissue factor initiates blood coagulation

Exposure of blood to cells expressing tissue factor (TF) on their surface is both necessary and sufficient to initiate blood coagulation *in vivo*, both in normal haemostasis and in pathological situations such as thrombosis. Figure 39.2 presents a version of the earlier cascade concept for intrinsic and extrinsic pathways of thrombin generation. Although the contact system does not appear to have a physiological role in haemostasis, it has emerged as a possible target for treatment of thrombosis without increasing the risk of bleeding. It also has to be considered during interpretation of the common coagulation tests that are used in clinical practice. TF is constitutively expressed at biological boundaries such as skin, organ surfaces, vascular adventitia and epithelial–mesenchymal surfaces, where it functions as a 'haemostatic envelope'. This ensures that, following disruption of vascular integrity, blood is immediately exposed to cells expressing TF, leading to the initiation of blood coagulation. The primary control of haemostasis is therefore the anatomical segregation of cells expressing functional TF from other components of the coagulation network present in blood.

Amplification of the initial stimulus

An updated concept of TF-initiated thrombin generation, including the important feedback reactions of thrombin, is shown in Figure 39.3. As stated above, it is now clear that the physiological initiator of blood coagulation is exposure of the circulating FVIIa and zymogen FVII to membrane-bound TF. Activation of FVII to the protease FVIIa and formation of a very high-affinity complex of TF with FVIIa result in the activation of FIX and FX by the TF–FVIIa (extrinsic tenase) complex. In the absence of its activated cofactor FVa, FXa generates only trace amounts of thrombin from prothrombin. Although insufficient to initiate significant fibrin polymerisation, thrombin formed in this initiation stage of coagulation is able to back-activate FV and FVIII by limited proteolysis. In the

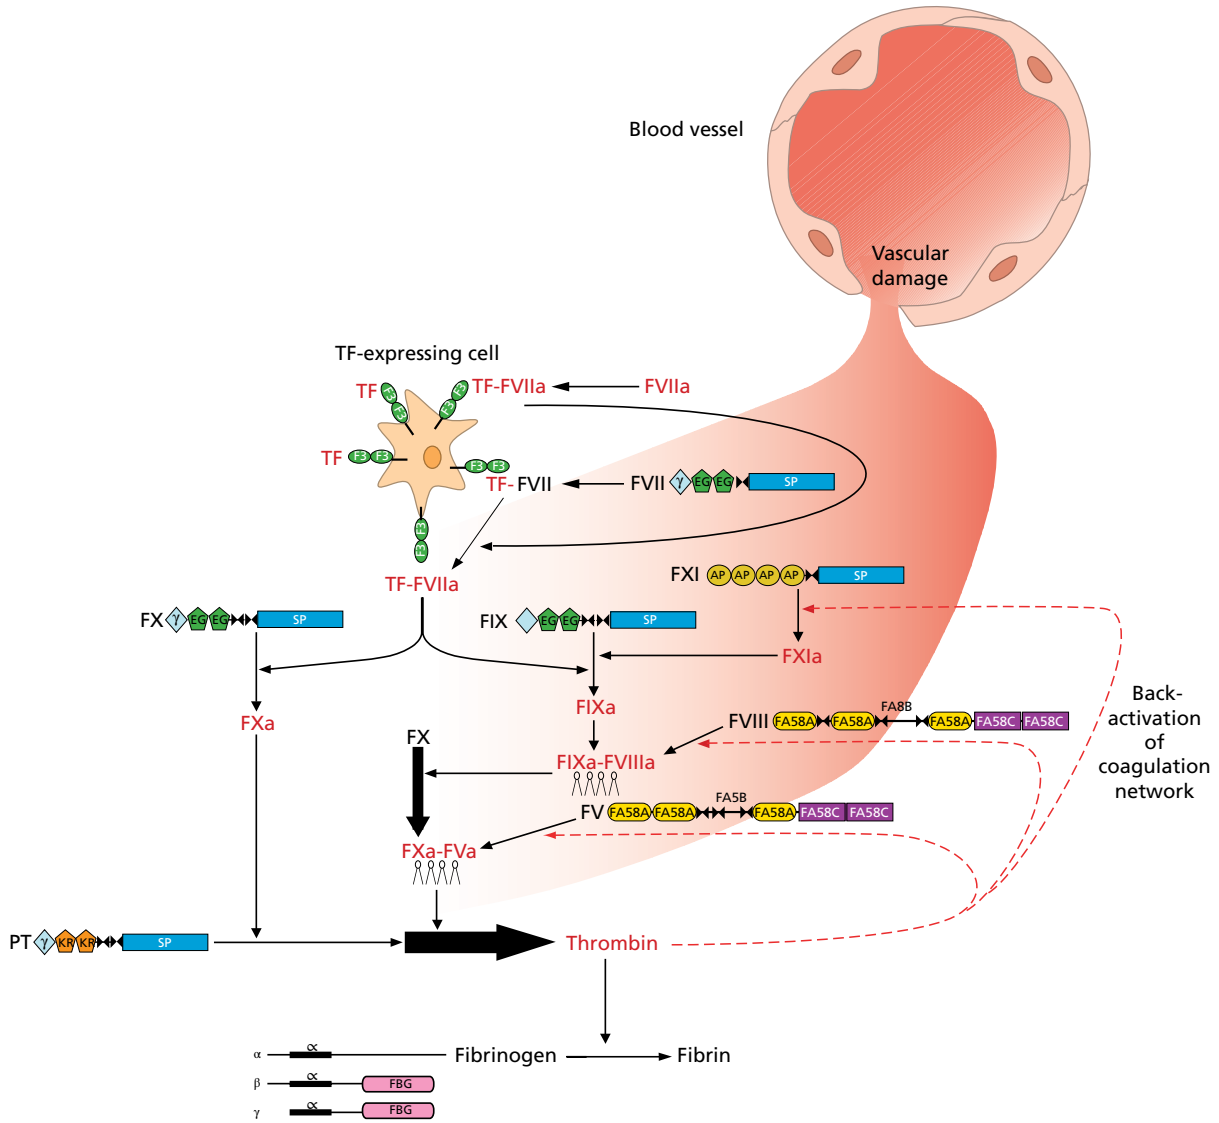

Figure 39.3 The haemostasis network: fibrin generation. Following vascular damage, blood coagulation is initiated by exposure of FVII/FVIIa to cells expressing the integral membrane protein TF. Activation of FVII to the protease FVIIa results in the activation of FIX and FX by the TF–FVIIa complex. In the absence of its activated cofactor FVa, FXa generates only trace amounts of thrombin. Although insufficient to initiate significant fibrin polymerisation, trace amounts of thrombin formed in this initiation stage of coagulation are able to back-activate FV and FVIII by limited proteolysis. In the amplification phase of coagulation, FVIIIa forms a complex with FIXa, activating sufficient FXa, that (in complex with FVa) leads to the explosive generation of thrombin, ultimately leading to generation of a fibrin clot. The tenase (FVIIIa–FIXa) and prothrombinase (FVa–FXa) complexes assemble on phospholipid surfaces. Colours and symbols as in Figure 39.1.

amplification phase of coagulation, FIXa forms a complex with FVIIIa. This is the intrinsic tenase complex (FVIIIa–FIXa) that activates sufficient FX to FXa to form a complex with FVa, producing the prothrombinase complex (FVa–FXa). This results in the explosive generation of thrombin, that ultimately leads to generation of a fibrin clot. Thrombin can also back-activate FXI to FXIa by limited proteolysis, and FXI further activates FIX to FIXa, providing further amplification.

A key feature of these processes is the assembly of multimolecular complexes on a phospholipid surface provided *in vivo* by cell membranes. For procoagulant complexes such as tenase and prothrombinase, this surface is provided by activated platelets. Each of these complexes consists of a cofactor (TF, FVa and FVIIIa), an enzyme (FVIIa, FIXa and FXa) and a substrate that is a zymogen (FIX, FX and prothrombin) of a serine protease. The product of one reaction becomes the

enzyme in the next complex. The procofactors FV and FVIII are themselves activated by limited proteolytic digestion.

Feedback inhibition of the procoagulant response

The TF–FVIIa complex is rapidly inactivated by tissue factor pathway inhibitor (TFPI), released from thrombin-activated platelets or found on the surface of endothelial cells, by the formation of a quaternary inhibited complex (Figure 39.4). This explains the requirement for further activation of FX via FIXa–FVIIIa, and back-activation of FXI by thrombin, to permit further activation of FIX. Figure 39.4 also indicates the role of one of the other important inhibitors of the network, antithrombin (AT), which damps down thrombin generation by forming inactive complexes with FIXa, FXa, FXIa and

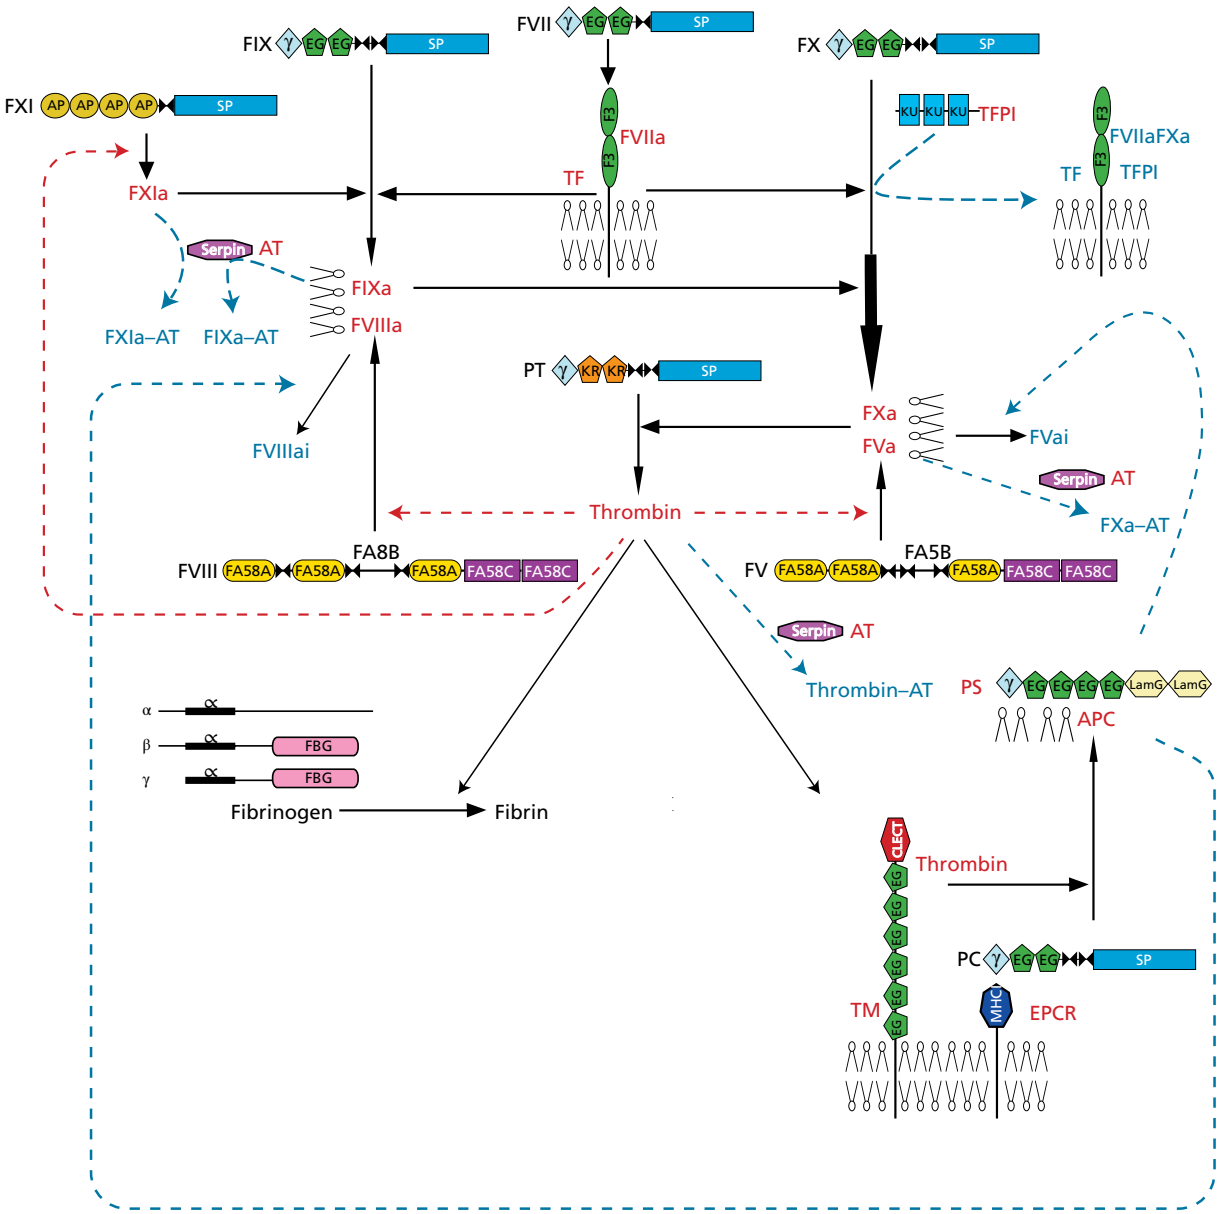

Figure 39.4 The haemostasis network: inhibition of thrombin generation. The initiation of blood coagulation via generation of FIXa and FXa by TF–FVIIa is shut down by the action of TFPI, which forms a quaternary complex with TF–FVIIa–FXa. Further generation of FIXa occurs following back-activation of FXI by thrombin. The serine proteases FIXa, FXa, FXIa and thrombin are all inhibited by AT. At the endothelial cell surface, thrombin bound to TM activates PC bound to its receptor EPCR. APC in complex with its cofactor PS inactivates FVa and FVIIIa by further proteolytic cleavages. Colours and symbols as in Figure 39.1.

thrombin. The rate of inhibition by AT is substantially increased by binding a variety of polysulfated mucopolysaccharides known as glycosaminoglycans (GAGs) on the surface of endothelial cells.

Thrombin also proteolytically activates an anticoagulant pathway, the protein C (PC) pathway (Figure 39.4). Thrombomodulin (TM), an endothelial cell surface receptor, plays a pivotal role in the activation of this anticoagulant pathway. TM binds thrombin and, by an allosteric mechanism, alters its substrate specificity. The procoagulant substrates of thrombin, including FV, FVIII and fibrinogen, are no longer efficiently proteolysed. The preferred substrate of the thrombin–TM complex is PC, a zymogen that is proteolysed to activated PC (APC). Thrombin binding to TM also enhances the substrate specificity to thrombin-activatable fibrinolysis inhibitor (TAFI). The activation of PC can be augmented by another cellular receptor, endothelial cell protein C receptor (EPCR), which provides a direct endothelial cell binding site for PC and thus increases the apparent affinity of the thrombin–TM complex for PC; however, not all endothelial cells coexpress TM and EPCR. In complex with its cofactor, protein S (PS), APC rapidly inactivates the procoagulant cofactors FVa and FVIIIa by specific proteolysis, forming a negative feedback loop. The PC pathway is most active in the microvasculature, where the relative density of TM is highest. *EPCR* expression by contrast is largely restricted to large vessels.

Fibrinolysis

The final step in the regulation of fibrin deposition is the prevention and/or rapid removal of insoluble fibrin by the fibrinolytic system (Figure 39.5) described more fully later in the chapter. Briefly, once sufficient fibrin is generated, it binds

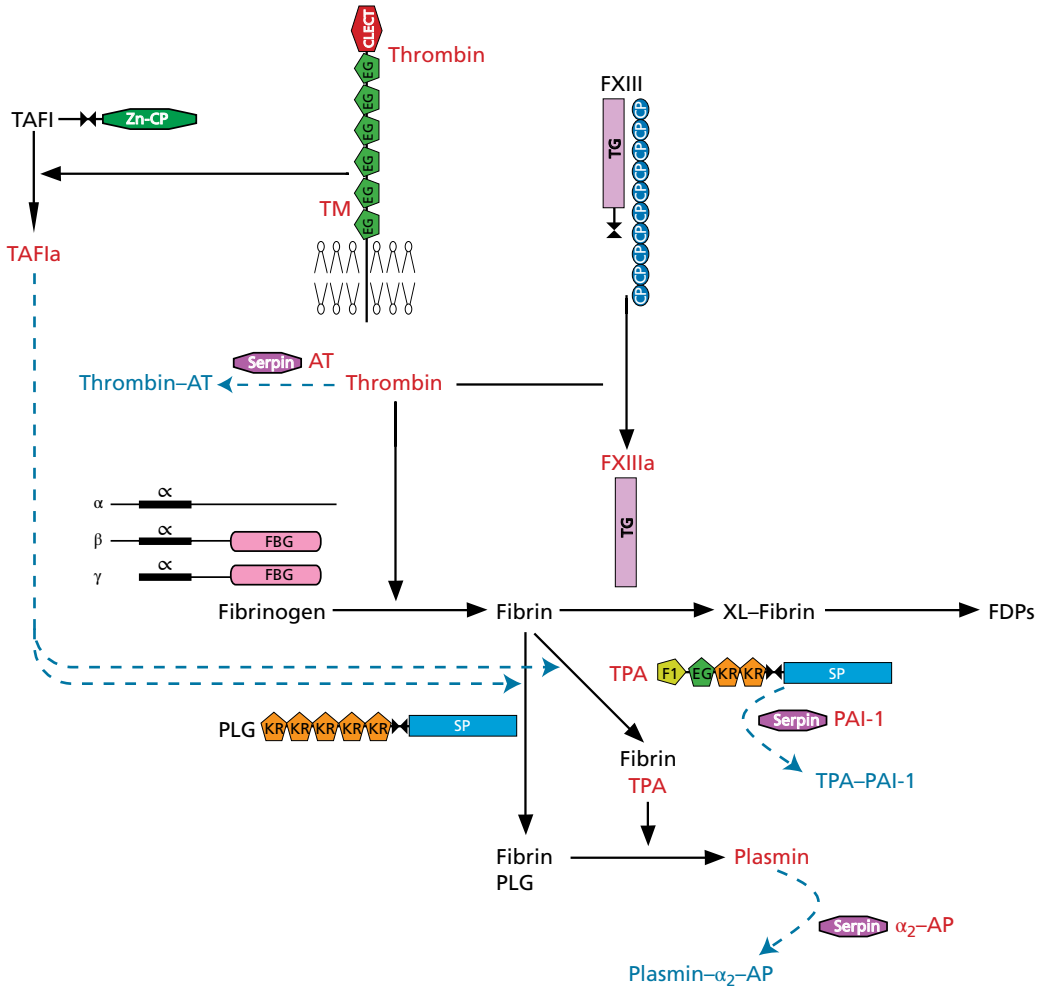

Figure 39.5 The haemostasis network: fibrinolysis. Both PLG and tPA bind to polymerised fibrin, promoting the cleavage of PLG by tPA to active plasmin, which then degrades cross-linked fibrin to soluble FDPs. Modulation of fibrinolysis is achieved by serpin inhibition: PAI-1 inactivates tPA, while α_2-antiplasmin (α_2AP) inhibits plasmin. Conversely, TAFIa removes Lys residues from fibrin, removing PLG- and tPA-binding sites, reducing plasmin generation. Colours and symbols as in Figure 39.1.

tissue plasminogen activator (tPA), leading to the increased activation of plasminogen (PLG). This results in the formation of plasmin at the site of the fibrin clot, which breaks down fibrin into soluble fibrin degradation products. The fibrinolytic system is also subject to inhibition through the action of inhibitors of tPA and plasmin, namely, plasminogen activator inhibitor (PAI)-1 and α_2-antiplasmin, respectively. In addition, the activated TAFI generated by the action of TM-thrombin serves as a negative regulator of fibrinolysis, enhancing the stability of fibrin clots.

Blood vessels

The endothelium

The endothelium functions in a multitude of physiological processes, including intracellular transport, the regulation of vasomotor tone and maintenance of blood flow. Endothelial cells possess surface receptors for a variety of physiological substances, for example thrombin and angiotensin II, which may influence vascular tone directly or indirectly through various haemostasis-related events.

The apical luminal surface of the endothelium has a polysaccharide-rich layer mainly composed of glycosaminoglycans, proteoglycans and glycoproteins known as the glycocalyx. It creates a barrier between circulating cells/molecules and the vessel wall. It plays a key role in regulating a number of processes: it participates in angiogenesis, exerts an anticoagulant effect, prevents leukocyte adhesion, acts as a selective permeable barrier and filter, operates as a mechano-transducer of shear stress and contributes to maintaining vascular tone. Heparan sulfate proteoglycan is the predominant constituent and bears a significant negative charge at physiological pH, which promotes electrostatic interactions with positively charged residues on circulating proteins such as AT, HCII and TFPI exerting an anticoagulant effect. Endothelial activation is characterised by shedding of the glycocalyx and increased expression of adhesion molecules.

Once activated, endothelial cells express a variety of intracellular adhesion molecules, some of which are released into the plasma. These include vascular cell adhesion molecule (VCAM), E-selectin, P-selectin, and von Willebrand factor (VWF), which modulate leucocyte and platelet adhesion, inflammation, phagocytosis and vascular permeability.

However, the endothelium should not be regarded as a simple homogeneous cell type. It would appear that endothelial cell phenotypes are differentially regulated. At any given point in time, structural and functional phenotypes may vary between segments of the vascular tree, and at any given location, the endothelial phenotypes may change from one moment to the next. Endothelial cell heterogeneity occurs between different organs, within the vasculature of a given organ, and even between neighbouring endothelial cells of a single vessel.

The platelet–vessel wall interaction

Healthy unperturbed endothelial cells exert a powerful inhibitory influence on haemostasis by virtue of the factors they release or express on their surface (see Figure 39.6a). Two of these, prostaglandin (PG)I_2 (or prostacyclin) and nitric oxide (NO), also known as endothelium-derived relaxing factors, have powerful vasodilator activity, acting on smooth muscle cells in the vessel wall (basal-directed secretion) and hence modulating blood flow. Both substances inhibit aggregation of platelets and leucocytes (luminal-directed secretion) by increasing intraplatelet levels of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), respectively (see below).

PGI_2 is the major prostaglandin synthesised by endothelial cells, a small amount also being produced by fibroblasts and smooth muscle cells. Its action on platelets involves binding to a specific G-protein-coupled receptor (PTGIR) that activates adenylate cyclase, thus increasing the intraplatelet cAMP concentration. This promotes Ca^{2+} uptake into the dense tubular system and inhibits phosphatidylinositol metabolism, both of which prevent platelet aggregation and the consequent release of storage granules containing procoagulant molecules such as VWF and FV. Thrombin, and other agents that are generated at the site of injury, stimulate the synthesis of PGI_2 by adjacent endothelial cells, which counteracts the platelet-aggregating activity of the protease and thereby helps to localise platelet plug formation. PGI_2 is rather unstable, with a half-life of only a few minutes in whole blood, and degrades spontaneously to 6-keto-$PGF_{1\alpha}$. This degradation product is biologically inert, but in some tissues, a variable proportion of PGI_2 may be enzymatically converted to 6-keto-$PGF_{1\alpha}$ or 6,15-diketo-13,14-dihydro-$PGF_{1\alpha}$, which retains some platelet-inhibitory activity.

The once-held belief that PGI_2 is a circulating hormone that limits platelet–platelet interactions within the bloodstream is probably false, as plasma levels of PGI_2 are at least two orders of magnitude below than that needed to inhibit platelet aggregation. Although in some settings, such as following severe trauma, it is possible that markedly increased systemic levels could occur transiently, it is more likely that PGI_2 serves mainly as a local hormone, principally concerned with vascular tone, but possibly also inhibiting the extension of the platelet plug beyond the immediate vicinity of any endothelial damage.

NO is synthesised in smooth muscle cells, macrophages and activated platelets, as well as by endothelial cells. Its synthesis and secretion may be constitutive (when it serves as a local hormone to 'fine tune' blood flow). Stimulated (inducible) synthesis of NO also occurs in endothelial cells exposed to cytokines such as interleukin (IL)-1, tumour necrosis factor (TNF) or endotoxin. This produces a slower but longer-lasting increase in NO level and can have undesirable side-effects, such as inflammation, cytotoxicity or prolonged hypotension. Like PGI_2, it has a very short half-life (3–5 s) and is rapidly oxidised to the inactive nitrite (NO_2^-) or nitrate (NO_3^-) forms.

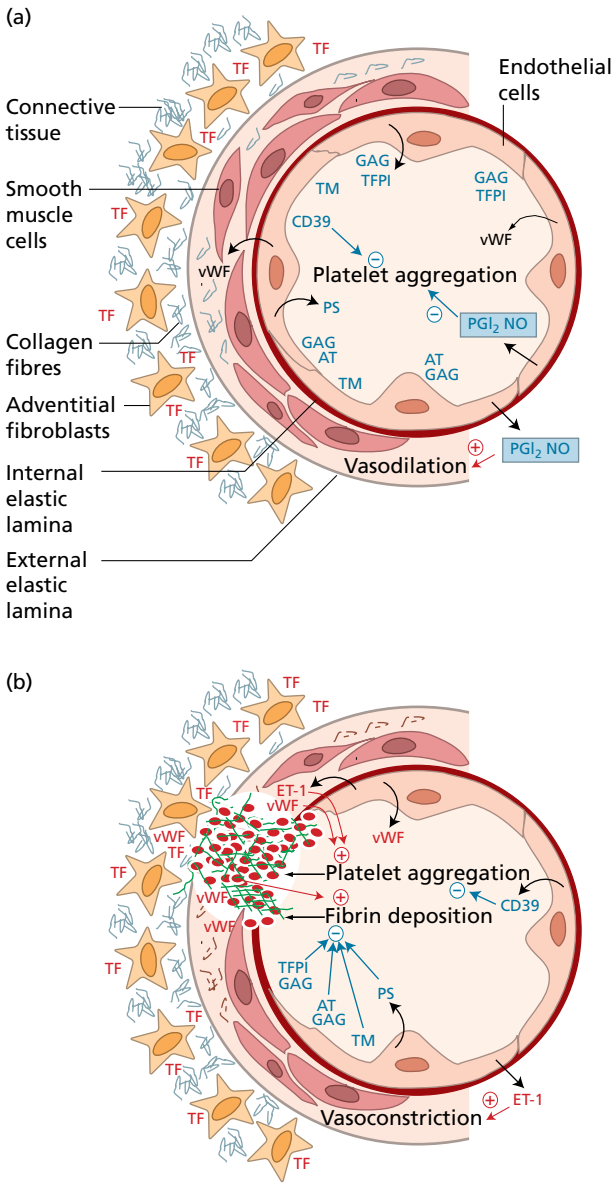

Figure 39.6 Blood vessel architecture and functions in haemostasis. (a) The anatomy of a generic vessel in the resting state. The layer thicknesses vary widely between arterial and venous circulation and between large and small vessels. In the absence of vessel damage, cells expressing TF are anatomically separated from components of the blood coagulation network, preventing initiation of coagulation. In addition, coagulation inhibitors present on the endothelial surface and inhibitors of platelet aggregation maintain vessel patency. (b) The localised haemostatic response to vessel injury: initiation of coagulation by TF exposure and platelet activation/aggregation by exposure of extravascular collagen to plasma VWF. Procoagulant responses away from the lesion site are damped down by anticoagulant and antiplatelet factors derived from the endothelium.

In addition to PGI_2 and NO, endothelial cells also express an ecto-ADPase (CD39) on their cell surface, which rapidly metabolises ATP and ADP, released from activated platelets, to AMP, thereby drastically reducing or abolishing platelet recruitment and aggregation in response to thrombin.

The 21-amino-acid peptide endothelin (ET)-1 is the predominant isoform of the endothelin peptide family, which also includes ET-2, ET-3 and ET-4. It exerts various biological effects, including vasoconstriction and the stimulation of cell proliferation in tissues, both within and outside the cardiovascular system. In the endothelium, ET-1 is predominantly released abluminally towards the vascular smooth muscle, where it acts as a potent vasoconstrictor and mitogen for smooth muscle cells. In addition, ET-1 stimulates the production of cytokines and growth factors. Furthermore, it stimulates neutrophil adhesion and platelet aggregation and is chemotactic for macrophages.

Thrombospondin (TSP)-1 is an abundant constituent of the α-granules of platelets and Weibel–Palade bodies of endothelial cells. TSP-1 expression is upregulated by vascular cells after injury and in chronic disease. Upon release, TSP-1 binds to the cell surface in a Ca^{2+}-dependent manner and interacts with a number of cellular membrane proteins, including integrins $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$, CD36 and the integrin-associated protein (IAP or CD47) and integrin-bound fibrinogen and fibronectin. TSP-1 appears to function by regulating the formation of multiprotein complexes that modulate cellular phenotype. The cellular response varies depending on the cell type as each cell expresses

a different repertoire of receptors. On the platelet, TSP-1 activates $\alpha_{IIb}\beta_3$ through its binding to IAP. This results in platelet spreading and aggregation.

von Willebrand factor

VWF is a multimeric glycoprotein that plays an important role in primary haemostasis by promoting platelet adhesion to the subendothelium at sites of vascular injury under high shear rate conditions. It is also a carrier of FVIII, and this association protects FVIII from rapid proteolysis and clearance. Failure of FVIII to bind VWF, as occurring in type 2N von Willebrand disease (see Chapter 41), leads to its rapid turnover and resulting FVIII deficiency. VWF is synthesised by endothelial cells, megakaryocytes and platelets. In endothelial cells, VWF may be secreted directly into the circulation or stored in Weibel–Palade bodies. The VWF produced in megakaryocytes and platelets is not secreted but stored in α-granules. Release of VWF from intracellular stores occurs following activation of endothelial cells or platelets. Some therapeutic products, such as desmopressin, work by stimulating release of stored VWF.

Mature VWF is composed of disulfide-linked subunits, each comprising 2050 amino acid residues and up to 22 carbohydrate side-chains. Each subunit has a molecular mass of approximately 278 kDa, of which 10–19% is carbohydrate. Two subunits joined at their C-termini by disulfide bridges form a dimer. Additional disulfide bridges between dimers lead to the formation of larger multimers that range in size from 500 kDa to in excess of 10,000 kDa (Figure 39.7). The ultra-large VWF multimers are predominantly stored, but when secreted by endothelial cells may appear as globular molecules or as thin filaments that are several microns long. These ultra-large VWF multimers can only be detected transiently in normal plasma because they are cleaved by a plasma metalloproteinase (ADAMTS-13). Deficiency or inhibition of ADAMTS-13 results in accumulation of ultra-large VWF multimers in plasma, leading to enhanced shear-induced platelet aggregation and microvascular thrombosis, as seen in thrombotic thrombocytopenic purpura (TTP) (see Chapter 46).

VWF contains binding sites for collagen, fibrinogen and the platelet receptor, glycoprotein (GP)Ib. When vascular injury exposes subendothelial collagen, VWF binds and becomes unwound from its globular form (Figure 39.7c). This exposes more binding sites and allows the capture of platelets from the circulation. Thus VWF and, to some extent, fibrinogen act as bridges between the platelet and the injured vascular wall. Variants in the genes encoding the GPIbα complex that lead to loss of function cause the bleeding disorder Bernard–Soulier syndrome. Conversely, gain-of-function variants in either VWF or GPIb that increase the interaction lead to type 2B von Willebrand disease or pseudo (platelet-type) von Willebrand disease (see Chapter 41).

Endothelial cell anticoagulant activities

Endothelial cells regulate coagulation by a number of mechanisms. The activity of the PC pathway is promoted by expression of two cellular receptors. TM is constitutively expressed on all endothelial cells, with the exception of the brain. EPCR is expressed strongly in the endothelial cells of arteries and veins in the heart and lung, less intensely in capillaries in the lung and skin, and not at all in the endothelium of small vessels of the liver and kidney. In addition, endothelial cells synthesise and secrete PS, the cofactor for APC in the inactivation of FVa and FVIIIa.

Endothelial cells regulate the initiation of coagulation by synthesising the main physiological inhibitor of the FVIIa–TF initiating complex, namely, TFPI. This is described in greater detail below. Endothelial cell-surface GAGs are important in binding TFPI, AT and HCII and also modulate the activity of AT, which inhibits thrombin and FXa, and to a lesser extent FIXa and FXIa.

Endothelial cell-derived fibrinolytic factors

Three important fibrinolytic factors are detectable in the vessel wall: tPA and PAI-1 are synthesised primarily by endothelial cells, whereas urinary plasminogen activator (uPA, urokinase) is mainly derived from fibroblast-like cells in the kidney and gut. Unlike VWF and P-selectin, tPA and PAI-1 are not stored in Weibel–Palade bodies and, in the resting state, synthesis and secretion are slow, resulting in low circulating levels. However, stimulated synthesis and release occur in response to a variety of stimuli.

Coagulation factors

A summary of the characteristics of the proteins discussed, including gene location, number of exons, molecular mass, circulating concentration, plasma half-life and presumed function, can be found in Table 39.1. The domain structure and modular nature of the proteins are shown in Figure 39.8. This demonstrates the similarity between coagulation factors that belong to the same protein family, such as the serine proteases (e.g. compare FVII, FIX, FX and PC). Many of the coagulation proteins were traditionally numbered from the mature N-terminus of the protein as +1, with the signal peptide and propeptide numbered negatively. However, following attempts to standardise systems for naming genes and variations within them, it was recommended that proteins should be numbered from the initiation methionine as +1 according to guidelines from the Human Genome Variation Society (HGVS). To reduce confusion, all amino acids in this chapter adhere to this guidance, but the reader should be aware that many historical publications will use this legacy numbering system, and therefore legacy descriptions are included in parentheses for clarity.

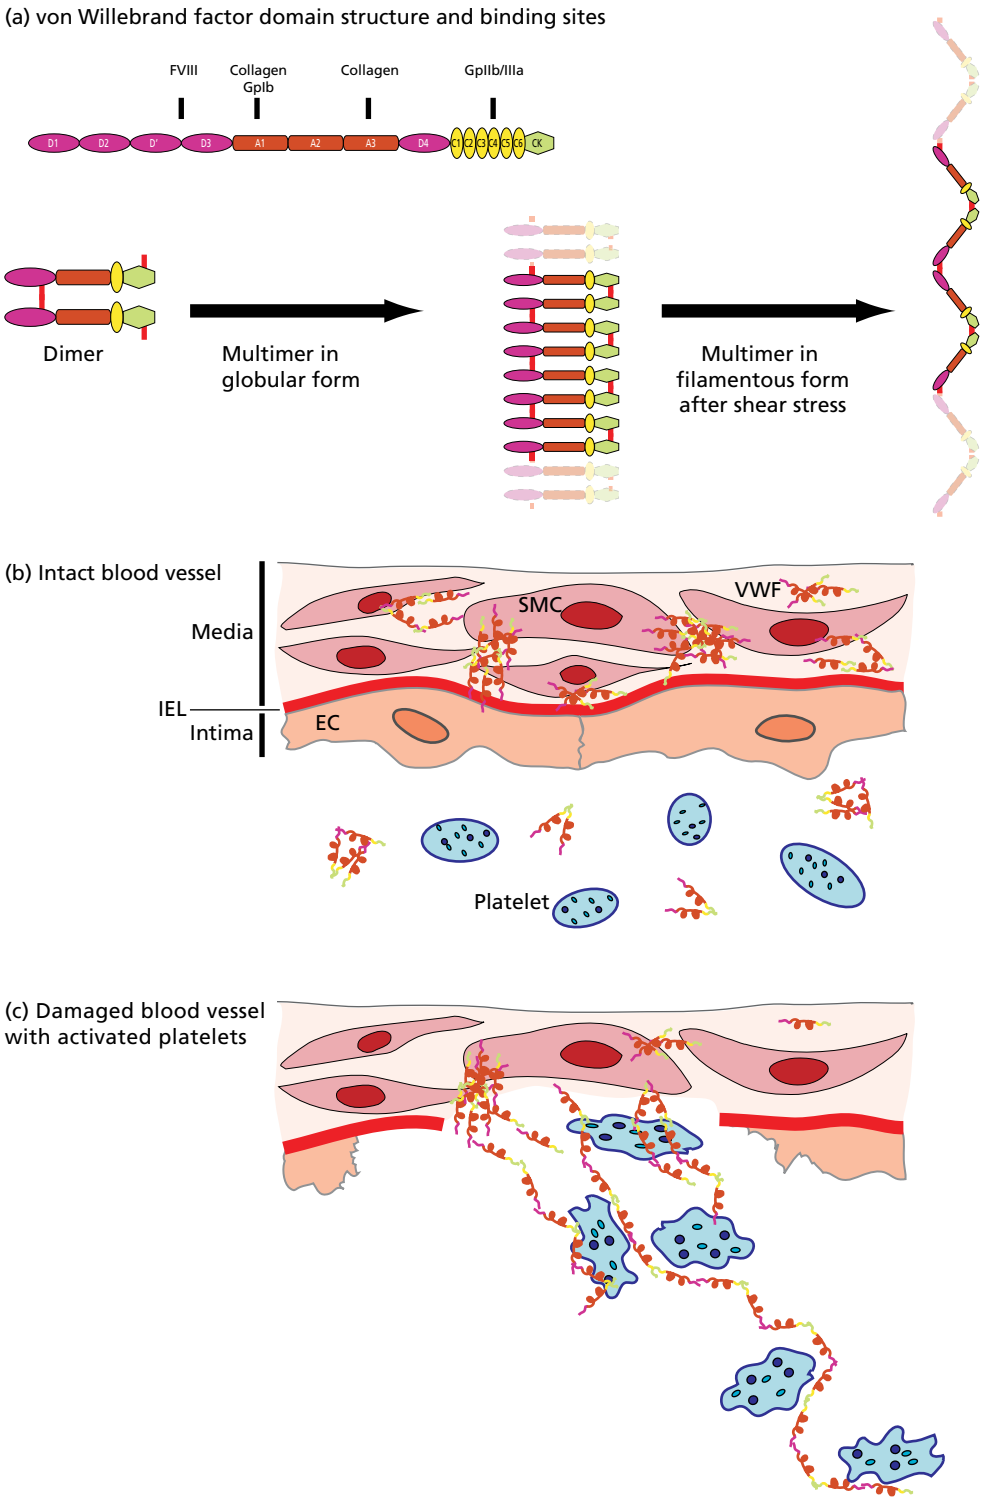

Figure 39.7 Role of von Willebrand factor (VWF) in haemostasis. (a) VWF domain structure of the primary translation product. The 22-amino acid secretory peptide (SP) is cleaved off after translocation of the primary translation product to the endoplasmic reticulum. Dimers are formed when individual monomers become joined through disulfide bonds at the C-terminus. Multiple dimers are then joined at the N-terminus to form high-molecular-weight multimers that take on a globular shape. This latter process requires the propeptide (D1–D2) which is then cleaved off in the trans-Golgi. When exposed to flowing blood under high shear stress, the multimers become filamentous, exposing their binding sites. (b) In the normal vasculature, the ultra-high-molecular-weight VWF multimers required for full VWF function are found only in the subendothelium. The circulation contains lower-molecular-weight multimers. After disruption of the endothelium (c), exposure of high-molecular-weight multimers to flowing blood applies shear stress, causing the multimers to unravel and capture activated platelets. The coagulation network forms on the surface of these platelets. Thus, VWF acts to localise the process of clot formation to the site of vascular damage. EC, endothelial cell; IEL, internal elastic lamina; SMC, smooth-muscle cell.

Table 39.1 Key proteins involved in the haemostatic network.

Common name	Abbreviation	Gene symbol	Gene location	No. of exons	Amino acids (mature)	M_r of monomer (kDa)	Plasma level (μg/mL)	Plasma level (nmol/L)	$t_{½}$ (hours)

* FXI circulates as a 160-kDa homodimer of two 80-kDa monomers.
† FXIII circulates as a 326-kDa tetramer of two A- and two B-chains.
‡ Fibrinogen circulates as a 340-kDa complex of two each of A-, B- and C-chains.

Tissue factor

The formation of the FVIIa–TF complex is regarded as the sole initiator of coagulation in both normal and pathological coagulation. The processed mature TF protein is a 263-amino acid protein after signal peptide cleavage. The 219-residue extracellular region consists of two fibronectin type III domains anchored into the cell membrane by a 23-residue transmembrane sequence. The extracellular region binds tightly to FVIIa to form a highly active procoagulant complex. The 21-residue cytoplasmic domain has been implicated in intracellular signalling; however, transgenic experiments in mice have shown that this domain is not required for either development or procoagulant function, so its role is still unclear.

Vascular adventitial cells, neuroglia, vascular smooth muscle and epidermal cells express TF constitutively. It therefore forms a protective envelope around blood vessels and organs, ready to initiate clotting as soon as blood leaks out of vessels. TF is also expressed by monocytes and endothelium after activation by inflammatory cytokines or by endotoxin, as occurs in sepsis, and

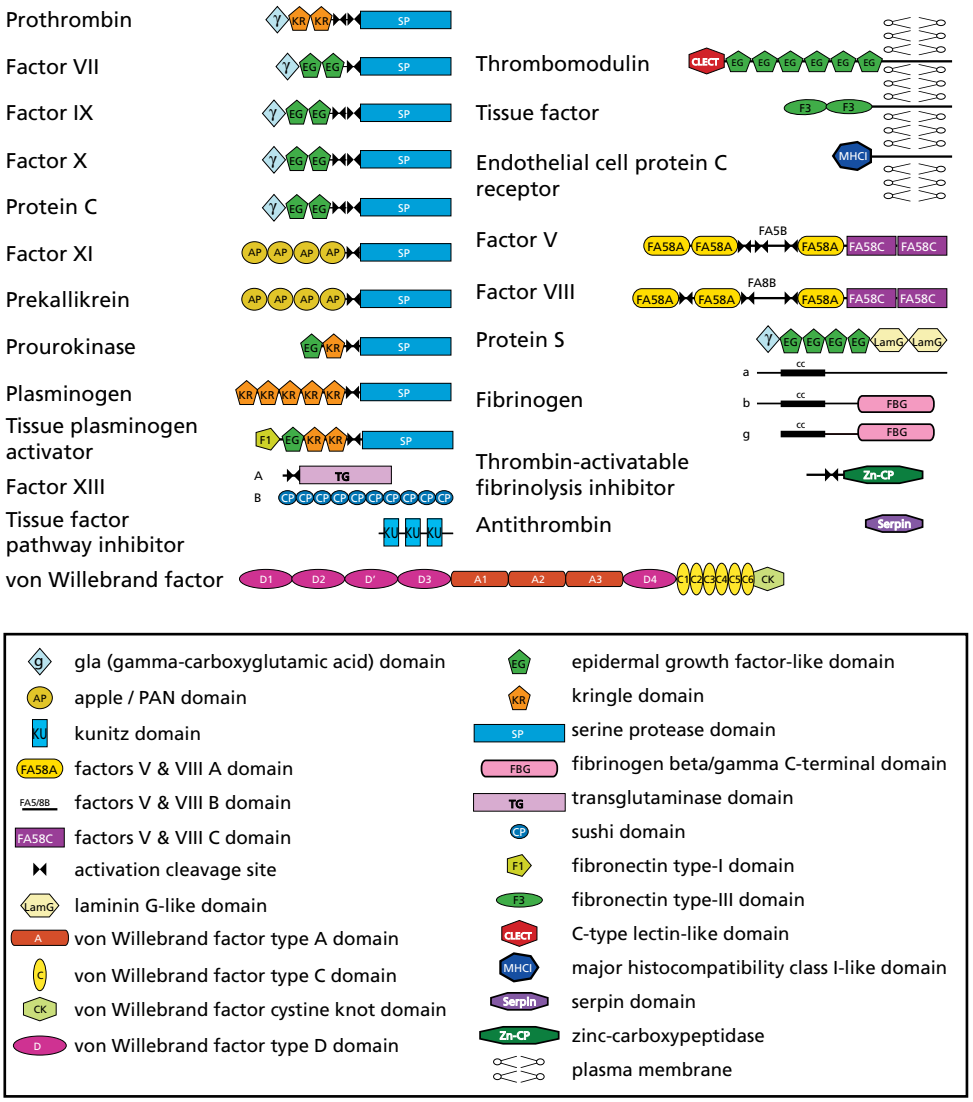

Figure 39.8 Modular organisation of haemostasis proteins. The evolutionary relationship of many factors is suggested by their modular organisation.

on cancerous tissues. Intravascular exposure of TF by any route, but particularly after atherosclerotic plaque rupture, can result in pathological thrombosis. Recent work has also focused on the novel hypothesis that functionally active TF can circulate in flowing blood on small procoagulant extracellular vesicles (exosomes), which may also be transferred from one blood cell type to another via specific receptor-mediated interactions. These procoagulant extracellular vesicles are often derived from tumour cells and can promote metastasis and pre-metastatic niche formation.

Factor VII

Plasma FVII/FVIIa binds to TF, for example after vessel trauma or plaque rupture, to form a complex that initiates coagulation by directly activating FX and to a lesser extent FIX. Approximately 1–2% of total circulating *FVII* is in the active form FVIIa. The FVII gene (*F7*) lies adjacent to the factor X gene (*F10*), suggesting gene duplication during evolution, and close to that of protein Z (*PZ*) at 13q34. In common with the other serine proteases of the coagulation network (FIX, FX, prothrombin and PC), as well as PS and PZ, FVII has an N-terminal domain that contains a number (9–12) of glutamic acid residues that are post-translationally modified by the addition of a carboxyl group to the γ-carbon by a vitamin K-dependent carboxylase. This γ-carboxyglutamic acid (GLA) domain confers affinity to negatively charged phospholipid membranes, such as those of activated platelets or endothelial cells, promoting the assembly of functional multiprotein complexes on these surfaces. Proteins containing GLA modules are commonly referred to as 'vitamin

K-dependent factors' as this vitamin is a cofactor in the carboxylation reaction. Blocking this post-translational modification with coumarin derivatives such as warfarin was one of the main treatments for the long-term prevention of thromboembolic events prior to the development of direct oral anticoagulants (DOACs). FVII in common with other GLA domain-containing proteins has a primary translation product that contains a propeptide sequence that directs the γ-carboxylation at 10 Glu residues within the GLA domain. The GLA domain is followed by two epidermal growth factor (EGF)-like domains, the connecting or activation peptide and the serine protease domain. FVII is activated by cleavage between residues Arg212 (152) and Ile213 (153), yielding a two-chain disulfide-linked FVIIa molecule; however, this has little catalytic activity until it is bound to TF. The half-life of FVII zymogen in plasma is 3–6 hours and, remarkably, the half-life of the FVIIa enzyme is 2–3 hours, probably because there is no plasma inhibitor capable of effectively neutralising free FVIIa. Recombinant FVIIa is in clinical use as a treatment for haemophilia with inhibitors and other severe heritable or acquired bleeding disorders.

Factor X

The gene (*F10*) and protein structures of FX closely resemble those of FVII. Unlike FVII, zymogen FX circulates as a two-chain disulfide-linked heterodimer due to excision of a tribasic peptide (Arg-Lys-Arg) at residues 179–181 (139–141) during synthesis. The light chain of FX therefore consists of the GLA domain with 11 γ-carboxyglutamic acid residues, the amphipathic helix and two EGF-like domains. The half-life of FX in plasma is 36 hours. FX is activated by either FIXa–FVIIIa or TF–FVIIa on phospholipid surfaces in the presence of Ca^{2+} ions by proteolytic cleavage at Arg234-Ile235 (Arg194-Ile195). FXa forms a phospholipid-bound complex with FVa, which efficiently activates prothrombin (prothrombinase complex).

Factor IX

The FIX gene (*F9*) is located at Xq26, about 15.2 Mb from the FVIII gene (*F8*); thus, deficiencies of both factors are X-linked disorders. Deficiency of FIX results in clinical haemophilia B, as the main function of FIX is to participate in the tenase complex (FIXa–FVIIIa). The FIX promoter has been extensively studied and includes sites for liver-specific transcription factors. The 5′ untranslated region of the *F9* gene has also been extensively studied and includes two sites for age-related gene regulation that play a role in the haemophilia B Leyden phenotype (FIX deficiency, which corrects spontaneously at puberty). The plasma half-life of FIX is 18 hours.

The mature protein is a single-chain molecule consisting of 415 amino acids, and the GLA domain contains 12 γ-carboxyglutamic acid residues. Either TF–FVIIa or FXIa cleaves FIX within the connecting peptide (between residues 191 and 192 (145–146) and 226 and 227 (180–181)). Unlike FVII and FX, FIX requires two proteolytic cleavages, releasing an activation peptide, in order to achieve full activation.

Factor XI

FXI is a zymogen of a serine protease that has four Apple (PAN1–4) domains and a serine protease domain in each monomer. The protein circulates as a homodimer, with the two monomer subunits linked via a series of interactions between the two Apple four domains that includes a disulfide bridge. Activation of FXI is by a single cleavage performed by thrombin. FXIa then activates FIX directly in free solution. FXI activation by the contact protein FXIIa was originally thought to be a relevant step in intrinsic or contact-activated coagulation (see Figure 39.2), but it is now considered that the feedback activation of FXI by trace thrombin provides a physiologically relevant route for generation of increased amounts of FIXa to assemble tenase during the amplification of the initial TF stimulus (see Figure 39.3). Thrombin activates FXI by proteolytic cleavage at Arg387-Ile388 (Arg369-Ile370).

There is increasing evidence that FXI has other roles in haemostasis, such as regulation of fibrinolysis by the thrombin-activatable fibrinolysis inhibitor (TAFI). The fact that bleeding symptoms in FXI deficiency correlate poorly with FXI procoagulant level, suggesting that these other functions may be important in determining the phenotype in this mild bleeding disorder.

Factor XIII

FXIII circulates as a tetramer of two A-chains and two B-chains. The B-chains function as carriers for the A-chains which, after activation by thrombin, function as a transglutaminase to cross-link fibrin and other proteins in the clot, notably antiplasmin, resulting in a stable structure. FXIIIa contains a free sulfydryl group at the active site. Platelets also contain FXIII A-chain dimers, which are fully functional after thrombin activation.

Factor VIII

The FVIII gene (*F8*) spans 187 kb of the X chromosome (Xq28) and encodes a protein of 2351 amino acids. After removal of the 19-amino acid signal sequence, a single chain of 2332 amino acids is transiently formed but is subsequently processed by a single proteolytic cleavage prior to release as a two-chain molecule. Because of internal homology, the FVIII domain structure can be represented as A1–A2–B–A3–C1–C2. The B domain is not necessary for procoagulant function, as B-domain-deleted FVIII has full activity. The B-domain sequences of FV and FVIII share little sequence identity, although their lengths are similar,

and both are heavily glycosylated. It is likely that the glycosylated B domain functions in promoting endoplasmic reticulum/Golgi transport since deficiency of LMAN1 (also known as ERGIC 53), a mannose-binding protein, results in combined deficiency of FV and FVIII. FVIII also has three short acidic interdomain peptides (a1, a2 and a3) that are closely implicated in FVIII function.

FVIII is the essential procofactor for activation of FX by FIXa in the tenase complex. It has no function until proteolysed to FVIIIa by thrombin or FXa at Arg391-Ser392 (Arg372-Ser373) and Arg1708-Ser1709 (Arg1689-Ser1690). FVIIIa is directly inactivated by APC cleavage at Arg355-Ser356 (Arg336-Ser337) and Arg581-Ser582 (Arg562-Ser563); however, functional activity of FVIIIa also decays rapidly by dissociation of the A2 subunit from FVIIIa.

Factor V

The mature protein product is 2196 amino acids in length after cleavage of a 28-amino acid signal peptide. The structure of FV, like that of FVIII, can be represented as A1–A2–B–A3–C1–C2. In contrast with FVIII, the B domain is required for full procoagulant function, and it circulates in a single chain form. FV also differs from FVIII, in that it lacks the three short acidic interdomain peptides (a1, a2 and a3) implicated in FVIII function.

FV is the procofactor for the activation of prothrombin by FXa. It has no cofactor activity until proteolysed by thrombin or FXa at Arg737-Ser738 (Arg709-Ser710), Arg1046-Thr1047 (Arg1018-Thr1019) and Arg1573-Ser1574 (Arg1545-Ser1547). FVa is inactivated by APC through cleavages at Arg534-Gly535 (Arg506-Gly507) and Arg1793-Leu1794 (Arg1765-Leu1766). The initial (and rate-limiting) cleavage is at Arg534 (Arg506). This is the site of the variant in FV Leiden (FV Arg534Gln (Arg506Gln)) that is resistant to APC, leading to the most common form of familial thrombophilia.

Fibrinogen

The fibrinogen gene cluster is located on chromosome 4q32 in the order β–α–γ, with β transcribed in the opposite direction to α and γ. The three chains of fibrinogen are disulfide cross-linked and folded together in an intricate manner. The overall structure of fibrinogen is a symmetrical dimer, $\alpha_2\beta_2\gamma_2$. Viewed by electron microscopy, the molecule is trinodular, with the outer two globular domains (fragments D) containing the C-termini of all three chains connected to the central globular domain (fragment E), which contains the N-termini of all six chains tethered together by disulfide bonds. Coiled regions, forming α-helical ropes, connect the lateral and central globular domains.

Polymerisation of fibrinogen occurs when thrombin cleaves two short, negatively charged fibrinopeptides A and B from the N-termini of the α- and β-chains, respectively. This reveals new N-terminal sequences in the fragment E region (called knobs) that fit into holes in the fragment D regions. Polymerisation then occurs spontaneously in a staggered half-overlap array, which can elongate indefinitely in either direction. Electron microscopy studies have been useful for resolving the molecular architecture of fibrillar fibrin formation, but from 1997, elegant crystal structures of parts of the fibrin(ogen) molecule were successfully produced in a number of laboratories. These structures reveal the mechanisms of fibrin polymerisation.

Prothrombin

The mRNA encodes a preproleader sequence similar to that found in other vitamin K-dependent proteins, followed by a GLA domain, two kringle domains, an activation peptide and a serine protease domain. FXa complexed with FVa activates prothrombin zymogen to thrombin on a phospholipid surface (prothrombinase) on cleavage of two peptide bonds. The first, between Arg314 and Thr315 (Arg271 and Thr272), releases the protease domain from the GLA and kringle domains; the second, between Arg363 and Ile364 (Arg320 and Ile321), generates the catalytic site of thrombin by a typical trypsin-like conformational rearrangement. Cleavage at Arg363 (Arg320) alone yields the protease (meizothrombin) that retains membrane-binding properties. Cleavage at Arg314 (Arg271) yields thrombin and severs covalent linkage with the N-terminal domain known as fragment 1.2. Fully cleaved thrombin is termed α-thrombin and is rapidly released from its site of production to participate in numerous haemostatic functions free in solution: acting as a procoagulant against many substrates including fibrinogen, FV, FVIII and FXI; acting in complex with TM as an anticoagulant against PC; and acting to activate cellular transmembrane protease-activated receptors (PARs). Thrombin also activates thrombin-activatable fibrinolytic inhibitor (TAFI), in complex with TM, inhibiting fibrinolysis.

Naturally occurring inhibitors of blood coagulation

In common with other defence mechanisms, such as those resulting in kinin release and complement activation, the blood coagulation process can be activated very rapidly when the need arises. This involves the generation of proteolytic enzymes, such as thrombin, that are potentially lethal if their action is not limited. For example, 10 mL of plasma can generate, in theory, sufficient thrombin to clot all of the fibrinogen in the body in 30 s. That it does not normally do so is due partly to the fact that the procoagulant response is most pronounced in the vicinity of the platelet plug forming at the point of vascular

injury, while elsewhere coagulation is inhibited by substances in plasma or on the vascular surface that exhibits anticoagulant activity.

Classification of physiological anticoagulants

Physiological anticoagulants fall into two main groups: those that inhibit the serine proteases of the coagulation cascade (both Kunitz-type and serpins) and those involved in destruction of the activated coagulation cofactors FVa and FVIIIa (components of the PC system). These inhibitors assume great physiological significance: relatively minor deficiencies (50–70% of average levels) of some of these inhibitors, such as might be found in individuals heterozygous for a genetic defect, are associated with an increased risk of thrombosis. Homozygous deficiencies are frequently either fatal in the first few years of life unless prophylactic replacement therapy is instituted or are not found in nature, suggesting early fetal loss.

In addition to the specific inhibitors, there are some other inhibitory mechanisms that do not fit into either of the above categories, one of these being the detoxifying property of the liver, which plays an important role in removal of activated clotting factors, both directly and after their combination with natural inhibitors. Furthermore, the removal of free thrombin occurs as a result of its adsorption onto fibrin or onto fibrin(ogen) degradation products. The latter, which cannot themselves take part in a clot, may interfere with normal fibrin polymerisation. Although less well-defined than the others, this group appears to be physiologically important, as qualitative defects of fibrinogen (dysfibrinogenaemias) that result in reduced thrombin binding may be associated with a thrombotic disorder (see Chapter 48).

Tissue factor pathway inhibitor: a Kunitz-type inhibitor

The various serpins found in blood (see below) probably play no physiological role in the inhibition of FVIIa in the initiating TF–FVIIa complex. Instead, the action of this serine protease–cofactor complex is modulated by TFPI, which is located on the endothelial cell surface, within platelets, in plasma and on monocytes. Two alternatively spliced isoforms of TFPI (α and β) have been identified in humans that differ in their domain structure and mechanism of cell-surface binding. Both directly inhibit FXa and in a FXa-dependent manner inhibit FVIIa by forming a quaternary complex of TFPI–FXa–TF–FVIIa.

TFPIα has an acidic N-terminal region followed by three Kunitz-type protease inhibitory domains (K1–K3) and a basic C-terminal region. K2 is responsible for binding and direct inhibition of FXa and K1 inhibits FVIIa in an FXa-dependent manner. K3 and the C-terminal region do not directly inhibit proteolysis, but they are necessary for rapid inhibition of FXa by K2. K3 binds protein S (PS) and reduces the Ki for FXa inhibition by TFPI approximately 10-fold.

TFPIβ has the N-terminal acidic region followed by K1 and K2 but lacks K3 and the C-terminal region of TFPIα. Instead, it has a different C-terminal region encoding a glycosylphosphatidylinositol (GPI) attachment sequence that anchors the protein directly to the cell surface.

Most TFPI in the vasculature (~85%) is associated with endothelial cells, particularly in the microcirculation, with a smaller amount (5–10%) being found in platelets and the rest in plasma. A twofold to fourfold increase in plasma TFPI following infusion of heparin suggests a pool of TFPIα is associated with endothelial GAGS via the basic C-terminal region; however, this pool of endothelial associated TFPI has been difficult to characterise. TFPIα is the only isoform found in platelets, whereas endothelial cells express both TFPIα and TFPIβ. TFPIα is localised to intracellular granules and is released after cellular stimulation by thrombin. The majority (80%) of circulating plasma TFPI is associated with lipoproteins and has undergone variable amounts of proteolytic degradation within its C-terminal region and as a result has reduced anticoagulant activity and is unlikely to play an important role as an *in vivo* inhibitor of blood coagulation. Plasma TFPIα accounts for approximately 20% of total plasma TFPI and circulates in complex with either FV or PS. Recent evidence suggests that TFPIα circulates in complex with PS through binding to K3, and this enhances inhibition of the TF pathway primarily by localising TFPI to the membrane surface. In addition, TFPI binds a form of activated FV that retains the acidic region of the B-domain. This interaction results in reduced FV activation and inhibition of prothrombinase activity.

Disruption of the murine *Tfpi* gene is incompatible with normal development, suggesting that a deficiency of functional *TFPI* might lead to clinical thrombosis. However, as the bulk of intravascular TFPI is associated with the endothelial cell surface, simple measurement of plasma TFPI levels is not a clear indicator of a deficiency state. Moderately low plasma levels can occur in DIC, septicaemia and following major surgery, possibly due to increased utilisation, but heparin infusion increases plasma TFPI in such patients. Whether congenital deficiency of TFPI is a risk factor for thrombosis remains uncertain: after several negative studies in this area, recently a case–control study found a relationship between low levels of free plasma TFPI (non-lipoprotein bound) and enhanced risk of deep vein thrombosis and myocardial infarction. Anti-TFPI antibodies are currently in clinical trials for the treatment of haemophilia. The principle is that reducing blockage of FXa can rebalance the defect due to loss of FVIII or FIX, whether this is due to a deficiency or an inhibitor.

Serine protease inhibitors (serpins) and heparin

Human plasma contains at least seven inhibitors of serine protease coagulation factors. Apart from α_2-macroglobulin, all are single-chain serpins of molecular mass 40–65 kDa.

Specificity is imparted by their tertiary structure, which engenders high affinity for a defined substrate or small range of substrates. Of this group, only AT and heparin cofactor II (HCII) assume haemostatic significance, acting predominantly on proteases generated late in the coagulation cascade (i.e. thrombin and FXa). A deficiency of any of the other serpins (although sometimes giving rise to a clinical disorder due to the failure of neutralisation of a serine protease not involved in coagulation pathways) is asymptomatic in terms of haemostasis.

Several serpins contain GAG-binding sites that, particularly in the case of AT and HCII, but to a lesser extent for PAI-1 and APC inhibitor, greatly enhance the rate of interaction with (although not the affinity for) their specific protease(s). Since a major source of heparin-like material is heparan sulfate on the endothelial cell surface, another possible function of the heparin-binding site of these inhibitors (especially AT and HCII) might be to allow them to exert a general and constitutive anticoagulant effect on intact vessels; this may also act to prevent extension of a procoagulant response beyond an area of damaged endothelium.

Antithrombin

AT (formerly ATIII) is a 58-kDa serpin that is synthesised principally in the liver, with a high plasma concentration of 2.4 μmol/L. The turnover of AT *in vivo* is complex, with a rapid initial clearance ($t_{½}$ 10 min) due to equilibration with endothelial cell-bound AT, a slower clearance ($t_{½}$ 3 hours) due to equilibration with the extravascular compartment and a much slower linear phase with an overall $t_{½}$ of 90 hours.

Disruption of the murine AT gene results in death of all embryos shortly before birth due to severe cardiac and hepatic thrombosis. In humans, homozygous null variants are presumed lethal as they are only observed in the heterozygous state. Deficiencies of AT characterised by the presence of a dysfunctional protein are associated with heritable thrombosis.

AT forms a stable complex with several serine protease coagulation factors, predominantly thrombin and FXa, but also to some extent FIXa, FXIa, FXIIIa and kallikrein. Initially, the serine at the active centre of the protease cleaves a peptide bond (involving Arg425 (Arg393)) in the 'reactive centre loop' near the C-terminus of AT: a conformational change in the serpin ensues, resulting in irreversible trapping of the protease against the inhibitor. The inactivated enzyme–serpin complex is then cleared rapidly. Complex formation is progressive and only with thrombin and FXa is it rapid enough to be of physiological significance. In purified *in vitro* systems, the $t_{½}$ is around 30 s for free thrombin, 90 s for FXa and 10–25 min for the other enzymes. In each case, the inhibitor–protease complex is rapidly cleared ($t_{1/2}$ 3 min) from the circulation by the liver.

Heparin, without altering the stoichiometry, induces a more than 2000-fold increase in the rate of thrombin inactivation by AT, such that its action becomes almost instantaneous ($t_{½}$ < 0.01 s). The unique mechanism of this activation involves release of the reactive centre loop from partial insertion in the β-sheet core of AT following heparin binding. Heparin also strongly enhances AT neutralisation of FXa and, to a lesser extent, FIXa, particularly in the presence of Ca^{2+}. The enhancement of AT inhibition of thrombin and FXa by heparin is the basis of its use as a therapeutic anticoagulant to prevent thromboembolism. At therapeutic concentrations, there is no significant effect on AT inhibition of FIXa and FXIa.

Heparin cofactor II

This 65-kDa serpin is present in plasma at the high concentration of 90 mg/L (1.2 μmol/L). It appears to be a specific inhibitor of thrombin and to have little or no anti-FXa activity. The rate of thrombin neutralisation by HCII is increased approximately 1000-fold by heparin, although because of its lower heparin affinity it requires 5–10 times more heparin than does AT. Interaction seems to depend largely on the high anionic charge of heparin and related GAGs. Details of the molecular mechanism of HCII interaction with thrombin have been elucidated by X-ray crystallography.

That HCII has some physiological significance is suggested by the fact that it falls in parallel with AT in DIC. However, as AT is in twofold molar excess over HCII, the latter cannot altogether compensate for a deficiency of AT, which, as stated above, is a well-established cause of a thrombotic tendency. Whether HCII deficiency leads to a similar clinical picture remains to be established, as few cases have yet been described and only occasionally has concomitant thrombotic disease been present. Mice with HCII knockout develop normally and do not show spontaneous thrombosis; however, they show an enhanced propensity to carotid occlusion after deliberate injury to the endothelium, corrected by infusion of purified HCII, suggesting that HCII has a role in prevention of arterial thrombosis.

Heparin and heparin-like substances in plasma

Although the term 'heparin' implies a single compound, it in fact refers to a heterogeneous mixture of sulfated polysaccharides that are all members of the GAG group. The major pharmaceutical source is porcine intestinal mucosa. By virtue of its strong positive charge, heparin combines non-specifically with a number of cationic proteins such as albumin and reacts in a highly specific way with β-lipoproteins, fibrinogen, HCII and AT. It also mobilises platelet factor (PF)4 and TFPI, which are bound to GAGs on the surface of endothelial cells, and releases lipoprotein lipase into plasma.

Unfractionated heparin (UFH) is an extremely heterogeneous polymer, being composed of between 10 and 100 saccharide units. Only about one-quarter of the polysaccharides has any anticoagulant activity *in vitro*. The pharmaceutical properties of heparin are unpredictable, because of its heterogeneity, with marked variation

in pharmacokinetics and side-effects. Apart from bleeding, the most serious side effect is heparin-induced thrombocytopenia (see Chapter 48). The realisation that the anticoagulant action of UFH was mostly delivered by short pentasaccharides has led to the use of more efficient fractionation procedures (including cleavage by nitrous acid, heparinase and oxidising agents), yielding a number of low-molecular-weight heparin (LMWH) preparations. LMWHs contain 10–20 saccharide units (4–6 kDa) and because of their more uniform composition have much better pharmacokinetics and fewer side-effects. Fondaparinux is a synthetic pentasaccharide that is now in therapeutic use and offers increased half-life compared with larger LMWHs.

UFH and the various LMWHs differ in their affinities for the plasma factors with which they interact and in the specific serine proteases that they inhibit. This, together with the timing of blood samples in relation to dosage interval, is critically important in laboratory monitoring of the therapeutic effect (see Chapter 47). The major anticoagulant activity of both UFH and LMWH is attributed to the pentasaccharide sequence containing at its centre a 2,3,6-(SO_3) trisulfated glucosamine group. It is this that binds to lysine or tryptophan residues in AT in the region of the D helix, inducing the conformational change in the inhibitor. A second anticoagulant action of UFH (at least 18 saccharide units are required) involves direct binding between thrombin (but not FXa or other proteases) and a heparin sequence adjacent to the pentasaccharide. This brings thrombin and AT into close proximity and is necessary for the inhibitory activity. As many chains in an LMWH have fewer than 18 saccharide units, they have less antithrombin action compared with their inhibition of FXa. There is no detectable heparin in normal plasma. However, endogenous heparin-like molecules (e.g. dermatan sulfate and heparan sulfate) are present on the surface of endothelial cells and, by enhancing the action of AT and HCII, these would have antithrombotic effects. Such mechanisms seem to be of clinical importance, as recurrent thromboses have been reported in association with several dysfunctional AT molecules that inhibit thrombin normally in the absence of heparin, but which do not show enhanced reactivity in its presence, presumably due to defects at the heparin-binding sites. As this leads to heparin resistance, alternative therapeutic anticoagulants or AT replacement therapy is required. At points of vascular injury, local accumulation of activated platelets provides a source of heparin-neutralising activity that could overcome the anticoagulant effects of endothelial cell-bound heparinoids and permit the procoagulant response to proceed.

Protein Z and protein-Z-dependent inhibitor

PZ is a 62-kDa vitamin K-dependent plasma protein that serves as a cofactor for the inhibition of FXa by PZ-dependent protease inhibitor (ZPI) a 72-kDa member of the serpin superfamily.

The organisation of the PZ gene and the structure of the molecule are very similar to those of coagulation factors FVII, FIX, FX and PC; however, the PZ 'serine protease' domain lacks the canonical active-site His and Ser residues and therefore cannot function as a protease. PZ circulates in plasma in a complex with ZPI. Inhibition of FXa by ZPI in the presence of phospholipid and Ca^{2+} ions is enhanced 1000-fold by PZ, but ZPI also inhibits FXIa in a process that does not require PZ, phospholipid or Ca^{2+}. ZPI activity is consumed during coagulation through proteolysis mediated by FXa (with PZ) and FXIa. PZ may serve to dampen the procoagulant response *in vivo* as PZ deficiency dramatically increases the severity of the prothrombotic phenotype of FV Leiden mice. Studies to determine the potential roles of PZ and ZPI deficiency in human thrombosis are in progress.

α_1-Antitrypsin

This is a serpin whose primary targets are pancreatic and leucocyte elastases. In coagulation, the major inhibitory activity is directed against FXIa and FXa, although the chief physiological inhibitor of FXIa is probably protease nexin 2. It has little effect on overall thrombin inhibition, and a straightforward deficiency of α_1-antitrypsin is not associated with hypercoagulability, although it does cause lung and liver disease.

An abnormal molecular form of α_1-antitrypsin in which there is a Met→Arg substitution at the active centre (antitrypsin Pittsburgh; Met358Arg) has been described, resulting in a higher affinity for thrombin. At a plasma concentration of 25 μmol/L, the variant circulates at a 10-fold higher level than AT and gives rise to a clinical bleeding tendency. However, it is unaffected by heparin.

Protease nexin 2

This is a Kunitz-type serine protease inhibitor that is found in the α-granules of platelets. Normally, there is very little in plasma, but it is released at sites of platelet activation, following which the single Kunitz domain enters into a tightly bound inhibitory complex with FXIa. It is one of several isoforms of Alzheimer β-amyloid protein precursor present in platelets. Deficiency of protease nexin 2 has not been described.

C1-esterase inhibitor

The primary target of this serpin is the activated form of the first component of complement, but it also contributes in a minor way to the neutralisation of FXIa and plasmin. Deficiency of the C1-esterase inhibitor, although of no haemostatic consequence, causes angioneurotic oedema, the characteristic lesions of which may sometimes be confused with haematomas.

α_2-Antiplasmin

This serpin is the principal inhibitor of the fibrinolytic enzyme plasmin. It also has weak activity against several coagulation proteases, especially the contact factors. However, any

anticoagulant action against proteases late in the coagulation cascade (e.g. FXa) is only apparent at concentrations well in excess of those in normal plasma. Its mechanism of action and clinical importance are discussed further in the section on fibrinolysis.

α_2-Macroglobulin

α_2-Macroglobulin is composed of four identical chains and has a molecular mass of 740 kDa. It is not a member of the serpin superfamily, and its effects are not restricted to serine proteases. It binds to coagulation factors at a site away from the active site, the interaction involving the formation of a bond between cysteine and glutamate residues in the inhibitor and a lysine residue in the protease. Inhibition is produced by stearic hindrance rather than by active site inactivation, and indeed the proteases retain some esterolytic and amidolytic activity, particularly against small peptides, a fact that should be borne in mind when using chromogenic substrates to assay coagulation inhibitors. It is responsible for approximately 50, 20 and 10% of the inhibition of kallikrein, thrombin and FXa, respectively.

Deficiency of α_2-macroglobulin is not associated with a thrombotic tendency. However, it is an acute-phase reactant, and it is possible that, when elevated under conditions of stress or when the other major antithrombins or antiplasmins are overwhelmed, it might become a significant inhibitor of coagulation or fibrinolysis. Moreover, it has been suggested that the increased level of α_2-macroglobulin that exists in children (150–200% of adult values) may compensate for a low level of AT and explain why thrombotic episodes do not usually occur before puberty in congenitally AT-deficient patients.

The protein C pathway: inhibition of cofactors FVa and FVIIIa

The activated forms of coagulation cofactors FV and FVIII (FVa and FVIIIa) are potent procoagulants that enormously enhance the activity of serine protease factors in the tenase and prothrombinase complexes (see above). It is not unexpected that these cofactors should be subject to a negative feedback mechanism that limits their procoagulant activity. This is achieved by a complex series of reactions collectively referred to as the protein C pathway. Four key factors are now known to be involved, and their role in the haemostatic network is shown in Figure 39.4.

Protein C

This vitamin-K-dependent serine protease has an identical modular composition to the procoagulant factors FVII, FIX and FX. It circulates in blood as a two-chain disulfide-linked molecule. During biosynthesis, the primary translation product is proteolytically processed, releasing the dipeptide Lys198Arg199 (Lys156Arg157). In order to exert its anticoagulant effect, PC must first be activated to APC. This is achieved by the action of thrombin, which cleaves the heavy chain to release a 12-residue Gly200–Arg211 (Gly158–Arg169) activation peptide, revealing the active site by the usual chymotrypsin-like mechanism. Thrombin activation of PC is slow in free solution but is markedly accelerated by specific endothelial cell receptors for both thrombin (TM) and PC (EPCR), which coordinate the assembly of a membrane complex for PC activation.

APC interacts with PS bound to the phospholipid surface of activated platelets, enhancing the anticoagulant activity of APC (see below) against FVa and FVIIIa. These procoagulant cofactors are inactivated by APC on the platelet surface by specific cleavage in their A domains, terminating the activity of the tenase and prothrombinase complex by disrupting their binding sites for FIXa and FXa, respectively. In the absence of PS, this reaction is inefficient. The most common form of familial thrombosis is FV Leiden, which is caused by a variant of Arg534 to Gln (Arg506 to Gln), which makes the molecule resistant to cleavage by APC. So common is this variant (5–8% of Caucasians), that it is likely to have a beneficial effect on bleeding at delivery balancing the mild prothrombotic effect. It appears that APC inactivation of FVa is a prerequisite for efficient inactivation of FVIIIa *in vivo*, as FVIIIa inactivation is also impaired in these patients, although there is no abnormality in the FVIII molecule. Since the discovery of FV Leiden, other less common FV variants have been found with a similar phenotype. None of the variants reported in the FVIII molecule has been shown to cause a similar prothrombotic phenotype. PC is synthesised in the liver, and being vitamin K-dependent, is often low in the newborn population. Even though its substrates (FVa and FVIIIa) are normal at birth, this deficiency is compensated for by the reduction in plasma of the vitamin K-dependent procoagulant factors (prothrombin, FVII, FIX and FX). Because warfarin treatment initially decreases PC levels faster than FVII, FIX, FX and prothrombin levels, it can paradoxically increase the procoagulant tendency when anticoagulant treatment is first begun. This is why warfarin is not used in the initial anticoagulant treatment of acute thrombosis. Disruption of the murine PC gene results in lethal perinatal consumptive coagulopathy, whereas in humans, homozygous PC deficiency is associated with lethal purpura fulminans (in the absence of PC replacement therapy) and heterozygous individuals have a high risk of venous thrombosis. There is increasing appreciation of the role of the PC pathway in regulation of inflammation and the concept of signalling mechanisms allowing 'cross-talk' between the haemostatic and inflammatory networks. This is well-demonstrated by the protective effect of administration of APC concentrate to animals with induced sepsis. However, the concentrate has not proven to be quite so

efficacious in human studies. Recently, variant recombinant PC molecules have been produced that appear to have either anticoagulant or anti-inflammatory effects independent of each other.

Thrombomodulin

TM is an integral transmembrane receptor found on endothelial cells in virtually all body tissues. It appears to be absent in the brain vasculature and in hepatic sinusoids and lymph node venules. TM is essential for normal fetal development as shown by mouse knockout studies, although $TM^{+/-}$ heterozygous mice appear to be completely healthy.

The protein has an extracellular region composed of an N-terminal lectin-like or CLECT domain, six EGF-like domains, a transmembrane sequence and a short cytoplasmic region. TM forms a complex with thrombin (via the protease's anion-binding exosite I and TM's EGF-like domains 4–6), preventing binding of the protease to its various procoagulant substrates (fibrinogen, FV, FVIII, FXIII and protease-activated receptors involved in platelet aggregation). TM also plays a part in binding of PC zymogen and, after formation of the TM–thrombin complex on the cell surface, there is a 20,000-fold increase in the rate of activation of PC, so that thrombin effectively becomes an anticoagulant. Binding of PC to TM is also enhanced by EPCR.

The TM–thrombin complex is short-lived, being endocytosed by endothelial cells, where the thrombin is taken up and degraded by lysosomes while TM re-circulates to the cell membrane.

Endothelial protein C receptor

EPCR is a transmembrane receptor on endothelial cells that binds PC and promotes its activation by the thrombin–TM complex. The extracellular portion of EPCR is related to the MHC class I/CD1 proteins; however, it lacks the α3 domain found in the extracellular portion of most of the family: there is good evidence that the α1 and α2 extracellular domains of EPCR interact with the GLA domain of PC. EPCR may function by localising the PC molecule to the endothelial cell surface, moving laterally on the cell surface to locate a thrombin–TM complex, then presenting the PC molecule optimally for thrombin cleavage to form APC.

The essential role of EPCR was demonstrated by targeted deletion of the murine *EPCR* gene, resulting in early fetal death, with evidence of thrombosis at the maternal–fetal interface. Abrogation of EPCR function *in vitro* reduces the rate of PC activation by thrombin–TM. In contrast, inhibition of EPCR action by a specific anti-EPCR monoclonal antibody in baboons given thrombin resulted in reduced APC levels amidst evidence of excessive coagulopathy. Blockade of EPCR on challenge with *Escherichia coli* also led to worse outcomes in an animal model of sepsis, whereas administration of APC improved survival in experimental sepsis.

Protein S

PS is a single-chain vitamin K-dependent glycoprotein chiefly synthesised in the liver by endothelial cells. Unlike the other vitamin K-dependent coagulation proteins, it is not a serine protease, having two C-terminal LamG domains rather than a serine protease domain, and the N-terminal GLA domain is followed by four EGF-like domains rather than the two usually seen in the serine proteases (see Figure 39.8). About 40% of the PS in plasma is in the free form, whereas the remaining 60% is associated in a complex with C4b-binding protein (C4bBP). Both forms bind strongly via the PS GLA domain to negatively charged phospholipids exposed on the surface of activated platelets. Free PS (although having no strong inhibitory effect on FVa or FVIIIa itself) forms a Ca^{2+}-dependent complex with APC, helping to orient the APC active site above the phospholipid surface and enhancing its anticoagulant activity against both proteins. However, C4bBP-bound PS does not enhance PC function against FVa. Free thrombin cleaves PS between the GLA domain and EGF1, removing its ability to bind to both phospholipid and PC and thereby abolishing its PC cofactor activity. Although PS was mainly considered to function as a cofactor in the activity of APC, it is now evident that PS also has an important role in the action of TFPIα in inhibiting TF-FVIIa-FXa and FXa.

Protein C inhibitors

As with other serine proteases, APC is subject to inhibition by serpins (half-life of APC in plasma is 15–20 min), including APC inhibitor (PCI), PAI-1 and α_1-antitrypsin. The relative contributions of these *in vivo* are difficult to assess. PCI slowly but progressively blocks the action of APC (and, to a much lesser extent, thrombin and FXa), in each case forming a 1:1 complex; in addition, PCI action is enhanced 20-fold by heparin and more weakly by other GAGs, but the physiological significance of this is uncertain. Despite the name, disruption of the murine *PCI* gene leads not to coagulopathy, but to infertility due to lack of inhibition of another protease target of the serpin, the sperm protein acrosin.

Fibrinolysis

It is widely acknowledged that the principal functions of the fibrinolytic system are to ensure that excess fibrin deposition is either prevented or rapidly removed. This is vital for ensuring that a localised procoagulant response is achieved without compromising blood circulation generally. Following re-establishment of

haemostasis, the fibrin mesh is removed during wound healing. The system of profibrinolytic and antifibrinolytic factors that has evolved to meet these requirements is closely coupled to that, which results in fibrin clot formation. Fibrinolysis is essentially a localised, surface-bound phenomenon, with most events being catalysed by the presence of cross-linked fibrin itself, i.e. 'fibrin orchestrates its own destruction'. For this reason, the assays of fibrinolytic factors carried out in the soluble phase, in particular in systemic blood, may be misleading and should be interpreted with great caution.

Components of the fibrinolytic system

These include plasminogen (PLG) and plasmin, several endogenous (tissue or plasma derived) or exogenous (e.g. bacterial or venom derived) PLG activators and a number of inhibitors of plasmin or of the PLG activators. Both endogenous and exogenous fibrinolytic factors have been used clinically to treat venous and arterial thrombosis, with varying degrees of success (see Chapters 49 and 50).

Plasminogen and plasmin

PLG is a single-chain glycoprotein zymogen of the serine protease plasmin, which carries out the enzymatic degradation of cross-linked fibrin. Besides its active site serine, plasmin contains five kringle domains, four of which have a lysine-binding site, through which the molecule interacts with lysine residues in its substrates (e.g. fibrin), its activators (e.g. tissue PLG activator and urinary PLG activator) and its inhibitors (principally PLG activation inhibitor type 1). In its native form, it has a glutamic acid residue at its N-terminus and is known as Glu-PLG. Conversion of PLG to plasmin can proceed via two routes. Most PLG activators (see below) cleave the Arg580–Val581 (Arg561–Val562) bond to form Glu-plasmin, a disulfide-linked two-chain molecule. The heavy chain is derived from the N-terminal region and bears the lysine-binding sites, whereas the C-terminal light chain contains the serine active centre. Glu-plasmin, despite being a serine protease, is functionally ineffective, as its lysine-binding sites remain masked. It is converted autocatalytically to Lys-plasmin by N-terminal cleavage, chiefly between Lys96 and Lys97 (Lys76 and Lys77), which exposes the lysine-binding sites and thus markedly enhances its interaction with fibrin.

Both Glu- and Lys-plasmin also attack the same Lys96–Lys97 (Lys76–Lys77) bond in Glu-PLG to form the zymogen Lys-PLG. This binds to fibrin before activation to the protease, bringing it into close proximity with the physiological PLG activators (which also bind to fibrin) that convert it to Lys-plasmin. As a consequence, the conversion of PLG to plasmin by tPA is enhanced by two to three orders of magnitude; this serves to localise the fibrinolytic response to the fibrin clot, where plasmin is to some extent protected from the effects of circulating antiplasmins, which (as indicated below) would otherwise neutralise plasmin extremely rapidly (<50 ms). The fact that Lys-PLG is potentially a much more effective agent in fibrinolysis than Glu-PLG is reflected in its half-life, which is around 20 hours compared with 50 hours for the latter.

Action of plasmin on fibrin and fibrinogen

Plasmin can hydrolyse a variety of substrates, including FV and FVIII, but its major physiological targets are fibrin and fibrinogen, which are split progressively into a heterogeneous mixture of small soluble peptides (plasmin attacks at least 50 cleavage sites in fibrinogen) known collectively as fibrin degradation products (FDPs).

The first stage in the proteolysis of fibrinogen involves the removal of several small peptides (fragments A, B and C) from the C-terminus of the A α-chains, each involving cleavage after a lysine residue. This is rapidly followed by removal of the first 42 amino acids from the N-terminal end of the B β-chain (the Bβ1–42 fragment). The large residual portion, which is known as fragment X, and which still contains fibrinopeptide A, remains thrombin-clottable and will agglutinate some species of *Staphylococcus* spp. Assay of the Bβ1–42 fragment released from fibrinogen by plasmin gives a sensitive index of fibrinogenolytic activity.

Asymmetrical digestion of all three pairs of chains of fibrin or fibrinogen then occurs with the release of the D fragment, in which the chains remained linked by disulfide bonds. The residue, known as fragment Y, is again attacked by plasmin, cleaving a second fragment D and leaving the disulfide-linked N-terminal ends of all six chains, which are referred to as fragment E. Fragments Y, D and E are not thrombin-clottable and do not agglutinate staphylococci. Their presence can be detected immunologically using specific antibodies, which provides a simple test for most FDPs, although carefully prepared serum must be used to prevent cross-reactivity of the antibody with fibrinogen in plasma. These assays detect the degradation products of both fibrin and fibrinogen indiscriminately.

Following thrombin generation and consequent activation of FXIII, intermolecular or intramolecular transamidation of the fibrin α- or β-chains by FXIIIa occurs, and then the action of plasmin yields characteristic D-dimer, D-dimer–E fragments and oligomers of fragments X and Y (collectively known as cross-linked FDP or XDP), in addition to X, Y, D and E. These XDPs can be detected very simply using monoclonal antibodies. Because the monoclonal antibodies to XDPs do not cross-react with fibrinogen, they can be detected directly in citrated plasma. The presence of D-dimers in blood samples can be used in a clinical algorithm that predicts the likelihood of the presence of venous thrombosis (see Chapter 49).

Furthermore, plasmin-induced cleavage of the N-terminal end of the β-chain of fibrin (the Bβ1–14 fibrinopeptide B fragment having been removed by thrombin) produces a β15–42 fragment, the detection of which indicates fibrin (as opposed to fibrinogen) degradation. Consequently, assays for the Bβ1–42 and β15–42 fragments used in combination may be clinically useful by indicating whether fibrinogen or fibrin has been degraded, and thus whether fibrinolytic activity is primary or secondary to fibrin formation. However, clinically, FDP assays are used to detect DIC, when mixed fibrin/fibrinogen degradation products appear in the circulation.

Plasminogen activators

Tissue plasminogen activator

tPA is a serine protease secreted by endothelial cells. It is not synthesised by the liver or kidney, but is found in most extravascular body fluids, including saliva, milk, bile, cerebrospinal fluid and urine. Intravascular tPA is quickly cleared by the liver or inactivated by the fast-acting tPA inhibitor (see below), the half-life of tPA in plasma being approximately 2 min. The resting level of tPA in plasma is around 70 pmol/L, most of which is in an inactive complex with tPA inhibitors (see below).

Several physical and biochemical stimuli, including venous occlusion, strenuous exercise, thrombin, adrenaline and vasopressin or its analogues such as desmopressin (see Chapter 41), markedly increase the rate of tPA release, although its biological activity remains negligible until it becomes bound to fibrin, whereupon its affinity for and action upon PLG is greatly potentiated. The activity of tPA is further enhanced by plasmin itself, which cleaves tPA at Arg310-Ile311 (Arg275-Ile276) into a two-chain molecule, whose binding sites are exposed, thus enabling it to form a complex with PLG and fibrin more readily. The ability of venous occlusion to stimulate tPA release from endothelial cells forms the basis of a test of fibrinolytic activity known as the 'cuff test'.

Both single-chain tPA and the two-chain form possess very little serine protease activity until they bind to fibrin, whereupon tPA affinity for, and activation of, fibrin-bound PLG is increased at least 100-fold. The principal interactions involve binding between the second kringle domain of tPA and lysine residues on the α- and β-chains of fibrin (in particular Lys157 on the α-chain of partly degraded fibrin). This association enhances cleavage of the Arg580–Val581 (Arg561–Val562) bond in adjacent PLG molecules, forming active plasmin.

Urinary plasminogen activator

So called because it was first extracted from urine, uPA is synthesised chiefly by the tubules and collecting ducts in the kidney and by fibroblast-like cells in the gastrointestinal tract. It is a serine protease secreted as an inactive single-chain zymogen (prourokinase) that is cleaved by activators in plasma (including kallikrein and plasmin) at Lys178–Ile179 (Lys158–Ile159) to produce active two-chain uPA. The protease activity of uPA is associated with the heavy chain, which may dissociate from the light chain carrying the PLG-binding site. The isolated heavy chains, which are also known as low-molecular-weight urokinase, are therefore poorer PLG activators than the two-chain form.

uPA cleaves the same Arg580–Val581 (Arg561–Val562) bond in PLG as tPA. Although uPA contains a kringle domain, this does not impart high affinity for fibrin, and it binds instead (via its EGF-like domain) to its cell-associated receptor. Thus, it has been proposed that uPA may be preferentially involved in cellular events (such as differentiation and mitogenesis) rather than with dissolution of fibrin clots.

Exogenous plasminogen activators

These are derived from non-human sources, including animals (e.g. vampire bat saliva and some snake venoms) and certain plants and microorganisms. The best known of these is streptokinase (SK), which is derived from some strains of β-haemolytic streptococci, and which has for many years been used, with moderate success, as a fibrinolytic agent for the treatment of life-threatening thrombotic states. Despite its name, SK is a non-enzymatic polypeptide that forms a stable complex with PLG, as a result of which the latter undergoes a conformational change, unmasking its serine-active centre. The 'plasmin' that is formed remains associated with SK but can convert free PLG to plasmin.

Inhibitors of fibrinolysis

The plasmin-generating potential of plasma is sufficient to completely degrade all the fibrinogen in the body in a very short period of time. It is prevented from doing so by the PLG activator inhibitors or PAIs, most of which belong to the serpin family, and by a number of circulating inhibitors of plasmin itself (the antiplasmins).

Inhibitors of plasminogen activation

Plasminogen activator inhibitor type 1

PAI-1 is a fast-acting serpin inhibitor of tPA, uPA and, to a small extent, plasmin and is secreted by endothelial cells. It is also found in platelet α-granules. In plasma, it occurs in two forms: a functionally active 'free' form (that is stabilised by association with vitronectin) and as an inactive complex with tPA. Basal PAI-1 concentration in plasma is low at 0.5 nmol/L, of which at least 80% is in complex with tPA or uPA. It follows a diurnal

rhythm, with an early morning peak that is around twice that in the late afternoon, and its activity is also increased by heparin. Elevated levels of PAI-1 are associated with an increased incidence of venous and arterial thrombosis, perhaps as part of a multi-factorial process involving metabolic disturbance and obesity. While common variants in the *PAI-1* gene (*SERPINE1*) were previously thought to increase the risk of thrombosis, genome-wide association studies have not shown any convincing effect.

The three main profibrinolytic serine proteases (tPA, uPA and plasmin) all cleave the same bond Arg369–Met370 (Arg346–Met347) in the reactive centre loop of PAI-1 and are thus inhibited in the same way as described in the section on AT. PAI-1 binds non-covalently to fibrin, but although it can then complex with and inhibit fibrin-bound tPA (with most of the complexes remaining bound to the fibrin), it does so less effectively than with free tPA. Soluble tPA–PAI-1 complexes are rapidly removed by the liver ($t_{½}$ 4 min), as are uPA–PAI-1 complexes that have dissociated from fibrin.

Plasminogen activator inhibitor type 2

This serpin inhibitor of tPA is mainly produced by the placenta and may thus contribute to the inhibition of fibrinolysis that occurs during pregnancy. It is also synthesised in monocytes and epidermal cells but is not usually found in the plasma of non-pregnant subjects. It is detectable in plasma from about the eighth week of pregnancy, rising to a peak at around 33 weeks and falling only slowly after delivery, the half-life being around 24 hours. Paradoxically, levels are often low in pre-eclampsia due to placental insufficiency. The inhibitory action of PAI-2 involves its Arg380–Thr381 residues, and it is more effective against uPA than tPA, although for both the potency is at least 10-fold less than that of PAI-1.

Similarly, other protease inhibitors such as α_1-antitrypsin, C1-esterase inhibitor, α_2-antiplasmin (see below), α_2-macroglobulin and protease nexin 1 (one of a group of cell membrane-bound heparin-potentiated serpins) also neutralise tPA, but at a rate that is probably too slow to be of physiological significance. However, α_2-macroglobulin is thought to be the major inhibitor of the SK–PLG complex.

Inhibitors of plasmin

As they do with thrombin and tPA, a number of the broad-spectrum inhibitors contribute to neutralisation of plasmin. By far, the most potent plasmin inhibitor is the serpin α_2-antiplasmin, a single-chain glycoprotein synthesised by the liver, which has a half-life of about 60 hours and shows considerable sequence identity with AT and α_1-antitrypsin. Its physiological importance is supported by the fact that a congenital deficiency (known as Miyasato disease) is associated with a clinically significant bleeding disorder due to uncontrolled fibrinolytic activity, and that levels are reduced in DIC and during thrombolytic therapy.

α_2-Antiplasmin

This serpin is the predominant plasmin inhibitor. It forms a stable complex with plasmin, in which the protease is completely inactivated. The reaction appears to involve the cleavage by plasmin of a specific Leu–Met bond in the inhibitor, exposing the reactive loop Arg376–Met377 (Arg364–Met365) peptide bond to the serine-active centre on the light chain of plasmin. Plasmin-modified α_2-antiplasmin can also bind to native Glu-PLG and to fibrin, the latter reaction being mediated by FXIIIa-mediated cross-linking. Thus, in addition to inactivating preformed plasmin, α_2-antiplasmin retards fibrinolysis by reducing PLG activation and by 'masking' the lysine-binding sites through which plasmin(ogen) interacts with fibrin. However, these subsidiary mechanisms for inhibiting fibrinolysis are to some extent overcome by any Lys-plasmin(ogen) present, which has a higher affinity than Glu-PLG for fibrin and is thus less susceptible to the action of α_2-antiplasmin.

In plasma (as opposed to on fibrin strands), although the concentration of PLG (~2 μmol/L) exceeds that of α_2–antiplasmin (~1 μmol/L), basal fibrinogenolytic activity is minimal because the tiny amounts of plasmin normally generated under physiological conditions are rapidly neutralised by the inhibitor. However, in certain pathological conditions (e.g. obstetric emergencies or snake bite) where extreme activation of fibrinolysis occurs, the latter may be swamped. Under these circumstances, other inhibitors, in particular α_2-macroglobulin and histidine-rich glycoprotein, may become clinically important. The action of α_2-macroglobulin on plasmin is similar to its effect on thrombin. Following the plasmin-induced cleavage of a specific Arg–Leu bond in the inhibitor, the latter forms a complex with the light chain of plasmin. The serine active site of plasmin is not involved, and the complex retains weak biological activity, albeit only briefly, until it is removed in the liver. Histidine-rich glycoprotein inhibits fibrinolysis by blocking the lysine-binding sites of PLG, thus preventing its interaction with fibrinogen.

Lipoprotein A

The protein portion of lipoprotein A is termed apo(a). It is synthesised in the liver and circulates in plasma. There is considerable structural homology with PLG, as it possesses both serine protease and kringle domains. It can compete with PLG for binding sites on fibrin(ogen) or tPA and may also increase PAI-1 expression, both actions potentially inhibiting fibrinolysis. That lipoprotein A has some clinical importance is indicated

by the finding that increased levels are associated with an increased incidence of thrombosis.

Thrombin-activatable fibrinolysis inhibitor

In the presence of thrombomodulin, thrombin activates carboxypeptidase B, also called TAFI, and TAFIa in turn inhibits fibrinolysis; this provides another link between coagulation and the fibrinolytic pathway. TAFI removes the C-terminal lysine residues formed by limited plasmin proteolysis of fibrin, removing the binding sites for PLG and tPA. Thus, the fibrin cofactor function in PLG activation is reduced, downregulating fibrinolysis. Mice with TAFI knockout have defective wound repair, and data from backcrossing against heterozygous PLG-deficient mice showed that TAFI modulates both fibrinolysis and cell migration *in vivo*.

CHAPTER 40

The vascular function of platelets

40

Introduction

Platelets circulate in the bloodstream in a quiescent state and undergo rapid activation at sites of vessel damage. To achieve this balance, endothelial cells constitutively release nitric oxide (NO) and generate prostacyclin to inhibit platelet activation through elevation of the cyclic nucleotides cGMP and cAMP. In addition, endothelial cells express the ecto-ADPase CD39, which metabolises ADP and ATP to adenosine, which inhibits platelet activation through the G protein-coupled adenosine A1 receptor. Under normal circumstances, platelets are unable to form stable contacts on endothelial cells, but this can occur on diseased or activated endothelial cells, or at sites of disturbed flow, including arterial bifurcations where plaques are commonly formed. Adhesion of platelets to endothelial cells promotes local inflammatory events that lead to endothelial cell activation and damage, and thrombo-inflammatory disorders such as atherosclerosis and deep vein thrombosis. Lesions in the endothelial layer expose subendothelial matrix proteins, particularly collagens and membrane surface-expressed tissue factor, which initiate haemostasis.

Platelets are now recognised to have a much wider physiological role than simply supporting haemostasis (Figure 40.1). Platelet-dense granules and α-granules are packed with a rich diversity of small molecules and proteins that play fundamental roles in many aspects of haemostasis, including vessel constriction, leucocyte recruitment and vessel repair, as well as in other pathways, including host defence. In addition, platelets release and support the formation of a variety of active lipid mediators including sphingosine 1-phosphate, thromboxane A_2 (TxA_2) and lysophosphatidic acid. The ability to generate such a cocktail of biological molecules may reflect the evolutionary relationship of the platelet to the haemocyte in invertebrates, which is involved in both the innate defence system and haemostasis. In mammals, two distinct sets of cells perform these functions, thrombocytes (or platelets) and leucocytes.

Platelets are a major therapeutic target in arterial thrombosis. However, careful consideration is required as to whether a patient should receive antiplatelet therapy and for how long, bearing in mind that such treatment always carries a risk of increased bleeding. The decision is based on the assessment of risk factors for arterial thrombosis, such as age, hypertension, smoking status and history of previous coronary artery or cerebrovascular disease, and the potential risk from excessive bleeding. It is now accepted that individuals judged to be at medium to high risk of thrombosis should receive some form of antiplatelet therapy (unless otherwise contraindicated), usually low-dose aspirin, and nearly always in combination with other treatments such as statins and blood-pressure-lowering drugs. In certain situations (e.g. newly inserted drug-eluting coronary artery stent, or recurrent events on a single antiplatelet agent), there is a role for using a $P2Y_{12}$ receptor antagonist such as clopidogrel or ticagrelor in combination with aspirin, but this is associated with an increased risk of bleeding. Stronger inhibitors of platelet function, namely blockers of the major platelet integrin αIIbβ3 (GPIIb-IIIa) such as eptifibatide, are used only in acute situations of thrombotic risk, for example in cases of unstable angina or angioplasty and stenting, because of their narrow therapeutic window.

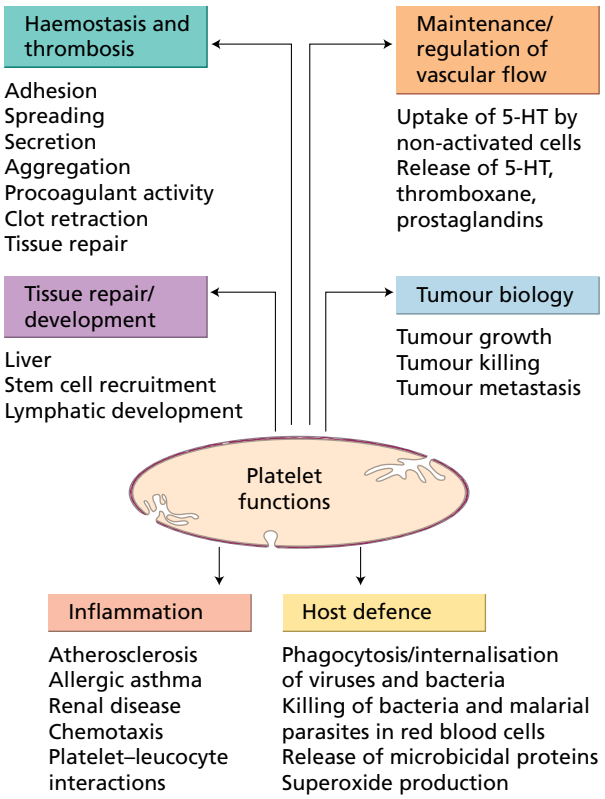

Figure 40.1 Functional roles of the platelet in the vasculature.

Platelet structure and organelles

Platelets are discoid in shape, with dimensions in the human of approximately 3.0×0.5 µm and a mean volume of 7–11 fL. This shape and small size enable platelets to be 'marginated' by red blood cells to the edge of the vessel, placing them in contact with vascular endothelial cells. The platelet count in humans is usually in the range $150–400 \times 10^9$/L. This count represents a considerable degree of redundancy for haemostasis, as major spontaneous bleeds are usually only seen when the platelet count falls below 20×10^9/L. Low platelet counts are also associated with increased risk of excessive bleeding during major trauma and surgery. For most forms of surgery (neurosurgery excluded) a platelet count of 50×10^9/L or above is acceptable to secure haemostasis during the procedure.

The discoid shape of the platelet is regulated by the platelet cytoskeleton, which consists of a spectrin-based membrane skeleton, circumferential bands of a single microtubule that lie beneath the plasma membrane, and a rigid actin filament network that fills the cytoplasm of the cell. The rigid structure is supported by two million copies of actin per platelet, of which approximately 40% in a circulating cell are assembled into actin polymers. These polymers connect with each other and with the cytosolic tail of the membrane glycoprotein (GP) Ibα via filamin in a lattice-like structure.

Platelets lack a nucleus and have a short lifespan of 10 days. They have a very limited ability to undergo protein synthesis as the result of residual mRNA that has been carried over from their precursor cell, the megakaryocyte. However, evidence suggests that activated platelets can synthesise a small number of key proteins (e.g. IL-1β) that may be of functional significance. The presence of low levels of platelet mRNA provides an opportunity to perform a limited number of genetic studies, although concern over contamination from nucleated cells, which express several orders of magnitude higher levels of mRNA, necessitates the need for confirmation of protein expression. Despite these concerns, the application of both genomic and proteomic approaches has given an unprecedented insight into the protein composition of the platelet; the challenge remains however to identify the function and interplay of the proteins, as many may be vestigial or have been carried over from the megakaryocyte.

Platelets contain four main types of storage granule: dense granules, α-granules, lysosomes and peroxisomes, and several mitochondria. There are between 5 and 9 dense granules in each platelet which contain high levels of ADP, ATP, polyphosphate, 5-hydroxtryptamine (5-HT: serotonin) and Ca^{2+}. There are approximately 80 α-granules per platelet and these contain a rich diversity of proteins and membrane receptors that support haemostasis, vascular repair, inflammation and host defence (Table 40.1).

Table 40.1 Platelet α-granule constituents. Examples of platelet α-granule constituents and their physiological roles are shown.

Physiological role	Constituent
Angiogenesis	VEGF-A, VEGF-C and PDGF
Antibodies	IgG
Coagulation cascade	Factor V, fibrinogen, tissue factor pathway inhibitor
Endothelial cell activation	TGF-β
Fibrinolysis	Plasminogen, PAI-1 and α_2-antiplasmin
Growth factors	PDGF, FGF, HGF, IGF-1 and EGF
Leucocyte recruitment	Chemokines: PF4, RANTES, β-thromboglobulin, ENA-78 and SDF-1α
Matrix breakdown	Hydrolytic enzymes MMP-2 and MMP-9
Membrane proteins	αIIbβ3, P-selectin, CD40L and TLT-1
Bacterial killing	Microbicidal proteins
Miscellaneous	Amyloid β-protein precursor and Gas6
Proteases	Protease nexin II
Platelet aggregation	Fibrinogen, fibronectin and VWF
Irreversible aggregation	Thrombospondin (locks fibrinogen bridges between αIIbβ3)

Major components of α-granules include clotting factors such as fibrinogen, VWF, factor (F) V, protein S and tissue factor pathway inhibitor (TFPI), the chemokines SDF-1α, PF4, β-thromboglobulin and CCL5 (also known as Regulated upon Activation, Normal T Cell Expressed and Presumably Secreted [RANTES]), the growth factors platelet-derived growth factor (PDGF) and vascular endothelial growth factor (VEGF) A and C. Platelet α-granules also express key transmembrane proteins including integrin αIIbβ3, P-selectin (CD62P), CD40L and TLT-1, the latter three only being expressed on the surface of activated cells.

Platelets are enriched in signalling and cytoskeletal proteins that enable them to undergo dramatic changes in morphology and which enable the aggregate to withstand the high shear forces of the vasculature. Platelets have a network of intracellular membranes known as the dense tubular system that release intracellular Ca^{2+} in response to the second messenger inositol 1, 4, 5-trisphosphate (IP3). They also have a network of invaginations of the surface membrane, known as the surface-connected canalicular system, which increase the surface area of the plasma membrane during platelet spreading.

Animal models in the study of platelet function

Genetically modified mice and other organisms, notably zebrafish, are used to address the *in vitro* and *in vivo* function of specific genes and proteins in platelets (and thrombocytes i.e. nucleated platelets – only mammals have anucleate platelets), but with the caveat of key differences to human platelets and vasculature with regard to rheology and protein composition. For example, the mouse genome lacks the gene for the only Fc receptor found on human platelets, FcγRIIA and mouse platelets do not express one of the major receptors for thrombin on human platelets, PAR1. There are also important differences in participation of protein isotypes in signalling cascades and various responses. The relevance of many of the *in vivo* models (such as tail bleeds and vessel wall injury by ferric chloride or laser ablation) to haemostasis and thrombosis in humans is also unclear, and no models fully recapitulate arterial thrombosis on ruptured atherosclerotic plaques. Nevertheless, the processes that govern platelet activation in mice and other species are shared with humans, and the value of animal models in analysing platelet activation and in studying haemostasis and thrombosis, and thereby establishing a foundation for ongoing and future clinical trials, is immense.

Platelet formation

Platelets are formed from megakaryocytes in the bone marrow. Approximately one million platelets are released into the blood every second. During megakaryopoiesis, the nucleus undergoes a process known as endomitosis that involves nuclear replication without cellular division, giving rise to DNA ploidy values that range from 4*n* to 128*n*, and cells that approach 50–100 μm in diameter (the largest of the bone marrow cells). The reason why endomitosis occurs is not fully understood, but it may simply reflect the need to increase the DNA content to enable the cell to expand its protein synthetic capacity to generate 2000–3000 platelets per megakaryocyte. In addition, it allows cell growth and differentiation to occur without interruption by nuclear and cell division.

The differentiation of bone marrow progenitor cells into megakaryocytes is regulated by the cytokine thrombopoietin (TPO). The TPO receptor, c-Mpl, is expressed on progenitor cells, megakaryocytes and platelets, and signals via the JAK family of tyrosine kinases. A mutation in *JAK2*, V617F, is the major cause of the myeloproliferative disorders, polycythemia vera, essential thrombocythemia and primary myelofibrosis (see Chapter 35). Platelet lifespan is determined by an internal molecular clock governed by time-dependent degradation of BCL-X_L which normally restrains BAK-1 and BAX from inducing apoptosis. In addition, platelets undergo desialylation as they age resulting in their eventual removal via the hepatic Ashwell-Morell receptor and induction of TPO synthesis. Circulating free levels of TPO are additionally controlled by binding and internalisation mediated through its receptor c-Mpl. The two feedback mechanisms provide a simple means of tightly controlling the platelet count. Thus, if the platelet count decreases, the free level of TPO rises and there is an increase in megakaryopoiesis and platelet formation. TPO mimetics (e.g. romiplostin and eltrombopag) are in clinical use for treatment of thrombocytopenia.

It has been proposed that megakaryocyte differentiation occurs in a defined compartment of the bone marrow known as the osteoblastic niche and that mature megakaryocytes subsequently migrate from this to sinusoidal endothelial cells in the vascular niche. Here, the megakaryocytes generate long thin processes known as proplatelets, which form platelets at their terminals. The proplatelet arms protrude between bone marrow sinusoidal endothelial cells and release immature preplatelets (which divide into platelets) and platelets into the bloodstream. As yet, it has not been possible to replicate the generation of *very large* numbers of platelets from a single megakaryocyte *in vitro*, possibly because of the interplay of the environment and role of shear. Several groups and biotech companies are active in this area which has the potential to replace platelet donation in transfusion medicine.

Thrombus formation

The events that underlie platelet adhesion and aggregation, and which lead to thrombus formation, at intermediate to high rates of shear (1000–5000/s) of the arteriolar system are discussed below and depicted in Figure 40.2.

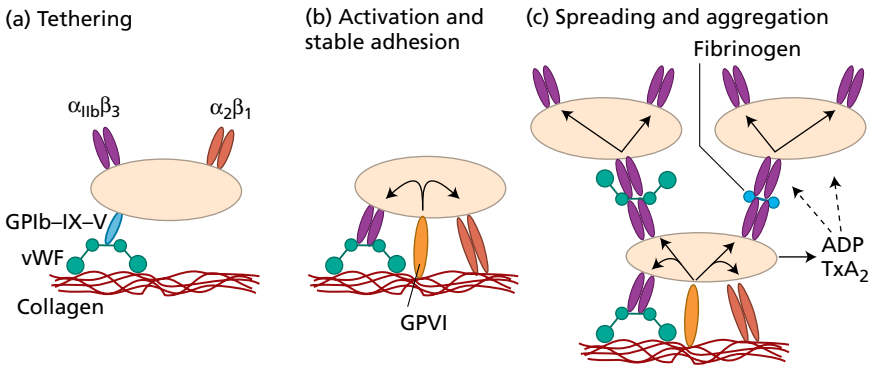

Figure 40.2 Thrombus formation at arteriolar rates of shear. Platelets are (a) tethered by VWF bound to immobilised collagen, which then (b) activates the low-affinity receptor GPVI leading to activation of integrins αIIbβ3 and α2β1, which bind to VWF/fibrinogen and collagen, respectively. This mediates stable adhesion and supports further activation of GPVI as a result of avidity. (c) The signals from GPVI and the two platelet integrins induce spreading of platelets on the matrix and release of the feedback messengers ADP and TxA_2 which activate further platelets. The generation of thrombin further supports platelet activation and generates fibrin-supporting clot retraction. The formation of a procoagulant surface supports formation of thrombin.

Platelet capture and stable adhesion

The initial event that takes place upon damage to the vasculature in the arteriolar circulation is the tethering or capture of platelets through the interaction of VWF with the GPIb-IX-V complex. VWF undergoes a conformational change on binding to collagen or in response to very high shear forces enabling it to bind to GPIbα. The fast on-rate of association between VWF and GPIbα enables capture of platelets at the high shear forces of the arteriolar system, but a fast off-rate of association means that this interaction is insufficient to give rise to stable adhesion. Thus, platelets translocate in the direction of flow on a surface of immobilised VWF (in the absence of collagen). Platelet capture is facilitated by the formation of membrane tethers, which are thin processes of membrane generated from the platelet surface by haemodynamic forces. These membrane tethers can extend up to 30 μm in length, with much of their length being derived from the large membrane component of the surface-connected canalicular system. The formation of membrane tethers helps to sustain adhesion within high-shear environments by minimising the drag on captured platelets.

The conversion to stable adhesion is dependent on activation of α2β1 and αIIbβ3 integrins, the collagen receptor GPVI, vessel-wall-generated thrombin and release of ADP. This transition can be readily demonstrated *in vitro* by comparing adhesion and aggregate formation when blood flows over immobilised VWF or a VWF/collagen surface, as illustrated in Figure 40.3. The majority of platelets translocate on a surface of VWF and form small stable aggregates only after several minutes. In comparison, platelets undergo rapid stable adhesion and form large aggregates on collagen. This process is mediated by the binding of plasma-derived VWF to collagen through its A3 domain, unmasking the binding site for GPIb within the VWF A1 domain and facilitating platelet capture and activation of GPVI by collagen, and release of the feedback mediators ADP and TxA_2.

The two major integrins that mediate stable adhesion on collagen are αIIbβ3 and α2β1 (GPIa/IIa), which bind to immobilised VWF and collagen, respectively. The role of α2β1 in this process is masked by the 50 times higher level of αIIbβ3, which is expressed at approximately 80,000 copies per platelet, with a further 40,000 copies on intracellular α-granules that become exposed on activation. The capture and recruitment of circulating platelets into a growing aggregate occurs in a similar way, with integrin activation mediated by the release of ADP and TxA_2, and the local formation of thrombin. Binding of VWF to integrin αIIbβ3 on activated platelets mediates tethering of non-activated platelets through GPIb-IX-V thereby recruiting them into the growing platelet plug.

At the lower shear rates (<500/s) in the venous system, platelets adhere directly to exposed subendothelial matrix proteins and undergo stable adhesion independent of VWF and GPIb-IX-V, with the release of ADP and TxA_2, and thrombin generation, sufficient to enable aggregate growth to occur.

Spreading

Platelets undergo a characteristic set of morphological changes on contact with a surface, known collectively as spreading, as illustrated in Figure 40.4. Initial shape change or rounding is followed by the generation of finger-like projections known as filopodia, which grow from the periphery of the cell, and the subsequent formation of lamellipodia. This is illustrated in Figure 40.4 with platelets spread on fibrinogen initially forming filopodia (100 s) with lamellipodia beginning to form at 200 s and being completely

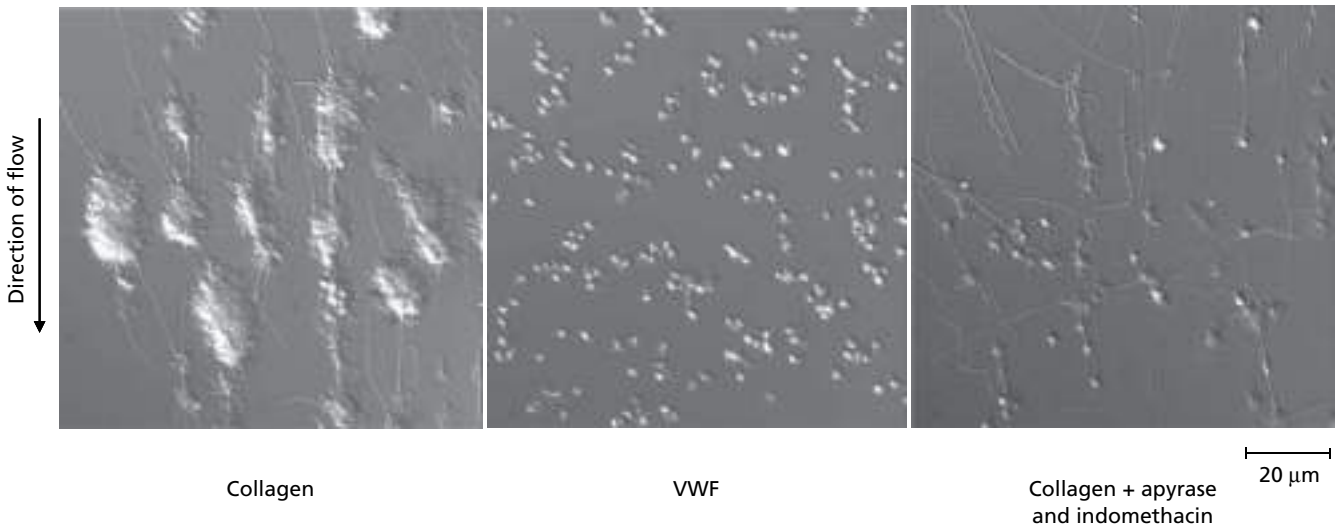

Figure 40.3 Platelet adhesion and aggregation at arteriolar shear. Human blood, anticoagulated with 40 µmol/L P-PACK, was flowed over collagen or VWF at a shear rate of 1000/s for 4 min and rinsed with Tyrode buffer for 5 min. Differential interference contrast images of adherent platelets were recorded. Where indicated, blood was pretreated with indomethacin (10 µmol/L) and apyrase (5 U/mL) to reduce the secondary mediators, TxA_2 and ADP respectively, prior to flow.

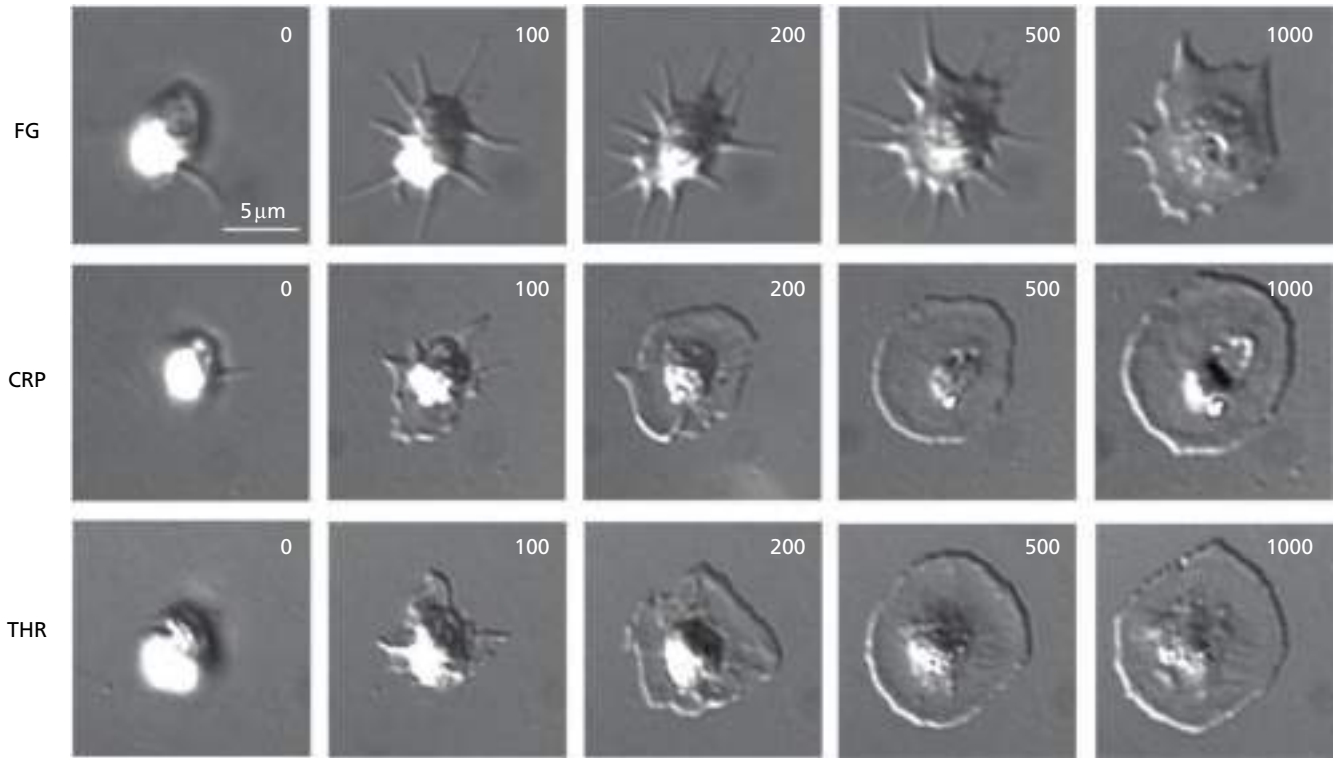

Figure 40.4 Morphological changes in washed human platelets followed adhesion. Human platelets were allowed to adhere to a surface coated with fibrinogen (FG), collagen-related peptide (CRP) or thrombin (THR). Representative morphology of a single platelet on each surface at specific time points (seconds) are shown (Source: Thornber *et al.* (2006) *FEBS. J.* **273**: 5032–43. Reproduced with permission of Wiley.)

formed at 1000 s. As these events proceed, granules and organelles are squeezed into the centre of the cell, resulting in a characteristic 'fried egg' appearance. These dramatic changes in morphology are brought about by a powerful severing and reassembly of the actin cytoskeleton. The spreading of platelets and formation of stress fibres helps to secure the platelet and thrombus against the flow and shear forces of the vascular system.

Granule secretion and TxA_2 formation

The secretion of ADP from dense granules and the *de novo* generation of TxA_2 from arachidonic acid, by the action of phospholipase (PL)A_2, play a feedback role in mediating platelet activation. Fusion of α-granules leads to expression of P-selectin on the platelet surface, which is the major ligand for P-selectin glycoprotein ligand (PSGL)-1 on leucocytes. The capture of leucocytes contributes to inflammatory events at the vessel wall including formation of neutrophil extracellular traps (NETs). Additional interactions further support the generation of NETs including the recent demonstration of binding of platelet αIIbβ3 to the choline transporter SLC44A2 on neutrophils.

Aggregation

Aggregation is the term used for the crosslinking of activated platelets through binding of bivalent or multivalent ligands to integrin αIIbβ3. It is distinct from agglutination which is a passive process mediated, for example, by the antibiotic ristocetin, which induces crosslinking of VWF to GPIb-IX-V. Ristocetin is routinely used to investigate possible defects or gain-of-function mutations in plasma VWF or GPIb.

Integrin αIIbβ3 is present in a low-affinity form on non-stimulated platelets and undergoes a conformational change to a high-affinity form in response to 'inside-out' signals. The subsequent binding of bivalent ligands to the integrin mediates platelet adhesion and aggregation. These interactions lead to clustering of αIIbβ3 on the platelet surface and the generation of 'outside-in' signals that regulate actin polymerisation (and therefore platelet spreading) and activation in synergy with other platelet receptors. Fibrinogen, VWF and fibronectin have similar affinities for integrin αIIbβ3, but fibrinogen is considered to be the major ligand because of its much higher concentration in plasma.

It has been proposed that aggregate growth is supported through homophilic and heterophilic interactions between additional platelet membrane proteins, either through the generation of intracellular signals or through adhesion. Examples include the role of semaphorin D in supporting signalling by GPVI and the binding of ephrins and eph-kinases which support activation through adhesion and signalling. In addition, an actin-dependent contractile mechanism has been shown to bring newly captured platelets into the aggregate. The overall significance of these interactions however is unclear and, as yet, there is no clear evidence of a bleeding diathesis resulting from defects in these 'late-events' in aggregation.

Fibrin generation and clot retraction

Critical to the formation of a stable aggregate, or thrombus, is fibrin, which is a polymerised fibrous protein generated by the action of the protease thrombin on fibrinogen. The formation of fibrin together with the platelets form the major components of the 'white' clot in the arterial circulation; this is in contrast to the 'red' clot in the venous system, which contains a high proportion of red blood cells. The true picture however is a spectrum from the arterial to the venous system, with a remarkable heterogeneity between vascular beds and individuals as elegantly reviewed by Weisel and Litvinov (2021).

The platelet thrombus is composed of core and shell regions

Advances in intravital microscopy and in fluorescent microscopy have revealed a much greater complexity in the composition of thrombi in mouse models than in *in vitro* assays. These studies have shown a temporal and spatial organisation of thrombi with a densely packed *inner core* composed of fibrin and an *outer shell* of loosely packed platelets held together by fibrinogen. The platelets in the core region are highly activated as shown by their dramatic change in morphology and the region is poorly penetrable to solutes (including fibrinolytics) whereas the shell is composed of large numbers of loosely packed platelets in their original biconcave shape. It has been proposed that the core reflects strong activation of platelets by thrombin (formed through the activation of tissue factor in the vessel wall) and the release of the feedback ligands ADP and TxA_2, as well as possibly activation by fibrin, which has been shown to activate GPVI. In contrast, thrombin is absent in the shell region and the levels of ADP and TxA_2 are lower (as they diffuse away from the shell) resulting in a much weaker degree of activation. In this model, the generation of ADP and TxA_2 are critical for the formation of the shell but not the core due to the redundancy with thrombin. This heterogeneity has significant implications for the mode of activation of antiplatelet and antifibrinolytic drugs.

The reader is referred to the review by Ivanciu and Stalker (2015) for further information on thrombus heterogeneity.

Procoagulant activity and microvesicle formation

Activated platelets provide a negatively charged phospholipid surface for the assembly of two multiprotein complexes that form part of the intrinsic and amplification pathways of coagulation, namely the tenase and prothrombinase complexes.

A complex of FIXa and FVIIIa on the negatively charged lipid surface converts FX to FXa (intrinsic tenase complex), which in turn forms a complex with FVa on the same surface to efficiently convert prothrombin to thrombin (prothrombinase complex). In this way, a large amount of thrombin is generated in the vicinity of the growing aggregate that serves to enhance platelet activation and convert fibrinogen to fibrin.

The platelet procoagulant response is dependent on exposure of phosphatidylserine (PS) elicited in response to stimulation by a combination of G protein-coupled and tyrosine kinase receptor agonists such as thrombin and collagen, respectively. PS exposure requires sustained entry of Ca^{2+} across the plasma membrane which can lead to zombification (or apoptosis) of platelets as a distinct phenotype with swelling, loss of granules and loss of aggregatory phenotype. This can be seen using fluorescent microscopy with distinct populations of platelets expressing PS (zomboid platelets) and activated αIIbβ3. A very small number of patients have been described with a mild bleeding disorder linked to defective procoagulant activity, a condition known as Scott syndrome. Scott syndrome is caused by mutations in the membrane transporter, transmembrane protein-16F (TMEM-16F).

The generation of procoagulant platelets shares similarities with the mechanisms that give rise to the formation of platelet extracellular vesicles (EVs), which are small membrane-bound vesicles of between 30 and 1000 nm. EVs and their functional significance is a highly active area that is held back by the challenge of studying such a small and heterogeneous population. EVs have been proposed to transfer microRNAs (miRNAs) to other cells to regulate gene expression as well as being biomarkers of platelet activation. Other biomarkers of platelet activation include soluble P-selectin and GPVI, with the latter being specific for platelet activation due to its restricted distribution.

Platelets in thrombo-inflammatory disease

For the first 100 years or more following their discovery in 1881, the focus of research on platelets has been on blood clotting. However, since the millennium, there has been a much wider appreciation of the role of platelets beyond haemostasis, notably in inflammatory processes and in vascular integrity. This has given rise to a new area of research known as thrombo-inflammation with the interplay of inflammation, platelets, coagulation factors and endothelial cells giving rise to plaques in the arterial system and thrombus formation on intact endothelial cell layers in the venous system (and conditions such as deep vein thrombosis). Thrombo-inflammatory processes are also observed in infectious diseases such as severe COVID-19 with endothelial cell activation being driven by the inflammation.

As described above, haemostasis in the arterial system is driven by exposure to the subendothelial matrix. This initiates a rapid cascade of events that lead to formation of a platelet plug in the subendothelium (haemostasis). Platelets are now recognised to participate in a second form of haemostasis in the venous system, known as inflammatory haemostasis, in which exposed sub-endothelial matrix promotes recruitment and activation of neutrophils and release of proteases that increase vascular permeability, leading to leakage of red blood cells. Unchecked by the adhesion of single and small clumps of platelets this generates characteristic red and purple spots on the skin known as petechiae. This is known as inflammatory haemostasis and is independent of integrin αIIbβ3 and GPIb-IX-V (Rayes *et al.* 2019). Petechiae are associated with low platelet counts and inflammation in the vessel wall. GPVI and a second receptor in platelets which signals through the same pathway, CLEC-2 (see below) have been shown to support inflammatory haemostasis in some but not all vascular beds in mouse models, but it is not known if this is the case in humans.

The pathological counterpart of inflammatory haemostasis is thrombo-inflammatory disease which is driven by a chain of inflammatory events that lead to endothelial cell activation, and recruitment of single or small clumps of platelets and coagulation factors leading to disorders such as deep vein thrombosis (DVT). We still know relatively little about this new area of thrombosis and the potential for therapeutic intervention, including by targeting GPVI and CLEC-2.

Platelet receptors

Receptors on platelets can be divided according to whether their major function is to mediate adhesion or to regulate activation (Figure 40.5).

Adhesion receptors

The major two adhesion receptors in platelets are GPIb-IX-V, which captures platelets in the high shear environment in the arterial circulation, and integrin αIIbβ3 which mediates stable adhesion and platelet aggregation. In addition, platelets express adhesion receptors for other matrix proteins including integrins α2β1, α5β1 and α6β1 which are receptors for collagen, fibronectin and laminin, respectively. Platelets also express receptors that mediate the interaction with other blood cells, including leucocytes, such as P-selectin which is expressed on activated platelets and binds to PSGL-1.

GPIb-IX-V

The GPIb-IX-V receptor consists of four subunits, GPIbα, GPIbβ, GPIX and GPV, and is restricted to platelets. There are 25,000 copies on the platelet surface making it the second most abundant membrane protein. It consists of two copies of GPIbα, GPIbβ and GPIX, and one copy of GPV. The principal ligand is

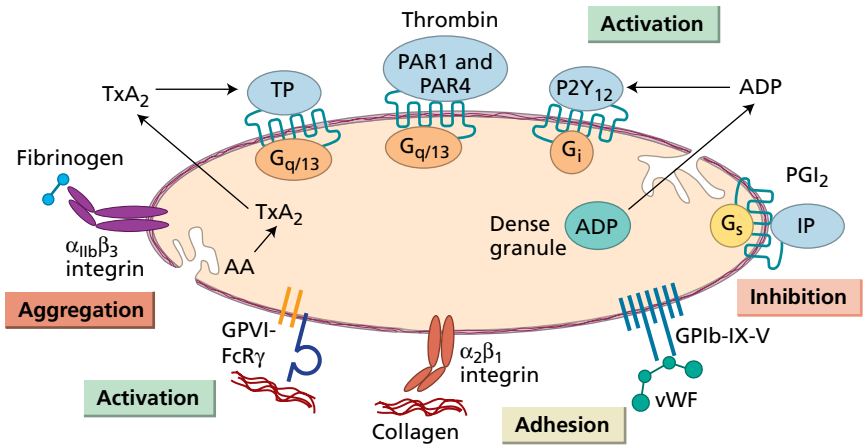

Figure 40.5 Schematic of major tyrosine kinase-linked and G protein-coupled receptors regulating platelets during haemostasis. The major signalling receptors that mediate platelet activation are the tyrosine kinase-linked receptor GPVI and the G protein-coupled receptors for TxA_2, thrombin and ADP. Of this group, the $P2Y_{12}$ ADP receptor is unique in that it synergises with the receptors for the other agonists to mediate powerful activation. The GPIb-IX-V complex is critical for platelet tethering and integrins α2β1 and αIIbβ3 for stable adhesion and, in the case of the latter, platelet aggregation. All three of these adhesion receptors also generate weak tyrosine kinase intracellular signals of uncertain significance. The prostacyclin receptor (IP) elevates cAMP and nitric oxide elevates cGMP (not shown) mediating powerful inhibition.

considered to be VWF, which binds to the GPIbα subunit. This also binds to other ligands as discussed below.

VWF consists of a series of multimers that vary in size from over 500 to over 10,000 kDa. The largest multimers of VWF are more effective in mediating platelet tethering and platelet activation. Ultra-large VWF is stored and released from endothelial cell Weibel–Palade bodies, and from activated platelets, and is broken down into the smaller multimers by the circulating metalloprotease ADAMTS-13. Deficiencies in ADAMTS-13 lead to the persistence of ultra-large VWF multimers in the circulation and a life-threatening thrombotic microangiopathy known as thrombotic thrombocytopenic purpura (TTP), characterised by VWF-rich platelet aggregates in the skin and vital organs (see Chapter 46). VWF circulates in plasma as a tightly bound complex with Factor VIII.

Upon binding to collagen, or upon exposure to ultra-high rates of shear, VWF undergoes a conformational change to an extended form that can reach several microns in length and which has multiple platelet and collagen binding sites. In this extended form, VWF is able to bind to the GPIb-IX-V complex and capture platelets in the high-shear environment of the arterial circulation. This is mediated by the fast on-rate of association of its A1 domain to the GPIbα subunit, but this also has a fast off-rate of association and signals from other receptors such as GPVI are required for integrin activation and stable adhesion.

GPIb-IX-V binds to several other cell-surface and plasma proteins, including integrin αMβ2 (also known as Mac-1 or CR3), P-selectin and thrombin (facilitating activation of PAR1 and PAR4 receptors). The interaction with αMβ2 and P-selectin contributes to attachment and transmigration of leucocytes through a mural thrombus, and the rolling of platelets on activated endothelium.

Mutations in *GPIbα*, *GPIbβ* and *GPIX*, but not in *GPV*, give rise to the severe bleeding disorder Bernard–Soulier syndrome (BSS), which is characterised by large platelets and thrombocytopenia (macrothrombocytopenia). Because of its severity, BSS is usually detected in early childhood, but in some cases, (notably in males) it may go undetected until adulthood.

Integrins

Integrins are heterodimeric-transmembrane proteins that mediate cell–cell and cell–matrix interactions and give rise to stable adhesive events and changes in cell morphology through the actin cytoskeleton. They are composed of α and β subunits which form a stable heterodimer. Intracellular signals, known as 'inside-out signals', convert integrins from a low to a high-affinity state promoting ligand binding. In turn, ligand binding generates 'outside-in signals' that remodel the cytoskeleton and generate other responses.

The integrin αIIbβ3 is the most abundant integrin on the platelet surface and constitutes approximately 15% of membrane proteins. Inside-out activation of αIIbβ3 is mediated by binding of the small G protein Rap1b to the cytoskeletal protein talin which in turn binds to the β3-tail. Outside-in signals from αIIbβ3 stimulate platelet spreading and clot retraction through PLCγ2 and the actin cytoskeleton, respectively. Activation of PLCγ2 by the integrin may be mediated through the platelet ITAM receptors GPVI and FcγRIIA (see below).

The so-called GPIIb-IIIa blockers were first introduced into the clinic in the 1990s. The original inhibitor, a chimeric Fab molecule, abciximab, was followed by two peptide inhibitors, eptifibatide and tirofiban, which bind to the Arg-Gly-Asp (RGD) binding sequence in the pocket of αIIbβ3. The RGD sequence is a common binding motif in matrix proteins including fibronectin, VWF and fibrinogen, although interestingly the latter binds to integrin αIIbβ3 through a KQAGDV sequence at the C-termini of its two γ-chains. GPIIb-IIIa blockers are used in the treatment of unstable angina and in percutaneous coronary interventions with their use limited to a hospital setting because of the risk of bleeding. Trials with orally active GPIIb-IIIa blockers were stopped due to increased mortality.

Four other integrins are found on platelets, these are: the collagen receptor α2β1, the fibronectin receptor α6β1, the laminin receptor α6β1 and the vitronectin receptor αvβ3. All of which are also found on other cells. Integrin α2β1 is considered to be the most important of these in platelet function as the result of binding to collagen. Their roles, however, are masked by integrin αIIbβ3, due to its much higher level of expression. No patients with a platelet-based bleeding disorder caused by variants in any of these four integrins have been identified. Conversely, mutations in either subunit of αIIbβ3 give rise to a major bleeding diathesis, known as Glanzmann thrombasthenia which is usually detected in early childhood due to its severity. Several hundred mutations have been identified with the majority leading to reduced expression enabling diagnosis by flow cytometry.

Platelet signalling receptors

Platelets are regulated by two major classes of signalling receptors, namely G protein-coupled receptors (GPCRs) and tyrosine kinase-linked receptors. Despite differences in the nature of their agonists and mechanisms of activation they stimulate common pathways, and cross-talk between the two receptor classes is a key feature of platelet activation. As an example, both G protein-coupled and tyrosine kinase receptors stimulate isoforms of phospholipase (PLC), namely β and γ, respectively, that generate the second messengers, IP3 and 1, 2-diacylgycerol (DG). They stimulate distinct isoforms of phosphatidylinositol 3-kinase (PI 3-kinase) which generates the lipid second messenger, phosphatidylinositol 3, 4, 5-trisphosphate (PIP3), which recruits proteins with a pleckstrin homology (PH) to the membrane including PLC and the tyrosine kinase Btk. In addition, G protein-coupled receptors stimulate Rho family small G proteins and adenylyl cyclase, mediating cytoskeletal rearrangement and platelet inhibition, respectively.

There are four classes of heterotrimeric G proteins which take their name from the α subunit which binds to the β and γ subunits. Three of the four classes of α subunit are stimulatory, with G_q activating PLC β (PLCβ), G_{13} activating Rho family small G proteins, and G_i activating PI 3-kinase and inhibiting adenylyl cyclase. G_s mediates inhibition through activation of adenylyl cyclase. Thrombin and TxA_2 receptors stimulate G_q and G_{13} family G proteins, and ADP $P2Y_{12}$ receptor stimulates G_i. Prostacyclin and adenosine receptors stimulate G_s.

The most powerful of the activating tyrosine kinase receptors signal through a motif that is found in Fc and antigen receptors in other blood cells known as an immunoreceptor tyrosine-based activation motif (ITAM) and composed of two YxxL sequences (single amino acid code) separated by 6–12 amino acids. Platelets express three ITAM receptors, GPVI-FcR γ-chain complex, the low affinity immune receptor FcγRIIA and the C-type lectin-like receptor CLEC-2. One ITAM sequence is present in each of the FcR γ-chain subunits and in the cytosolic tail of FcγRIIA. The conserved tyrosines are phosphorylated by constitutively active Src family kinases in the membrane enabling binding of the tandem SH2 domains in the tyrosine kinase Syk. This leads to the autophosphorylation of Syk and a signalling pathway that involves a third family of tyrosine kinases, the Tec family, with Btk being the major isoform in platelets, which culminates in the activation of PLCγ2. CLEC-2 has a single YxxL group in its cytosolic tail, known as a hemITAM, with activation of Syk crosslinking two receptors. A schematic of ITAM signalling is shown in Figure 40.6.

ITAM receptors are inhibited by a class of membrane protein that contain a closely related motif known as an immunoreceptor tyrosine-based inhibition motif (ITIM), composed of two repeats of a YxxI/V/L sequence. Phosphorylation of the two conserved tyrosines in the motif leads to recruitment of the two tyrosine phosphatases to the membrane, SHP-1 and SHP-2, which dephosphorylate key proteins in the ITAM pathway. G6b-B is the only ITIM to be shown to have a major role in regulating platelet activation by ITAM receptors.

G protein-coupled receptors

$P2Y_1$ and $P2Y_{12}$ ADP receptors

ADP is a critical feedback agonist mediating activation through the synergy of $P2Y_1$ and $P2Y_{12}$ receptors, which activate G_q and G_i family heterotrimeric G proteins, respectively. The physiological significance of the $P2Y_1$ receptor is uncertain due to its low level of expression (~150 copies per platelets) and redundancy in its mode of signalling with the thromboxane TP receptor and the two thrombin PAR1 and PAR4 receptors. $P2Y_{12}$ is the target of the widely used antiplatelets, the thienopyridines clopidogrel and prasugrel and the ADP analogue ticagrelor. The $P2Y_{12}$ receptor signals through the G_i of G proteins and undergoes powerful synergy with G protein-coupled and tyrosine kinase-linked receptors that activate PLC isoforms even though it only induces weak activation on its own. Over 50 patients have been reported with function-disrupting mutations in $P2Y_{12}$ in association

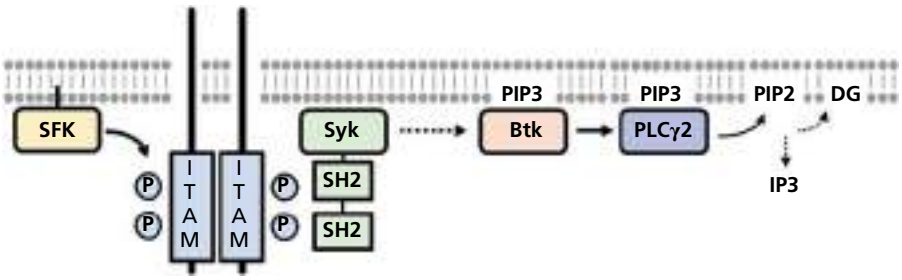

Figure 40.6 Schematic of ITAM signalling. An ITAM has the conserved sequence $YxxLx_{6-12}YxxL$ (single amino acid code). Receptor crosslinking induces phosphorylation of the two conserved tyrosines by a Src family kinase (SFK) leading to binding of the tyrosine kinase Syk through its tandem SH2 domains. Syk regulates a signalling cascade (depicted by the dotted line) consisting of adapter protein and SFKs that leads to activation of the Tec family kinase, Btk, and PLCγ2, and the generation of the second messengers inositol 1, 4, 5-trisphosphate (IP3) and 1, 2-diacylglycerol (DG). Platelets express two ITAM receptors, GPVI-FcR γ-chain and FcγRIIA. Platelets also express the hemITAM receptor CLEC-2 which has a single YxxL sequence in its cytosolic tail with Syk crosslinking two phosphorylated receptors. P depicts phosphorylation of the ITAM sequences: other phosphorylations are not shown.

with a bleeding diathesis. As yet, no patients have been identified with mutations in $P2Y_1$.

There are significant differences between the two thienopyridine $P2Y_{12}$ receptor antagonists, clopidogrel and prasugrel, and ticagrelor. Clopidogrel is a prodrug that is metabolised by the liver to an active metabolite that covalently modifies, and therefore irreversibly inhibits, $P2Y_{12}$. The related thienopyridine prasugrel is metabolised to the same active metabolite but through a pathway that is not governed by polymorphisms in cytochrome P450 enzymes. Ticagrelor is an orally available non-competitive antagonist that also inhibits uptake of adenosine, possibly accounting for its more powerful action, which needs to be balanced against an increased risk of bleeding.

Thromboxane TP receptor

Ca^{2+}-mobilising receptors activate PLA_2 and induce the liberation of arachidonic acid in platelets for metabolism by lipoxygenase and cyclooxygenase enzymes. The latter leads to further metabolism by thromboxane synthase and the generation of TxA_2 which activates platelets through the thromboxane prostanoid (TP) receptor. TxA_2 is rapidly metabolised to the stable metabolite TxB_2 which is used as a measurement of the activation of the cyclooxygenase pathway. The stable mimetic, U46619, is used in experimental and diagnostic studies due to the instability of TxA_2.

The antiplatelet action of aspirin is mediated through covalent modification of platelet cyclooxygenase and inhibition of TxA_2 formation. The irreversible nature of the acetylation, in combination with the inability of platelets to synthesise significant levels of proteins, means that the concentration of aspirin required for inhibition is lower than that required to target cyclooxygenase in other cells, and is the rational for use of 'low dose' aspirin as an antiplatelet agent. Aspirin has been shown to reduce the mortality of myocardial infarction and major vascular events by approximately one-quarter.

A handful of patients have been shown to have function-disrupting mutations in the thromboxane receptor, many of which are heterozygous, and an even smaller number have shown to have homozygous mutations in $cPLA_2$. The low number of patients could reflect redundancy in the thromboxane pathway in platelet activation or increased embryonic lethality.

PAR1 and PAR4 thrombin receptors

Thrombin is the most powerful of the platelet agonists inducing activation through the proteolytic cleavage of PAR1 and PAR4 receptors, thereby generating tethered ligands that induce receptor activation. The action of the two thrombin receptors is terminated by internalisation. Synthetic peptides corresponding to the newly exposed receptor-specific sequences known as thrombin receptor-activating peptides (or TRAPs) are used to selectively activate the two PAR receptors. It is proposed that PAR1 mediates rapid activation and that PAR4 mediates sustained activation, although this is an over-simplification. PAR1 and PAR4 signal through G_q and G_{13} heterotrimeric G proteins activating PLC and Rho family G proteins. An orally active PAR1 receptor antagonist voraxapar was approved by the FDA as an antiplatelet agent in 2014 for patients with a history of myocardial infarction or peripheral arterial disease but has not gained widespread use due to cost and risk of bleeding. A PAR4 antagonist, BMS-986120, has been developed and was entered into a phase III trial which was prematurely stopped for reasons that are not known. No

patients with defects in either receptor have been identified, possibly because the absence of one receptor is masked by the other or because homozygous mutations are lethal due to their role in other cell types, including vascular endothelial cells.

5-HT$_{2A}$ receptors

Platelets contain very high levels of 5-HT taken up by an active transport mechanism and stored in dense granules. Release of 5-HT induces powerful vasoconstriction, thereby limiting blood loss. 5-HT mediates very weak platelet activation and this plays little or no role in haemostasis or thrombosis.

α_{2A}-adrenoceptor

Adrenaline activates the α_{2A}-adrenoceptor, which is coupled to the G_i family of proteins, predominantly G_z. As is the case for the P2Y$_{12}$ ADP receptor, the α_{2A}-adrenoceptor undergoes synergy with Ca^{2+}-mobilising receptors but has little effect on its own. While studies in α_{2A}-adrenoceptor knockout mice have provided evidence for a minor role in supporting haemostasis, there is little evidence to suggest this is the case in human. Adrenaline is frequently used in aggregation studies on patients with a suspected platelet-based bleeding disorder, although interpretation of results is challenging as a proportion of healthy donors are unresponsive. As such, it is difficult to see the rational for the continued use of adrenaline.

Tyrosine kinase receptors

GPVI-FcRγ

Collagen is the most thrombogenic component of the subendothelial matrix with up to nine forms in the vessel wall, with types I and III being the predominant two in the deeper layers and type IV in more superficial layers. The major activating receptor for collagen on platelets is GPVI which is expressed at ~4000 copies per platelet. The majority of collagens activate GPVI, with the sheet-like collagen type IV being a notable exception.

Collagen is composed of three helical chains, which form a superhelical structure that is interrupted by non-helical regions. Synthetic collagen peptides based on repeating trimers in the helix have been designed to bind selectively to GPVI or to the collagen integrin receptor α2β1. Peptides that are specific to GPVI have a backbone of glycine-proline-hydroxyproline (GPO) residues and are known as collagen-related-peptides (CRP), whereas peptides that bind to α2β1 are interspersed with one or more GER-containing motifs, such as GFOGER.

GPVI is also activated by a large number of endogenous and exogenous ligands, including fibrin and the snake toxin convulxin, and has been proposed to be a pattern recognition receptor to account for this promiscuity. A key feature in GPVI-activating ligands is the presence of multiple epitopes leading to receptor clustering. The potential significance of the activation of GPVI by so many ligands, including fibrin, is unclear.

GPVI is found only in platelets and megakaryocytes. It has been shown to be absent in two patient groups. The first to be identified were individuals with immune thrombocytopenia caused by auto-antibodies to GPVI which induce shedding of the glycoprotein receptor and a lowering of the platelet count. These patients have a mild to severe bleeding diathesis depending on the degree of thrombocytopenia. The second consists of a small number of patients with an inherited defect that results in the absence of *GPVI* expression. The majority of these have the same mutation that introduces a stop codon prior to the membrane sequence and prevents expression. The patients have a mild bleeding diathesis that diminishes with age. To date, eleven unrelated families have been identified in Chile with this mutation but as yet none have been found outside of the country. The insertion is believed to be present in just under 0.3% of the Chilean population indicating that there are ~4000 GPVI-deficient individuals in the country. Identifying many more of these will help to establish whether a bleeding diathesis is always present in the absence of GPVI and whether loss of the collagen receptor provides protection from cardiovascular disease. This has important implications for development of GPVI inhibitors as novel antiplatelets.

A GPVI blocking Fab, glenzocimab (ACT-017), has entered a phase II trial for ischaemic stroke in addition to the best emergency standard of care. The results of this study are eagerly awaited. Small molecule inhibitors of Syk and Btk tyrosine kinases used in the treatment of immune thrombocytopenia and B cell malignancies, respectively, also block GPVI and are well tolerated. The advantage of inhibitors of Syk and Btk is their oral availability and more powerful action due to inhibition of other tyrosine kinase signalling receptors. On the other hand, they will also have an increased spectrum of off-target effects. As yet, no inhibitor of Syk or Btk has entered into trial as an anti-thrombotic.

CLEC-2

CLEC-2 is a C-type lectin-like receptor that is expressed at high level on platelets and at a lower level on a subset of myeloid cells. The endogenous ligand for CLEC-2 is the transmembrane protein podoplanin, which is found in many cell types including epithelial cells, inflammatory macrophages, stromal cells and lymphatic endothelial cells. Podoplanin is absent in the vasculature consistent with a negligible role for CLEC-2 in haemostasis.

Mice with a constitutive deletion of podoplanin or CLEC-2 exhibit blood-lymphatic mixing and impaired development of the cerebrovasculature, and die shortly after birth due to a failure in lung inflation (as a result of fluid build-up in the lymphatics). The deletion of CLEC-2 post-development is well tolerated, and

the primary role of the podoplanin-CLEC-2 axis in the adult appears to be in supporting inflammation following upregulation of podoplanin on macrophages and stromal cells. CLEC-2 has also been shown to support inflammatory haemostasis in combination with GPVI in mice models.

The podoplanin-CLEC-2 axis has been shown to drive thrombo-inflammation at sites of inflammation in the vessel wall following stasis or infection in mouse models. Podoplanin is also upregulated in human in the inflamed liver and in DVT suggesting it may represent a novel target for intervention. CLEC-2 is also activated by haem suggesting it may play a role in haemolytic microangiopathies, including haemolytic urinary syndrome and sickle cell disease.

FcγRIIA

The human but not rodent genome encodes for a low-affinity immune receptor, FcγRIIA, which is expressed on a variety of leucocytes and on platelets, and binds to the Fc tail of IgG presented as immune complexes. FcγRIIA is expressed at a similar copy number to GPVI and CLEC-2.

Activation of FcγRIIA underlies heparin-induced thrombocytopenia (HIT) which is caused by antibodies to PF4 in complex with heparin. In a small number of individuals, the presence of these can give rise to life-threatening thrombosis. HIT is thought to be mediated by preformed antibodies to PF4 that form part of an evolutionary defence mechanism against infection. This explains the unusually rapid time of onset within 5–30 days of first exposure to heparin.

Recently, a very rare (~1 in 50,000) disorder with a high rate of mortality (20–50%), known as vaccine-induced-immune-thrombotic-thrombocytopenia (VITT) has been recognised that has a number of similarties to HIT. VITT has an onset within 5–30 days following the first dose of adenovirus-based vaccines against COVID-19 and is associated with high levels of D-dimer and PF4-antibodies despite the patients not having been exposed to heparin. The binding of PF4 to the adenovirus has been proposed to trigger the generation of the high titre of high-affinity antibodies to the chemokine which leads to the formation of circulating immune complexes and activation of FcγRIIA on platelets and neutrophils. It is unclear why only 10% of recipients form antibodies to PF4 and why only a fraction of these go on to have VITT.

A similar mechanism to HIT and VITT has been speculated in other rare disorders associated with catastrophic thrombosis.

Inhibitory pathways

Cyclic nucleotides

Platelets have powerful inhibitory mechanisms that ordinarily prevent activation in intact healthy vessels. The major inhibitory pathway is through elevation of the cyclic nucleotides cGMP and cAMP which mediate their effects by activation of cGMP-dependent protein kinase (PKG) and cAMP-dependent protein kinase (PKA). The two kinases phosphorylate a broad range of shared and distinct substrates resulting in the inhibition of small G proteins, Ca^{2+} release, cytoskeletal remodelling and PLC. Cyclic nucleotides are metabolised by a family of phosphodiesterases (PDEs), including PDE3 which is a substrate for PKG leading to elevation of cAMP. Thus, some of the effects of cGMP are mediated by an increase in cAMP. Cilostazol and dipyridamole selectively inhibit PDE3 and PDE5 isoforms and are used as weak antiplatelet agents, often in combination with aspirin. One of the prominent substrates for both PKA and PKG is vasodilator-stimulated phosphoprotein (VASP), which is used to monitor activation by flow cytometry.

The major pathway for regulation of cGMP is through release of NO from endothelial cells which is also mimicked by nitrate-based vasodilators. Platelets express several G protein-coupled receptors that couple to the G_s heterotrimeric G protein, including the prostanoid EP and IP receptors, and the adenosine A1 receptor. Prostacyclin released from endothelial cells is considered to be the major regulator of cAMP in platelets.

ITIM receptors

Platelets express several ITIM-containing membrane proteins including PECAM-1 and G6b-B, and TLT-1 which is present on α-granules. PECAM-1 was the first membrane ITIM protein to be identified but its role remains uncertain as mouse models have shown only a mild phenotype and patients with defects in PECAM-1 have not been reported. In contrast, studies on mouse models and a handful of individuals who lack G6b-B have revealed a critical role in maintaining the levels of GPVI and CLEC-2 and the platelet count. This is presumed to be mediated by inhibition of constitutive signalling by the two receptors which lead to their shedding from the membrane and platelet removal by the reticuloendothelial system. The cytosolic tail of G6b-B is constitutively phosphorylated on tyrosines in its ITIM which recruit the tyrosine phosphatases SHP1 and SHP2 to the membrane. The functional significance of TLT-1 on platelet α-granules is not known.

Platelet-based bleeding problems

Bleeding can be due to abnormalities in platelet function or number, or due to antiplatelet medication. Patients with platelet disorders present with a typical mucocutaneous bleeding pattern of variable severity and are often prone to bleeding during surgery and trauma. However, inherited platelet defects are an uncommon cause of bleeding and are difficult to diagnose and manage, with wide variation in practices between laboratories. Before any platelet function test is requested, a full clinical

history is taken to help determine the underlying cause of the bleeding problem. This includes studying the pattern of bleeding, whether it is lifelong or recent, triggered by trauma (e.g. surgery or accident), is present within other family members and associated with any medication the patient may be taking. Von Willebrand disease (VWD) is the most commonly inherited bleeding disorder but presents with a platelet-like bleeding pattern and so measurement of VWF and other coagulation factors is performed ahead of platelet function assays. Although bleeding histories are subjective and can vary within a lifetime, they remain an important screening method for diagnosing a potential platelet defect. The International Society of Thrombosis and Haemostasis (ISTH) has introduced a bleeding assessment tool (BAT) based on a questionnaire which is now routinely used. However, it is also important to exclude acquired defects of platelet function, including those caused by concomitant prescribed and non-prescribed medications and other clinical disorders. A complete drug history is therefore important, as aspirin and non-steroidal anti-inflammatory drugs are the commonest causes of an acquired platelet defect and so testing may have to be deferred and repeated.

Inherited platelet defects can be classified according to the severity of bleeding, with severe disorders such as Glanzmann thrombasthenia and BSS usually being detected very early in life, while more mild bleeding disorders (e.g. due to $P2Y_{12}$ deficiency) often not being detected for many years and influenced by other acquired and genetic defects. There is overlap between symptoms in milder platelet defects and the normal population and it is now widely recognised that most platelet-based bleeding defects are polygenic, with even the severity of Glanzmann thrombasthaenia and BSS varying markedly between individuals. Further information on inherited platelet bleeding disorders is given in Chapter 44.

Platelet function testing

Platelet function tests are primarily used to aid diagnosis of patients presenting with bleeding problems. Normal platelet function is highly dependent on extracellular Ca^{2+} and Mg^{2+} concentrations and so the choice of anticoagulant is important. Most current testing is still performed on citrated blood within a few hours of sampling.

Global tests of platelet function are initially used as screening tests during the laboratory investigation of individuals with suspected haemostatic defects. Since global tests do not enable specific diagnosis of platelet disorders, they are normally performed as the first part of a two-step strategy that requires further testing with more specialised assays to confirm or refute any clinical diagnosis. The most commonly proposed rationale for testing global platelet function as a first-line investigation is exclusion of a platelet function disorder so that further specialised testing can be avoided. For this reason, global platelet function tests are usually initially performed at the same time as global assays of coagulation pathway function (prothrombin time activated partial thromboplastin time and functional fibrinogen assay), VWF screening tests (VWF:Ag, VWF:RCo and FVIII:C) and measurement of platelet number with a full blood counter. The most widely performed test for initial global screening platelet function disorders are currently the closure time within the platelet function analyser (PFA)-100/200 with the bleeding time no longer recommended.

The bleeding time was the first *in vivo* test of platelet function and is performed by timing the arrest of bleeding from standard-sized cuts made in the skin of the forearm. Most clinicians consider the test to be poorly reproducible, invasive, insensitive (particularly to mild platelet defects) and time-consuming. Despite these drawbacks, the test is surprisingly still used in some countries. A number of *in vitro* tests that attempt to accurately simulate platelet function have been developed. The most widely used of these is the PFA-100/200. This simulates high-shear platelet adhesion to foreign surfaces (e.g. collagen) and monitors the drop in flow rate as a small aperture is closed by platelet adhesion and aggregation. The PFA-100/200 instrument provides an optional replacement of the bleeding time as a limited screening test. Although the instrument has a good negative predictive value for eliminating *severe* platelet defects and VWD, it is very important that further diagnostic tests are still performed if clinical suspicion of a platelet defect is strong.

Automated cell counting of whole blood in the modern full blood count investigation is an essential screening test in patients with abnormal bleeding. Modern blood counters can rapidly detect abnormalities in platelet number, platelet size distribution and mean platelet volume (MPV) and provide a reliable method for screening samples from patients, provided good quality control procedures are followed within the laboratory. Normal results will therefore rapidly eliminate thrombocytopenia and anaemia as potential causes of bleeding and ensure that any platelet function tests that are being performed will not be affected by low platelet counts. If any abnormalities in platelet count, MPV or distribution are flagged by the instrument, then a blood smear should be examined to confirm defects in platelet number, size and granule content. Whole-blood morphology may also assist in the diagnosis of platelet disorders by indicating abnormalities such as red cell schistocytes in TTP or neutrophil inclusions and giant platelets in MYH-9-related disorders.

Depending on the results of clinical and laboratory screening of patients, a series of diagnostic platelet function tests are then performed. Since the 1960s, light transmission aggregometry (LTA) became the gold standard of platelet function testing and has revolutionised our ability to identify and diagnose a wide variety of platelet defects. Conventional Born aggregometers monitor the changes in light transmission that occur in a suspension of platelets in plasma or a physiological buffer that are stimulated with different concentrations of various agonists (e.g. ADP, collagen, adrenaline and ristocetin). Typical parameters

recorded from LTA tracings include shape change, lag phase, rate of aggregation, and maximal and final extent of aggregation. These parameters, coupled with the pattern of primary and secondary aggregation responses obtained with different dosages of different agonists, enable the experienced operator to diagnose specific signalling defects. Modern aggregometers are now multichannel, fully computerised, easy-to-use compact instruments and some can also simultaneously measure ATP secretion levels by luminescence. About 96 well plate aggregation testing is also available but is primarily used for research purposes and is not yet in routine use in the clinical testing laboratory.

Measurement of the storage and release of the dense granular nucleotides can also be performed by a variety of methods for confirming either storage and/or release defects, although recent surveys suggest that measurement of secretion is underused. The interpretation of aggregation traces remains challenging due to the feedback actions of ADP and TxA_2. Whole-blood impedance-based aggregometers are now common and measure the changes in electrical resistance between two electrodes caused by platelet adhesion and aggregation after addition of agonists, but are heavily influenced by platelet count.

Flow cytometry provides an exquisite, sensitive and powerful tool for studying and diagnosing various platelet defects. Flow cytometric analysis of platelets is performed in fresh whole blood or in platelet-rich plasma, and the technique can be used with very small fluid volumes, even in thrombocytopenia. This technique is used to determine the copy density of platelet membrane glycoproteins and receptors and is therefore useful for confirming the absence of various glycoproteins or receptors in disease.

Platelet function testing can also be performed and the ability of platelets to degranulate, express activation markers (e.g. P-selectin) and expose procoagulant phospholipids can be studied. A major limitation of the above tests is that they are performed at low shear conditions and therefore do not mimic accurately many of the important physiological processes of platelet adhesion, activation and aggregation that occur at higher shear rates *in vivo*. There is clearly still no gold standard for platelet testing, and indeed there may never be, and LTA remains the most widely used test. However, a variety of screening and diagnostic tests coupled with an accurate bleeding history will always be required to confirm a platelet-based bleeding disorder, simply because of the heterogeneity in the range of disorders encountered coupled with the cross-talk between receptors.

Platelets and thrombosis

There has been widespread interest in using platelet function tests to reliably detect platelet hyper-reactivity in patients with arterial thrombosis but this is not recommended in part because these are complex diseases resulting from insults to the vessel wall. Nevertheless, this interest, as well as clinical discussion of aspirin or clopidogrel 'resistance', which is more correctly termed as treatment failure, has resulted in the development of a variety of instruments for platelet function testing (e.g. Platelet Mapping System, VerifyNow, Plateletworks and Aspirinworks). The VerifyNow test was originally developed as a whole-blood cartridge-based test to monitor αIIbβ3 blockade because of the narrow therapeutic window and increased bleeding risk associated with these types of drugs. The test has also been adapted to measure aspirin and $P2Y_{12}$ blockade with two other cartridge formulations.

Platelet responsiveness to antiplatelet drugs can be easily monitored by the tests mentioned, as well as by LTA, whole-blood aggregometry and PFA-100/200. Poor responders or 'resistant' individuals can therefore be identified, although it is still unclear how to manage them and whether there is a clinically relevant relationship between poor response and outcome. Emerging evidence suggests that the true incidence of so-called aspirin resistance is probably very low (when non-compliance is accounted for) and that many studies are measuring platelet hyper-reactivity and not blockade of cyclooxygenase type 1. Although recent meta-analyses suggest that this could nevertheless be clinically informative, it is still unclear how to reliably identify these patients, with which test and cut-off (as different tests give different results) and then actually how to manage these patients.

Testing is therefore still very much in the clinical research setting. Indeed, ISTH Scientific and Standardisation Committee guidelines suggest that aspirin resistance should not be routinely monitored and the wider question remains whether routine testing of platelet hyper-reactivity and/or drug responsiveness is actually clinically necessary. There is a spectrum of platelet responsiveness within the normal population and those individuals with a stable or even an acquired hyper-reactive phenotype could theoretically be at higher risk of thrombosis.

Clopidogrel resistance is a different phenomenon as this is a prodrug that requires metabolism by liver cytochrome P450. This results in the generation of an active metabolite that irreversibly inhibits the $P2Y_{12}$ receptor. Differences in the efficiency of metabolism between individuals (related to their P450 genotype) taking standard clopidogrel dosing results in a spectrum of responsiveness but results from recent meta-analyses suggest that the overall significance of this remains unclear and do not recommend patients for genotyping. While there is a variety of tests available to monitor the efficacy of clopidogrel, including LTA, whole-blood aggregation (Multiplate), VASP phosphorylation and VerifyNow, one of the problems facing the investigator is not only which test to use, but also the definition of a suitable cut-off defining a non-response and how to effectively manage these individuals. Increased use of ticagrelor has also reduced any need for testing. Although there are emerging clinical cardiology guidelines, they do not include routine monitoring of platelet responsiveness because of the wide spectrum of response between individuals and lack of strong evidence of the relationship between testing and clinical outcome.

Genetics of platelet function disorders

Inherited platelet function disorders (IPFDs), associated with normal or reduced platelet counts, are individually rare, but collectively they account for a significant proportion of bleeding diatheses. Inherited platelet disorders include defects in adhesion, receptor signalling, secretion, cytoskeleton, procoagulant activity and production.

Identification of the underlying genetic defects is difficult and often complex in the majority of PFD cases. This is due to the variable clinical expression of the bleeding symptoms and the relative redundancy of known platelet receptor and signalling pathways. Causative mutations for PFDs have therefore only been identified in a small number of patients. For example, the number of patients with mutations in the G_i-coupled $P2Y_{12}$ ADP receptor is still relatively low despite its critical role in platelet activation. In most cases, the defect is frequently recessively inherited and the patients are either homozygous or compound heterozygous for *P2RY12* mutations. Similarly, only a handful of functionally disrupting mutations have been reported in the G_q-coupled thromboxane receptor, of which all patients are heterozygous for the mutation. A significant number of mutations in PFDs are indeed heterozygous, but many are unlikely to cause extensive bleeding in isolation. This is illustrated in some patients with heterozygous *P2RY12* defects diagnosed with type 1 VWD, a finding which emphasises the heterogeneity and polygenic nature of PFDs and reflects the complexity of disorders of primary haemostasis.

In the last 25 years, DNA-based technologies have played a significant role in the characterisation and diagnosis of PFDs. Currently, the most time- and cost-efficient means of screening genes is whole exome sequencing (WES). WES enables the detection of genetic variation throughout the protein-coding fraction of the genome. The main challenge in applying WES for gene discovery is filtering out the large numbers of irrelevant variants (typically in excess of 20,000 per individual). However, the 'unbiased' nature of this approach means we are not limited by preconceptions as to likely causative mutations. This powerful technique is illustrated in regard to platelet biology by the discovery of the gene, neurobeachin-like 2 (*NBEAL2*), for Grey platelet syndrome, an autosomal recessive bleeding disorder characterised by large platelets that lack α-granules. WES has also been utilised for the identification of activating causative mutations in *STIM1* and *ORAI1* for Stormorken syndrome leading to increased platelet procoagulant activation. A more extensive section on congenital platelet disorders is covered in Chapter 44.

The most recent sequencing technology to emerge is whole genome sequencing (WGS), which is now the method of choice as costs are reduced and sequence variation databases are improved. Alternatively, a more gene-specific targeted platform may be the method of choice to reduce the time to diagnosis, by allowing the capture and sequencing of a panel of genes of relevance to bleeding and thrombotic disorders, and is playing an increasingly important role in the first-line investigation of patients with PFDs. Insights into the underlying mechanisms of platelet function through genetic investigation in patients will, in turn, lead to more effective treatments for bleeding and cardiovascular disease in the future.

The challenge for the clinician is to know when to send samples for genetic analysis, given the issues of interpretation. This field is still evolving but over time we will know more about our genomes and those of family members and this will play an increasingly important role in treatment and therapeutic development. Below, we have listed a sequence to aid diagnosis of a platelet function disorder, acknowledging that practices will vary between centres and countries:

- Personal bleeding history including challenges to haemostasis – surgical, dental, menstrual and childbirth
- Family history of bleeding disorders
- Medication review including drugs known to inhibit platelet function e.g. anti-inflammatories, SSRIs
- BAT score
- Exclusion of other common haemostatic disorders e.g. thrombocytopenia, von Willebrand disease, dysfibrinogenaemia with basic coagulation testing (PT, APTT and fibrinogen)
- Platelet aggregometry
- Genetic testing
- More specialist functional and genetic tests in a research laboratory

Conclusions and future developments

Given that platelets were considered to be just pieces of circulating dust about 150 years ago, they are now one of the most important cells in pathology, including both in thrombosis and thrombo-inflammatory disease. We now know the composition of the megakaryocytic/platelet genome and proteome but the challenge remains to identify which of these components are functionally important in the many roles of platelets. Progress in this area is held back by the anucleate nature of the platelet which prevents standard approaches in molecular biology. The promise of the function of large numbers of platelet genes being identified through the study of patients with platelet-based bleeding disorders has had only limited success as the majority of disorders are polygenic.

The ultimate goal of platelet research remains the development of improved antithrombotic agents that provide effective treatment without an increased risk of bleeding. Although it may never be possible to fully attain this goal, this is beginning to appear possible in certain disorders as we begin to understand more about the events that underlie thrombus formation such as the involvement of the podoplanin-CLEC-2 axis in thrombo-inflammation and FcγRIIA in VITT. The demonstration that inhibitors of tyrosine kinases used in patients with ITP and

cancer are well tolerated and causes minimal bleeding opens up the potential for repurposing as novel antiplatelets that are likely to cause less bleeding than current drugs.

CHAPTER 41

Haemophilia and von Willebrand disease

41

Michael A Laffan

Department of Immunology and Inflammation, Faculty of Medicine, Imperial College London, London, UK

Introduction

The existence of lifelong bleeding disorders and their familial occurrence was noted in the medical literature as early as the 16th century. Early writers were impressed by the helplessness of the physician in the face of haemophilic bleeding. Although long recognised, the pathophysiology and genetics of these disorders were not fully understood until the latter half of the 20th century. Advances in protein chemistry and molecular biology now allow a comprehensive understanding of normal coagulation, the physiological defect in haemophilia and the underlying molecular genetics. These in turn have driven new approaches to therapy. An earlier chapter outlines the normal coagulation mechanism. In this chapter, the clinical features, pathogenesis and principles of management of the most common inherited bleeding disorders, haemophilia and von Willebrand disease (VWD), are described.

Haemophilia

Pathophysiology of haemophilia

Haemophilia A and B are caused by deficiency of factor FVIII and FIX respectively. FVIII and FIX are the two components of the intrinsic tenase (see Chapter 39). Consequently, their absence causes virtually identical patterns of bleeding as well as routine blood coagulation screen results with the PT and APTT. Combined with the fact that they are both encoded on the long arm of the X chromosome, they present almost indistinguishable sex-linked clinical syndromes and specific assays are therefore required to determine which is present. In both cases, failure to form the intrinsic tenase complex results in failure to produce the thrombin burst characteristic of normal coagulation. As a result, a loose friable fibrin mesh is produced that is easily dislodged and which has increased susceptibility to fibrinolysis. Fibrinolytic breakdown of the clot is also favoured by the failure of the weak thrombin burst to activate the thrombin-activated fibrinolysis inhibitor (TAFI). The consequent failure to consolidate the primary haemostatic (platelet) plug results in the characteristic bleeding pattern of haemophilia, which is both delayed after trauma and much prolonged. Replacement by intravenous infusion of the deficient factor can normalise the haemostatic mechanism.

Clinical features

Haemophilia A and B affect approximately 1 in 10,000 and 1 in 50,000 live births respectively and are equally common in all ethnic groups. The vast majority of patients are male, but haemophilia can occur very rarely in females (see below). The severity and frequency of bleeding are inversely related to the residual level of FVIII or FIX. Table 41.1 summarises this relationship and gives the relative frequency of the categories, based on UK national data (www.ukhcdo.org). The ankles, knees and elbows are most affected but any joint can be the site of bleeding. If untreated, this intracapsular bleeding causes severe swelling, pain, stiffness and inflammation, which gradually resolves over days or weeks. It is

Table 41.1 Haemophilia A*: clinical severity.

FVIII (units/dL)	Bleeding tendency	Relative incidence (%)
<1	Severe: frequent spontaneous† bleeding into joints, muscles and internal organs	50
1–5	Moderate: some 'spontaneous' bleeds, bleeding after minor trauma	30
>5–45	Mild: bleeding only after significant trauma, surgery	20

*This table is also applicable to FIX, FX and FII deficiencies, but not to FVII, FXI, FV, FXIII or von Willebrand factor deficiencies (see text).
†'Spontaneous' bleeding refers to those episodes in which no obvious precipitating event preceded the bleed. No doubt, minor tissue damage consequent on everyday activities actually initiates bleeding.

not clear why bleeding in haemophilia shows a predilection for joints and also muscles, but it has been suggested that low levels of tissue factor (TF) expression in synovial tissue may be at least part of the explanation because this makes thrombin generation more dependent on feedback amplification by the intrinsic pathway. There is some suggestion that bleeding in severe FIX deficiency is slightly less frequent. This is disputed but it may be related to the fact that genuine null mutations are more common in haemophilia A. The two disorders were not clearly distinguished until the middle of the 20th century. Haemophilia B then acquired the alternative name 'Christmas disease' after one of the boys in the first report in 1952. Bleeding into muscles and joints is the hallmark of haemophilia although the pattern of bleeding described below is now often masked by the use of prophylaxis.

Blood is highly irritating to the synovium and causes an immediate inflammatory reaction in the joint. In the longer term, blood and particularly increased iron deposition promote a chronic proliferative synovitis resulting in overgrowth of friable and highly vascular synovium which has an increased tendency to further bleeding, thus setting up a vicious cycle. As a result of the vicious cycle of bleeding and synovial hypertrophy, a particular joint frequently becomes the 'target joint' in an individual, whereas other joints may be relatively spared. Iron stimulates release of inflammatory cytokines which causes release of enzymes such as matrix metalloproteases and plasmin which degrade collagen. In addition, the cytokines promote H_2O_2 release which in combination with free Fe^{2+} generates OH^- radicals which cause chondrocyte apoptosis and loss of cartilage. The bone beneath the cartilage is also affected with osteoclast activation, bone resorption and subchondral cysts visible on X-rays. (Figure 41.1) An important observation has been that the initiation of arthropathy may require only one or two haemarthroses which means that a therapeutic strategy to prevent bleeds must be started as early as possible.

Figure 41.1 Radiograph of knee joint showing advanced haemophilic arthropathy. Note the loss of cartilage, eburnation, deformity subluxation, osteophytes, subchondral cysts and irregularity of joint contours.

Muscle bleeding can be seen in any anatomical site, but it most often presents in the large load-bearing groups of the thigh, calf, posterior abdominal wall and buttocks. Local pressure effects often cause entrapment neuropathy, particularly of the femoral nerve with iliopsoas bleeding. This causes a common symptom triad of groyne pain, hip flexure and cutaneous sensory loss over the femoral nerve distribution. Bleeding into the calf, forearm or peroneal muscles can lead to compartment syndrome with ischaemic necrosis and contracture.

Haematuria is less common than joint or muscle bleeding in individuals with haemophilia, but severely affected patients may have one or two episodes per decade. These may be painless and resolve spontaneously, but if bleeding is heavy, it can produce clot colic. Usually, no anatomical abnormality is found to account for the haematuria on radiological investigation.

Central nervous system bleeding is uncommon but can occur after minimal head injury, including birth trauma and remains

a significant cause of death in haemophilia A. Intestinal tract bleeding frequently presents with haematemesis and melaena and should be routinely investigated for peptic ulceration or malignancy. It may also present as obstruction due to intramural haemorrhage.

Oropharyngeal bleeding, although uncommon, is clinically dangerous, as extension through the soft tissues of the floor of the mouth can lead to respiratory obstruction. Bleeding from the lip or tongue after laceration can be very persistent and troublesome due to fibrinolytic substances in saliva and the impossibility of immobilising the tongue.

Surgery and open trauma invariably lead to dangerous haemorrhage in the untreated individual with haemophilia. There may be persistence of haemorrhage, often after an initial short-lived period of haemostasis. Clots, if formed, are bulky and friable and break down, with recurrent haemorrhage occurring intermittently over days and weeks. Nowadays this is only seen in patients who are resistant to conventional replacement therapy due to the presence of inhibitors (see below) or when patients with mild or moderate haemophilia present after their first surgical or dental procedure. Bruising is a common feature of haemophilia A but is usually only of cosmetic significance as it remains superficial and self-limiting. Large extending ecchymoses may occasionally require treatment.

Presentation

If a mother is a known carrier of severe haemophilia, the absence of FVIII or FIX in a cord blood sample will establish the diagnosis in the infant. It is not infrequent for prenatal genetic diagnosis to be carried out by means of amniocentesis after 36 weeks in order to guide management of delivery. Mild degrees of deficiency may be more difficult to confirm until later due to liver immaturity (FIX) or stress response (FVIII). However, haemophilia may be sporadic, and in approximately one-third of cases, there is no family history. In such cases, haemophilia may come to light in the neonatal period with cephalohaematoma or other bleeding resulting from the trauma of birth. In cultures where early circumcision is the rule, this will cause prolonged haemorrhage. Quite often, the diagnosis is delayed until it is noticed that the infant has many large bruises from hand pressure when being picked up or from minor knocks on the cot. These sometimes cause diagnostic confusion and the erroneous label of 'non-accidental injury' may be applied, with psychological trauma to the parents and child. Soon after the infant starts to walk actively, joint bleeding begins to appear. In other children, excessive bleeding from the eruption of primary dentition or from lacerations prompts performance of diagnostic tests. When there is no family history, the median age of diagnosis for severe haemophilia is 8 months. Levels of 1.0–5.0 iu/dL (moderate haemophilia) may be sufficient to largely prevent spontaneous bleeding and delay diagnosis until bleeding occurs after trauma or surgery. Mild cases may only present in adulthood when severe trauma or surgery provokes unusual bleeding.

Investigation of coagulation defects and haemophilia

Investigation of a suspected inherited bleeding disorder usually begins with routine screening tests of coagulation, which although considerably removed from normal *in vivo* coagulation mechanisms, remain useful in detecting and diagnosing coagulation disorders. The principal routine tests in common use are the prothrombin time (PT) and the activated partial thromboplastin time (APTT); also known as the partial thromboplastin time with kaolin (PTTK) or the kaolin cephalin clotting time (KCCT). These tests require the activity of all the conventional procoagulant factors except FXIII; however they do not require the presence of platelets (they are performed using platelet-poor plasma and exogenous phospholipid) and do not activate the protein C/protein S system.

Prothrombin time

In the PT, coagulation is triggered using a thromboplastin, i.e. tissue factor (TF) plus phospholipid, typically relipidated recombinant human TF or occasionally derived from animal tissue (rabbit brain). The plasma is recalcified and the clotting time recorded. The PT will be prolonged by deficiencies of FVII, FX, FV, FII or fibrinogen.

Activated partial thromboplastin time

The APPT is triggered using a negatively charged surface (e.g. kaolin, micronised silica or ellagic acid) to initiate contact activation followed by phospholipid (to mimic platelet membrane) and calcium to allow the coagulation cascade to progress. It is thought that activation of coagulation rarely proceeds by this route *in vivo* and consequently deficiency of the contact factors is not associated with any increased tendency to bleeding. The APTT will be prolonged by deficiencies of FXII, FXI, FIX, FVIII, FX, FV, FII, fibrinogen, prekallikrein and high-molecular-weight kininogen. It is, therefore, prolonged in haemophilia A and B.

Thrombin time

The thrombin time is performed simply by adding a dilute preparation of thrombin to citrated platelet-poor plasma and recording the clotting time. Prolongation of the thrombin time therefore implies that there is either an inhibitor of thrombin present (most commonly the effect of heparin) or that there is a problem with fibrin cleavage or polymerisation. It is extremely sensitive to the presence of unfractionated heparin but is also prolonged by low or abnormal fibrinogen and hypoalbuminaemia. It is normal in haemophilia.

Inhibitors

The simplest interpretation of a prolonged test of coagulation is that one or more of the factors required for its execution is deficient in the patient's plasma. However, an alternative explanation is that an inhibitor of coagulation, usually an antibody, is present. The presence of an inhibitor is typically demonstrated by mixing normal and test plasma (with a prolonged clotting time) in equal proportions. Correction of the prolonged clotting time by the normal plasma indicates a coagulation factor deficiency and failure to correct indicates the presence of an inhibitor. The mixture may need to be incubated for 2 hours for inhibitors of FVIII to manifest their effect.

When an inhibitor is detected, further tests are performed to determine whether it has specificity for a particular clotting factor or not. In practice, it may be easier to proceed directly to factor assays now they are more readily available. Non-specific inhibitors usually fall into the class of antiphospholipid antibodies and are paradoxically associated with thrombosis rather than bleeding (see Chapter 48). In previously normal patients, specific inhibitors are most commonly directed against FVIII, resulting in an 'acquired' haemophilia. In patients with haemophilia, they prevent the correction of the factor deficiency by normal plasma or therapeutically by factor concentrate.

Specific factor assays

When initial tests or clinical history suggests factor deficiency, then specific factor assays are performed to determine which is affected. This is most usually done by performing a bioassay in which the ability of the test plasma to correct the defect in plasma lacking a specific factor is measured. Bioassays have the advantage of directly measuring the biological activity of the factor in question but because they also utilise other plasma components, they are susceptible to numerous interferences and confounding effects. This can be avoided in some cases by using artificial small substrates (chromogenic substrates). This aids automation and avoids interference but often does not capture all aspects of the molecule's biological activity: for example, mutations in the *FIX* GLA domain may be missed. Finally, the physical amount of the factor present can be assessed immunologically. Immunological assays are accurate and precise but do not give information about the functional activity of the molecules that have been measured.

FVIII assays

In many laboratories, the FVIII assay is a modified APTT which is often referred to as a 'one-stage assay' because the activation of FVIII and progression to the coagulation endpoint take place in a single step. However, it is also possible to construct a 'two-stage assay' in which the FVIII is activated in a first step and its activity (the amount of Xa generated) is measured in a second separate step. Chromogenic FVIII assays also use a two-stage procedure. The two assays normally give similar results but the distinction is important because some defective FVIII molecules give different results in the two assays. Most commonly in these cases, the one-stage assay gives a higher result than the two-stage but the patient's bleeding phenotype is more in keeping with the latter (lower) result. Thus the assessment of the severity (and sometimes even the diagnosis) of the haemophilia can be mistaken if the two assays are not carried out and compared. This is referred to as 'one stage – two stage discrepancy'. The reverse phenomenon is also encountered but is less common and appears to be infrequently associated with bleeding. Factor concentrates and the products of gene therapy may also give different results with the two assays which is important when monitoring therapy.

Laboratory diagnosis of haemophilia

Initial tests show a prolonged APTT, normal PT and thrombin time (if performed) and a normal platelet count. This should prompt specific factor assays of FVIII, FIX and FXI. When a low FVIII result is encountered it should be ensured that this is not the result of von Willebrand disease.

Treatment

Clotting factor concentrates

The discovery in the early 1960s that FVIII was concentrated in cryoprecipitate and the subsequent development of lyophilised concentrates, prepared from many thousands of donors, made home treatment feasible and promised the prospect of a normal life for people with severe haemophilia. Similar concentrates containing the Vitamin K-dependent factors were developed for Haemophilia B. However, use of such plasma-derived concentrates was associated with the transmission of hepatitis C virus (HCV), hepatitis B virus (HBV) and HIV. Although these infections were present at only low frequency in the donor population, concentrates were made from many thousands of donations and there was a very high risk that batches of concentrate were infected, especially with HCV. After 1985 virucidal methods (such as terminal dry heat treatment, solvent/detergent treatment, nanofiltration and pasteurisation) were rigorously applied in conjunction with donor selection and plasma pool screening and quarantining, reducing the risk of transmitting these viruses to close to zero. However, there remains the problem of transmission of non-lipid-coated viruses (such as hepatitis A and parvovirus), which can survive solvent/detergent sterilisation and the possibility that new viruses will emerge. For these reasons, products are required to undergo more than one inactivation

process. For FIX concentrate, the process of nanofiltration has been used, which can prevent transmission of non-lipid-coated viruses. The prion protein responsible for variant Creutzfeldt–Jakob disease (vCJD) can be transmitted by blood products, but fortunately, this has not emerged as a problem in concentrates, although concentrates are no longer produced from plasma collected in countries with notable vCJD in the donor population. Consequently, the plasma-derived clotting factor concentrates in use at present are high-purity products with high specific activity and excellent safety.

Recombinant FVIII and FIX

The *FVIII* and *FIX* genes were cloned in 1984 and 1982, respectively. This has allowed the manufacture of the recombinant proteins in cell culture, which therefore eliminates the risk of disease transmission from donors. Progressive refinements have in many cases eliminated all additional animal protein from the cell culture medium and any protein added as stabiliser in the lyophilised product. Recombinant FVIII can be made either from the wild-type 'full-length' cDNA or from cDNA that has the large B domain deleted. The B domain has been shown to be completely dispensable for the procoagulant function of FVIII and its absence does not change the half-life of the molecule. Recombinant FIX is made for the wild-type 'full-length' cDNA.

Subsequently, recombinant technology has allowed the development of modified bioengineered FVIII and FIX molecules with enhanced pharmacokinetics by coupling to other molecules such as polyethylene glycol (PEG), albumin or the immunoglobulin Fc fragment. Clinical studies have demonstrated both safety and efficacy of these extended half-life (EHL) products with prolongation of plasma half-life by a factor of 1.5 for FVIII and up to 5 for FIX. This facilitates effective prophylaxis regimens and reduces burden on patients and families.

Alternatives to factor VIII and factor IX

Rebalancing therapy

Although difficult to prove, some clinical observations suggested that the bleeding phenotype was less severe in those haemophilia patients who had also inherited a prothrombotic trait such as antithrombin deficiency or Factor V Leiden. This was the stimulus for development of several therapies to deliberately lower the level of natural anticoagulant protein activity as a means of restoring the balance of coagulation rather than by restoring procoagulant protein levels. There is clear evidence that this approach is at least partially successful for all the natural anticoagulants, but the ones that have made most progress are antithrombin, TFPI and protein C. Different methods have been used for each: siRNA for antithrombin, monoclonal antibodies for TFPI and creation of a novel serpin for activated protein C. While proof of principle has been established and rates of haemarthrosis clearly reduced using these methods, their safety remains uncertain and thrombotic events have complicated the AT and TFPI studies. They all have the advantage of working for both haemophilia A and B, being unaffected by anti-FVII or anti-FIX antibodies and allowing use of novel molecules with longer half-lives which can be administered subcutaneously. Their place in therapy will rest on further safety and efficacy data.

Bispecific antibody to mimic factor VIII

The function of FVIII is to bring together FIXa and FX on a phospholipid surface and thereby increase the efficiency of FX activation by five orders of magnitude. After much effort, a bispecific human antibody was generated which was able to perform the same function. Although the antibody has a much lower efficiency than FVIII, it is able to support thrombin generation equivalent to approximately 10% of FVIII according to most estimates. Again it is not inhibited by anti-FVIII inhibitors and can be given subcutaneously at 1–4 weekly intervals making it extremely convenient for prophylaxis, without the peaks and troughs seen with concentrates and consequently extremely popular. Additional FVIII can be given to non-inhibitor patients for breakthrough bleeds or for surgery.

Treatment of bleeding in haemophilia

Since the development of replacement therapy, the goal of treatment for haemophilia patients has been the prevention of bleeding and arthropathy, and ultimately to support people with haemophilia to be able to live a life that is not impeded by haemophilia. The severity and frequency of haemarthrosis depend on both the clotting factor level and the level of activity. Only a small amount of factor activity is needed to prevent spontaneous haemarthrosis.

After trauma or at the onset of bleeding, therapeutic infusion of replacement factor should be administered as early as possible and to a haemostatic level to stop or prevent haemorrhage. The dosing of factor replacement is still based on theoretical calculations and clinical experience. Guidelines for the treatment of haemorrhagic episodes in haemophilia are given in Table 41.2, with the estimated likely effective level required for haemostasis. If sufficient factor is available, it is feasible to restore the factor level into the normal range and maintain it there by continuous infusion or frequently repeated infusions.

Formulae based on plasma volume and expected recovery give a rough guide to dosage required to achieve a given level, but where the level is critical, as for surgery or when there is serious bleeding, it should always be checked by assay after administration. On average, FVIII infusion produces a plasma increment of 2 iu/dL per unit infused per kilogramme

Table 41.2 Indications and guidelines for factor replacement in haemophilia A and B.

Site of haemorrhage	Optimal factor level (%)	Dose (units/kg body weight)		Duration (days)
		FVIII	FIX	
Joint	30–50	20–30	30–50	1–2
Muscle	30–50	20–30	30–40	1–2
Gastrointestinal tract	40–60	30–40	40–60	7–10
Oral mucosa	30–50	20–30	30–40	Until healing
Epistaxis	30–50	20–30	40–60	Until healing
Haematuria	30–100	25–50	70–100	Until healing
Central nervous system	60–100	50	80–100	7–10
Retroperitoneal	50–100	30–50	60–100	7–10
Trauma or surgery	50–100	30–50	60–100	Until healing

(*Source:* Escobar (2003). Reproduced with permission from Wiley.)

body weight, and FIX infusion a rise of 1iu/dL. From these observations, a simple formula can be derived:

$$\text{Dose to be infused}\,(\text{u}) = \text{Weight}\,(\text{kg}) \times \text{Desired rise}\,(\text{iu/dL})\,/\,\text{K}$$

where K is 1.5–2 for FVIII concentrate and 0.8–1.0 for FIX concentrate. The lower recovery for FIX reflects the fact that a substantial proportion leaves the blood and binds to collagen in the vessel wall and surrounding tissue. Some evidence suggests that this extravascular FIX makes an important contribution to haemostasis.

Assessing the duration of treatment required is a matter of clinical judgement according to the individual circumstance. Cover for surgery, other than very minor procedures, requires maintenance of normal FVIII levels for at least 1 week, followed by a period at reduced dosage during convalescence. This can be achieved either by repeated bolus injections (every 8–12 hours for FVIII and 12–24 for FIX), paying particular attention to trough levels, which should not fall below 50 iu/dL, or by continuous infusion. The half-life of FVIII varies considerably and may be particularly short in children, requiring more frequent dosing. It should also be noted that the doses required during the immediate peri- and post-operative period may be considerably more than expected. The use of EHL products can now make perioperative management considerably simpler and extend the dosing intervals quoted above.

Prophylaxis

The original rationale for prophylaxis, begun in 1958 in Malmö, was the observation that spontaneous bleeding was seen less frequently and less severely in individuals with a factor level of 1.0–4.0 iu/dL and these levels could be achieved in severe patients using regular infusions of plasma derivatives. Although this has been successful in greatly reducing the number of bleeding episodes, it has been realised that it does not completely prevent the development of joint damage which is also seen in patients with moderate haemophilia.

Today prophylaxis is regarded as the standard of care for all those with severe haemophilia and should also be considered for the majority of those with moderate haemophilia. Regular prophylactic treatment is begun at around the age of 1 year, before the onset of joint bleeds, so-called primary prophylaxis. Standard half-life FVIII is administered every second day at a dose of 25–40 units/kg. The goal is to adjust the dose and frequency to maintain peak and trough levels that fit with the patient's activity of lifestyle and prevent all bleeding episodes. Evidence from trials indicates that the risk of bleeding rises as the length of time spent with FVIII levels below 1.0 iu/dL increases. Historically, the Malmö model was effective in reducing haemophilic arthropathy. (Figure 41.2). More recently, a large, randomised study comparing prophylaxis with enhanced on-demand therapy showed that after 6 years of therapy, 93% of those on primary prophylaxis had a normal joint score on magnetic resonance imaging (MRI) compared with only 55% on intensive on-demand regimens. However, as protection from bleeding improves, so levels of activity increase and the intensity of treatment has to be increased in parallel to match this. Regrettably, children on apparently effective prophylactic regimens are still entering their third decade with significant arthropathy, frequently in the ankles and having to undergo joint fusion. In some cases, joint damage has developed without overt bleeds leading to the hypothesis that subclinical 'microbleeds' may be occurring, although this remains unproven. The current goal of prophylaxis is to achieve an annualised bleeding rate of zero but achieving this as well as a full range of activity still incurs a considerable treatment burden and requires multidisciplinary support.

Factor concentrates must be delivered via a peripheral vein for prophylaxis. However, if this is not possible then the implantation of an indwelling venous access device (e.g. Port-a-Cath)

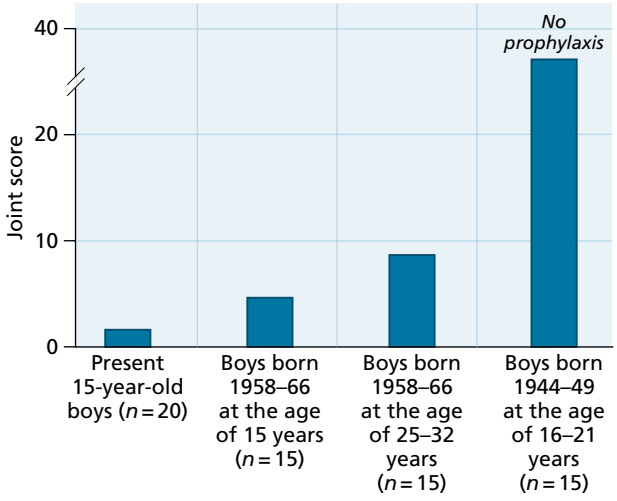

Figure 41.2 Orthopaedic joint scores for patients intensively treated in the present. A group of 15-year-old boys compared with a less intensively treated group at different ages and with patients not receiving prophylaxis (historical control subjects) (Source: United Kingdom Haemophilia Centre Doctors' Organisation (2003). Reproduced with permission of Wiley.)

may be necessary. Another alternative is the fashioning of a small arteriovenous fistula in the arm. EHL concentrates can reduce the need for this by allowing longer intervals between treatment. At present, this is every third day for haemophilia A and weekly or fortnightly for haemophilia B, but new products may extend this further. Use of EHLs has also increased levels of activity and quality of life. The bispecific antibody can simplify prophylaxis further for haemophilia A by providing good protection from bleeds (70% of patients with zero bleeds), injections 1–4 weekly and subcutaneous administration. The benefit is more dramatic in patients with inhibitors to FVIII (see Section below) for whom there was previously no adequate prophylactic therapy.

In older patients who have established joint disease or have had previous joint bleeds, prophylaxis is also effective in reducing bleeding episodes and/or slowing progression and even improving joint disease. This 'secondary or tertiary' prophylaxis may be used continuously or for a limited period to allow the synovial hypertrophy in a target joint to regress or be targeted to periods when bleeding is more likely (such as a particular activity).

Tranexamic acid

A significant component of the bleeding tendency in haemophilia is the increased susceptibility of the clot to fibrinolysis. Tranexamic acid is a lysine analogue that competes with fibrin for binding to the kringle domains of plasminogen thus preventing its binding to fibrin and inhibiting its conversion to plasmin. This anti-fibrinolytic effect makes tranexamic acid a useful adjunctive therapy in haemophilia, especially for bleeding at sites of increased fibrinolytic activity such as the oral mucosa. It can be given orally or intravenously, ideally beginning before surgery, at a dose of 1 g tds (20 mg/kg/day for children in divided doses). For oral bleeding, a mouthwash can be prepared (5% w/v) which is also useful. Dose adjustment is required in renal impairment.

Desmopressin

Desmopressin (1-deamino-8-d-arginine vasopressin) can be used to treat mild haemophilia A and provides a non-plasma alternative to concentrates. It has no effect on FIX deficiency. It acts via the V_2 receptors on endothelial cells to stimulate exocytosis of Weibel–Palade bodies which contain VWF and, in some tissues, also FVIII. In practice, this effect can be used to elevate the plasma FVIII level two to fourfold above baseline. Desmopressin is a synthetic analogue of vasopressin and retains the antidiuretic action of the natural hormone but not it's vasopressor activity. Patients are advised to restrict their fluid intake after desmopressin. This is especially important in young children in whom unrestricted fluid intake may result in hyponatraemia and convulsions. Desmopressin is contraindicated in elderly patients and those with vascular disease because arterial thrombosis has been reported following desmopressin in these circumstances.

Desmopressin can correct the haemostatic defect in mild haemophilia A sufficiently to cover minor surgery or treat a minor bleeding episode. A typical regimen would be to give 0.3 μg/kg body weight either by slow intravenous infusion over 20 min or by subcutaneous injection. Desmopressin also releases tissue plasminogen activator and so tranexamic acid is frequently given as well. A high-concentration nasal spray is also available that delivers 150 μg per actuation. The effect is maximal at approximately 60 min after either intravenous or subcutaneous administration. The half-life of the endogenously released FVIII is about 8 hours but may be shorter in some cases and the fall-off should be documented. The dose can be repeated and although tachyphylaxis occurs such that the second dose may produce a rise of only 30% of the first, there is often no further drop with succeeding doses. If repeated doses are given over a short interval (e.g. 48–72 hours), the FVIII response to desmopressin injection should be assayed to ensure that the reserves are not exhausted.

Complications of therapy

Inhibitors

Antibodies to the FVIII replacement (inhibitors) are most common in patients with severe Haemophilia A. In people with severe Haemophilia A they are most likely to develop during

childhood within the first 25 exposures to FVIII; after which they are infrequent, but do rarely develop after years of exposure, typically after periods of intensive FVIII treatment. Inhibitors are detected in around 25–30% of people with severe haemophilia A at some stage in their treatment. However, many of these are low-level transient inhibitors that are not a long-term problem for treatment. The cumulative incidence of high-responding inhibitors is in the region of 10–15%. The likelihood of an individual developing an inhibitor is strongly dependent on the underlying *FVIII* mutation. Patients with large deletions or stop codons in the light chain appear to be particularly prone to inhibitor development. Approximately 25% of patients with the common intron-22 inversion develop inhibitors.

Inhibitors in moderate and mild haemophilia are far less common. However, some missense mutations causing milder haemophilia A, particularly those in the FVIII light chain, are strongly associated with inhibitor development. Typically such patients develop inhibitors when FVIII is administered in large amounts (e.g. severe bleeds) or in association with inflammatory stimuli (e.g. surgery). Because the development of inhibitors is unpredictable, it is important to test for their emergence at clinic visits, and before and after operations in all patients that have been exposed to FVIII concentrates.

Antibodies to FVIII frequently have a time-dependent component in their action and an incubation time of 2–4 hours is required to reliably measure the full effect of the antibody. Inhibitors usually inactivate FVIII in a predictable linear manner (type 1 kinetics) but they may not inactivate all available FVIII (type 2 kinetics). Type 2 kinetics are seen particularly in mild and moderate haemophilia as well as in acquired haemophilia. Inhibitors are most commonly quantitated using the Bethesda assay where 1 Bethesda unit (BU) is the amount of antibody that reduces the FVIII activity in pooled normal plasma by 50% after 2 hours incubation. Some inhibitors are 'low-responding' and remain at a low or moderate level (<5–10 BU) after further FVIII exposure, whereas in high responders treatment with FVIII, elicits a sharp anamnestic rise after 5–8 days and inhibitor levels may reach hundreds or thousands of BU. Low responders can be treated repeatedly with high doses of FVIII concentrate. However, high responders are refractory to treatment with FVIII concentrate, and therefore alternative therapies are required.

Inhibitors in haemophilia B are much less common than in haemophilia A. Only about 2–3% of patients with severe haemophilia B will develop inhibitors, but interestingly many of these inhibitors present with anaphylaxis to infusions of FIX concentrate, sometimes after only one or two exposures. Unlike FVIII inhibitors, FIX inhibitors are not time-dependent, but can be similarly quantitated by a modified Bethesda assay. The majority of patients who develop inhibitors have large gene deletions or nonsense mutations occurring in the first 20% of the *FIX* gene.

Inhibitors: treatment and prevention of bleeding

For patients with Haemophilia A and antibodies to FVIII, effective prophylaxis is now available using the bispecific antibody which is as effective as for non-inhibitor patients. There is no such FIX substitute for patients with HB although the rebalancing therapies offer the prospect of a suitable prophylactic agent.

For treatment of bleeding episodes or for surgery, a bypassing agent will often be required to achieve haemostasis. The currently available bypassing agents are human recombinant FVII (rFVIIa) and a plasma-derived prothrombin complex concentrate that contains activated coagulation factors (factor eight inhibitor bypassing activity, or FEIBA). The mode of action of rFVIIa is not clear but it appears to bind to the surface of activated platelets at the site of injury and promotes FXa formation there. Recent evidence suggests that platelets may be able to synthesise TF or at least acquire it from circulating microparticles. High concentrations (30–90 nmol/L) of FVIIa are required to generate sufficient FXa and FIIa to achieve haemostasis. The advantages of recombinant FVIIa include viral safety, low systemic activation of coagulation, effectiveness independent of inhibitor titre, and an excellent overall safety profile allowing home use and ease of administration. The main disadvantage is the short 2-hour half-life and therefore the need for frequent administration at standard dose (90 mcg/kg), although this may be partially overcome by using a single 270 mcg/kg dose for mild to moderate bleeds.

Both native and activated prothrombin complex concentrates appear to be able to bypass the need for FVIII and have a role in the treatment of patients with FVIII antibodies. Their efficacy appears to derive from a combination of activated clotting factors and the elevation of prothrombin concentration, which is a major determinant of thrombin generation. The activated prothrombin complex concentrates (APCC) contain more of the FVIII bypassing activity and are designed specifically for use in patients with FVIII inhibitors. Activated prothrombin complex concentrates have proved efficacious in controlling bleeding in many situations. Currently, the principal problem with APCC is that when used in combination with the bispecific antibody, it can produce a syndrome of microangiopathy and thrombosis. It is recommended that this combination is avoided. Other problems with APCC are that it is plasma-derived and it contains some FVIII, which may cause an anamnestic rise in inhibitor titre. On the other hand, its longer dosage interval (given once or twice daily) makes it simpler to use. A major problem with both bypassing agents is that there is no reliable laboratory measure of their haemostatic effect.

Treatment of inhibitors: immune tolerance

Until alternative molecules capable of reproducing normal levels of FVIII or FIX activity are developed, it will remain desirable to eradicate FVIII or FIX inhibitors, a process referred to as immune tolerance induction (ITI).

FVIII inhibitors: For haemophilia A basic ITI regimens involve the continued administration of FVIII, and both low-dose (50 units/kg 3 times per week or alternate days) and high-dose (200 units/kg/day) regimens have been used. Neither regimen has been conclusively shown to be superior but the response is more rapid and bleeding events are fewer, in the high-dose regimen. Both may need to be continued for 12 months or more. Overall, the success rate is approximately 70%, after which prophylaxis must be maintained to prevent re-emergence of the antibody. The success is greatest in those with a historic peak titre below 200 BU, and where there are no interruptions to the ITI regime. For resistant cases, second-line approaches include the use of a FVIII concentrate containing VWF (for FVIII inhibitors), combination with monoclonal anti-CD20 antibody, or corticosteroids, alkylating agents, plasmapheresis and immunoglobulin (Malmö regimen). Success is defined as normalisation of the FVIII recovery and a FVIII half-life greater than 7 hours. Following successful immune tolerance, if regular FVIII prophylaxis is stopped, for example in order to use the bispecific antibody as subcutaneous prophylaxis, there is a risk of immune tolerance 'escape' and the FVIII inhibitor returning; this decision therefore needs to be considered very carefully.

FIX inhibitors: Immune tolerance for FIX inhibitors is generally less successful and is sometimes precluded by anaphylactic responses making more elaborate regimens necessary beginning with very low doses of FIX and administration by continuous infusion. It may also be complicated by the development of nephrotic syndrome.

The ageing haemophilia population

Although HIV and HCV remain significant complications of therapy, improvements in both haemophilia care and antiviral treatments have resulted in significant increases in median life expectancy for individuals with haemophilia over recent years. Increasing numbers of patients are living beyond 65 years of age. In addition to the joint and muscle problems of haemophilia, older patients face the same medical conditions associated with ageing in the general population, such as cardiovascular disease and cancer. Care can become very complex, such as use of antithrombotic therapy for cardiovascular disease in a patient with an inherited bleeding disorder. For example, intensive prophylaxis to maintain FVIII above 0.3–0.5 iu/mL may be required to allow anticoagulation for AF or dual antiplatelet therapy following coronary stent placement. Multidisciplinary and cross-specialty coordination is key to successful management.

Molecular genetics of haemophiia A

The *FVIII* gene (Figure 41.3) spans 190 kb of the X chromosome. The protein-coding regions (exons) are separated by 25 introns, some of very large size (e.g. intron 22 is over 35 kb). FVIII is synthesised in endothelial cells especially in the liver, spleen and lymph nodes. The amino acid sequence contains a triplicated region (A1, A2 and A3 in Figure 41.3), whose elements are more than 30% homologous with each other. A second duplicated homology region (C1, C2) is responsible for the phospholipid-binding properties of the molecule. The third type of sequence in the protein is the heavily glycosylated B domain, which is coded entirely within exon 14, connects A2 and A3, and is removed on thrombin activation of FVIII.

The processed mRNA specifies a protein of 2351 amino acids, from which a 19-amino-acid N-terminal leader sequence is cleaved on secretion. The mature plasma protein initially consists of a single chain of 2332 amino acids, but as a result of proteolysis circulates as a series of light-chain and heavy-chain heterodimers with B domains of varying length.

The vast majority (>90%) of FVIII circulates in complex with VWF, in the absence of which its half-life is extremely short. Studies of FVIII have identified the A3 (1648–1689), C1 and C2 domains as important for VWF binding but it is uncertain how many of these interact directly with VWF because in isolation the recombinant fragments have a much lower affinity. After thrombin activation, the cofactor consists of a heterotrimer: the N-terminal A1 and the A2 domains are isolated by cleavages at 372/373 and 740/741, and held together by charge interactions including a divalent cation-dependent linkage (see Figure 41.3). The B domain is discarded by the cleavages at 740/741 and 1689/1690. Thrombin cleavage also results in release of FVIII from VWF.

Protein C inactivates FVIIIa by cleavage at 336/337 and 562/563 totally but *in vivo* inactivation of FVIIIa is also due to spontaneous dissociation of the heterotrimer. The crystal structure of FVIII has been reported and several of the interactions mapped including the FIX-binding site on the A2 and A3 domains. The C domains appear to be responsible for phospholipid binding.

Thanks to the development of rapid sequencing methods, the mutations in nearly all patients with haemophilia A can be identified (Table 41.3). Consequently, a large database of mutations has accumulated and is maintained at https://databases.lovd.nl/shared/genes/F8. These include large deletions and missense mutations, as well as nonsense, frameshift, splicing (affecting mRNA processing) and insertional mutations. Surprisingly, about half of all severe haemophilia A is due to a major inversion (Figure 41.4) that occurs quite frequently during male gametogenesis (approximately 1 in 10,000 spermatozoa).

Molecular genetics of haemophilia B

The *FIX* gene lies telomeric to the *FVIII* gene on the X chromosome at Xq27.1 and is considerably smaller extending for only 34 kb in length. It comprises eight exons producing

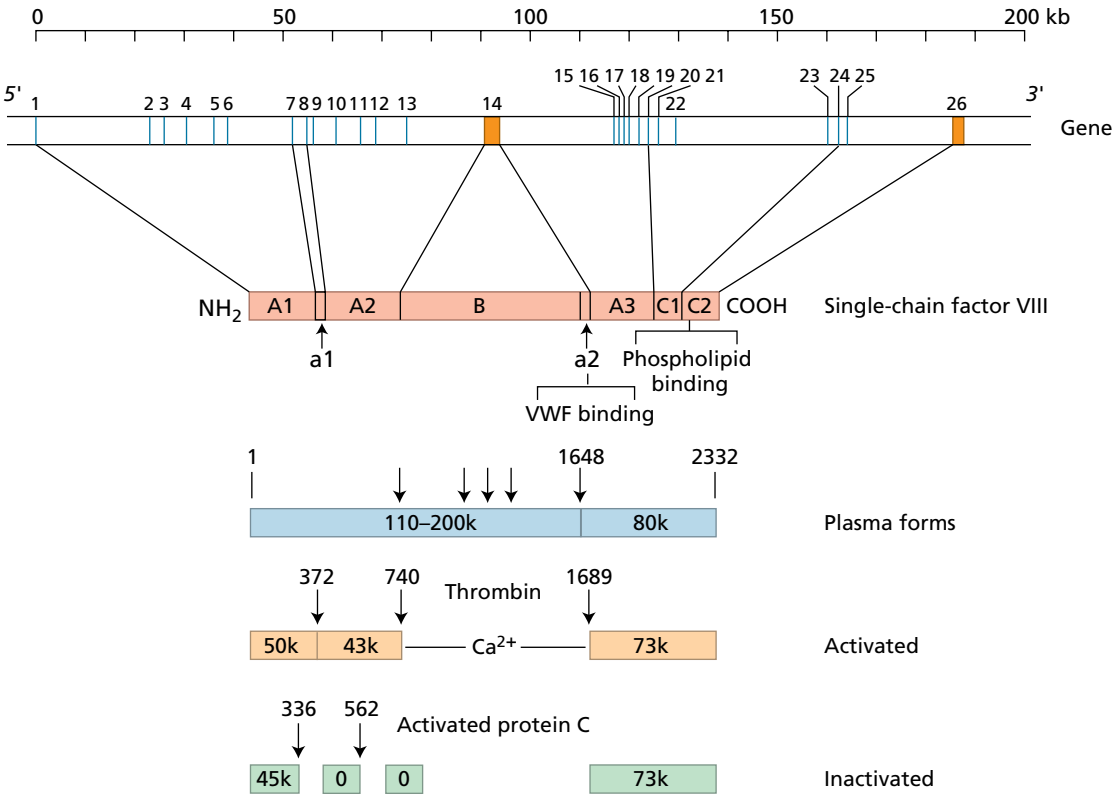

Figure 41.3 The *FVIII* gene and protein. Top line, scale for gene in kilobase pairs of DNA; second line, location of exons (protein-coding segments) of the *FVIII* gene shown as solid bars; second to third line, corresponding domains of *FVIII* gene and protein; fourth line, plasma FVIII is heterogeneous due to cleavage at various points within the B domain during synthesis and secretion, yielding heterodimers in which the heavy chain (N-terminal segment) pairs from 740 to 1648 amino acids; fifth line, thrombin activation releases the a2 segment from the light chain, the B domain from the heavy chain and cleaves between the A1 and A2 domains; bottom line, inactivation of factor VIIIa by activated protein C is accompanied by cleavages at 336, releasing the a1 domain and 562 in the middle of the A2 domain.

a 2.8 kb transcript mRNA encoding the protein of 461aa. FIX is synthesised in the liver and has a domain structure similar to the other serine proteases of the coagulation cascade, comprising a signal peptide, a GLA domain, two EGF domains and a serine protease domain. The single-chain zymogen can be activated by both FXIa and the TF-VIIa complex; in both cases, two cleavages after Arg 191 and Arg 226 release an activation peptide creating a disulfide-linked two-chain active enzyme. The mutation spectrum responsible for Haemophilia B is quite different from that responsible for Haemophilia A primarily because there is no single mutation corresponding to the intron 22 inversion. Instead, the majority of mutations responsible for severe Haemophilia B are missense mutations rather than nonsense mutations as for Haemophilia A (https://databases.lovd.nl/shared/genes/F9). This may account for any difference in phenotype but again it is large deletions that are associated with the highest risk of inhibitor formation. The normal plasma concentration of FIX (~90 nM) is much higher than that of FVIII (~0.4 nM).

Gene therapy for haemophilia

Haemophilia is an excellent model for gene therapy (GT) because the clinical manifestation is the result of a deficiency of the single gene product and only a small amount of protein is required to ameliorate symptoms. Providing the protein enters the blood, the site of synthesis should not matter. In recent years a series of trials using *FVIII* and *FIX* genes in adeno-associated virus (AAV) vectors have achieved successful and long-lasting expression with resultant reduction in bleeds and concentrate requirement, often with cessation of prophylaxis. The AAV viruses have relative tropism for the liver and the construct typically contains a liver-specific promoter for expression in that organ. This is the physiological site of synthesis for FIX but not for FVIII which may contribute to differences in the patterns of expression.

The first studies dealt with FIX due to the smaller size of the gene and its lower immunogenicity. Gene therapy for FIX has

Table 41.3 Mutations responsible for haemophilia A.

Mutation type	No. of mutations observed	Percentage
Intron 22 inversion		
Distal	260	30.7
Proximal	37	4.4
Rare	5	0.6
Total	302	35.7
Intron 1 inversion		
Total	8	1.0
Point mutations		
Missense	323	38.2
Nonsense	79	9.3
Total	402	47.5
Small deletions or insertions		
Small deletions	63	7.5
Small insertions	22	2.6
Combination of insertions and deletions	1	0.1
Total	86	10.2
Large deletions (>50 bp)		
Total	25	3.0
Splice-site mutations		
Intronic	20	2.4
Cryptic	2	0.2
Total	22	2.6

been enhanced by utilising the FIX Padua variant which has a specific activity approximately 8 times that of wild-type FIX allowing higher levels of FIX activity to be achieved, often in the normal range, with relatively low levels of protein expression and vector doses.

Gene therapy for FVIII is more difficult because even after deletion of the B-domain the gene construct remains slightly too large to fit within AAV and so multiple transfection of cells with partial constructs is required. GT for both FVIII and FIX has been complicated by immune reactions to the viral capsid and possibly innate immune responses which manifest as liver enzyme elevation and loss of protein production. Most GT recipients have been treated with temporary immunosuppression to suppress these reactions. At present, most gene therapy programmes utilise AAV which are non-integrating episomal viruses but other approaches such as haematopoietic stem cell transduction, and vectors such as lentivirus, remain in development. The significance of rare integration events is not yet clear but has not resulted in any problems so far.

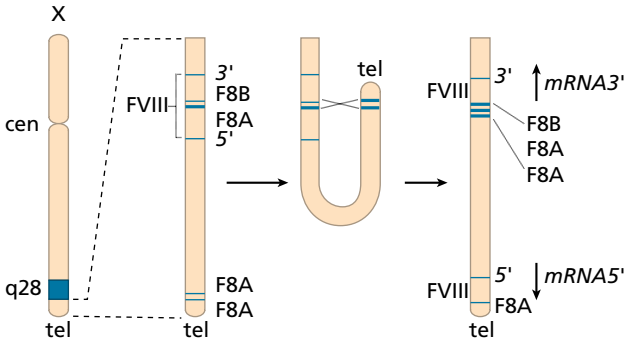

Figure 41.4 How the tip flips: the mechanism of inversion through intron 22. The mutation is responsible for up to half of all cases of severe haemophilia A. During spermatogenesis, at meiosis the single X pairs with the Y chromosome in the homologous regions, but there is nothing to pair with most of the long arm of X. Unfortunately, the possibility of intrachromosomal pairing and crossover exists because there are three copies of a gene designated *F8A*, one lying within intron 22 and two in the opposite orientation situated 400 kb telomeric to the *FVIII* gene. Crossover with either the distal or the proximal *F8A* copy divides the *FVIII* gene in two, such that separately transcribed mRNAs are produced, neither of which encodes functional FVIII.

Haemophilia A and B in females

True homozygous haemophilia A is rare and even rarer for haemophilia B, but well described, being due to the marriage of a female carrier of haemophilia to an affected male. Haemophilia A and B have also been described in females with Turner syndrome.

More commonly, carriers of haemophilia may have haemophilia themselves due to skewed X chromosome inactivation (Lyonisation). X-chromosome inactivation allows only one *FVIII/FIX* gene to function in each female cell. Because the process is random, carriers of haemophilia A or B have on average 50% of the mean normal level of the clotting factor but skewing of the inactivation towards the X chromosome containing the abnormal or the normal *FVIII/FIX* gene may occur, resulting in a clotting factor level that is either well within the normal range or low enough to produce a mild, or even moderate, haemophilia phenotype. In this case, bleeding is similar to males with the same factor level with the additional problems of HMB and pregnancy and responds to factor replacement. It is important to note that while a low level of FVIII/FIX strongly implies carriership, a normal FVIII/FIX level does not exclude it.

As a result of *de novo* mutations, especially the FVIII intron 22 inversion in spermatogenesis, new cases may present with no family history of haemophilia. In such women, careful investigation is essential to ensure the correct diagnosis is made – haemophilia carrier, mosaic, VWD type 1 or VWD type 2N (see below) – due to the reproductive implications. Molecular analysis is often required to clarify the diagnosis.

Current techniques make definitive diagnosis by identification of the causative mutation in patients and carriers straightforward in the vast majority of cases. In identified carriers, antenatal diagnosis can be carried out when pregnant and although typically only offered in cases of severe haemophilia specific diagnosis can be made by molecular analysis of chorionic villus biopsy at 11–12 weeks' gestation or third-trimester amniocentesis. The sex of the fetus can be determined from free fetal DNA in maternal blood at 8–9 weeks gestation. Pre-implantation genetic diagnosis (PIGD) with selection of unaffected embryos for reimplantation has been successfully carried out for haemophilia.

General organisation of haemophilia care

As these are relatively uncommon disorders, with effects on patients and families at all stages of life who require care and support services across the whole field of medicine and social services, it is now accepted that this is best delivered by specialised comprehensive care centres. The staff of a major comprehensive care centre will include physicians, nurses, physiotherapists, psychologists, laboratory scientists and social workers, devoting all or a substantial part of their time to haemophilia care. Key link specialties, where often joint clinics may be held include obstetrics, gynaecology, rheumatology and orthopaedics. Access to specialised care for patients with HIV and HCV infection is still important.

Within the NHS, a service specification has been developed to support and set out the provision of haemophilia services. It is recognised that not every centre can provide every facility and that there should be a wide distribution according to population density. The functions of a centre are to provide 24-hour emergency treatment for haemophilic patients and their families and a full range of diagnostic tests for identifying new patients and monitoring treatment. Full records should be kept of all treatments, whether given in hospital or as home therapy and progress monitored through regular follow-up. Paediatric centres are best located within paediatric units. Genetic counselling, including carrier detection and antenatal diagnosis, must be available for families of patients with haemophilia. All patients should have direct or indirect access to a large centre providing all these facilities and treating a large number of patients. On diagnosis, all patients are issued with a special medical card indicating laboratory test results, inhibitor status, main centre and local centre for treatment. Despite the setbacks in the 1980s due to virus transmission, the trend continues to be an ever-improving life expectancy and social participation, based on continuing medical progress and multi-professional input. The younger generation of people with haemophilia is now treated with virus-safe or recombinant concentrates and has escaped both HIV and liver disease, and can lead virtually normal lives

Acquired haemophilia

This chapter is devoted primarily to the inherited form of haemophilia arising from mutations in the *FVIII* and *FIX* genes but haemophilia can also arise as a result of autoantibodies that neutralise FVIII cofactor activity. The incidence is approximately 1.5 per million per year and it tends to occur predominantly in older patients, although there is also an increased frequency after pregnancy and in association with other autoimmune disorders. The antibodies usually show time-dependent (type 2) neutralisation of FVIII and a residual FVIII level is often detectable. The pattern of bleeding is distinct from that in inherited haemophilia, with a much greater incidence of soft tissue and mucosal bleeding, often out of proportion to the FVIII level. Treatment for bleeding is generally the same as for inhibitors in hereditary haemophilia and suppression of the inhibitor requires immunosuppressive therapy (e.g. corticosteroids, cyclophosphamide and anti-CD20 antibody). In some cases, a suitable alternative for haemostasis is porcine FVIII which functions well in human plasma but is frequently neutralised less efficiently by human anti-FVIII antibodies, especially in acquired haemophilia. A recombinant porcine FVIII has been developed and licensed for use when antibody cross-reactivity is demonstrated to be low. It has the advantage that the response can be measured using a FVIII assay and so indicate the efficacy of treatment.

von Willebrand disease

Although described in 1926, our understanding of this complex and variable bleeding disorder remains far from complete. The basic defect common to all variants is a deficiency of one or more aspects of VWF functional activity. The abnormality may be quantitative and/or qualitative.

von Willebrand factor

von Willebrand factor (VWF) is a large plasma glycoprotein encoded by a gene on chromosome 12p13, which was cloned simultaneously by several groups in 1986. The pre-pro-VWF primary translation product comprises a 22-amino-acid signal peptide, a 741-amino-acid propeptide and the 2050-amino-acid mature subunit. The pro-VWF monomer is now described as comprising three types of domains (A, C and D) arranged as follows: NH_2–D1–D2–D′–D3–A1–A2–A3–D4–C1–C2–-C3-C4-C5-C6-CK–COOH. (Figure 41.5) These can themselves be broken down into smaller ancestral units. VWF is produced predominantly in vascular endothelial cells and also in megakaryocytes, although plasma VWF derives entirely from endothelial cell production. After translation, the monomer enters the endoplasmic reticulum and the signal peptide is removed. The monomers then dimerise via the C-terminal

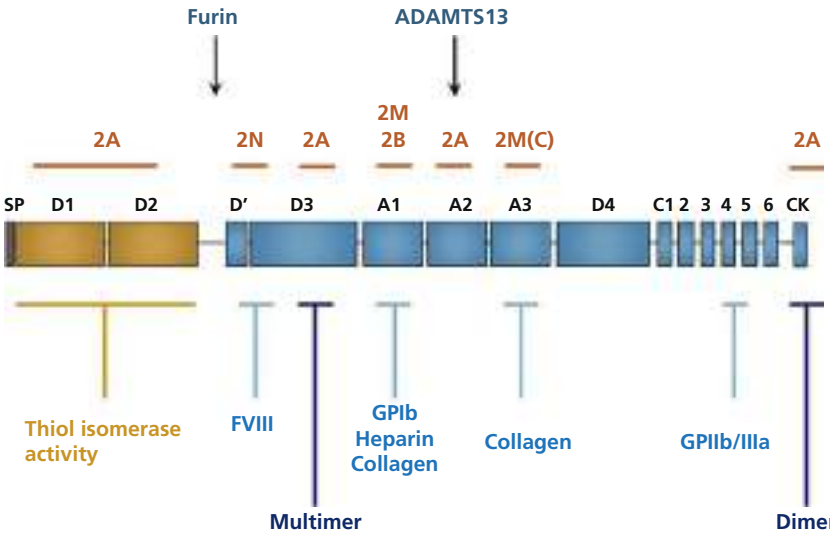

Figure 41.5 The domain structure of the primary VWF translation product. The SP-D1D2D′D3A1A2A3D4C1-C6CK domain structure is shown with the binding properties of the domains indicated below including the sites involved in dimerisation and multimerisation. Variants responsible the different type 2 variants cluster in the are shown above the domains. Variants responsible for type 1 and type 3 are distributed throughout the molecule and are not shown. Cleavage by Furin removes the propeptide before or soon after secretion. The ADAMTS13 cleavage site in the A2 domain is also shown. SP, signal peptide; CK, cysteine knot. 2M(C) indicates a type 2M pattern caused by defective collagen binding.

cysteine knot (CK) domain before leaving the endoplasmic reticulum for the Golgi, where the dimers are joined via their N-termini to form a series of multimers (or more strictly concatemers) with molecular masses ranging from 1000 to 20,000 kDa. Following translation and during subsequent processing the molecule is extensively glycosylated with N- and O-linked glycans that form 20% of its final molecular weight. Importantly, approximately 13% of the N-linked glycans terminate in an ABO blood group antigen. In endothelial cells, multimerised VWF is then tightly packed in helical structures within Weibel–Palade bodies, some of which pass directly to the cell surface to release their contents (constitutive pathway) while others are delayed in the cell for later release or in response to inflammatory stimuli (regulated pathway). Platelet VWF does not contribute significantly to plasma VWF and is stored in the α-granules of platelets prior to release upon platelet activation. During synthesis, the VWF propeptide, which is essential for multimerisation, is cleaved from the mature molecule, stored with VWF in the Weibel–Palade bodies and released with it into plasma but is not known to have any further function thereafter. Some VWF is also secreted from the base of the endothelial cell where it binds directly to collagen in the subendothelial matrix. Factor VIII (FVIII) is also synthesised in endothelial cells and stored with VWF in the Weibel-Palade bodies.

Rapid release of VWF and FVIII from the endothelial Weibel–Palade storage granules via the regulated pathway can be induced by a number of agonists including thrombin, adrenaline, histamine and vasopressin. This can be turned to advantage by using desmopressin to treat mild forms of VWD. Elevation of plasma VWF due to increased synthesis and secretion occurs as part of the acute-phase response to injury, inflammation, infection and neoplasia and also in pregnancy and hyperthyroidism. The confounding effects of stress and inflammation need to be taken into account when measuring VWF levels for diagnosis.

The two principal functions of VWF are (i) adhesive, binding to matrix molecules, particularly collagen, at sites of vascular injury and subsequent capture of platelets to form the primary haemostatic plug and (ii) the stabilisation of FVIII in the circulation. The adhesive function of VWF requires functional binding sites for collagen and the platelet glycoproteins GPIb and GPIIb/IIIa (also known as integrin $\alpha_{IIb}\beta_3$) and is also dependent on the presence of large VWF multimers. The VWF released from endothelial cells into plasma is in the form of ultra-large multimers, which are subsequently cleaved into smaller forms by the action of the plasma metalloprotease ADAMTS-13. This is of critical importance because it is the high-molecular-weight multimers that have the greatest collagen- and platelet-binding activity: absent cleavage allows ultra-large multimers to persist in the circulation resulting in the formation of platelet microthrombi and vascular occlusion (in thrombotic thrombocytopenic purpura; TTP). Conversely, excessive cleavage results in the loss of high-molecular-weight multimers, loss of haemostatic function and increased bleeding as seen in some forms of acquired von Willebrand syndrome and some type 2A VWD (see 'classification of VWD' below).

VWF also binds to a number of other molecules present in the Weibel–Palade bodies such as osteoprotegerin and angiopoietin 2 but the functional importance of this is not entirely clear, although VWF is now known to play an important role in angiogenesis and wound healing.

FVIII and VWF (Figure 41.6) circulate together as a complex in which VWF protects FVIII from degradation, so that a deficiency of VWF or a reduction in its ability to bind FVIII may result in a low FVIII plasma level. Therefore, deficiency of VWF can give rise to a dual haemostatic defect: reduced plasma levels of FVIII (due to its shorter half-life in the absence of VWF) and a defect in primary haemostasis because of the failure in assisting platelets to adhere to the cut edges of blood vessels (see Chapter 40). Clearly, the multistep synthesis, assembly and secretion of VWF and its multiple binding

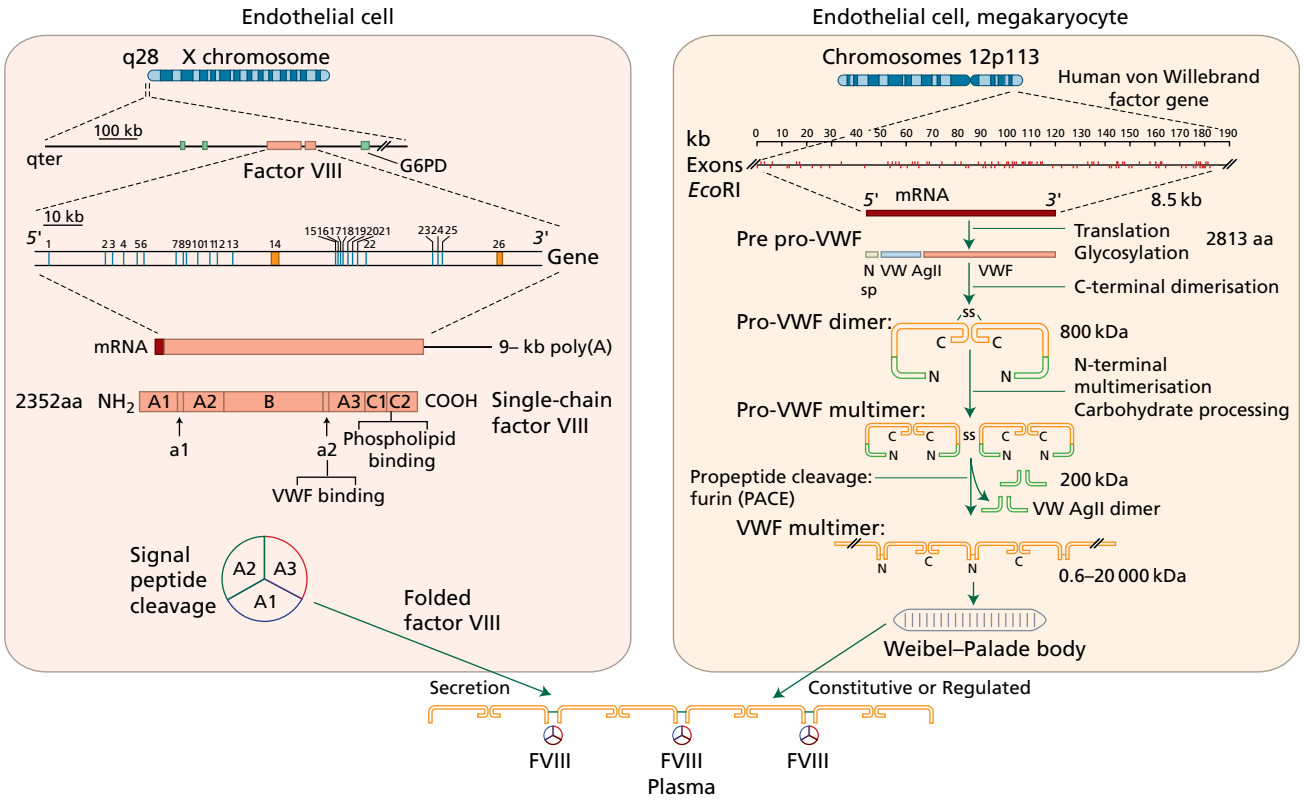

Figure 41.6 Assembly of FVIII–VWF complex. FVIII synthesised by endothelial cells as a single chain is partially proteolysed and probably complexed with VWF prior to release. VWF is synthesised as a single-chain precursor, which dimerises with disulfide bond formation, then multimerises with further disulfide exchange, with concomitant loss of a large propeptide segment. The propeptide is essential for multimer formation and probably functions as an acidic disulfide isomerase. In megakaryocytes VWF is stored in alpha granules.

interactions provide many ways in which mutations of the *VWF* gene can lead to loss of function. In particular, the multimeric structure is susceptible to dominant-negative effects of mutant alleles which can result in premature multimer termination. Genome-wide association studies have identified many genes which contribute to determining the plasma VWF level either by modifying synthesis, storage and secretion or by modifying clearance from the circulation. Chief amongst these is the *ABO* locus which is responsible for approximately 20% of the variation, with blood group O individuals having VWF levels 30% lower than those who are non-O.

The diagnosis of VWD is based on the recognition that for normal VWF function, it must be (i) present in adequate amounts, (ii) have a normal multimeric structure and (iii) have intact functional domains (binding sites). When any of these properties is only slightly reduced, the presence or absence of a bleeding tendency may also depend on the quality and quantity of the other haemostatic components, particularly platelets and collagen, with which VWF must interact to complete the process of primary haemostasis. This 'net effect' problem is the likely explanation for the variable phenotype associated with mildly low levels of VWF and the associated diagnostic confusion.

Clinical features

The clinical features of VWD vary according to the severity of the deficiency. The most common clinical picture is of a mild to moderately severe bleeding tendency characterised by bruising, epistaxis, prolonged bleeding from minor cuts, heavy menstrual bleeding and excessive, but not often life-threatening, bleeding after trauma or surgery. Patients often present for investigation in the second or third decade after prolonged bleeding from dental extraction or surgery has aroused clinical suspicion. Heavy menstrual bleeding (HMB), unexplained by local or hormonal factors, can also be the presenting symptom: an estimated 20% of women with HMB have VWD and data suggest this is widely underappreciated and under-investigated.

The distribution of bleeding in VWD can be explained on the basis that VWF is required for platelet adhesion at high shear rate, which is the condition of flow found in the smallest blood vessels exposed to trauma in skin and mucous membranes. Type 2A VWF

is particularly associated with bleeding from the gut which may be complicated by the development of angiodysplasia. Much less common is autosomal recessive (type 3) VWD, where VWF is completely absent and FVIII:C levels are usually around 1.0–2.0 iu/dL. These patients have a bleeding tendency that also has features of severe haemophilia A, with haemarthroses, muscle bleeds and life-threatening haemorrhage after trauma as well as a propensity to small-vessel bleeding (due to lack of VWF adhesive function), which is not a feature of haemophilia A.

Mild bleeding symptoms of the type typical of VWD are very common in the general population and thus have a low specificity for the presence of a bleeding disorder. It is now recommended that a simplified bleeding score (e.g. the international Bleeding Assessment Tool: BAT) is used to assess the likelihood of a significant defect in haemostasis before referring for investigation and that the result is borne in mind when interpreting the results of laboratory analyses. It will have greatest value when administered early in consultation, for example in primary care.

Laboratory diagnosis

Preliminary diagnosis

After obtaining a suggestive personal history and a family history, the laboratory diagnosis of VWD rests on assessing both the amount of VWF present (VWF:Ag) and its functional capacity. VWF:Ag is measured using immunological techniques; either an ELISA or an immunoturbidimetric assay. At present, it is generally possible to assess three important functions of VWF:

1. Platelet-dependent function: This function describes the ability of VWF to bind to and agglutinate platelets. It depends on the presence of high-molecular-weight VWF multimers and a functional binding site for platelet GPIb. Originally, dilutions of patient plasma were tested for their ability to promote platelet agglutination in the presence of the antibiotic ristocetin which serves to unfold the VWF molecule and mimic the effect of shear flow. This function was called ristocetin cofactor activity (VWF:RCo). A number of modifications now allow this to be performed on an automated analyser, using lyophilised platelets or recombinant GPIb bound to latex or magnetic particles (VWF:GPIbR). A further development utilises a mutant GPIb molecule that does not require ristocetin to interact with VWF (VWF:GPIbM). This avoids interference from naturally occurring variants that alter ristocetin binding but not platelet GpIb binding. Finally, an antibody to the A1 domain has been used to assess platelet binding activity (VWF:Ab). Automation has greatly improved the precision of these assays. Table 41.4

2. Collagen-binding function (VWF:CB): This is performed in an ELISA-based assay in which a well coated with collagen is used to capture VWF. It is dependent on the presence of high molecular weight multimers, as well as the functional binding sites for collagen on the A3 and A1 domains.

Thus, both VWF:RCo and VWF:CB are sensitive to the loss of high-molecular-weight multimers but measure different binding properties of VWF. They should be seen as complementary rather than alternative assays.

3. FVIII binding (VWF:FVIIIB): Assessed first by a FVIII assay and then if this is reduced, by an assay of VWF FVIII-binding capacity using a modified ELISA-based technique.

Secondary tests for classification of VWD

If a deficiency suggestive of VWD is detected then further tests, particularly multimer analysis (by electrophoresis) and ristocetin-induced platelet aggregation (RIPA) should be performed to allow accurate classification. (Figure 41.7)

Table 41.4 Assays or von Willebrand factor.

Measure	Definition	Method
VWF:Ag	Immunologically detected protein	ELISA or immunoturbidimetric assay
VWF:RCo	Ristocetin-induced platelet aggregation	Platelet aggregometry Automated analyser turbidimetric assay with modifications applied.
VWF:GPIbR	Aggregation of particles coated with recombinant GPIb in presence of ristocetin.	Immunoturbidimetric or Chemoluminescent
VWF:GPIbM	Aggregation of particles coated with a gain of function recombinant GPIb (ristocetin not required)	Immunoturbidimetric
VWF:Ab	Binding of antibody to VWF A1 domain	Immunoturbidimetric
VWF:CB	VWF binding to collagen	ELISA. Plate usually coated with mixture of type I/type III collagen.
VWF:FVIIIB	Factor VIII binding to VWF	ELISA. Plate coated with VWF and bound FVIII detected by antibody or chromogenic assay

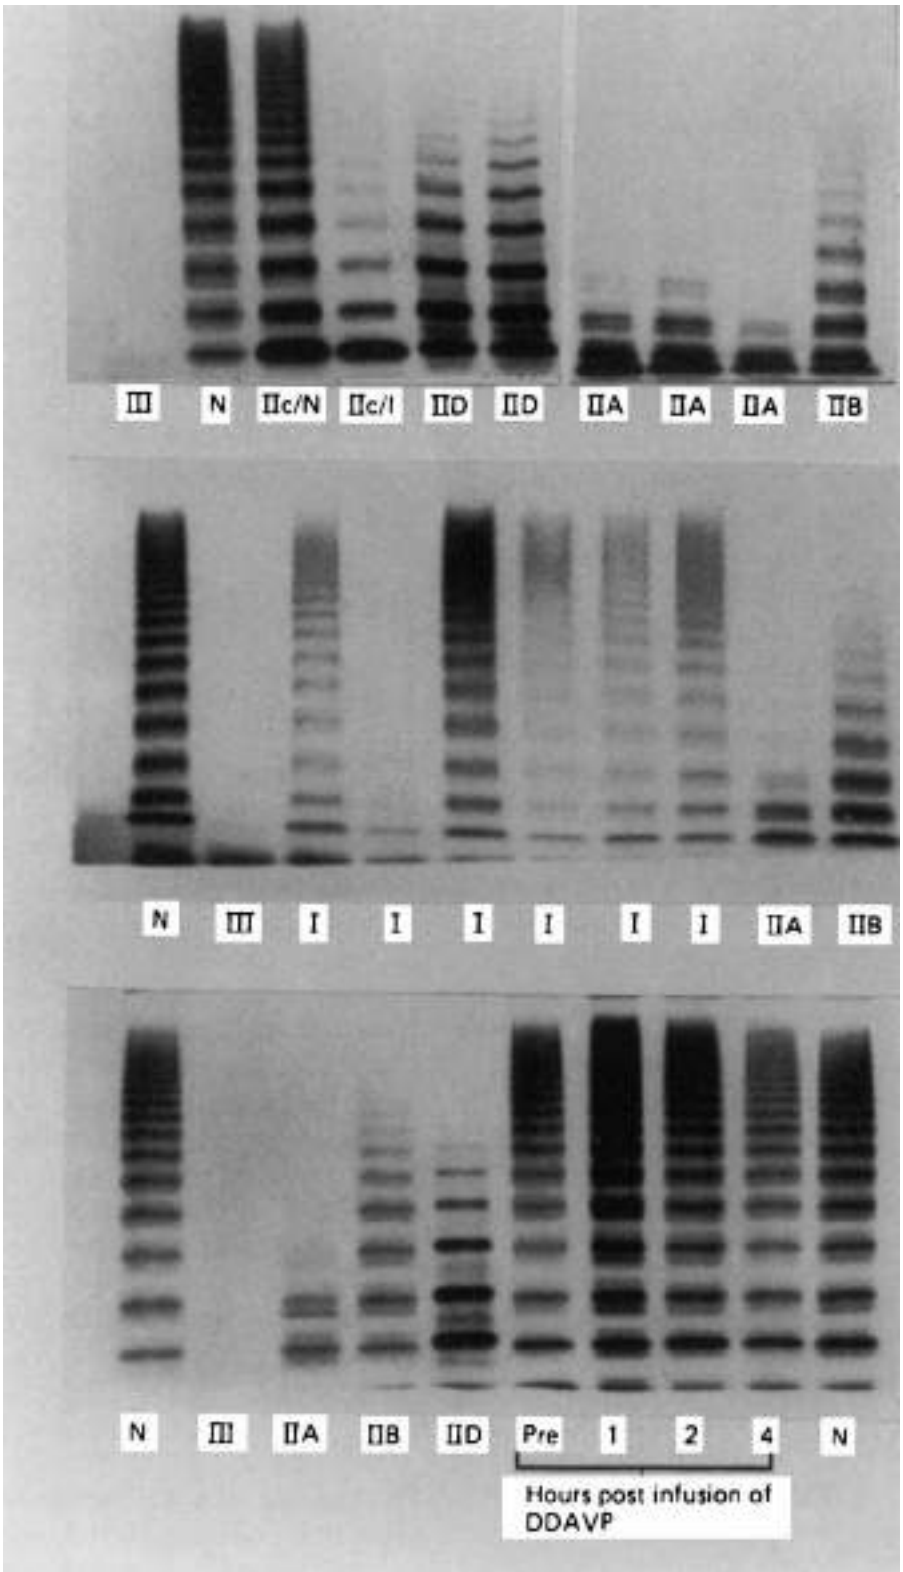

Figure 41.7 Multimer analysis of VWF from patients with VWD and normal control subjects. Note that many cases classified at present as type 2A were previously subdivided according to the details of the abnormality of triplet pattern.

Table 41.5 Classification of von Willebrand disease.

Type	Description	Comments	Inheritance
1	Partial quantitative deficiency of VWF	Requires a function:antigen ratio >0.6 or >0.7 according to various guidelines.	Mostly autosomal dominant inheritance when VWF <0.3 IU/mL. Levels >0.3 IU/ml may not segregate with *VWF* and associated variants show variable penetrance
1C	Quantitative deficiency (type 1) arising from accelerated clearance	Defined by >30% fall from peak at 4 hours post desmopressin or propeptide:antigen ratio >3	Archetype is VWF Vicenza due to the variant R1205H: inherited as autosomal dominant.
2	Qualitative VWF defects		
2A	Decreased VWF-dependent platelet adhesion with selective deficiency of high-molecular-weight multimers	Some controversy exists regarding classification of VWF mutations associated with subtle reductions in HMW multimers	Mostly autosomal dominant
2B	Increased affinity for platelet GPIb	Should be distinguished from platelet type pseudo-VWD (PT-VWD), using either platelet agglutination tests or genetic testing. Cases with normal VWF multimer and platelet count have been described	Autosomal dominant
2M	Decreased VWF-dependent platelet adhesion without selective deficiency of HMW multimers	This also includes defects of VWF collagen binding. May be combined quantitative/qualitative defect	Autosomal dominant
2N	Markedly decreased binding affinity for FVIII	Should be distinguished from mild haemophilia A	Reduced VWF:FVIII binding defects are frequently identified in a compound heterozygote state with a VWF null allele rather than the classical homozygous form
3	Virtually complete deficiency of VWF	Equivalent to <0.03 iu/mL in most antigen assays	Autosomal recessive, frequent null VWF alleles. Bleeding symptoms in 26–48% of obligate carriers

(*Source:* Modified from Laffan *et al.* (2014),)

(Table 41.5). The classification of VWD has been examined many times and extensive guidelines are available, detailed in the bibliography. What follows is necessarily a limited summary of much work.

Type 1 VWD is defined as a simple quantitative deficiency of VWF and the VWF present should be functionally normal with a normal multimeric pattern. In practice it is acceptable that the ratio of function to antigen (VWF:RCo/VWF:Ag) should be >0.7 and there should be no significant loss of high-molecular-weight multimers, even though on close inspection some subtle abnormalities of multimer pattern may be discerned. Some patients have a parallel reduction in antigen and function due to accelerated clearance of VWF from the circulation. This is now designated as type 1C and the archetypal variant is VWF Vicenza due to a R1205H change in VWF. Accelerated clearance of VWF can be detected by measuring an elevated ratio of VWF propeptide to VWF:Ag but is defined as a >30% fall from the post-desmopressin peak in 4 hours.

The characteristic of the 2A, 2B and 2M variants is a functional deficiency of VWF activity, which is reduced to below 0.7 of the antigenic measure. In type 2A, this results from a lack of high- and intermediate-size VWF multimers, whereas in type 2M a similar loss of platelet-binding activity is seen despite the presence of normal VWF multimeric composition and is caused by mutations in the *VWF* GPIb-binding site in A1. Loss of high-molecular-weight multimers in type 2A may arise from failure of intracellular assembly and processing or from accelerated proteolysis in the circulation due to mutations close to the ADAMTS-13 cleavage site. If multimer analysis is not available then a loss of high molecular weight multimers can be inferred from a reduction in both VWF:RCo and VWF:CB. VWD due to an isolated collagen-binding defect without loss of

high-molecular-weight multimers is rare, although a number of cases have been reported. The associated bleeding disorder is mild, perhaps because VWF contains two collagen-binding sites and the variants remain classified as 2M.

In type 2B, VWF binds prematurely to platelets in the circulation. *In vivo*, this results in the loss of high-molecular-weight multimers and platelets from the circulation due to formation of platelet aggregates and to increased cleavage of platelet-bound VWF by ADAMTS-13. The abnormality is detected in the laboratory by agglutination of platelets at a low concentration of ristocetin (0.5–0.7 mg/mL) that has no effect with normal VWF: the patient is then said to have positive ristocetin-induced platelet agglutination or RIPA. If normal washed platelets are resuspended in the patient's plasma, the phenomenon is reproduced, demonstrating that the abnormality is in the plasma. Thus RIPA should be performed as part of the diagnostic work-up for low VWF, as it is important to detect this variant (see below), which does not always show up in the other tests. Indeed a recent analysis showed that many patients with type 2B VWD have normal platelet counts and VWF multimer patterns. Most recent guidelines suggest that genetic analysis for variants in the A1 domain may be a preferred alternative to RIPA.

Type 2N VWD is characterised by VWF which has reduced affinity for FVIII (VWF:FVIIIB) but is normal in other respects. Preliminary investigations reveal only a reduced FVIII level (5–35%), which is easily mistaken for mild haemophilia. Inheritance is autosomal recessive which may provide a clue to diagnosis, but confirmation requires an assay of VWF FVIII-binding capacity or genetic analysis of FVIII and the VWF FVIII-binding site in the D′ domain.

Overall, the majority of patients are found to be type 1, which accounts for 75% of kindreds. Types 2A and 2B are fairly common, together accounting for about 15% of kindreds. Type 3 is the least frequent and has a prevalence of 1–2 in 10^6. Although classification has proved useful in understanding VWD and can help in planning treatment, some forms remain difficult to classify and may show features of more than one type.

Problems in diagnosis of type 1 VWD

The diagnosis of type 1 VWD implies that the patient has a significantly low level of VWF, which is responsible for an increased tendency to bleed. It is often not easy to be certain of this conclusion for the following reasons.

1. Slightly low levels of VWF are common in the population. Although the lower end of the normal range for VWF in the general population is approximately 50 iu/dL, most of the 2.5% of the population who have levels below this have normal haemostasis. In particular, individuals with blood group O have VWF levels on average 30% lower than those with non-O blood groups and the lower end of a 'blood group O normal range' is approximately 35 iu/dL. Thus the lower limit of the normal range is not the minimum level required for normal haemostasis. Nonetheless, individuals with blood group O are overrepresented in the group with type 1 VWD and there is a continuous relationship between bleeding tendency and VWF level that extends into the normal range without a clear cut-off between normal and abnormal. A firm diagnosis of VWD can be made when VWF function is <30 iu/dL but those with levels 30–50 iu/dL can be regarded as having 'low VWF'. This indicates that their VWF level is a risk factor for bleeding but will not always lead to a positive bleeding phenotype, most likely only when collagen and platelet function are insufficient to compensate.

2. A history of minor bleeding episodes (e.g. easy bruising and epistaxes) is very common in the population and is not a good predictor of more serious bleeding in other circumstances such as operations. On the other hand, a negative bleeding history may be because the patient has not yet have been exposed to a significant test of haemostasis.

3. As a result of the two points above, a history of, say, easy bruising and slightly low VWF levels will often be found together. However, this does not necessarily mean that the patient has VWD and caution should be exercised in drawing this conclusion as it has many consequences for the patient. Nonetheless, recent international guidelines have suggested that all patients in this group may benefit from being diagnosed as VWD largely on the basis that this will improve their access to treatment.

4. Intercurrent events such as stress, exercise, illness and pregnancy may all elevate the VWF level, making it difficult to be certain that a representative measure of VWF levels has been obtained from a single sample. It is, therefore, necessary to perform carefully standardised sets of assays and obtain concordant results on at least two occasions to be sure of the diagnosis and its severity.

5. The family history is often unhelpful, particularly in mild cases where penetrance is weak or variable. This is partly due to the modifying effects alluded to in (1) above and it is now evident that in some families, VWD does not segregate with the *VWF* gene. A large number of genetic variants in a wide variety of genes including *ABO* have been found to modulate VWF levels.

Treatment

Patients with mild or moderate VWD usually only need occasional treatment. Where possible, local control of bleeding should be used – such as the Mirena coil or combined oral contraceptive pill for HMB, referral to ENT for recurrent nose bleeds. The simplest general treatment is inhibition of fibrinolysis using tranexamic acid. Minor bleeding can sometimes be managed in this way and the addition of tranexamic acid mouthwash is often useful for oral cavity bleeding. Tranexamic acid is also frequently used in conjunction with desmopressin

which is the first choice specific treatment for minor bleeding after local measures have failed in type 1 VWD. Desmopressin will produce a brisk rise in VWF and FVIII levels (30 min after intravenous infusion) and a shortening of the bleeding time (for details of desmopressin therapy, see section on management of mild haemophilia A earlier in the chapter). Desmopressin is much less effective in types 2A and 2M, presumably because the patient's released VWF is abnormal and still unable to promote platelet adhesion. Almost all patients with a bleeding history and 'low VWF' will respond well to desmopressin providing there is not another contraindication. Desmopressin is generally regarded as contraindicated in type 2B VWD, as the released abnormal VWF will cause circulatory platelet aggregates to form, with a further fall in the platelet count. Before relying on desmopressin for therapy, patients should be given a test dose in order to determine the response at 30–60 min because this varies considerably. In addition, the duration of the response is also variable and further samples at 4–6 hours should be taken because some forms of type 1 VWD are characterised by a much-shortened survival of VWF (type 1C). A therapeutic trial may also be worthwhile in type 2A as some individuals do respond sufficiently for it to be useful. In type 2N, the FVIII response is of normal magnitude but is of limited efficacy due to its short duration, emphasising the importance of making the correct diagnosis, although this may still be useful for minor procedures.

In patients in whom desmopressin is ineffective or contraindicated, it is necessary to use a VWF-containing concentrate. Factor concentrates will always be required for treatment of type 3 VWD, most type 2 and those type 1 variants with inadequate desmopressin responses. Until recently all such concentrates were plasma-derived. Apart from the safety of the plasma source, the key feature of an effective concentrate is a full complement of high-molecular-weight multimers with a VWF:RCo/VWF:Ag ratio close to 1. Cryoprecipitate fulfils this requirement but cannot be subjected to viral inactivation procedures and is therefore not recommended as first-line therapy.

Most plasma-derived concentrates contain both FVIII and VWF in varying proportions. Because endogenous FVIII synthesis is normal, repeated treatment with these concentrates can result in high levels of FVIII which has been associated with thrombosis. Caution and monitoring are therefore required.

Recombinant VWF concentrate differs in some important respects. Firstly, it has not been exposed to plasma ADAMTS13 and contains ultra-large VWF multimers with correspondingly high specific activity. Secondly, it has a slightly different glycosylation profile and a longer half-life of survival in plasma. Thirdly, it does not contain any FVIII. When using either rVWF or high-purity plasma concentrates containing only VWF it is important to remember that following infusion there is a delay of approximately 6–12 hours before the level of FVIII rises substantially and, if rapid correction is required, FVIII concentrate should also be given.

Although many concentrates will not correct the bleeding time, this is not necessarily a bar to effective haemostasis. This seemingly paradoxical result may be because intra-platelet or extravascular VWF may be present. In situations when concentrates fail to stop bleeding, cryoprecipitate and platelet concentrates may prove effective.

Clinical course and complications

Patients with types 1 and 2 VWD lead relatively normal lives, with normal life expectancy. Menstruation is seldom a cause of severe blood loss, although HMB is common. This can usually be managed satisfactorily with hormonal therapy. If these are not effective, then additional tranexamic acid and even self-administration at home of desmopressin by intranasal or subcutaneous routes can be useful. Finally, intermittent prophylaxis with VWF concentrate can be employed. During pregnancy, the VWF levels rise spontaneously to the normal or low-normal range in most patients with type 1 VWD. In type 2 VWD, the response is unpredictable and should be closely monitored. Type 2B VWD is particularly complicated in pregnancy because the rise in endogenous VWF production exacerbates the thrombocytopenia. Patients with severe type 3 disease have a clinical course resembling severe or moderately severe haemophilia A, including the development of joint damage and should be considered for prophylaxis. Some patients with other forms of VWF will have recurrent bleeding and should also be considered for prophylaxis. A small number of patients with type 3 disease develop antibodies to VWF, which inhibit its platelet adhesion-promoting property and cause rapid removal from the circulation of infused material. Unlike anti-FVIII antibodies, some anti-VWF antibodies may mediate anaphylactic shock.

Molecular genetics

The cloning of VWF cDNA and its gene has led to progress in identifying the underlying mutations responsible for the various phenotypes. A database of mutations responsible for VWD has been established and curated at https://databases.lovd.nl/shared/genes/VWF

Type 1

There have been extensive studies to determine the molecular basis of type 1 VWD and a number of important points have emerged. Firstly, in about 35% of cases reported to have VWD, the disorder does not segregate with the VWF locus and is therefore presumably results from a combination of other modifying genes, in particular the ABO locus. However, this figure depends on the definition of type 1 VWD and the phenomenon is most common in individuals with VWF levels above 30 units/dL and includes a disproportionate number of blood group O individuals. The likelihood of the disorder segregating with the VWF gene and of a causative mutation being identified increases significantly as the VWF level falls and a mutation is found in all

cases where the VWF multimer pattern is abnormal. Amongst those with type 1 VWD and an identified mutation, mutations are widely scattered throughout the molecule.

Type 2

Mutations responsible for type 2 VWD affect a relevant functional site in the molecule and the corresponding portion of the gene. Mutations causing types 2M and 2B both affect the binding site for platelet GPIb on VWF and are found within the A1 domain of the molecule. They are inherited dominantly. As discussed above, type 2A may arise from increased susceptibility to proteolysis by ADAMTS-13 caused by mutations in the A2 domain. Otherwise, type 2A mutations are scattered throughout the gene but particularly in the propeptide, D′–D3 and the cysteine knot. In general, type 2A is dominant but occasional recessive forms occur. Mutations causing type 2N are found in the FVIII-binding site in the D′ domain but because the binding capacity of VWF greatly exceeds the FVIII concentration the inheritance is recessive.

Type 3

Type 3 is characterised by the complete absence of VWF and so arises from inactivating or null mutations in both VWF alleles and is inherited in an autosomal recessive manner. The rare patients who develop antibodies to VWF nearly all have large deletions of their VWF gene.

Pseudo von Willebrand disease (platelet-type)

Several families have been described with a disorder closely resembling type 2B VWD, but in whom mixing experiments show the defect to be in their platelets rather than their plasma. Patients with pseudo-VWD or platelet-type VWD (PT-VWD) have moderately reduced levels of VWF:Ag and platelets, with an enhanced response of their platelet-rich plasma to low levels of ristocetin (0.5 mg/mL). The addition of normal cryoprecipitate to their washed platelets causes spontaneous aggregation, whereas the reverse experiment is without effect (compare with type 2B). Missense mutations in platelet membrane GPIb, such that it spontaneously binds higher multimers of VWF, have been shown to be the underlying cause of this autosomal dominant mild bleeding syndrome. Treatment has not been extensively evaluated, but it should probably be with normal platelet concentrates, rather than desmopressin or cryoprecipitate. Thus this syndrome should be excluded by mixing tests as above or by genetic analysis before diagnosing type 2B VWD.

Acquired von Willebrand syndrome

In a number of circumstances, patients may acquire a deficiency of VWF function that is not inherited. The commonest association is with a paraprotein that binds to VWF and accelerates clearance, producing a type 2A or type 3 pattern. Severe aortic stenosis or extracorporeal circuits can cause sufficient shear stress on VWF to accelerate ADAMTS13 cleavage and cause an acquired von Willebrand syndrome that resolves immediately after valve replacement or release from the pump. A similar phenomenon occurs in myeloproliferative disease when thrombocytosis is present and excess binding of VWF to platelets promotes its cleavage by ADAMTS13. VWF synthesis is reduced in hypothyroidism (Table 41.6). Treatment of the underlying disorder will improve the syndrome. If urgent treatment is required, then replacement therapy may be necessary (taking into account accelerated clearance) and IgG paraproteins will usually respond to intravenous immunoglobulin.

Table 41.6 Disorders associated with acquired von Willebrand syndrome and mechanism responsible.

Disorder	Mechanism	Treatment
Hypothyroidism	Reduced synthesis	Correct thyroid status
Aortic stenosis	Shear stress and increased ADAMTS-13 cleavage	Replace aortic valve
Myeloproliferative	Adherence to platelets and increased ADAMTS-13 cleavage	Restore platelet count to normal
IgG paraprotein	Immune	IVIG, chemotherapy to reduce paraprotein
IgM paraprotein	Immune	Chemotherapy (IVIG ineffective)
Wilms tumour	Adsorption	Tumour removal if possible

IVIG, intravenous immunoglobulin.

CHAPTER 42

Rare inherited coagulation disorders

42

Flora Peyvandi and Marzia Menegatti

Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Università degli Studi di Milano, Milan, Italy

Introduction

The rare coagulation disorders (RCDs), including the inherited deficiencies of coagulation factors fibrinogen, prothrombin, factor (F)V, combined FV and FVIII, FVII, FX, FXI, FXIII and of multiple deficiency of vitamin-K-dependent factors, are usually transmitted in an autosomal recessive manner. The incidence of RCDs in the general population is therefore low, and homozygous or double heterozygous deficiencies vary from 1 in 500,000 for FVII deficiency to 1 in 2 million for prothrombin (FII) and FXIII deficiencies (Table 42.1). This incidence is also strongly influenced by ethnicity and is significantly increased by a high rate of consanguinity in the population.

The most recent evaluation of the distribution of the RCDs is available on the World Federation of Haemophilia website (WFH, http://www.wfh.org/) whose survey is aimed at collecting epidemiological data and at providing information to haemophilia organisations and treatment centres involved in reducing or preventing complications of bleeding. This survey, including the participation of about 125 countries worldwide, tripled the number of identified patients. Amongst these FVII and FXI deficiencies appear to be the most prevalent RCDs, representing 40 and 24% of the total number of affected patients, respectively, followed by fibrinogen (11%), FV and FX (8% and 6%), FXIII (7%) and combined FV and FVIII (2%) deficiencies, while the rarest disorder was FII deficiency with a prevalence of 2% (Figure 42.1).

Clinical symptoms

Clinical symptoms amongst patients with RCDs differ significantly from one disorder to another, and from one patient to another, affected with the same disorder. Significant bleeding manifestations usually show in homozygous or compound heterozygous patients, while heterozygous patients, with approximately half-normal levels of coagulation factors are usually asymptomatic. The most commonly reported symptoms are mucosal tract bleeding and excessive bleeding at the time of invasive procedures, delivery in women and circumcision in boys (where it is customary). Bleeds that endanger life, such as in the central nervous system (CNS), and gastrointestinal (GI) bleeding appear to be less frequent than in haemophilia. These symptoms are more frequent in FX deficiency. Particular care should be paid to women affected by RCDs as they may experience excessive monthly bleeding associated with menstruation. Indeed, heavy menstrual bleeding (HMB) is not the only gynaecological problem that women with RCDs are more likely to experience, they are also at risk of increased bleeding from conditions such as haemorrhagic ovarian cysts, endometriosis, endometrial hyperplasia, polyps and fibroids. Pregnancy and childbirth, two important stages in the life of a woman, pose particular clinical challenges in women with RCDs, since information about these issues is very scarce and limited to just a few case reports.

Table 42.1 General features of autosomal recessive deficiency of coagulation factors. Prevalence refers to the severe form of deficiencies due to homozygous or compound heterozygous mutations.

Deficiency	Estimated prevalence*	Gene (chromosome)
Fibrinogen	1 in 1 million	*FGA*, *FGB, FGG* (all on 4q28)
Prothrombin (Factor II)	1 in 2 million	*F2* (11p11–q12)
Factor V	1 in 1 million	*F5* (1q24.2)
Combined factor V and VIII	1 in 1 million	*LMAN1* (18q21.3–q22) *MCFD2* (2p21–p16.3)
Factor VII	1 in 500,000	*F7* (13q34)
Factor X	1 in 1 million	*F10* (13q34)
Factor XI	1 in 1 million	*F11* (4q35.2)
Factor XIII	1 in 2 million	*F13A1* (6p24–p25) *F13B* (1q31–q32.1)
Vitamin-K-dependent coagulation factors	Reported in <50 families	*GGCX* (2p12) *VKORC1* (16p11.2)

* Including dysfunctional proteins.

Classification

The rarity of the RCDs limits our knowledge of their natural history. It is now well known that every RCD can have several bleeding symptoms, ranging from minor post-trauma bleeding to the most severe episodes, which may appear at birth or later in life. In some deficiencies, the residual coagulant activity level is directly proportional to the risk of developing a haemorrhage, but this is not true for all types of deficiencies. This information has been finally made available, in recent years, thanks to publication in the scientific literature of registries and databases collecting data on different aspects of specific deficiencies. Amongst these, the European Network on Rare Bleeding Disorders (EN-RBD), based on a cross-sectional study using data from 489 patients involving 13 European treatment centres, for the first time evaluated the correlation between the coagulant plasma activity level and clinical bleeding severity in each RCD. Clinical bleeding episodes were classified into four categories of severity, based on the location and the potential clinical impact, as well as the trigger for bleeding (spontaneous, after trauma or drug-induced). By means of linear regression analysis, this study found a strong association between coagulant activity level and clinical bleeding severity for fibrinogen, combined FV + VIII, FX and FXIII deficiencies. A weak association was found in FV and FVII deficiencies, while coagulation-factor activity level of FXI could not predict clinical bleeding severity. From the same study, it was also clear that the minimum level to ensure complete absence of clinical symptoms is different for each disorder. This leads to the conclusion that RCDs should not be considered as a single class of disorders, but instead, studies should focus on the evaluation of specific aspects of each individual RCD (see Table 42.2).

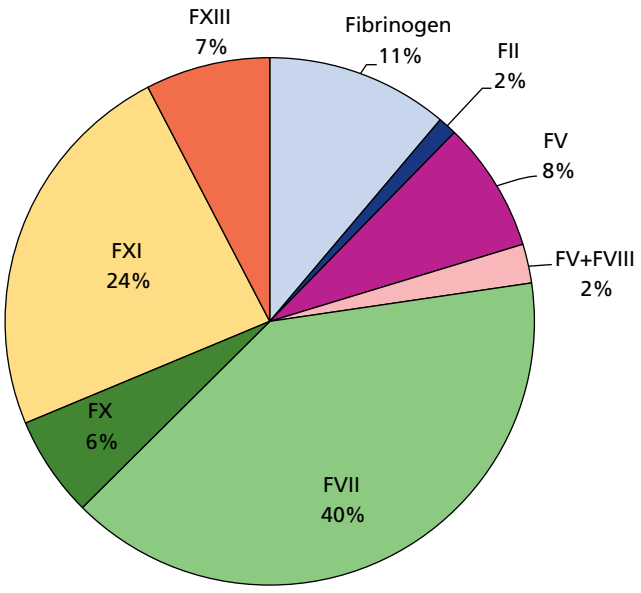

Figure 42.1 Worldwide distribution of rare coagulation disorders derived from World Federation of Haemophilia (WFH).

Laboratory diagnosis

The laboratory diagnosis of RCDs is currently carried out by means of coagulation screening tests, such as the activated partial thromboplastin time (aPTT) and the prothrombin time (PT), applied to subjects reporting a clinical and family history of bleeding. A prolonged aPTT with a normal PT is suggestive of FXI deficiency (after exclusion of FVIII, FIX and FXII deficiencies). The reverse pattern (normal aPTT and prolonged PT) is typical of FVII deficiency, whereas the prolongation of both tests directs further analysis towards possible deficiencies of FX, FV or prothrombin or to combined deficiencies. All coagulation tests that depend on the formation of fibrin as the endpoint will be affected by fibrinogen deficiency; hence, beside PT and aPTT, thrombin time (TT) should be performed. Abnormal results of screening tests should be followed by appropriate specific assays combined with mixing studies (50:50) to exclude the presence of a natural inhibitor of any deficient factor. Factor antigen assays are not strictly necessary for diagnosis and treatment but are can be used to distinguish type I from type II deficiencies; these measurements are very important in fibrinogen or FII deficiency, where normal antigen levels and reduced coagulant activity (dysfibrinogenaemia

Table 42.2 General recommendations for treatment and long-term prophylaxis in patients with inherited bleeding disorders.

	On-demand			Reported dose schedule for successful long-term prophylaxis			
Deficient factor (plasma half-life)	**Recommended trough levels**	**Product and dosages**	**Recommended trough levels (to maintain patient asymptomatic) after publication of the EN-RBD results**	**Products**	**Dose**	**Frequency**	**Notes**
Fibrinogen 2–4 d	0.5–1 g/L	Fibrinogen concentrate (50–100 mg/kg)	1 g/L	Fibrinogen concentrate	30–100 mg/kg	1/week	Afibrinogenaemic patients with recurrent life-threatening bleedings or undergoing surgeries. In afibrinogemic women, high level of fibrinogen is recommended to prevent early fetal loss (>1.0 g/L throughout pregnancy) and placental abruption during labour and to prevent PPH (ideally >2.0 g/L)
Prothrombin 3–4 d	20–30%	SD-treated plasma (15–20 mL/kg) PCC (20–30 units/kg)	>10%	PCC	25–40 units/kg	1/week	—

and dysprothrombinaemia) can be associated with a risk of thrombosis. The standard laboratory clotting tests (PT, aPTT, fibrinogen level, platelet counts) are normal in FXIII deficiency. Its diagnosis can be detected by the demonstration of increased clot solubility in 5 M urea, dilute monochloroacetic acid or acetic acid. However, this method, qualitative and poorly standardised, detects only severe FXIII deficiency (with activity <5%), thus leading to a possible underdiagnosis. FXIII activity should be determined quantitatively by specific assays measuring ammonia released during the transglutaminase reaction or the incorporation of radioactive amines into proteins. In this case, a plasma blanking procedure is mandatory to avoid FXIIIa-independent ammonia release that can lead to incorrect results in the low-activity range below 5–10%.

Molecular diagnosis

Molecular diagnosis is based on the search for causative mutations in the genes encoding the corresponding coagulation factors. Exceptions are combined deficiency of FV and FVIII, caused by mutations in genes encoding proteins involved in FV and FVIII intracellular transport (*MCFD2* and *LMAN1*), and combined deficiency of vitamin-K-dependent proteins (FII, FVII, FIX and FX), caused by mutations in genes that encode enzymes involved in post-translational modification and in vitamin K metabolism (*GGCX* and *VKOR*). Due to the high allelic heterogeneity in RCDs, the best option is still to screen the entire gene, at least the coding portion and splice-site regions. Information on already identified mutations causing RCDs is easily traceable from the mutation database on the ISTH website (http://www.isth.org/MutationsRare Bleedin and also https://www.lovd.nl/). Missense mutations are the most frequent gene abnormalities, representing 50–80% of all identified mutations, except for *LMAN1* variants, where the most frequent mutations are insertions/deletions (50%). Insertion/deletion mutations represent 20–30% of the gene variations of the fibrinogen, *FV MCFD2* and *FXIII* genes and less than 15% of the remaining coagulation-factor gene mutations. Splicing and nonsense mutations comprise 5–15% of all identified mutations in all coagulation factors. Variants located in the 3′ and 5′ untranslated regions of the genes are the least frequent types of mutation (less than 5%). Despite significant advances in our knowledge of the genetic basis of the RCDs, the 'traditional' and standardised methods such as the Sanger sequencing and the Multiplex Ligation-dependent Probe Amplification (MLPA) fail to detect a genetic defect in 5–10% of patients affected with severe clotting-factor deficiencies. In these patients, the use of next-generation sequencing (NGS) might help to identify non-coding variants, novel genes and novel pathways in coagulation disorders. NGS platforms sequence millions of small fragments of DNA which need bioinformatic analysis to map the individual reads to a human reference genome. Each of the three billion bases in the human genome is sequenced multiple times, providing high depth to deliver accurate data and an insight into unexpected DNA variation. The explosion in data requires careful examination to determine the relationship with phenotype without assuming that every variant is pathogenic. Early work conducted in mouse models showed that complete absence of almost all coagulation factors led to a severe clinical phenotype often incompatible with life.

Global haemostasis tests

Tests investigating global haemostatic capacity, such as the thrombin generation test (TG) and thromboelastography (TEG) are of interest because standard coagulation tests, such as PT or aPTT have only limited sensitivity to reduction in coagulation factor levels. Therefore, global haemostasis tests may provide a more accurate evaluation of an individual's overall *in vivo* haemostatic state and response to treatment. They have been used to evaluate haemostasis in patients with RCDs and haemophilia and are now becoming a new laboratory strategy to determine the effectiveness of therapies and to monitor treatment in various bleeding situations in RCDs, in particular in those deficiencies, such as FXI, where standard assays fail to determine the bleeding risk.

Treatment

Treatment of RCDs is a difficult task, since information on management is often scarce, and replacement therapy of coagulation factors may require the prescription of unlicensed products that are not readily available. The main treatments are represented by non-transfusion adjuvant therapies (antifibrinolytic amino acids, oestrogen/progestogen) and replacement therapy for the deficient coagulation factor. Unfortunately, information on the safety and efficacy of the few available products in RCDs is sparse, and experience in their optimal use is significantly more limited than that available for haemophilia. The avoidance of transmission of blood-borne infectious agents is the primary requisite in the choice of replacement material. Solvent/detergent-treated plasma is an important source of replacement that is an option for the majority of these disorders. However, plasma-derived virus-inactivated concentrates or recombinant products should be preferred, when commercially available. Plasma should not be used when there are available concentrates since if repeated infusions are needed, as may occur during surgery or CNS bleeding, it may cause fluid overload. An updated online registry of the available clotting factor concentrates is published by the WFH (https://elearning.wfh.org/resource/online-cfc-registry/). A patient's personal and family history of bleeding are important guides for management. The conventional treatment for RCDs is given on an 'on demand' basis and is administered as

soon as possible after onset of bleeding; however, in clinically severe cases, a prophylactic regimen should be considered, as in afibrinogenemia and severe case of FVII and FX deficiency. Dosages and frequency of treatment depend on the minimal haemostatic level of the deficient factor, its plasma half-life, and the type of bleeding episode. The choice of prophylaxis is determined by the frequency of bleeding, the risk of severe spontaneous bleeding, and the risk of long-term disabilities associated with the occurrence of bleeding, despite on-demand treatment. General recommendations for treatment on demand and prophylaxis are summarised in Table 42.2.

Fibrinogen deficiency

Fibrinogen deficiency is heterogeneous and two main phenotypes can be distinguished: plasma levels of the protein are either not measurable or very low, leading to afibrinogenaemia and hypofibrinogenaemia. In other cases, low clottable fibrinogen contrasts with normal or moderately reduced fibrinogen antigen leading to dysfibrinogenaemia and hypodysfibrinogenaemia. As mentioned above, the laboratory determination of TT is a useful screening test in addition to PT and aPTT. However, the molecular defect may also have an impact on the results of the coagulation factor assays. Fibrinogen disorders have a heterogeneous genetic background. Fibrinogen is produced in the hepatocyte from three homologous polypeptide chains, Aα, Bβ and γ, which assemble to form a 340-kDa hexamer. The three genes encoding fibrinogen Bβ (*FGB*), Aα (*FGA*) and γ (*FGG*), ordered from centromere to telomere, are clustered in a region of approximately 50 kb on chromosome 4 in humans. Patients with afibrinogenemia are homozygotes or compound heterozygotes, while individuals with hypofibrinogenemia are usually heterozygotes. Dysfibrinogenemia is usually associated with autosomal dominant inheritance with two hotspots described, mutations located at *FGA p.Arg35* and *FGG p.Arg301*. These mutations are usually clinically benign, however, there are several other mutations that are associated with bleeding or thrombosis and predictive for the clinical phenotype, making genetic diagnosis beneficial where performance of TT is not part of routine coagulation.

Dysfibrinogenaemic and hypofibrinogenaemic patients are usually asymptomatic, while those with afibrinogenaemia have a bleeding tendency that usually manifests in the neonatal period, with 85% of cases presenting umbilical cord bleeding. Bleeding may also occur in the skin, gastrointestinal tract (GI), genitourinary tract or the CNS, while persistent damage to the musculoskeletal system and resulting handicap is less frequent. A milder symptom such as epistaxis is also frequent. Women may suffer from menometrorrhagia, but some have normal menses. First-trimester abortion is common in women with afibrinogenaemia, but less common in those with dysfibrinogenaemia. The conventional treatment is episodic and on-demand, but effective long-term secondary prophylaxis with administration of fibrinogen every 7–14 days has been described after CNS bleeds. However, high-level replacement, e.g. during pregnancy and the puerperium, should be moderated by the fact that thromboembolic events can occur.

The treatment of choice should be fibrinogen concentrate in case of afibrinogenemia and prophylaxis needs to be considered in those with a history of bleeding and for prevention of recurrent abortions in women.

Prothrombin deficiency

FII, a vitamin-K-dependent glycoprotein synthesised by the liver, is the zymogen of the serine protease α-thrombin and is encoded by a gene of approximately 21 kb located on chromosome 11. Prothrombin deficiency is one of the rarest inherited coagulation disorders, with a prevalence of about 1 in 2 million. As with fibrinogen deficiency, two main phenotypes can be distinguished: hypoprothrombinaemia (both activity and antigen levels are low) and dysprothrombinaemia (normal synthesis of a dysfunctional protein); hypoprothrombinaemia associated with dysprothrombinaemia was also described in compound heterozygosis.

Severe deficiency of FII, a condition in which plasma levels are <5% (homozygous or double heterozygous patients), is always characterised by severe bleeding, including prolonged post-injury bleeding, mucosal bleeding and subcutaneous and muscle haematoma. Conversely, GI bleeding episodes were reported in only a few cases. Dysprothrombinaemia manifests as a variable bleeding tendency that is usually less severe than true deficiency, while heterozygous subjects are usually asymptomatic although, occasionally, excessive bleeding after surgical procedures can be observed. In homozygous women, menorrhagia is frequent.

Replacement therapy is needed only in severe patients, in case of bleeding or to ensure adequate prophylaxis before surgical procedures. Since no FII concentrate exists, prothrombin complex concentrate (PCC) can be used for treatment. However, most PCCs contain other vitamin-K-dependent coagulation factors, which could potentially induce thrombotic complications. The novel non replacement therapies down-regulating natural anticoagulants might be a good therapeutic choice in the future.

Factor V deficiency

FV has a double role in the coagulation process: it is a protein cofactor required by the prothrombinase complex for thrombin generation but also contributes to the anticoagulant pathways by helping downregulation of FVIII activity and

supporting the survival of TFPI in plasma. The majority of individuals with FV deficiency are characterised by concomitant deficiency of FV activity and antigen levels (type I deficiency), but approximately 25% have normal antigen levels, indicating the presence of a dysfunctional protein (type II deficiency). FV is mainly secreted by hepatocytes but there is some evidence that it can also be synthesised *in vivo* in the megakaryocyte/platelet lineage. FV protein is encoded by a large (80 kb) and complex (25 exons) gene located on chromosome 1. Severe deficiency typically presents early in life, nonetheless, it is clinically heterogeneous, and sometimes, despite severe deficiency, patients may not bleed as much as expected. This has been attributed in part to the concomitant reduction in TFPI which circulates bound to the short splice variant form of FV. Observations made in the past few years point to an important role for platelet FV that provides new insight into this discrepancy. Megakaryocytes can synthesise FV; however, the majority of platelet FV is endocytosed from the plasma pool by megakaryocytes. Following endocytosis, FV is modified intracellularly; these changes to platelet FV appear to provide the cofactor with unique physical and functional characteristics, which render it more procoagulant compared with its plasma counterpart. Platelet degranulation and release of platelet FV at the site of vascular injury is thought to be a critical contributor to the local FV concentration. Furthermore, there is some evidence that, because platelet FV is locally released in high concentrations, it is less susceptible to inhibition and may function normally in haemostasis.

Noteworthy, loss-of-function mutations leading to FV deficiency are usually associated with a haemorrhagic disorder.

Symptomatic patients usually present with umbilical stump bleeding, skin and mucosal tract haemorrhages; epistaxis and menorrhagia are relatively frequent, even in patients with measurable FV levels. Postoperative and oral cavity haemorrhages are common, but not fully predictable, as these symptoms also occur with plasma levels as high as 5–10%. Haemarthroses and haematomas occur in only 25% of patients, and life-threatening bleeding episodes (GI and CNS bleedings) are rare. In patients with mild to moderate deficiency, therapy with antifibrinolytic drugs is sufficient to control epistaxis, menorrhagia or other non-life-threatening mucosal bleedings. Menorrhagia can also be managed directly using oral contraceptives, progestin-containing intrauterine devices, endometrial ablation or hysterectomy. Replacement therapy with FV has still to be administered as FFP, preferably virus inactivated, because no FV concentrate is yet available. A FV concentrate has been recently developed for clinical use in deficient patients and it has been shown to correct laboratory parameters (PT, PTT and thrombin generation) in severe FV deficiency plasmas. Unfortunately, this FV did not become available for the therapeutic use in FV deficiency. It has also been suggested that in cases of severe bleeding not controlled with FFP replacement, or in case of inhibitor development, platelet transfusions may be considered. A case of severe FV deficiency associated with multiple episodes of intracranial bleeding at birth was reported, where the inhibitor development owing to FFP infusion was managed by additional administration of platelets or rituximab.

Combined deficiency of factor V and factor VIII

Combined FV and FVIII deficiency (F5F8D) is characterised by concomitantly low levels (usually 5–20%) of the two coagulation factors, both as coagulant activity and as antigen. It appears that the concomitant presence of two coagulation defects does not enhance the haemorrhagic tendency observed in each defect separately. In 1988, F5F8D was shown to be causally associated with mutations in the *LMAN1* gene, encoding lectin mannose-binding protein (previously named *ERGIC-53*), a 53-kDa type 1 transmembrane protein that acts as a chaperone in the intracellular transport of both factors. In 2003, another locus associated with the deficiency was identified in about 15% of affected families, without mutations in *LMAN1*. This was named the *MCFD2* gene, encoding multiple coagulation factor deficiency (MCFD)2 protein, which acts as a cofactor for *LMAN1*, specifically recruiting correctly folded FV and FVIII in the endoplasmic reticulum. Further studies have failed to identify additional components of the *LMAN1::MCFD2* receptor complex, supporting the idea that causes of F5F8D might be limited to *LMAN1* and *MCFD2*. The phenotypes associated with mutations in *MCFD2* and *LMAN1* are indistinguishable and manifested only by deficiencies of FV and FVIII, although a selective delay in secretion of the cargo protein procathepsin C has been observed in HeLa cells over-expressing a dominant-negative form of *LMAN1*.

Recent studies, using thrombin-generation assays, showed that low levels of FV are accompanied by low TFPI levels thus supporting sufficient thrombin generation for optimal procoagulant activity.

Symptoms are usually mild, with a predominance of easy bruising, epistaxis and bleeding after dental extractions. Menorrhagia and postpartum bleeding have also been reported in affected women. More severe symptoms, such as haemarthroses and umbilical cord bleeding, are observed very seldom and GI and CNS bleeding have been reported in only a few patients. Soft-tissue haematomas are unusual. Because of the mild clinical pattern, bleeding episodes are usually treated on demand and do not require regular prophylaxis. These cases can be treated with desmopressin, as the low FVIII is usually of more significance than the low FV. More severe cases may need to be treated with FVIII concentrate and/or FFP as sources of both FV and FVIII may be needed when their different plasma half-lives (FV 36 hours, FVIII 10–14 hours) have to be taken into account.

Factor VII deficiency

FVII deficiency is the most common autosomal recessive coagulation disorder (1 in 500,000). A typical feature of this disease is its clinical heterogeneity, which ranges in severity from lethal to mild, or even asymptomatic forms. FVII is synthesised in the liver and is encoded by the FVII gene (*F7*) located on chromosome 13, 2.8 kb upstream of the *FX* gene. Plasma levels of FVII coagulant activity (FVII:C) and FVII antigen (FVII:Ag) are influenced by a number of genetic and environmental factors (sex, age, cholesterol and triglyceride levels) and it is also well known that FVII levels are modulated by *F7* polymorphisms. The majority of patients have concomitantly low levels of FVII:C and FVII:Ag, but several cases are characterised by normal or low borderline levels of FVII:Ag, contrasting with lower levels of FVII:C.

The severity of symptoms of FVII deficiency is variable: some patients do not bleed even with a very low level of FVII:C, while others with similar levels of coagulant activity have frequent bleeding. Life- or limb-endangering bleeding manifestations are relatively rare, the most frequent symptoms being epistaxis and menorrhagia. However, CNS bleeding was also reported to have high incidence (16%) in a series of 75 patients, the study concluded that the greatest risk factor for development of bleeding was trauma related to the birth process. Thrombotic episodes have also been reported in 3–4% of patients with FVII deficiency, particularly in the presence of surgery and replacement treatment, but spontaneous thrombosis may also occur; therefore, it can be inferred that patients affected with FVII deficiency are not protected from thrombosis.

A number of therapeutic options can be offered to patients with FVII deficiency, including FFP and PCCs (however, concentrations of FVII in FFP and PCC are low and therefore these are not the best treatments), plasma-derived FVII concentrates and recombinant FVIIa, which has to be considered the optimal replacement therapy because it can be used at very low dose (10–20 μg/kg) and is free from infection risk. Prophylaxis has been a debated issue in FVII deficiency, particularly in those patients with a severe bleeding history. However, the short half-life of infused FVII makes it difficult to establish a standardised protocol for prophylaxis. To improve rFVIIa half-life, longer-acting rFVIIa molecules have been generated by fusion protein or conjugation technologies: a rFVIIa molecule fused to albumin (rVIIa-FP) showed prolongation of half-life but is not yet in clinical use.

The occurrence of frequent menorrhagic symptoms is almost invariably associated with chronic anaemia associated with iron deficiency in women with the severe form of FVII deficiency. Pregnancy itself does not require special precautions and uncomplicated delivery is possible without prophylaxis. However, all cases of postpartum bleeding reported so far occurred in women with low FVII coagulant activity (<15 units/dL) not receiving prophylaxis. Therefore, delivery should take place with the protection of short-term replacement.

Factor X deficiency

FX is a glycoprotein that plays a pivotal role in the coagulation cascade, being the first enzyme in the common pathway of thrombin formation. FX is mainly synthesised by the liver and is encoded by the *FX* gene (*F10*), comprising 22 kb and located on chromosome 13, a few kilobases downstream of *F7*. FX deficiency may occur with concordant reduction in coagulant activity and antigen, or low coagulant activity contrasting with normal or low borderline antigen values.

In FX deficiency, the bleeding tendency may appear at any age, although the more severely affected patients (FX coagulant activity <1%) present early in life with umbilical stump, CNS or GI bleeding. Patients with severe deficiencies also commonly experience haemarthroses and haematomas. The most common bleeding symptoms reported at all levels of severity are epistaxis and menorrhagia.

Data from the UK Haemophilia Centre Doctors' Organisation (UKHCDO) registry shows that the proportion of patients with this deficiency who require treatment is much higher than that of other rare coagulation deficiencies. Heterozygous patients have also been reported to have bleeding after delivery that required treatment. Freeze-dried human coagulation FIX and FX concentrate with specified amounts of FX (and FIX) has facilitated prophylaxis in patients with FX deficiency and was developed in response to concerns about variability in coagulation factors in PCCs. Clinical trials investigating the pharmacokinetics of a high-purity plasma-derived FX concentrate have been also completed (ClinicalTrials.gov identifiers: 00930176, 01721681, and 01086852). An analysis of the clinical trial results together with post-marketing data showed only nonserious adverse reactions, with no inhibitor development and no thromboembolic events, resulting in a good safety profile of pdFX.

Therapeutic options for the control of menorrhagia are both medical (e.g. antifibrinolytics, oral contraceptives, levonorgestrel intrauterine device and clotting factor replacement) and surgical (e.g. endometrial ablation and hysterectomy). Although FX plasma concentrations increase slightly in pregnancy, women with the severe form of the deficiency and a history of adverse pregnancy outcomes (such as abortion, placental abruption or premature birth), may benefit from continuous replacement therapy.

Factor XI deficiency

FXI deficiency is characterised by a decrease in the functional activity of this plasma protein, usually accompanied by correspondingly low FXI antigen levels. More rarely, normal or borderline levels of plasma FXI antigen are associated with a dysfunctional form of the protein. The estimated prevalence of the severe FXI deficiency in most populations is about 1 in

1 million, but is reported to be much higher in Ashkenazi Jews, heterozygosity being as high as 8%.

FXI is mainly synthesised in the liver, although tiny amounts of transcript can also be detected in megakaryocytes and platelets. The protein is encoded by the *FXI* gene, comprising 23 kb and located on chromosome 4. At variance with other RCDs, whose pattern of inheritance is autosomal recessive, in some cases of *FXI*, missense mutations were shown to exert a dominant negative effect through heterodimer formation between the mutant and wild-type polypeptides, resulting in a pattern of dominant transmission. The existence of a platelet FXI transcript, originating from the skipping of exon 5, was hypothesised for a long time, but never confirmed by subsequent work. Nonetheless, data support the view that FXI transcripts undergo alternative splicing, leading to the synthesis of FXI isoforms whose physiological role and importance still need to be demonstrated.

The relationship between FXI levels in plasma and the bleeding tendency is not as clear-cut as for other coagulation factor deficiencies as also shown by the EN-RBD results. Usually, patients with severe FXI deficiency (1% or less) are mildly affected and most bleeding manifestations are injury-related. The phenotype of bleeding is not correlated with the genotype, but when a site of injury with local high fibrinolytic activity is involved (e.g. urogenital tract, oral cavity after dental extraction or tonsillectomy), the risk of bleeding is increased (49–67%) in comparison to sites with less local fibrinolytic activity (1.5–40%). Surprisingly, patients with low, but detectable, levels of FXI (1–5%) are also mild bleeders, so that clinical phenotypes are not strikingly different in these two groups. The most frequent symptom is oral and postoperative bleeding, which occurs in more than 50% of patients. Women with FXI deficiency are prone to excessive bleeding during menstruation, but case series of women affected by severe FXI deficiency showed that 70% of pregnancies were uneventful, despite no prophylactic treatment.

Treatment is based on the use of antifibrinolytic agents, FFP and FXI concentrate. Recombinant FVIIa has been successfully used in surgeries, but care should be taken to reduce the risk of complications such as thrombotic events (especially with FXI concentrate), volume overload, allergic reactions and development of inhibitors. Future studies are needed to confirm the role of rFVIIa in surgery and FXI deficiency. Patients with a partial deficiency in FXI who have no bleeding history do not require prophylactic treatment.

Factor XIII deficiency

FXIII is a transglutaminase and functions to cross-link the α and γ fibrin chains. It also cross-links antiplasmin to fibrin overall resulting in a stronger clot with an increased resistance to fibrinolysis. The plasma factor consists of two catalytic A subunits (FXIII-A) and two carrier B subunits (FXIII-B). FXIII-A is synthesised in cells of bone marrow origin, while FXIII-B is produced in the liver. The corresponding genes are located on chromosomes 6 and 1. FXIII deficiency is, together with prothrombin deficiency, the rarest of the recessively transmitted coagulation factor deficiencies (1 in 2 million). In inherited FXIII deficiency, plasma levels of FXIII-A measured as functional activity or immunoreactive protein is usually extremely reduced, whereas the FXIII-B subunit is reduced, but always at measurable levels. Patients with FXIII-A deficiency have a bleeding tendency that is usually severe, particularly because of the early onset of life-threatening symptoms such as umbilical cord and CNS bleeding occurring in up to 80 and 30% of patients, respectively. Ecchymoses, haematomas and prolonged bleeding following trauma are also typical. Haemarthroses and intramuscular haematomas may appear unexpectedly, although less frequently. In women of reproductive age, miscarriage and intraperitoneal bleeding are often reported. All these symptoms usually lead to an early diagnosis, so that patients who survive are often treated prophylactically, starting early in life.

This approach to treatment is rendered simple and feasible by the fact that plasma levels of FXIII of 2–5% are sufficient to prevent severe bleeding and that the long *in vivo* half-life of the factor (11–14 days) makes it possible to infuse cryoprecipitate or concentrates at intervals of 1 month or longer. The recent prospective data collection project (PRO-RBDD; www.rbdd.org) showed that a level of 15% of FXIII clotting activity may represent a good therapeutic target to maintain patients without bleeding.

Plasma-derived FXIII has been used for several years and shown to be safe and effective; however, a recombinant FXIII-A_2 concentrate (rFXIII-A_2) has also become available Its approval was based on the evaluation in the mentor™ clinical trial programme (mentor™1, 2 and 5), in which 82 patients were monitored closely showing that monthly rFXIII-A2 prophylaxis has a good safety profile and provides a low bleeding rate in adults and children with FXIII-A deficiency. Results on the long-term safety and effectiveness of rFXIII-A2 prophylaxis in real-world use from a non-interventional post-authorisation safety study mentor™6 confirmed that it is well tolerated as long term care.

Only a few cases of inherited FXIII-B deficiency have been reported to date, and only 16 causative mutations have been identified; FXIII-B deficiency bleeding symptoms appear milder than in FXIII-A-deficient patients.

Vitamin-K-dependent coagulation factors deficiency

Vitamin-K-dependent coagulation factors such as FII, FVII, FIX and FX require γ-carboxylation of glutamic acid residues in their Gla domains to enable binding of calcium and attachment to phospholipid membranes. The γ-carboxylation is catalysed

by hepatic γ-glutamyl carboxylase (GGCX) and its cofactor, reduced vitamin K (KH_2). During the reaction, KH_2 is converted to vitamin K epoxide (KO), which is recycled to KH_2 by the vitamin K epoxide reductase (VKOR) enzyme complex. Heritable dysfunction of GGCX or the VKOR complex results in the secretion of poorly carboxylated vitamin-K-dependent coagulation factors, leading to combined deficiency of the vitamin-K-dependent clotting factors. The γ-carboxylation of glutamic acid residues is also required for activity of the anticoagulant factors protein C, protein S and protein Z, but although protein S and protein C levels are low in VKCFD, there are no reports of venous or arterial thrombosis. Thus, the effect of VKCFD is clearly towards bleeding. The GGCX and VKOR proteins are encoded by two corresponding genes: *GGCX* (13 kb, 15 exons) located on chromosome 2 and the unusually small *VKORC1* (5126 bp, 3 exons) located on chromosome 16; the latter gene was so named because of evidence suggesting that VKOR is a multisubunit complex.

VKCFD is a rare autosomal recessive bleeding disorder that often presents during infancy, although the routine administration of vitamin K may delay the diagnosis of VKCFD in neonates. Severe symptoms, such as intracranial haemorrhage or umbilical stump bleeding, are usually associated with factor levels below 5 units/dL. Severely affected children may also present with skeletal abnormalities such as nasal hypoplasia, distal digital hypoplasia, epiphyseal stippling and mild conductive hearing loss. Older patients can present with easy bruising and mucocutaneous or postsurgical bleeding.

Treatment with oral or parenteral vitamin K should be started as soon as possible in all patients at diagnosis. However, some patients show insufficient response, and there are limited data on the effectiveness of prophylaxis with weekly administration of vitamin K_1 10 mg. In fact, massive parenteral doses of vitamin K do not always correct FII, FVII, FIX and FX activities and there is clear biochemical evidence that the molecules are not fully carboxylated by such treatment. In this group of patients, factor replacement by virally inactivated FFP could also be used in cases of acute bleeding episodes or before surgery. PCC is the alternative choice when a rapid increase in clotting factor levels is necessary.

Concluding remarks

Rarity of RCDs limits the in-depth analysis of their clinical and laboratory features and limit their knowledge, in particular amongst general physicians, increasing the risk of misdiagnosis and fatal consequences. Therefore, the establishment of global networks of treatment centres is mandatory to improve the amount of collected data, to strengthen the power of the analysis deriving from such data, and to improve and standardise laboratory assay to define the minimum residual level of coagulation factor to ensure a normal haemostatic process. The resulting definition of the clinical endpoints will facilitate the design of appropriate clinical trials for the evaluation of the safety and efficacy of novel drugs. Multinational multicentre data collection for long-term post-registration surveillance remains an important milestone in the study of RCDs.

Introduction

Acquired disorders of haemostasis are a heterogeneous group of conditions with varied and often complex aetiologies. Patients may have multiple and overlapping causes for bleeding and distinct conditions often have similar pathophysiologies. To manage acquired haemostatic failure it is important to understand the mechanisms by which haemostatic disturbance occurs and how these apply in different ways to a variety of conditions.

Systemic disease may present to haematologists with symptoms of bleeding or bruising or abnormalities of coagulation tests. Alternatively, patients with known disorders may need haematological input to manage symptoms or at the time of invasive procedures. Assessment of patients with symptoms of bleeding or bruising requires clinical review and laboratory investigation. Serial laboratory testing is often required because the haemostatic disturbance may evolve rapidly. The possibility of a congenital disorder and potential role of anticoagulant or antiplatelet drugs should be considered.

Haematologists are also often involved in the management of acutely bleeding patients who may have complex medical conditions and in whom bleeding is usually multifactorial. Critical to optimising the management of these patients is a well-organised multidisciplinary team approach. Hospitals should have systems in place to respond rapidly to massive haemorrhage and hospital transfusion committees should establish protocols for these medical emergencies. Laboratories should be geared to producing accelerated full blood count (FBC) and coagulation results and point-of-care tests of haemostasis may be useful. The rapid supply of red blood cells and components and efficient transfer of these to the patient is vital to success. 'Fire drills' to test responses to emergencies are good practice.

Tests of coagulation and point-of-care testing

Routine tests of haemostasis

To investigate a patient suspected of an acquired haemostatic defect, a platelet count is required and examination of the blood film is often useful. Routine coagulation tests include the prothrombin time (PT), activated partial thromboplastin time (APTT) and Clauss fibrinogen level. Derived fibrinogen assays should not be used because results are likely to be misleading.

If screening tests are abnormal, correction studies help to distinguish factor deficiencies from inhibitors. Comparison of TT with the reptilase time or direct measurement of heparin anti-Xa levels will establish whether abnormal results are due to heparin. Measurement of fibrin breakdown products, such as D-dimers, is required for investigation of possible disseminated intravascular coagulation (DIC). Measurement of individual coagulation factor and von Willebrand factor (VWF) levels may be required. Assessment of platelet function may be useful in some circumstances, through platelet aggregation studies, platelet nucleotides or a bleeding time, although these results may be difficult to interpret in the context of an acquired haemostatic defect. The role of global platelet function analysers such as PFA-100 remain to be defined but are available in many hospitals.

Thromboelastometry

Tests based on thromboelastometry are point-of-care tests that assess the viscoelastic properties of whole blood under low-shear conditions and their use is becoming increasingly common. Their main advantages are the assessment of the different components of clot formation, including platelets and coagulation factors and rapid availability of results. They are used to guide blood product administration in patients undergoing liver transplantation, cardiopulmonary bypass and at the time of traumatic or obstetric haemorrhage. The main instruments are TEG, ROTEM and Sonoclot, and these measure the viscoelastic properties of an evolving clot using distinct technologies. Results are displayed graphically and show the developing and dissolving clot, although current assays are relatively insensitive to fibrinolysis and cannot be used to routinely guide tranexamic use. Heparinase cups can be used to investigate the underlying haemostasis of heparinised samples. Surrogate assays that reflect the contribution of fibrinogen to haemostasis are available. If thromboelastometry is used in these circumstances, hospitals should have agreed algorithms for interpretation and consequent infusion of blood products and undertake internal and external quality control.

Thrombin generation assays

These tests measure the amount of thrombin generated over time and may reflect an individual's coagulation potential. Assays are initiated by the addition of a trigger, usually tissue factor (TF), to recalcified plasma in the presence of phospholipids. Thrombin is detected through cleavage of a chromogenic or fluorogenic substrate. When low concentrations of TF are used, contact activation must be inhibited by corn trypsin inhibitor. Several variations of these assays have been developed by varying the concentrations of TF, corn trypsin inhibitor, phospholipid and protein-C-sensitising reagents such as soluble thrombomodulin. The clinical utility of thrombin generation assays remains to be demonstrated and they are not routinely available.

Activated clotting time

This test is used to monitor anticoagulation with heparin during cardiopulmonary bypass (CPB) surgery. It uses whole blood and has a linear response at the high concentrations of heparin used during CPB, extracorporeal membrane oxygenation and percutaneous coronary intervention. The APTT cannot be used because the assay is insensitive to the high heparin concentrations. Measured using a specialised analyser, the activated clotting time (ACT) target range varies according to the method and usually falls within 70–180 s. During heparinisation for CPB, the usual goal is to achieve 400–500 s. Off-pump cardiac surgery has been described using less anticoagulation and lower ACT target ranges of 200–300 s.

Disseminated intravascular coagulation

Background

DIC is characterised by the loss of localisation or compensated control of intravascular activation of coagulation. Arising from diverse causes (Table 43.1), its pathology can manifest systemically and contribute to a worse prognosis for the patient. Uncoupling of the highly regulated balance between procoagulant, anticoagulant, profibrinolytic and antifibrinolytic processes can result in simultaneous bleeding and microvascular thrombosis at different vascular sites (Figure 43.1). Removal of the inciting cause is the best means of restoring haemostatic control but may not be possible. Sepsis and trauma cause more than half the cases of DIC.

Table 43.1 Clinical conditions associated with disseminated intravascular coagulation.

Sepsis/severe infection
Potentially any microorganism, including Gram-positive and Gram-negative bacteria, viruses, fungi and rickettsial infections
Malaria and other protozoal infections
Trauma
Serious tissue injury
Head injury
Fat embolism
Burns
Malignancy
Solid tumours
Haematological malignancies (e.g. acute promyelocytic leukaemia)
Obstetric complications
Placental abruption
Amniotic fluid embolism
Pre-eclampsia
Intrauterine fetal demise
Vascular abnormalities
Giant haemangiomas (Kasabach–Merritt syndrome)
Large vessel aneurysms (e.g. aortic)
Severe toxic or immunological reactions
Snake bites
Recreational drugs
Severe transfusion reactions
Transplant rejection
Miscellaneous
Severe pancreatitis
Heat stroke
ABO mismatch transfusion

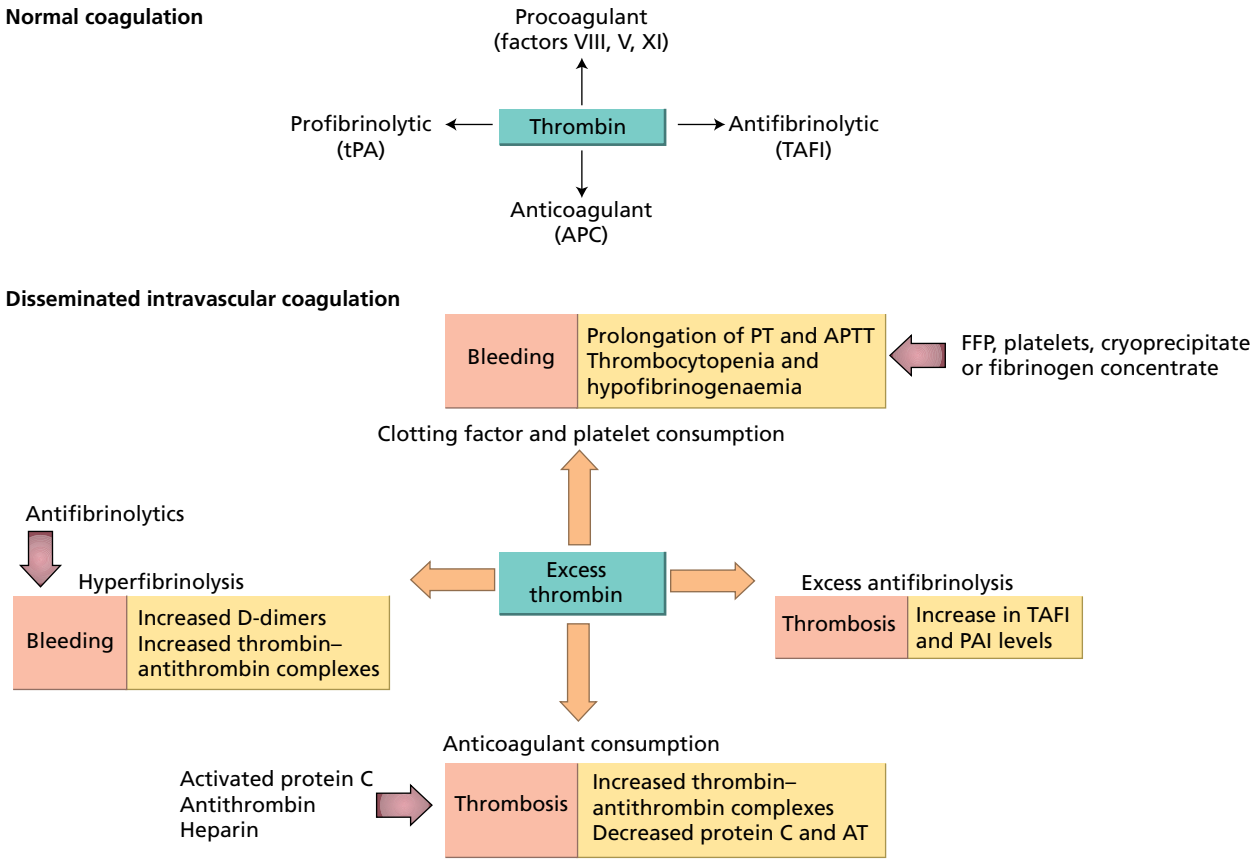

Figure 43.1 The changes in disseminated intravascular coagulation are compared with the normal coagulation. The excess thrombin generation in DIC leads to either bleeding or thrombosis (depicted in red boxes) based on the predominant coagulation change (shown in yellow boxes) that has occurred. The therapeutic intervention in each setting is given by the arrow towards each double box. AT, antithrombin; PAI, plasminogen activator; TAFI, thrombin activatable fibrinolysis inhibitor.

Pathophysiology

There are several important themes in the pathophysiology of DIC (Figure 43.1): first is the central role played by the generation of thrombin; second, mechanisms that perpetuate thrombin generation allowing it to become pathogenic in its dissemination; third, parallel and concomitant activation of inflammation and fourth, the importance of the endothelial microvasculature in this process.

Excess bleeding in DIC is partly attributable to the depletion of coagulation factors and platelets. However, other factors may contribute, including abnormal platelet function and hyperfibrinolysis. An additional factor possibly is the widening of the endothelial gap junctions caused by inflammation due to the underlying disease and lack of protection for the endothelial integrity provided by the platelets. Conversely, microvascular thrombosis can be precipitated by reduced levels of circulating anticoagulant proteins as well as loss of cell surface receptors, such as thrombomodulin, and glycans from endothelium.

Thrombin generation *in vivo*

The TF pathway plays a major role in initiating thrombin generation. In health, TF is extravascular mainly present on fibroblasts and smooth muscle cells surrounding blood vessels In contrast, in sepsis, infecting micro-organisms induce TF expression on monocytes and other inflammatory cells, while in trauma tissue factor and phospholipid can be released from injured tissues such as the brain. During obstetric complications, the placenta and amniotic fluid act as rich sources of TF, while malignant cells release TF-bearing extracellular vesicles in the cancer setting. Although the TF pathway is considered more important in thrombin generation in DIC, the contact pathway through factor (F) XII activation contributes to the pathological state by activation of the kallikrein–kinin system, causing vasodilatation, hypotension and activation of fibrinolysis. In situations of severe sepsis and septic shock, these intrinsic pathway components become much more relevant and can contribute significantly to the morbidity and mortality of the patients.

Mechanisms for disseminating and sustaining thrombin generation

When the inciting insult is persistent or severe, the amount of thrombin generated becomes continuous and excessive. This can lead to consumption and depletion of coagulation and anticoagulant factors. Increased exposure of negatively charged phospholipid surfaces facilitates the assembly and enhances the rate of coagulation reactions. Such surfaces, rich in phosphatidylserine and phosphatidylethanolamine, are provided by externalisation of the inner leaflet of cell membranes upon activation and apoptosis. Cell damage also leads to the generation of extracellular vesicles from platelets, monocytes and endothelial cells that express tissue factor and increase the circulating surface area for coagulation reactions. Phospholipid surfaces are also provided by very low-density lipoprotein, which can increase several-fold in severe sepsis to further enhance and sustain thrombin generation. Polyphosphate released from activated platelets and invading microorganisms in sepsis can accelerate coagulation via the contact pathway and also inhibit tissue factor pathway inhibitor and delay clot lysis by stimulating thrombin-activatable fibrinolysis inhibitor. Together, these mechanisms promote a spatially and temporally expanded response that is the hallmark of DIC.

Links between inflammation and coagulation

Once activated, the inflammatory and coagulation pathways interact to amplify the response. Cytokines and proinflammatory mediators such as tumour necrosis factor (TNF), interleukin (IL)-1 and high mobility group box protein (HMGB)-1 induce activators of coagulation. Thrombin and other serine proteases interact with protease-activated receptors (PARs) on cell surfaces to promote inflammation. When this process escapes, the well-developed local checks, it results in a dysregulated response that fuels a vicious cycle. An important role in interactions between coagulation and the complement system has also been increasingly identified in DIC.

Endothelial cell activation and dysfunction

Dysfunction and failure of the endothelium can lead to the development or propagation of DIC. The degree to which this occurs and the dominance of thrombotic or bleeding sequelae depend on the cause of DIC and host-related factors. Damage to and activation of the endothelium downregulates and depletes its anticoagulant receptors, such as thrombomodulin and endothelial protein C receptor, exposes subendothelial collagen that binds activated platelets, and releases plasminogen activator inhibitor (PAI)-1, which inhibits fibrinolysis, and ultra-large VWF multimers, which increase platelet aggregation. Endothelial dysfunction can lead to the depletion of nitric oxide and resultant uninhibited platelet activation.

Neutrophil extracellular traps and histones

Neutrophils release extracellular traps (NETs), web-like structures with cytosolic and granular proteins assembled on chromatin, which aid in the removal of pathogens. NETs can activate coagulation by assisting in the extracellular delivery of tissue factor, degrade tissue factor pathway inhibitor, stimulate platelets causing aggregation, and cause endothelial damage. Thus, a beneficial antimicrobicidal function can become deleterious, causing disseminated coagulation. Further, high levels of histones have been detected in the plasma of experimental animals, and human patients with sepsis and trauma. Extracellular histones released after cell damage can cause massive thromboembolism associated with consumptive coagulopathy and are major mediators of death in sepsis. It can also cause acute lung injury in trauma models and may be a useful therapeutic target.

Clinical features

The perturbed coagulation associated with DIC can manifest clinically at any point in a spectrum varying from bleeding to thrombosis. Although bleeding, ranging from oozing at venepuncture sites to major gastrointestinal or intracranial haemorrhage, is the archetypal and most obvious manifestation of DIC, organ failure due to microvascular thrombosis is more common and often unrecognised. For example, in meningococcal septicaemia and rarely pneumococcal infection, thrombosis of the adrenal vessels can lead to adrenal insufficiency and Waterhouse–Friderichsen syndrome.

Diagnosis

DIC is a clinicopathological syndrome and, as such, there is no single laboratory test that can confirm or refute the diagnosis. In clinical practice, the diagnosis is usually made by a combination of routinely available coagulation tests in a clinical situation where DIC is suspected. DIC must be differentiated from other acquired disorders of haemostasis (Table 43.2). The typical findings are a prolonged PT and APTT (although may not be seen in 50% of cases with evidence of DIC), elevated products of fibrin breakdown (e.g. D-dimer), thrombocytopenia and falling fibrinogen. However, results within the normal range do not exclude a significant consumptive coagulopathy, because the acute-phase response shortens the APTT and increases fibrinogen. A fall in platelet number within the normal range may be significant.

It is important to recognise that DIC is a dynamic process and thus interpreting a series of laboratory tests over time is more relevant than looking at a single set of results. The ISTH Sub-Committee of the Scientific and Standardisation Committee on DIC has recommended the use of a scoring system for overt DIC (Table 43.3). This has been prospectively validated, indicating a very high sensitivity and specificity. A strong correlation

Table 43.2 Differential diagnosis of disseminated intravascular coagulation (DIC).

Condition	Similarities	Differences
Liver disease	Bleeding common PT, APTT abnormal Platelet count low Fibrinogen low	D-dimer usually normal* FVIII levels not affected
Microangiopathic haemolytic anaemia (e.g. HELLP, TTP)	Red cell fragmentation on blood film Microthrombi common Platelet count low	Bleeding uncommon Coagulation tests normal† ADAMTS13 below 10% in TTP
Hyperfibrinolysis	PT, APTT abnormal Fibrinogen low D-Dimer increased	Platelet count normal
Catastrophic antiphospholipid antibody syndrome	PT, APTT abnormal Platelet count low	Fibrinogen not low D-dimer normal‡
Massive transfusion	PT, APTT abnormal Fibrinogen low Platelet count low	D-dimer normal

* Unless additional disorders which increase the D-dimer coexist.
† Unless coexisting DIC.
‡ Some antibodies can affect the D-dimer results. HELLP, haemolysis, elevated liver enzymes, low platelet count (syndrome); TTP, thrombotic thrombocytopenic purpura.

between an increasing DIC score and mortality has been demonstrated. The optical light transmittance profile of the APTT, referred to as the biphasic waveform, correlates well with the overt DIC score and occurs independently of prolongation in the clotting times in patients with DIC. However, this is only available on some analysers.

Table 43.3 ISTH Sub-Committee of the Scientific and Standardisation Committee on DIC recommended scoring system for overt disseminated intravascular coagulation (DIC).

1 Risk assessment: does the patient have an underlying disorder known to be associated with overt DIC?
If yes, proceed
If no, do not use this algorithm
2 Order global coagulation tests (platelet count, PT, fibrinogen, soluble fibrin monomers or FDPs)
3 Score global coagulation test results
Platelet count ($\times 10^9$/L): >100, score 0; <100, score 1; <50, score 2
Elevated fibrin-related marker (e.g. soluble fibrin monomers or FDPs): no increase, score 0; moderate increase, score 2; strong increase, score 3
Prolonged PT (s): <3, score 0; >3 but <6, score 1; >6, score 2
Fibrinogen (g/L): <1 g/L score 1, fibrinogen ≥1 g/L score 0
4 Calculate score
5 Score ≥5 compatible with overt DIC. Repeat scoring daily

FDPs, fibrin degradation products; PT, prothrombin time.

Treatment

The mainstay of treatment of DIC is to remove the underlying cause. However, DIC often continues after appropriate treatment for the underlying condition. Supportive therapy with blood products may be necessary. Although the efficacy of blood product replacement has not been proven in randomised controlled trials, it is a biologically rational option to replace both thrombin-promoting and thrombin-opposing proteins, particularly when there is significant depletion of these factors in a patient who is either bleeding or at risk of bleeding. In those patients not bleeding, transfusion of platelets or plasma should not be undertaken based on laboratory results alone. There are no clinical or experimental data to suggest that platelet or plasma transfusions worsen the thrombotic process.

In patients with DIC and bleeding or at high risk of bleeding (e.g. after invasive procedures) and a platelet count less than 75×10^9/L, transfusion of platelets should be considered, especially because platelet function may be impaired. In bleeding patients with DIC and prolonged clotting times, fresh-frozen plasma (FFP) should be administered. If fluid overload is an issue, prothrombin complex concentrates (PCCs) could be considered, but these will only correct vitamin-K-dependent components. Activated PCCs may precipitate or worsen DIC. Severe hypofibrinogenaemia (<1.5 g/L) requires the use of cryoprecipitate or fibrinogen concentrate to correct.

The role of heparin in DIC remains controversial and unproven. A prophylactic dose of low-molecular-weight heparin is given to all patients with no evidence of active bleeding.

Since reduction of natural anticoagulants is often observed, trials using these agents have been conducted. However, no benefit has been found with activated protein C and its use is not recommended for DIC. Similar results were found with antithrombin infusions. The phase 3 SCARLET (Sepsis Coagulopathy Asahi Recombinant LE Thrombomodulin) trial was designed to determine the impact of soluble human recombinant thrombomodulin on 28-day mortality in patients with sepsis-associated coagulopathy. No difference was found in mortality between thrombomodulin and placebo while major bleeding was slightly more frequent in the thrombomodulin group.

Coagulopathy associated with COVID-19

Coronavirus disease (COVID-19) is caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The majority of patients who develop COVID-19 experience mild respiratory symptoms, but a significant minority require hospitalisation. A common complication of COVID-19 is thrombosis, primarily in the lungs but also in the different circulatory beds including both arterial and venous distributions. The epicentre of this infection is the lungs where an activated immune system can trigger thrombosis similar to other immunological disorders (termed 'immunothrombosis' or 'thromboinflammation'). Immunothrombosis can either be due to high viral load and the resulting vigorous immune response or to an exaggerated immune response. Thrombi usually commence in the pulmonary microvasculature which, if uncontrolled, can lead to pulmonary thrombi and spread of thrombi into the systemic circulation. Another reason for the high incidence of thrombi in COVID-19 is possibly the direct viral invasion of the endothelium (viral endothelialitis) which causes large amounts of ultra-large von Willebrand factor multimers to be released, although this remains contentious.

One of the most consistent laboratory findings in most hospitalised patients with COVID-19 is elevated D-dimers. Since D-dimers are a marker of clot breakdown, anticoagulation was applied to all inpatients with increasing doses considered for those with higher D-dimer values and critically ill. However, a proportion of D-dimers were from the intrapulmonary (extravascular) fibrinolysis and hence not from thrombi dissolution. In these cases, D-dimers correlated with mortality due to the worsening lung status from acute lung injury but not with thrombi formation. With respect to other laboratory parameters, severe thrombocytopenia is extremely rare and should raise the possibility of immune or drug-induced thrombocytopenia. PT and APTT are rarely abnormal except in late stages (Figure 43.2). Fibrinogen was markedly elevated in many patients but may be reduced in very severe cases. Several other tests have been suggested to correlate with COVID-19 severity including VWF/ADAMTS-13 ratio, complement activation markers, neutrophil extracellular traps and histones

Prevention of thrombosis is a crucial part of COVID-19 management. All hospitalised patients should receive prophylactic anticoagulation in the absence of any contraindications. Low-molecular-weight heparin is commonly chosen due to the ease of administration and good bioavailability. With respect to dosing, at the time of writing,

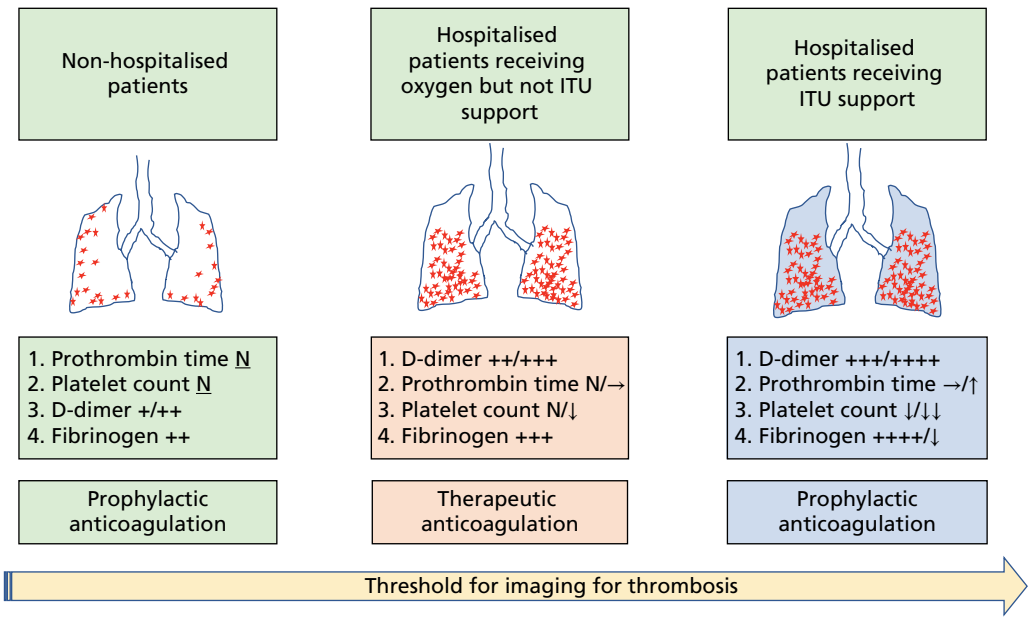

Figure 43.2 Changes in routine coagulation tests associated with COVID-19 infection.

randomised trials have shown therapeutic anticoagulation to increase mortality rates in patients requiring organ support or intensive care admission, while those who need supplemental oxygen but not yet receiving high-flow oxygen or ventilation benefit from therapeutic anticoagulation since it can reduce the need for organ support and mortality. A low threshold should be used for imaging to confirm thrombosis and therapeutic anticoagulation administered if proven to have thrombosis (Figure 43.2).

Changes in coagulation parameters vary with the severity of COVID-19 infection. The advice regarding anticoagulation is based on data available at the time of writing but this is a rapidly evolving field and management advice may change.

Haemostatic dysfunction in acute promyelocytic leukaemia

Acute promyelocytic leukaemia (APL), in particular the microgranular variant (AML-M3v), is associated with major coagulation disturbance, including DIC in at least 80% of cases. Although the introduction of all-*trans* retinoic acid (ATRA) and arsenic trioxide as differentiation agents has markedly reduced the rate of early haemorrhagic death and almost 90% of patients are cured, the 10% mortality from bleeding complications has not improved. Bleeding does not correlate with the clotting parameters, but with a high white cell count (see also Chapter 32).

The causes of coagulopathy and bleeding include hyperfibrinolysis (which is often the dominant process), DIC, thrombocytopenia, enhanced proteolysis and disruption of endothelial barrier integrity. APL blast cells express TF and annexin II which can act as a cell surface receptor for plasminogen and tissue plasminogen activator (tPA). Release of extracellular vesicles from blasts may also play a role. Cancer procoagulant, a cysteine proteinase detected on APL blast cells, can activate FX independent of FVII and is progressively reduced once patients have been commenced on ATRA. ATRA has also been demonstrated to inhibit vascular endothelial growth factor (VEGF) production, which indirectly limits TF production. Elastase, cathepsin-G and proteinase-3 are present in the granules of the APL blasts and can directly degrade fibrinogen, α_1 -antitrypsin, C1 esterase inhibitor and VWF, inducing the loss of high-molecular-weight multimers.

Management of the haemostatic abnormalities revolves around supportive care, including platelet transfusions to maintain a count of at least 30×10^9/L (or 50×10^9/L if the patient is bleeding) and the adequate replacement of fibrinogen to at least 1.5 g/L. The use of antifibrinolytic agents is supported by some evidence but remains controversial. Although markers of coagulation activation and fibrinolysis fall rapidly and completely following the start of ATRA therapy, there appears to be a slower resolution of procoagulant markers (up to 30 days). This may partly explain the clinical observation of thromboembolic events occurring in patients on ATRA, and prophylactic use of low-molecular-weight heparin or other anticoagulants should be considered once bleeding manifestations have settled.

Vitamin K and related disorders

Vitamin K metabolism

Vitamin K ('K' denoting *Koagulation*) is a group of lipophilic and hydrophobic vitamins that are needed for the post-translational modification of proteins. Vitamin K is a cofactor for gamma-glutamyl carboxylase, an enzyme that catalyses the carboxylation of glutamic acid (Glu) residues in several proteins (Figure 43.3). This reaction results in vitamin K 2,3-epoxide, which is recycled to reduced vitamin K by vitamin K epoxide reductase (VKOR), the enzyme inhibited by coumarin anticoagulants (Figure 43.3).

The Gla domains of the vitamin-K-dependent coagulant and anticoagulant proteins (FII, FVII, FIX, FX and proteins C and S) allow calcium-dependent binding to negatively charged phospholipids of activated cell membranes. This enhances the rate of the enzymatic reactions and localises them to the site of vessel injury. In the bones, carboxylation of the Gla protein osteocalcin is essential for incorporation of calcium into hydroxyapatite crystals. Retrospective studies suggest that long-term therapy with coumarin-based anticoagulants can affect vertebral bone density and fracture risk. Warfarin therapy is also associated with arterial calcification due to inhibition of matrix gamma-carboxyglutamate Gla protein.

Vitamin K deficiency

Vitamin K deficiency can occur at any age but is more common in infants because vitamin K does not cross the placenta, breast milk has low levels, there is low colonic bacterial synthesis and maternal ingestion of drugs that inhibit vitamin K. The clinical presentation of vitamin K deficiency in infants is bleeding. It was previously called 'haemorrhagic disease of the newborn' but is now termed vitamin K deficiency bleeding (VKDB). Supplementation of vitamin K is necessary to

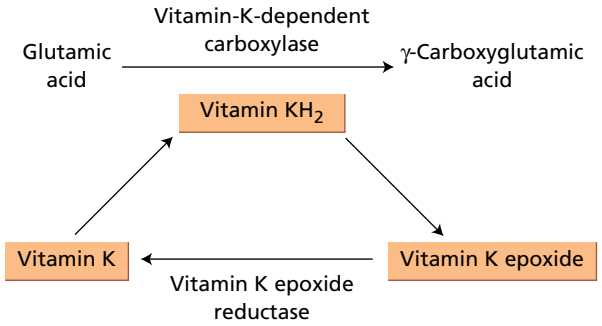

Figure 43.3 Vitamin K metabolism.

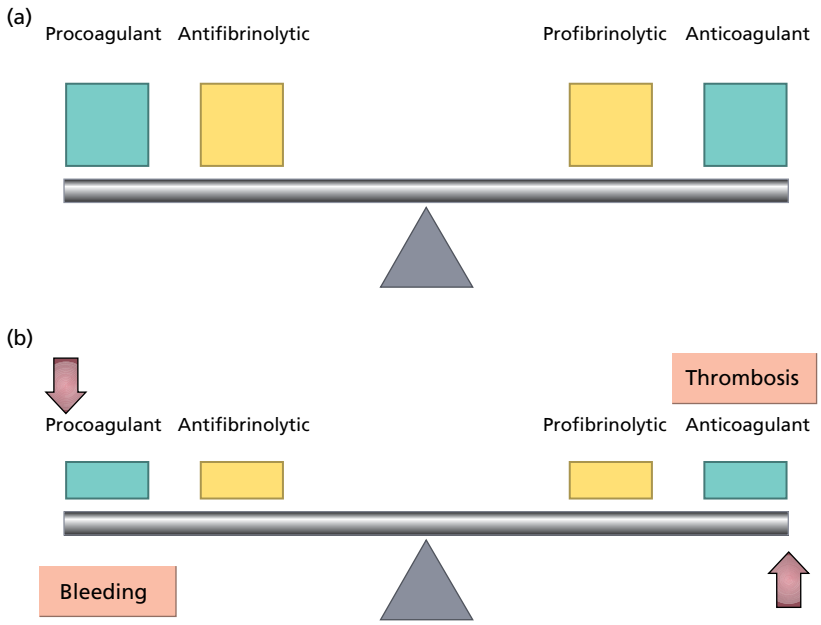

Figure 43.4 Haemostatic disturbance in liver disease. The haemostatic system in liver disease (b) compared with normal haemostasis (a). In healthy adults, the procoagulant and anticoagulant systems and the profibrinolytic and antifibrinolytic systems form a balance that is not easily disturbed. In patients with liver impairment, all four components are variably reduced and additional stimuli like infections or renal failure can upset the balance very easily, leading to either bleeding or thrombosis.

reduce the risk of bleeding, especially in exclusively breast-fed babies. A single intramuscular injection of vitamin K 1 mg prevents VKDB; however, if oral replacement is used, prolonged administration is required, although the exact dose is controversial.

In adults, vitamin K deficiency is uncommon due to recycling of the vitamin and an adequate gut flora. However, a poor dietary intake in combination with antibiotic therapy can cause deficiency. Other causes of vitamin K deficiency include malabsorption and cholestatic liver disease.

Vitamin-K-dependent coagulation factors in healthy full-term infants are about half of normal adult values. Adult values are reached by about 6 months, except for protein C, which does not reach adult levels until adolescence. Coagulation tests should be compared with age-matched reference ranges to distinguish physiological and pathological deficiencies.

VKDB in young children has been classified into early, classical and late types. The clinical features are shown in Table 43.4. The diagnostic criteria for VKDB include a PT more than 4 times control in the presence of at least one of: (i) a normal platelet count, normal fibrinogen level and absent fibrinogen degradation products, (ii) normalisation of coagulation tests after parenteral vitamin K administration or (iii) the presence of proteins induced by vitamin K absence or antagonism (PIVKA) in plasma. The presence of PIVKA without a coagulation deficit is a marker of subclinical vitamin K deficiency.

The treatment of a non-life-threatening bleed is with vitamin K_1 (phytomenadione) given slowly intravenously. A dose

Table 43.4 Features of vitamin K deficiency bleeding (VKDB).

	Early VKDB	Classical VKDB	Late VKDB
Presentation	First 24 hours of life	Days 2–7 of life	Day 8–6 months of life
Cause	Infants of mothers on vitamin-K-inhibiting drugs	Inadequate feeding	Cholestasis or malabsorption syndromes
Clinical presentation	Severe, with intracranial and intrathoracic bleeds	Milder, with gastrointestinal or umbilical bleeds being common	Severe, with high incidence of intracranial bleeds with 'warning bleeds' in up to one-third
Incidence of intracranial haemorrhage	High	Rare	Very high

of 1–2 mg is enough to fully correct the deficiency in infants aged up to 6 months, higher doses offering no advantage in efficacy or speed of reversal. There have been reports of anaphylactic reactions although these are rare. The PT should improve within 48 hours and if this has not occurred after three doses, continuation of vitamin K is unlikely to help in most cases and an alternative cause of the prolonged PT sought. Oral replacement may be used if there is no active bleeding and absorption is normal. Patients with severe bleeding should be treated with FFP or PCC.

Poisoning following the accidental ingestion of large doses of warfarin or compounds with similar properties and long half-lives is suggested by poor correction of PT or International Normalised Ratio (INR) with normal doses of vitamin K. Serum assays of warfarin concentration can be undertaken for confirmation.

Haemostatic disturbance in liver disease

Almost all procoagulant factors, natural anticoagulants and inhibitors of coagulation are synthesised in the liver (Figure 43.4). The liver is also involved in the clearance of activated clotting factors. The effect of liver disease on haemostasis is therefore complex and a balance between procoagulant and antithrombotic changes (Figure 43.4; Table 43.5). Routine coagulation tests such as PT and APTT are commonly prolonged in liver disease but are only sensitive to decreases in procoagulant factors and hence are liable to over-estimation of the haemostatic defect. Patients with liver disease have similar thrombin generation to healthy control individuals when tests are performed in the presence of thrombomodulin to make them sensitive to protein C levels.

Acute hepatitis

Patients with acute hepatitis are often thrombocytopenic (platelets $100–150 \times 10^9$/L). The mechanism for this may be immune, due to concurrent hypersplenism or to DIC. Platelet function may be impaired in acute hepatitis, although this is unlikely to be of clinical significance. In acute liver disease, biosynthesis of clotting factors is impaired, and this may be reflected in a prolongation of coagulation tests. The PT and FV, FVII, antithrombin and protein C levels are the most sensitive to hepatic biosynthetic dysfunction. The PT and FVII level predict survival in acute liver disease. The plasma fibrinogen may be raised in acute hepatic disturbance as part of an acute-phase response and a low fibrinogen is associated with a poor prognosis. A pattern of reduced fibrinogen and increased fibrin degradation products seen in acute liver disease may be due to hyperfibrinolysis.

Chronic liver disease

Thrombocytopenia

Thrombocytopenia and platelet dysfunction are common in chronic liver disease. Mild to moderate thrombocytopenia is seen in about 30% of patients with chronic liver impairment, 76% in cirrhosis and about 90% of patients with terminal liver disease. In patients with cirrhosis, this is frequently related to hypersplenism, secondary to portal hypertension. In addition, folate deficiency and the direct toxic effect of ethanol on megakaryocyte function may contribute.

A more profound thrombocytopenia in patients with hepatitis C virus (HCV) infection may be autoimmune and, although the response to steroids may be poor, eradication of HCV may be associated with an increased platelet count. Thrombopoietin receptor agonists increase platelet counts to more than 100×10^9/L in the majority of patients with cirrhosis associated with HCV infection.

A variety of platelet aggregation abnormalities has also been demonstrated in liver disease although their clinical significance is debated. VWF may be increased 10-fold and can

Table 43.5 Causes of increased bleeding tendency or coagulation abnormalities in liver disease.

Decreased coagulation factors
Decreased synthesis
Vitamin K deficiency
Increased clearance
Abnormal coagulation factors due to hypocarboxylation
Decreased platelets
Sequestration in spleen or liver
Thrombopoietin deficiency
Destruction due to toxins or antiplatelet antibodies or toxins
Toxic effect of alcohol on marrow
Dysfunctional platelets
Altered platelet arachidonic acid metabolism
Defective signal transduction
Storage pool deficiency
Abnormalities of the platelet glycoproteins
Increased platelet inhibitors nitric oxide and prostacyclin
Hypofibrinogenaemia
Impaired synthesis
Loss into extravascular spaces (ascites)
Increased catabolism
Loss due to massive haemorrhage
Abnormal fibrinolysis
Increased release and decreased clearance of tissue plasminogen activator
Decreased synthesis of α_2 -antiplasmin, plasminogen and thrombin-activated fibrinolysis inhibitor
Infections
Endogenous heparinoids: anti-FXa activity
Renal failure
Sinusoidal endothelial cell dysfunction
Hypothermia

support platelet adhesion despite reduced aggregation. However, desmopressin did not show any efficacy in reducing blood loss in patients undergoing partial liver resection or liver transplantation.

Procoagulant and anticoagulant factors

Coagulation factor and natural anticoagulant synthesis are affected by chronic liver disease. FIX is usually reduced less than FII, FVII, FX and protein C. The levels of these factors, especially FVII, falls proportionately with increasing severity of disease, and FVII is an independent predictor of survival (level below 34% associated with 93% mortality). Chronic liver impairment leads to vitamin K deficiency, mainly by decreased absorption from the gut as a result of reduced bile salt secretion in cholestasis (parenteral vitamin K responsive) and decreased synthesis in parenchymal disease (parenteral vitamin K non-responsive). The PT has been incorporated into prognostic indices of chronic liver disease, such as the Child–Pugh and Mayo End-Stage Liver Disease scores. Despite the prolongation of clotting tests such as PT and APTT, bleeding after liver biopsy or other invasive procedures in patients with cirrhosis is rare, suggesting that these tests are not on their own indicative of the haemorrhagic tendency. The levels of anticoagulant proteins, antithrombin and proteins C and S are reduced in a similar manner to procoagulant factors, potentially retaining the net balance in haemostasis. It is common practice to use the INR instead of the PT to access patients with liver disease. However, the INR is Standardised for patients taking vitamin K antagonists and its use in patients who have liver disease would require determination of an international sensitivity index (ISI) relevant to liver disease.

Bacterial infection and variceal bleeding may be associated with increased heparinoid and anti-Xa activity.

Fibrinogen

Most patients with stable chronic liver disease have normal or increased fibrinogen, although in advanced disease fibrinogen falls. This may be due to impaired synthesis, loss into extravascular spaces (ascites), increased catabolism or massive haemorrhage. Some patients develop dysfibrinogenaemia due to increased activity of sialyltransferase expressed by immature hepatocytes generated during hepatic injury, which leads to low-molecular-weight fibrinogen with abnormal α-chains and higher sialic acid content. Dysfibrinogenaemia is reflected by a prolonged TT and/or reptilase time.

Fibrinolysis

Cirrhosis may be associated with accelerated fibrinolysis due to decreased clearance of tPA, and decreased synthesis of α_2-antiplasmin and thrombin-activatable fibrinolysis inhibitor (TAFI). Hyperfibrinolysis has also been found to be a predictor of the first episode of upper gastrointestinal bleeding in cirrhotic patients with portal hypertension. On the other hand, life-threatening haemorrhage in patients with liver disease is more often related to portal hypertension (the localised coagulation problem used to be termed 'accelerated intravascular coagulation and fibrinolysis') than to net dysfunction of the clotting cascade, wherein the varices play a major part. A rebuttal to the concept of hyperfibrinolysis in cirrhosis comes from the fact that markers for hyperfibrinolysis such plasmin-antiplasmin complexes may be spuriously elevated in patients as a consequence of defective clearance and do not equate to hyperfibrinolysis as defined in other clinical states like trauma. Renal failure is also common in advanced liver disease (hepatorenal syndrome), which can exacerbate a bleeding risk.

Management of haemostatic impairment

The management of a bleeding patient with hepatic dysfunction depends on the site of bleeding and the haemostatic dysfunction. Clotting function should be assessed by means of the PT, APTT, TT and fibrinogen and D-dimer levels, although the results should be interpreted in the clinical context before transfusions are undertaken. Vitamin K should be administered intravenously (10 mg daily for 3 days) to aid biosynthesis of vitamin-K-dependent factors. The widespread practice of managing the coagulopathy of liver disease with transfusions of FFP or platelets should only be considered in the presence of active bleeding. Modification of risk factors for bleeding other than laboratory values, such as sepsis, renal impairment and anaemia should be considered if possible.

There are no evidence-based guidelines to treat active bleeding or establish safe coagulation levels for liver biopsy and similar procedures although consensus guidelines recommend a platelet count of at least 50×10^9/L (transjugular route is safer than percutaneous for liver biopsy). Based on the lack of evidence that increasing platelet counts can decrease bleeding risk, the society of liver disease recommends performing both low- and high-risk procedures without correcting the platelet count. Thrombopoietin receptor agonists have been trialled in this setting to increase the platelet count and may reduce the need for platelet transfusion.

Correction of the coagulopathy is particularly important before the placement of an intracranial pressure transducer in patients with hepatic encephalopathy. Spontaneous intracranial bleeding has been reported in such patients, though rarely, and this remains one of the principal concerns regarding abnormal coagulation in liver disease. In patients with evidence of increased fibrinolysis, antifibrinolytic drugs such as tranexamic acid should be considered.

Liver transplantation

The changes in the balance of haemostasis seen during liver transplantation are complex and multifactorial and can be due to surgical and non-surgical causes. Traditionally, the process of liver transplantation is split into three stages: stage I, the pre-anhepatic stage, which ends with the occlusion of the recipient's hepatic blood flow; stage II, the anhepatic phase, which ends with the re-perfusion of the donor liver; and stage III, the reperfusion and neohepatic period.

The risk of bleeding in the pre-anhepatic stage is related directly to the preoperative haemorrhagic risk related to the underlying liver disease. A reduction in procoagulant factors may be seen, especially if large blood losses necessitate transfusion, leading to dilution. During the anhepatic stage, studies have reported enhanced fibrinolytic activity. Reperfusion of the liver during the postanhepatic phase is associated with a dramatic increase in fibrinolysis in almost three-quarters of patients. Usually, hyperfibrinolysis subsides within an hour, but in a damaged donor liver, sustained increased fibrinolytic activity may be observed. The endothelium of the donor liver is an important source of tPA; the ischaemic damage to the graft during preservation may explain the dramatic increase in plasminogen activators. After re-perfusion, the release of heparin-like compounds has also been observed. In the postoperative period, a reduction in platelet count is related to platelet activation and blood loss, in addition to low thrombopoietin levels. The levels of this hormone increase significantly on the first day after liver synthetic function is restored, with the platelet count normalising in 2 weeks.

There is little evidence that one can predict the transfusion requirement of a patient by examining the preoperative coagulation results. The profound coagulation abnormalities seen in fulminant hepatic failure should be corrected preoperatively; however, correction of a mild coagulopathy in a patient with chronic liver disease is less likely to be of benefit. During surgery, the aim is to transfuse blood components to prevent the development of intractable coagulopathy. Near-patient tests of haemostasis performed on whole blood are often used in theatre to complement the tests performed in the coagulation laboratory. Many departments use algorithms based on coagulation and near-patient testing to guide FFP, red cell, cryoprecipitate and platelet transfusion during the procedure. Aprotinin can be administered to counteract the increase in fibrinolysis observed.

Hypercoagulability in liver disease

Tipping off the balance in the complex interplay between endogenous procoagulants and the anticoagulant system in liver disease can lead to a hypercoagulable state, in contrast to the common assumption of an 'auto-anticoagulated state'. The hypercoagulable events may be clinically evident, as with portal vein thrombosis and venous thromboembolism, but in the microvasculature can contribute to porto-pulmonary hypertension, liver fibrosis, thrombosis of extracorporeal circuits and progression of non-alcoholic steatohepatitis to cirrhosis. Hypercoagulation in liver disease may be related to poor flow, endothelial dysfunction and vasculopathy associated with a chronic inflammatory state, increased levels of FVIII and VWF, or decreased synthesis of the naturally occurring anticoagulant proteins. Hepatic fibrogenesis may be caused by tissue ischaemia and direct thrombin-mediated stellate cell activation by PAR-1 cleavage.

Haemostatic disturbance in renal disease

Bleeding is a frequent cause of morbidity and mortality in patients with renal failure. Common manifestations are gastrointestinal bleeding from angiodysplasia and peptic ulcers, as well as prolonged bleeding from skin puncture sites. Subdural haematomas and haemorrhagic pericarditis are also seen, although bleeding at the time of renal biopsy is rare. Bleeding is seen despite normal or elevated circulating levels of coagulation factors, suggesting that platelet abnormalities are the likely cause. This is supported by the finding of a prolonged bleeding time and reduced platelet aggregation to various agonists. Severe thrombocytopenia (platelets $<50 \times 10^9$/L) secondary to renal failure is rare and its presence should suggest concomitant conditions such as HCV infection or vasculitis.

Platelet dysfunction with renal failure is multifactorial and can be divided into: (i) intrinsic platelet defects, (ii) abnormal interaction of platelets with the endothelium, (iii) effects of uraemic toxins, (iv) effects of anaemia on platelets and (v) dialysis-related. Intrinsic platelet abnormalities reported in association with uraemia are shown in Table 43.6. The interaction between uraemic platelets and the endothelium can be markedly reduced, due partly to impaired VWF binding to platelets and increased endothelial production of nitric oxide, an inhibitor of platelet aggregation. Uraemic patients with prolonged bleeding times also have raised prostaglandin (PG)I_2 levels.

Anaemia-related haemostatic dysfunction is primarily a result of reduced displacement of platelets to the vessel wall by red cells.

Table 43.6 Platelet abnormalities reported in uraemia.

Decreased GPIb complexes
Reduced serotonin and ADP in the delta granules
Increased levels of cyclic AMP
Defective ristocetin-induced platelet aggregation
Abnormal mobilisation of free cytoplasmic calcium in response to agonists
Reduced release of arachidonic acid from membrane phospholipids
Decreased conversion of arachidonic acid to thromboxane A_2
Abnormal dense-granule and α-granule secretion
Abnormal cytoskeletal assembly
Deficient tyrosine phosphorylation

Dialysis can improve bleeding symptoms. Antiplatelet drugs, antibiotics, oral anticoagulants (especially those that can accumulate in renal failure) and heparin may contribute to the bleeding risk.

The bleeding time better correlates with clinical bleeding than tests of renal function, although measurement is rarely clinically useful. Adequate dialysis will improve symptoms and the bleeding time in most patients. Intravenous, subcutaneous or intranasal administration of desmopressin in conjunction with antifibrinolytics has also been used successfully to control uraemic bleeding. Although the response is brief (4–8 hours), the rapid onset of action is beneficial. Care is required to avoid hyponatraemia. Desmopressin is thought to improve platelet function by the enhanced release of endothelial VWF multimers and also by increasing phospholipid expression.

Correction of anaemia with erythropoietin so that the haematocrit exceeds 30% improves platelet interaction with the vessel wall and has also been shown to increase the number of reticulated platelets. Other potentially beneficial effects of erythropoietin include improved platelet intracellular calcium mobilisation, increased expression of GPIb and improved platelet signal transduction.

Pregnancy-related haemostatic dysfunction

Normal pregnancy is associated with physiological changes in haemostasis, with increased levels of procoagulant proteins such as fibrinogen, VWF and FVIII and a fall in anticoagulants such as protein S. These changes partly contribute to the increased risk of venous thromboembolism during pregnancy.

Obstetric haemorrhage is the most common cause of severe pregnancy-related morbidity. The cause of bleeding is often multifactorial, with a combination of physical and acquired haemostatic defects. Consumption leads to depletion of platelets and coagulation factors, particularly fibrinogen. An aggressive consumptive coagulopathy is seen with amniotic fluid embolus which is often fatal. Consumptive coagulopathy may also be triggered by placental abruption, intrauterine fetal death, pre-eclampsia and acute fatty liver of pregnancy. Once bleeding and resuscitation has started, a dilutional coagulopathy may exacerbate the haemostatic failure and contribute to the ongoing bleeding.

Treatment requires rapid recognition of bleeding and a coordinated response from obstetricians, midwives, anaesthetists and haematologists. Obstetric management should be optimised. Assessment of haemostatic failure requires an urgent FBC and a coagulation screen that includes a Clauss fibrinogen because the PT and APTT may be normal despite a low fibrinogen. Thromboelastometry in combination with a validated algorithm is becoming more commonly used because laboratory coagulation tests are often too slow to manage patients adequately. In the absence of thromboelastometry empirical blood product replacement may be required. In patients with severe haemostatic failure, a standard dose of FFP (15 mL/kg) is unlikely to be adequate to correct the haemostatic defect and the use of larger volumes should be anticipated. Platelets should be maintained above 75×10^9/L and cryoprecipitate used to maintain fibrinogen above 2 g/L if bleeding is ongoing. Some centres use fibrinogen concentrate in obstetric haemorrhage to rapidly correct hypofibrinogenaemia. The use of rFVIIa or prothrombin complex concentrate is not recommended in guidelines.

As soon as bleeding has been controlled, the patient is likely to be at high risk of venous thromboembolism; this should be assessed and appropriate thromboprophylaxis started.

Haemostatic dysfunction associated with cardiopulmonary bypass surgery

Coronary artery bypass graft (CABG) surgery is associated with excessive bleeding in about 10% of cases. Re-operation for bleeding is required in 3–10% of cases. Bleeding is more common with revision procedures and prolonged time on bypass. A surgically correctable source of bleeding may be found. Bleeding due to haemostatic disturbances can be patient-related or CPB related. Antiplatelet, anticoagulant or fibrinolytic drugs, particularly at the time of emergency CABG after stenting procedures, commonly contribute to perioperative bleeding. Despite its antiplatelet activity, aspirin has not been demonstrated to cause increased blood loss after CABG.

Haemostatic abnormalities associated with CPB are related to the interaction of blood with the extensive non-endothelial bypass surfaces and retransfusion of pericardial blood leading to contact activation. All coagulation factors except factor VIII are reduced during CPB. CPB decreases both the number and function of platelets. Platelet counts fall by 25–60% within 15 min of first passage of blood through the primed CPB circuit, in association with a prolonged bleeding time. The platelet count rarely falls below 100×10^9/L and persistent or profound thrombocytopenia should prompt consideration of alternative causes, including heparin-induced thrombocytopenia.

The observed changes in platelet function in patients undergoing CPB are due to modification of membrane components with loss of receptors, decrease in granule contents, aggregation to fibrinogen adsorbed onto the bypass circuit, mechanical trauma, exposure to hypothermia and heparin. Following CPB, platelet function returns to normal within 1 hour, although the platelet count may take several days to normalise. Coagulation factors fall because of haemodilution, which can be exacerbated by use of cell-salvage systems. Fibrinolysis is also enhanced by returned blood from the pericardiotomy suction.

Blood component administration in patients with excessive bleeding related to CABG is often empirical, with replacement of FPP and platelets. Near-patient whole-blood thromboelastometry has been used to assess haemostasis and fibrinolysis and shown to help rationalise blood product usage. Heparinase cups are often used to assess haemostasis in heparinised samples. The off-licence use of PCCs and fibrinogen concentrates has also been reported. Randomised studies do not support the use of

rFVIIa and it has been associated with increased thrombotic adverse events. Tranexamic acid and aprotinin are often used to inhibit fibrinolysis.

Haemostatic dysfunction associated with trauma

Acute traumatic coagulopathy (ATC) has been described to occur early during severe trauma and is caused by the trauma directly, shock and endothelial activation. It is characterised by increased activated protein C secondary to soluble thrombomodulin, inhibition of FV, dysfibrinogenaemia and hyperfibrinolysis. As bleeding and resuscitation progress a dilution coagulopathy contributes to the overall trauma-induced coagulopathy (TIC) (Figure 43.5). The aetiology of TIC is multifactorial and the important initiators include tissue injury with tissue factor exposure and increased thrombin generation, early reduction of fibrinogen, physiological and therapeutic haemodilution of coagulation factors and platelets, inflammation, hypothermia and acidosis. Recent work exploring mechanisms suggest tissue injury and trauma-related shock activating the various aspects of the haemostatic system, especially the vascular endothelium. In addition, the host response includes activation of the immune system leading to immunothrombosis. A varying balance between fibrinolysis and antifibrinolytic factors also comes into play with a predominant hyperfibrinolysis state due to increased tPA and reduced PAI-1 (usually early) leading to bleeding while a balance towards the antifibrinolytic pathway (usually later and after the initial hyperfibrinolysis) predisposes to thrombosis. Tranexamic acid is therefore recommended to be given before 3 hours; after this time, its use has been associated with worsening outcomes. Viscoelastic testing may be helpful in delineating this differential activation and may guide appropriate therapy including that of blood products.

Massive blood loss and resuscitation contributes to deficiencies of haemostatic factors and up to half of the fibrinogen and one-third of platelets may be lost before treatment of the injury has begun. The presence of an abnormal coagulation test on arrival in the emergency department correlates with the severity of injury and the mortality rate.

Guidelines on triggers for blood product support are evolving and different specialties have produced variable advice; an example is given in Table 43.7. Many trauma centres use thromboelastometry to guide blood product replacement. Recent observations, predominantly based on experience of battlefield trauma, have prompted recommendations for aggressive and early plasma and platelet replacement with a ratio of 1:1:1 for red cells, FFP and platelets. Issues such as hypothermia and acidosis need to be addressed by using prewarmed fluids and extracorporeal warming devices and appropriate resuscitation.

Trauma and shock cause endothelial dysfunction and contribute to acute traumatic coagulopathy. Resuscitation may result in haemodilution and contribute to trauma-induced coagulopathy. Hyperfibrinolysis is common early in severe trauma but antifibrinolytic mechanisms take over later during the process.

Coagulopathy in massive blood loss

Massive blood loss is usually defined as one blood volume (about 5 L in an adult) in 24 hours or 50% blood volume in 3 hours or more than 150 mL/min. The associated coagulopathy is complex and multifactorial. It is partly dilutional, as blood is replaced with volume expanders and red cells, but DIC, hypoxia, hypothermia and acidosis contribute in some clinical situations. Haemostatic management should be to maintain a platelet count of at least 75×10^9/L, a threshold that is likely to be reached after a two-blood-volume

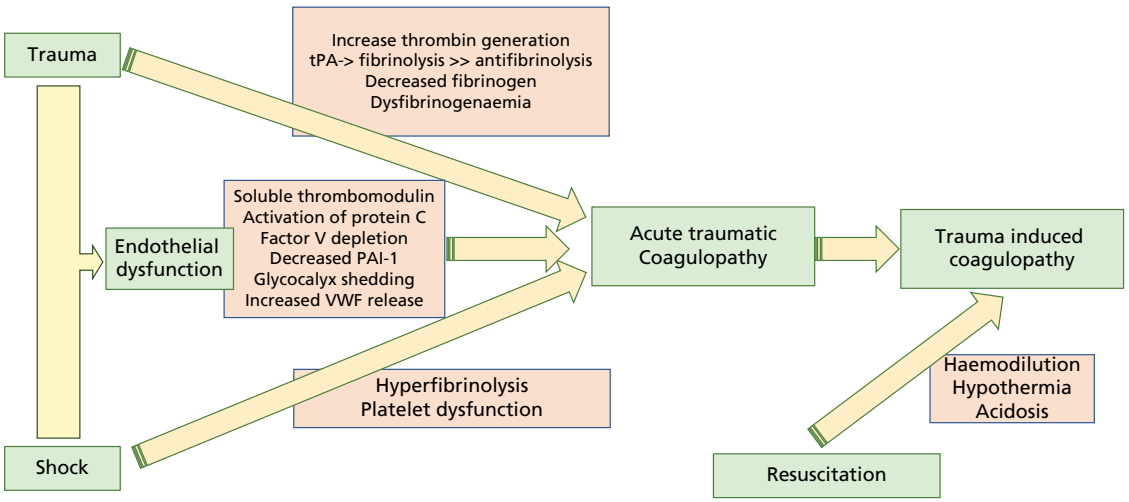

Figure 43.5 Mechanisms of haemostatic dysfunction during severe trauma.

Table 43.7 Guide to blood product replacement in massive blood loss.

1 Give tranexamic acid before 3 hours
2 Control bleeding using surgical and/or radiological interventions
3 Restore an appropriate circulating blood volume
4 Control exacerbating factors: hypothermia and acidosis
5 Blood product support as detailed below
Red cells
Use O-negative red cells first
If no record of red cell antibodies, ABO- and Rh-compatible cross-matched blood should be available within 30 min (maximum 45 min)
Replace red cells as required to maintain circulating blood volume
Use blood warmer to avoid hypothermia
Fresh-frozen plasma
Transfuse FFP in fixed ratio with red cells to prevent coagulopathy to maintain PT and APTT <1.5 times normal
If PT and APTT >1.5 times normal FFP at doses >15 mL/kg will be required
Platelet transfusion
Transfuse platelets in fixed ratio with red cells to maintain platelet count $>50 \times 10^9$/L
Fibrinogen
Maintain at least >1.5 g/L
Cryoprecipitate (dose: two donation pools)
Fibrinogen concentrate (50 mg/kg will increase fibrinogen by about 1 g/L)

haemorrhage. A higher platelet count of about 100×10^9/L will be needed in major trauma or central nervous system bleeding. Fibrinogen should be maintained above at least 1.5 g/L, a level that is likely to be reached after about a 1 to 1.5-blood-volume haemorrhage, assuming no significant additional consumptive coagulopathy. FFP should be transfused to maintain PT and aPTT less than 1.5 times normal.

Haemostatic therapy is to infuse platelets and FFP in volumes likely to maintain a safety margin above these critical levels (see also Chapter 19). Hypofibrinogenaemia unresponsive to FFP may require cryoprecipitate or fibrinogen concentrate. It is important to predict ongoing dilution and consumption of coagulation factors and to replace these expectantly if bleeding continues. Regular measurement of FBC and coagulation screens (including Clauss fibrinogen) are important for monitoring replacement treatment, although often these are not available rapidly enough to guide initial management and empirical treatment may be required in the early phases (see Table 43.7). Many centres are using thromboelastometry-guided treatment in this situation.

Bruising

Purpura simplex (normal easy bruising)

Distinguishing normal from pathological bruises may be difficult and individuals have variable thresholds for presenting for medical review. If bruising is not associated with other symptoms suggestive of a bleeding disorder and routine tests of coagulation (including VWF levels and platelet number) are normal, the patient can be reassured. Drugs such as non-steroidal anti-inflammatory agents or selective serotonin reuptake inhibitors are sometimes implicated.

Non-accidental bruising

Bruising is a common feature of non-accidental injury in both children and adults. Bruises that affect unusual sites, are in different stages of maturation, or shaped like a hand or instrument should raise concern. Any bruising in a non-mobile baby should be investigated although this may be seen in severe haemophilia. In the case of children, appropriate liaison with child safeguarding agencies should be undertaken, although the possibility of an underlying congenital or acquired bleeding disorder should also be thoroughly investigated. Self-harm may also present with bruising and should be suspected if the pattern of bruising is atypical. Deliberate ingestion of anticoagulants and long-acting vitamin K antagonists is also possible.

Senile purpura (atrophic or actinic purpura) and steroid-related purpura

Bruising is more common in elderly people due to atrophy of subcutaneous tissues and loss of collagen and elastin fibres in subcutaneous tissues. Blood vessels in the skin can be broken by minor trauma or shearing forces and typically purpura are seen on hands and forearms. If routine tests of platelet number and coagulation are normal, no further investigation is required. Long-term steroid use is also associated with bruising secondary to atrophy of collagen fibres supporting blood vessels.

Painful bruising syndrome (psychogenic purpura)

Diamond–Gardner syndrome is a rare condition most commonly seen in women with psychological problems. It is also called painful bruising syndrome and psychogenic purpura. It presents with painful ecchymotic lesions, mostly on the extremities and the face and rarely on less accessible parts of the body. The skin lesions can be preceded by paraesthesia or pain and are usually reported after surgery or minor trauma sometimes at site distant from the surgery. The usual tests for haemostasis reveal no abnormalities. The cause of the bruising is poorly understood, although Diamond and Gardner suggested the

possibility of a local reaction to the patient's own red cell stroma and gave it the name 'autoerythrocyte sensitisation syndrome'.

Scurvy

Scurvy is caused by a lack of vitamin C (ascorbic acid), which is required for the hydroxylation of prolyl and lysyl residues in the formation of mature collagen. Vitamin C deficiency renders the collagen unable to self-assemble into rigid triple helices, resulting in blood vessel fragility and poor wound healing. The characteristic clinical finding is perifollicular haemorrhage but large ecchymoses can occur on the legs and trunk. Follicular hyperkeratosis and corkscrew hairs are other cutaneous features. Bleeding gums are common. Scurvy is more common in people with poor nutrition, especially if dependent on alcohol. The diagnosis is clinical, although plasma or leucocyte vitamin C can be measured. A prompt response to vitamin C treatment is also diagnostic.

Inherited disorders of collagen and elastic fibres

Ehlers–Danlos syndrome (EDS) is a group of dominantly inherited disorders of connective tissue characterised by lax hyperelastic skin, joint laxity, spontaneous dislocation and poor wound healing. There are six subtypes and subtype IV is associated with severe varicosities and spontaneous rupture of major blood vessels. Bruising is seen in 90% of patients and has also been reported in people with lax joints who do not fulfil the criteria of EDS. Although mild platelet and coagulation factor dysfunction has been reported in association with EDS, they are likely to be coincidental. Some patients have a prolonged bleeding time and this can respond to desmopressin. Other disorders such as osteogenesis imperfecta may also be associated with bruising. Cutis laxa is not associated with abnormal bruising.

Haemostatic dysfunction associated with vasculitis

The vasculitides are a heterogeneous group of disorders characterised by inflammation within blood vessel walls of different organs. It is classified by the size of the blood vessel involved and can be associated with both thrombosis, for example, Behçet's disease (see Chapter 57), and haemorrhage. The classic presentation of Henoch–Schönlein purpura is palpable purpura without thrombocytopenia or coagulopathy, arthritis/arthralgia, abdominal pain and renal disease. Henoch–Schönlein purpura is more commonly associated with bleeding than thrombosis.

Arteriovenous malformations

Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) is a dominantly inherited, highly penetrant, familial disease in which telangiectasia develop on the skin and mucous membranes. Large arteriovenous malformations may occur in solid organs. International consensus diagnostic criteria have been developed based on epistaxis, mucocutaneous telangiectasia, visceral lesions and an affected first-degree relative.

Mutations in the *ENG* gene (encoding endoglin) and *ACVLR1* gene (encoding activin receptor-like kinase 1) have been described. These genes encode proteins that are involved in signalling by the transforming growth factor (TGF)-β superfamily. Increased levels of VEGF have been demonstrated in HHT. Genetic testing may be useful to inform asymptomatic family members or in people in whom the diagnosis is unclear.

Cerebral, pulmonary and neurological involvement is described more commonly with *ENG* mutations, whereas liver involvement has been associated with *ALK1* mutations, although members of the same family can have variable phenotypes. Typical telangiectatic lesions are red 0.5–3 mm spots that blanche with pressure and are often noted on the skin of face and lips and mucosal surfaces of the tongue and mouth. Lesions may not be present in young children and progress with increasing age. Symptoms range from cosmetic, recurrent epistaxis and mouth bleeding to iron deficiency and intracranial haemorrhage. Septic emboli may occur and antibiotic prophylaxis at the time of invasive procedures such as dental extraction is recommended. Occasionally bleeding can occur from internal organs without visible lesions.

Virtually all internal organs can be affected. The lungs develop pulmonary arteriovenous fistulae in about 30% of patients, leading to haemoptysis, sometimes catastrophic, hypoxia, dyspnoea, pulmonary hypertension, high-output cardiac failure and clubbing. Transient ischaemic attacks, cerebral infarction and systemic emboli due to right-to-left shunting occur in about half of the patients with pulmonary arteriovenous fistulae. Pulmonary arteriovenous fistulae may worsen during pregnancy. Liver involvement is present in the majority of patients and, though often asymptomatic, can lead to cirrhosis, portal hypertension and high-output cardiac failure. Conjunctival telangiectasia may cause benign bleeds, while more serious retinal bleeds can occur. Intracranial haemorrhage is associated with arteriovenous fistulae, but embolisation, including septic emboli, may also cause cerebral symptoms.

Options for symptomatic lesions include local treatment, such as laser therapy of skin and mucosal telangiectasia and embolisation of arteriovenous malformations in lung or nervous system. Systemic treatment with oestrogens and tranexamic acid may reduce bleeding symptoms. If successful, liver transplantation may lead to reversal of cardiopulmonary changes. Experimental treatments include thalidomide and bevacizumab to inhibit VEGF.

Kasabach–Merritt syndrome

Kasabach–Merritt syndrome is a rare condition in which a vascular tumour (Kaposiform haemangioendothelioma) is associated with thrombocytopenia, hypofibrinogenaemia and

bleeding, which can be life-threatening. The thrombocytopenia in Kasabach–Merritt syndrome is presumed to be due to platelet adhesion to the abnormally proliferating endothelium. This leads to activation of platelets with secondary consumption of clotting factors, including VWF, resulting in systemic haemostatic failure. Excessive flow and shear rates secondary to arteriovenous shunting also contribute and microangiopathic haemolysis may be seen. The platelet count is often less than 20×10^9/L and the platelet half-life dramatically reduced. Intralesional bleeding can cause rapid enlargement of the haemangioma and can worsen the consumptive coagulopathy. Intralesional thrombosis may rarely occur, causing spontaneous resolution of some lesions. Management involves supportive care and, if possible, removal of the lesion. Steroids, interferon, chemotherapy with vincristine, radiotherapy, embolisation and antiangiogenic agents have been tried.

Microthromboembolic disease

Cholesterol embolism

Cholesterol embolism is a complication of widespread atherosclerotic disease. Rupture of an atherosclerotic plaque can occur spontaneously or, more commonly, at the time of vascular surgery or invasive procedures. Anticoagulant or fibrinolytic therapy can weaken thrombi that usually prevent the release of cholesterol crystals. The characteristic presentation is with limb small vessel occlusion, sometimes called purple toe syndrome, with well-preserved peripheral pulses, which may occasionally lead to gangrene. Another common skin finding is livedo reticularis, where the cutaneous venous plexus becomes visible because of increased amounts of desaturated venous blood. Organ involvement from cholesterol emboli is dependent on the vascular supply, with renal ischaemia being the commonest. The diagnosis is often missed unless the occurrence of the clinical features is related to the triggering procedure. Fundoscopy can reveal the presence of retinal cholesterol crystals (Hollenhorst plaques) in about 25% of cases. Biopsy of the cutaneous lesion or the affected organ is required for definitive diagnosis. The prostacyclin analogue iloprost has been used successfully in painful cutaneous necrotic lesions and renal insufficiency in a single report.

Fat embolism syndrome

Fat embolisation is characterised by release of fat droplets into the systemic circulation after a traumatic or iatrogenic event. Its incidence depends on the bone involved (fractures of the femoral shaft >tibia or fibula >neck of femur), isolated or multiple fractures, age (10–40 years) and gender (occurs more in males). Although more common after lower limb fractures, fat embolism syndrome can also occur after liposuction, bone marrow harvesting, total parenteral nutrition, sickle cell crisis and pancreatitis. Classically, it presents with the triad of respiratory distress, mental status changes and petechial rash 24–48 hours after pelvic or long-bone fracture. The rash is pathognomonic and is seen usually on the conjunctiva, oral mucous membranes and upper body, possibly due to embolisation of fat droplets accumulating in the aortic arch. The diagnosis is made clinically because laboratory and radiographic diagnosis is non-specific and inconsistent. Thrombocytopenia is common, due to platelet activation and consumption into the thrombi. Management is supportive to ensure haemodynamic stability. Aspirin and corticosteroids have also been shown to be helpful, although the use of heparin is controversial.

Warfarin-induced skin necrosis

Warfarin-induced skin necrosis is a rare condition that is due to microvascular thrombi provoked by a transient imbalance between procoagulant and anticoagulant factors. It most commonly affects the breasts, buttocks and thighs. It may occur on initiation of warfarin, especially in patients with heterozygous protein C or protein S deficiency because of the relatively short half-life of these proteins compared with prothrombin. It is also seen in association with heparin-induced thrombocytopenia. It is prevented by bridging the initiation of warfarin with heparin and avoiding high-loading doses. Treatment requires discontinuation of warfarin and starting therapeutic heparin. Intravenous infusions of protein C concentrate may also be used in the short term.

Haemostatic dysfunction associated with paraproteinaemia and amyloidosis

Paraproteinaemia

Bleeding and thrombotic complications both occur in association with paraproteinaemias. Abnormalities in laboratory tests are found much more frequently than clinical effects and these are being recognised more often, associated with increased surveillance. Bleeding is more common in Waldenström macroglobulinaemia and amyloidosis than multiple myeloma. Amongst myeloma patients, bleeding is most common in those with IgA paraproteinaemia. The circulating paraprotein in these conditions can: (i) cause hyperviscosity and lead to arterial and retinal bleeds due to abnormal wall shear stress; (ii) inhibit function or increase clearance of VWF/FVIII complex leading to acquired von Willebrand syndrome (aVWS); (iii) impair platelet aggregation; (iv) inhibit fibrin polymerisation and (v) have heparin-like anticoagulant function that can be reversed by protamine. Acquired VWS is most commonly seen with IgM paraproteins. Management of these conditions is directed towards the underlying cause and decreasing the paraprotein level. Plasma exchange is of help as a temporary measure. See below for management of aVWS.

Amyloidosis

The pathophysiology of bleeding associated with systemic amyloidosis is multifactorial. The type of amyloidosis and the pattern of organ involvement are important determinants of the haemorrhagic tendency (Chapter 29). AL amyloidosis, where liver and spleen involvement is frequent, is the commonest type associated with bleeding. FX deficiency is seen most commonly; however, decreased levels of all factors, including VWF, have been reported. The coagulation factor deficiencies are thought to be due to adsorption onto amyloid fibrils. Abnormal fibrin polymerisation and hyperfibrinolysis can also contribute to bleeding. Prolongation of the TT is the most common abnormality, seen in up to 90% of patients. A prolonged PT and APTT suggest FX deficiency. Abnormal coagulation screening tests are correct with normal plasma supporting the absence of a circulating inhibitor.

Platelet dysfunction may be seen, due to the binding of the amyloid light chains to the platelet membrane. Deposition of amyloid fibrils in the blood vessel wall and perivascular tissue may lead to impaired vasoconstriction and vessel fragility. This is exemplified by cerebral amyloid angiopathy, which can lead to intracerebral haemorrhage, especially in elderly non-hypertensive individuals. The microvascular involvement also explains the 'raccoon eyes' (bilateral periorbital purpura from coughing or prolonged inverted positioning for lower gastrointestinal procedures) and the 'pinch purpura' (skin pinching leading to purpura). Several treatments have been described, including factor replacement with FFP or PCCs, platelet transfusion, desmopressin and rFVIIa. Severe FX deficiency can be difficult to manage and first-line therapy is with PCCs or FFP although rapid clearance of FX may be seen.

Acquired inhibitors of coagulation factors

Inhibitory autoantibodies to all coagulation factors have been described, although those against FVIII and VWF are most common.

Acquired haemophilia A

Acquired haemophilia A has an annual incidence of about 1.5 per million and usually affects older patients with a median age of about 75 years. It affects males and females equally, except in younger patients where there is a female preponderance associated with pregnancy. Acquired haemophilia A presents with a typical bleeding pattern that is distinct from that seen in congenital haemophilia. Widespread subcutaneous bleeding is common, as are muscle bleeds and gastrointestinal and genitourinary bleeding. Neurovascular compression may be limb-threatening. Haemarthroses are relatively uncommon. Fatal bleeding, such as intracranial, pulmonary, gastrointestinal and retroperitoneal, occurs in about 3–8% of cases (Table 43.8). Patients remain at risk of severe bleeding until the inhibitor has been eradicated, even if they present with mild bleeding. Acquired haemophilia A is associated with an underlying autoimmune (systemic lupus erythematosus or rheumatoid arthritis), malignant, lymphoproliferative or dermatological (pemphigoid) disease or pregnancy in about half of cases (Table 43.9). If acquired haemophilia A

Table 43.8 Bleeding symptoms in patients with acquired haemophilia A*.

Site of bleeding	All bleeds at presentation (%)	Bleeds requiring treatment (%)
	N = 172	*N* = 65

presents in association with pregnancy, it may recur in subsequent pregnancies and, if antenatal, the fetus may be affected due to passive transfer of antibody.

Early diagnosis and urgent treatment of bleeding are key to successful management. The diagnosis is suggested by the clinical presentation and an isolated prolonged APTT. FVIII inhibitors are time and temperature-dependent dependent and mixing studies with normal plasma must be incubated for 1–2 hours otherwise the diagnosis may be missed. The diagnosis is confirmed by a low FVIII and positive Bethesda titre (Figure 43.6). In some cases, diagnosis is complicated because all the intrinsic factors may appear to be low due to inhibition of FVIII in the factor-deficient plasma used to assay other intrinsic factors. Dilution will result in increased levels of the non-specifically reduced factors while FVIII remains low. It is important to exclude a lupus anticoagulant because this can also be associated with an apparently low FVIII and an APTT that does not correct with normal plasma, a chromogenic FVIII assay will not be affected by a lupus anticoagulant. Acquired FVIII inhibitors have complex kinetics so that not all FVIII is inhibited in a Bethesda assay. It is therefore often not possible to measure the inhibitor titre accurately. The FVIII level and inhibitor titre are not predictive of the severity of the bleeding but an undetectable level of FVIII and inhibitor above 20 BU means that the person is less likely to achieve a remission with steroids alone.

Treatment involves minimising invasive procedures, protecting the patient from trauma, treatment of bleeds and eradication of the inhibitor. At present, the available therapies to treat bleeds are with recombinant porcine FVIII or bypassing agents, namely rFVIIa or the activated PCC FEIBA (factor eight inhibitor bypassing activity). FEIBA and rFVIIa are equally efficacious. Multiple doses of bypassing agents may be required to control bleeds and prevent recurrence. There is a risk of thrombosis associated with bypassing agents, particularly in elderly patients. Human FVIII is unlikely to be efficacious in acquired haemophilia A, although mild bleeds in patients with low-titre inhibitors and measurable FVIII may respond to desmopressin. Recombinant porcine FVIII is efficacious if the anti-porcine titre is low, however, exposure to recombinant porcine FVIII is likely to lead to an increase in

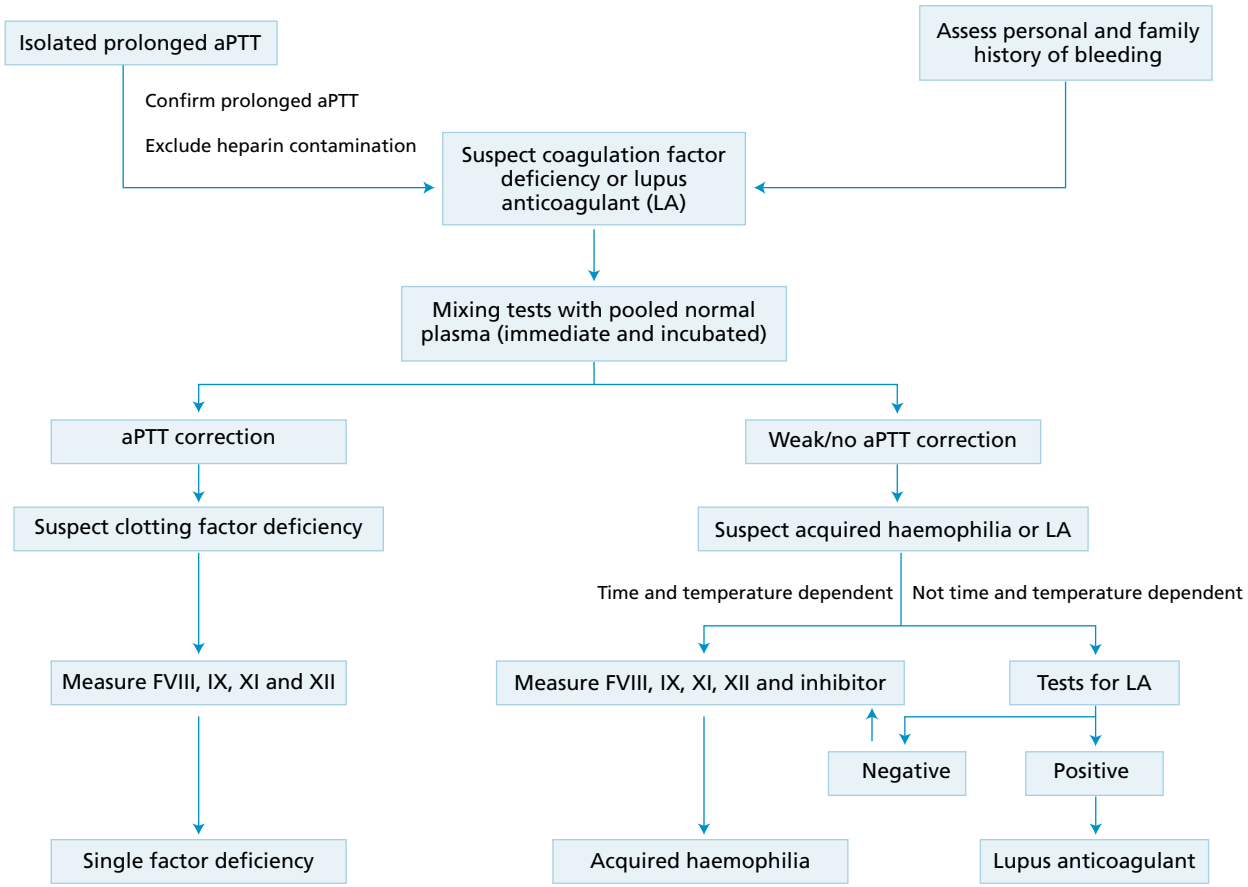

Figure 43.6 Diagnostic algorithm for an isolated prolonged APTT and possible acquired haemophilia A. A chromogenic FVIII level may be useful in complicated cases. Many centres proceed directly to factor assays and testing for a lupus anticoagulant rather than performing correction studies.

anti-porcine inhibitor titre. There are some case reports of the use of off-label Emicizumab although the safety of this treatment is unclear and it interferes with disease monitoring.

FVIII levels must be measured to monitor response to treatment and to decide on frequency and dose. If measureable levels can be achieved efficacy is good and this mode of treatment has not been associated with an increased risk of thrombosis. If standard haemostatic treatment fails, FVIII and immunoadsorption may be used, although this treatment modality is only available in a few specialised centres.

Immunosuppression should be started as soon as the diagnosis is made and is usually with steroids alone or steroids plus a cytotoxic agent such as cyclophosphamide or azathioprine, there are anecdotal reports of the use of mycophenolate. A response is usually seen after 2–3 weeks, but full remission takes a median of about 5 weeks. If first-line therapy fails, rituximab, ciclosporin or combinations of cytotoxic agents may be used. Intravenous immunoglobulin does not increase the response rate to other immunosuppressive agents.

Acquired von Willebrand syndrome

Acquired von Willebrand syndrome may be associated with an autoantibody, typically in the context of monoclonal gammopathy of undetermined significance, Waldenström macroglobulinaemia and other lymphoproliferative diseases and systemic lupus erythematosus. The antibody leads to either rapid clearance of VWF/FVIII or functional inhibition of VWF. Low VWF:Ag, VWF:RCo, FVIII and VWF:CB are found, and measurement of the VWF propeptide may be useful in demonstrating rapid clearance. *Ex vivo* mixing studies will not demonstrate an inhibitor if the mechanism is of increased clearance.

Low VWF levels are also seen in hypothyroidism and increased VWF is associated with hyperthyroidism. In myeloproliferative disorders high molecule weight VWF multimers may be consumed or degraded. Increased proteolysis of VWF in high-shear environments such as leaking cardiac values, extracorporeal circuits leads to a syndrome of acquired type 2A VWS. AVWS has also been reported in association with malignancy and it is suggested that it may be adsorbed onto malignant cells. Hydroxyethyl starches used as plasma expanders have been associated with bleeding secondary to VWF deficiency. Treatment options include desmopressin and VWF concentrates. High-dose intravenous immunoglobulin may increase the baseline VWF/FVIII and improve the recovery and half-life of infused VWF concentrate.

Acquired factor V deficiency

Acquired inhibitors to FV may arise spontaneously but are usually associated with exposure to topical thrombin preparations that have trace amount of bovine FV. Laboratory findings are of prolonged PT and APTT that do not correct with normal plasma. Patients may respond to FFP and, in resistant cases, platelets may be useful because they provide surface-associated FV which appears to bypass the inhibitor.

Acquired protein S deficiency

Autoantibodies to protein S have been reported in association with infection, particularly chickenpox. Patients present with skin necrosis and DIC.

Prothrombin deficiency associated with lupus anticoagulant

Although lupus anticoagulants are typically associated with thrombosis, occasionally cross-reactivity with prothrombin can lead to a bleeding disorder. Acquired deficiencies of other procoagulant and antifibrinolytic proteins have occasionally been described. Bleeding manifestations are variable and some patients with markedly abnormal laboratory tests do not bleed.

Introduction

A normal haemostatic system is able to provide a sequence of local events that culminates in the spontaneous arrest of bleeding from a traumatised blood vessel followed by sealing of any vascular discontinuity. Three closely related biological systems are involved: platelets, blood vessels and coagulation proteins. Platelets are anucleate cells that derive from cytoplasmic fragmentation of bone marrow megakaryocytes with a life span in the bloodstream of about 7–10 days. Platelets have a complex ultrastructure comprising a multitude of molecules that allow their adhesion and aggregation (a type of muscle-like contraction) and the malfunction of any of these may promote a specific disease (Figure 44.1). In the resting state, platelets normally do not interact with endothelial cells or other blood cells but do so when the vessel wall is disrupted. Adhesion to exposed subendothelial components allows platelet activation, aggregation and release of active substances from intracellular organelles such as adenosine diphosphate (ADP) that amplify and propagate platelet activation and aggregation into a plug that fills in any voids in a severed blood vessel. During this primary haemostasis phase, platelets transiently stop the bleeding from damaged blood vessels and provide a surface onto which plasma fibrinogen starts to polymerise into a fibrin mesh that strengthens the platelet plug, the so-called secondary haemostasis phase. Clinically, abnormalities of platelet adhesion and aggregation present with a history of spontaneous and/or easy bruising and a prolonged skin bleeding time or abnormal closure time on the Platelet Function Analyser (PF100). Abnormal bleeding due to defective primary haemostasis, that is, numerical or functional platelet defects, shows characteristic features distinct from those seen in disorders of secondary haemostasis, that is, plasma coagulation factors defects (Table 44.1). The occurrence of superficial bleeding in patients with platelet disorders as opposed to deeper bleeding in patients with clotting factor disorders is a useful clinical point, but it must be remembered that platelets and coagulation activation occurs almost simultaneously. Bleeding due to platelet abnormalities manifests as haemorrhages from small vessels: petechiae usually develop on the skin and the visible mucous membranes, but they may be distributed throughout the body, including internal organs. Characteristically, bleeding resulting from platelet disorders is immediate and transient, tends to stop promptly with local pressure and does not recur when the pressure is removed. When this pattern of bleeding occurs in the neonatal period, in infancy and in childhood, a congenital platelet disorder should be suspected. However, the disease may be clinically silent and the patient may enter adulthood without incurring in any bleeding episodes.

The family history is of major importance, providing a characteristic pattern of inheritance, but it should be remembered that a negative family history does not exclude an inherited platelet abnormality; in fact, the family history is usually negative in autosomal recessive traits. A comprehensive medical history and a careful clinical examination of the patient presenting with a haemorrhagic disorder are crucial for the correct diagnosis: the garnered information may dictate the choice of laboratory tests and together they may lead to the diagnosis, when possible, of the platelet abnormality. Congenital platelet defects may give rise to bleeding syndromes of varying severities and

are difficult to classify because of the rarity of several forms, the heterogeneity and the incomplete knowledge about many of them. Table 44.2 classifies congenital platelet disorders into two main groups: thrombocytopenias and thrombocytopathies. Each group is further divided according to specific criteria based on functional and biochemical defects. Such a classification, as others, should be viewed as tentative, because some disorders may be characterised by multiple pathogenetic factors, whereas some others are grouped together for convenience of classification rather than on their known physiopathology.

Thrombocytopenias

Thrombocytopenia defines a subnormal number of platelets in the peripheral blood, usually below 150×10^9L. Acute thrombocytopenia is the most frequent cause of severe bleeding and the risk of haemorrhage is inversely proportional to the platelet count, with spontaneous bleeding occurring more frequently at a platelet count below 20×10^9L. When automated methods are used, pseudo-thrombocytopenia can be observed. Different mechanisms can cause a false low platelet reading, and this phenomenon may occur in a wide variety of clinical disorders. Non-technical factors inducing pseudo-thrombocytopenia include paraproteins, cold agglutinins, giant platelets, previous contact of platelets with foreign surfaces (i.e. dialysis membrane), lipaemia and EDTA. The possibility of a pseudo-thrombocytopenia must be ruled out through manual counting and/or examination of an adequately stained blood film before concluding that a patient has true thrombocytopenia.

Table 44.1 Main specific clinical differences between diseases of coagulation factors and platelet disorders.

Findings	Disorders of coagulation	Platelets/vessels
Onset of bleeding	Delayed after trauma	Spontaneous or immediately after trauma
Mucosal bleeding	Rare	Common
Petechiae	Rare	Characteristic
Deep haematomas	Characteristic	Rare
Ecchymoses	Large and solitary	Small and multiple
Hemarthrosis	Characteristic	Rare
Bleeding from superficial cuts and scratches	Minimal	Persistent; often profuse
Sex of patient	80–90% male	Equal

Table 44.2 Classification of congenital platelet disorders.

		Thrombocytopenias with increased platelet size
b	Trombocytopathies	
1	Disorders of platelet adhesion functions	
2	Disorders of platelet signalling transduction functions	
3	Disorders of platelet aggregation functions	

Non-inherited congenital thrombocytopenia

Congenital thrombocytopenia not ascribed to inherited causes may be the result of different pathogenetic mechanisms: most likely it is due to deficient marrow platelet production or enhanced platelet destruction.

Alloimmune thrombocytopenia

Immune thrombocytopenia may also result from the placental transfer of platelet antibodies formed as the result of active immunisation of the mother by fetal platelet isoantigens if the fetus has inherited a paternal platelet-specific antigen that induces antibody formation (see also Chapter 54). Transplacental passage of the maternal antibody, usually of the IgG isotype, may induce severe fetal thrombocytopenia. This usually occurs when the mother has PlA1-negative platelets

and the fetus carries PlA1-positive platelets. Newborns may show severe petechiae, purpura and/or bleeding at the time of birth; alternatively, they may appear normal at delivery and manifest severe bleeding within the first postnatal week. In this case, thrombocytopenia usually improves within 1 month, but severe and fatal intracranial haemorrhages may occur.

Drugs and chemical agents

The maternal use of drugs and chemical agents during pregnancy may cause thrombocytopenia by suppressing platelet production, by damaging platelets directly or by inducing the formation of platelet antibodies. Maternal ingestion of ethanol, thiazides, chlorpropamide, tolbutamide, oestrogens, steroids and other drugs may selectively suppress thrombopoiesis. Alkylating agents, antimetabolites or chemotherapeutic drugs capable of crossing the placenta may induce predictable marrow suppression leading to severe thrombocytopenia in newborns. The maternal ingestion of quinine, quinidine, hydralazine, or antibiotics known to induce immune thrombocytopenia may induce congenital immune thrombocytopenia. In these newborns, thrombocytopenia usually improves rapidly, and it is unlikely to cause severe or fatal haemorrhages.

Bone marrow infiltration

Congenital thrombocytopenia caused by bone marrow infiltration is extremely rare, being limited to cases of disseminated reticuloendotheliosis and congenital leukaemia. Thrombocytopenia with or without associated myeloid and erythroid depression occurs in children with numerous infiltrative disorders, including solid tumours, Gaucher's disease, Niemann–Pick disease and the mucopolysaccharidoses.

Infection

Thrombocytopenia, usually mild, but at times very severe, is commonly seen in infected new-born: several mechanisms are probably responsible, indeed viral infections may directly impair platelet production as a result of direct megakaryocyte invasion, while the formation of antigen–antibody complexes in response to the viral infection indirectly allows the sequestration of platelets by the reticuloendothelial system. Maternal infection with toxoplasma, cytomegalovirus, rubella, herpes viruses or hepatitis varicella, as well as recent maternal vaccinations (rubella), may induce congenital thrombocytopenia.

Other causes

Children born to women with chronic idiopathic thrombocytopenic purpura may develop congenital thrombocytopenia due to maternal autoantibodies crossing the placenta and binding to fetal platelets. Other causes of congenital thrombocytopenia secondary to increased platelet consumption or destruction include common maternal disorders (pre-eclampsia, systemic lupus erythematosus or other autoimmune diseases, particularly if the mother has antiphospholipid antibodies). Finally, a moderate to severe thrombocytopenia has been described in giant cavernous haemangioma, where platelets are consumed primarily within the tumour itself and the severity tends to parallel the size of the vascular tumour, whether or not in association with a degree of disseminated intravascular coagulation.

Inherited thrombocytopenias

Several inherited diseases may manifest with thrombocytopenia, as an accompanying feature of a generalised bone marrow failure (Fanconi's anaemia) or of metabolic diseases causing marrow infiltration (Gaucher's disease). These and other complex clinical syndromes (i.e. Noonan's syndrome, CATCH 22 syndrome, etc.) will not be discussed in this chapter. Inherited thrombocytopenias are very rare. In some instances, thrombocytopathy may coexist with thrombocytopenia (i.e. Bernard–Soulier syndrome, Wiskott–Aldrich syndrome, etc.). These conditions will be discussed in the appropriate section according to the most prominent defect. Helpful criteria to classify inherited thrombocytopenias are platelet size and the presence (syndromic) or the absence (non-syndromic) of other clinical features.

Inherited thrombocytopenias with reduced platelet size

The Wiskott–Aldrich syndrome (WAS) is a rare (1/250,000) X-linked recessive disorder characterised by eczema, susceptibility to infections due to defective cellular and humoral immunity, and thrombocytopenia with reduced platelet size. The gene responsible for WAS maps to Xp11.1 and codes for a protein, WASp, expressed only in haemopoietic-derived cells and involved in the transduction of the signals from the cell surface receptor to the actin cytoskeleton. Intermittent bleedings, recurrent bacterial and viral infections and progressive eczema develop during the first months of life. Death at an early age commonly results from intracranial haemorrhage, infection or lymphoreticular malignancy. A number of kindreds have been reported in whom X-linked thrombocytopenia (XLT) occurred alone or in association with partial manifestations of WAS; indeed, a pathogenic variant within the WAS gene is also responsible for XLT (X-linked thrombocytopenia); affected patients suffer mainly from isolated bleeding episodes. Pathogenic variants in the *FYB* gene coding for adhesion and degranulation-promoting adaptor protein lead to impaired cytoskeleton remodelling that prevents full megakaryocyte maturation, leading to thrombocytopenia. Biallelic-null pathogenic variants in the *PTPRJ* gene

coding for tyrosine phosphatase also impairs megakaryocyte maturation, leading to thrombocytopenia as well as platelet dysfunction.

Inherited thrombocytopenias with normal platelet size

Congenital lack of megakaryocytes is a rare form of thrombocytopenic purpura in the newborn and may occur with skeletal, renal or cardiac malformations. Isolated congenital amegakaryocytic thrombocytopenia (CAMT) is an autosomal recessive syndrome leading to bone marrow aplasia later in childhood. This disorder is associated with abnormalities in the expression or function of the thrombopoietin receptor c-MPL, of which a series of pathogenic variants have been identified. Skeletal anomalies are often associated such as bilateral agenesis of the radius (thrombocytopenia with absent radii (TAR) syndrome). The TAR syndrome is an autosomal recessive disease characterised by severe, even fatal, haemorrhagic manifestations. The molecular basis of the syndrome is due to alterations of the *RBM8A* gene and often involves a microdeletion on chromosome 1q21.1. In some infants, the ulnae and humeri may also be absent alongside other skeletal abnormalities. Proximal radioulnar synostosis, syndactyly and other skeletal abnormalities are reported in association with an autosomal dominant congenital amegakaryocytic thrombocytopenia in infants carrying heterozygous pathogenic variants of the *HOXA11* gene. Less commonly, children present with cardiac and other minor defects. An autosomal dominant, though moderate form of thrombocytopenia with a mild or absent bleeding tendency has been associated with pathogenic variants in the *ANKRD26* gene (ANKRD26-related thrombocytopenia) and with haematological malignancies, in particular acute myeloid leukaemia. The Schulman–Upshaw syndrome, caused by pathogenic variants in the *ADAMTS13* gene, is characterised by a neonatal thrombotic thrombocytopenic purpura (congenital microangiopathic haemolytic anaemia) that relapses frequently but is responsive to fresh frozen plasma infusion. Rare pathogenic variants in genes that regulate different steps of megakaryocyte maturation may give rise to thrombocytopenia with normal size: a pathogenic variant in the mitochondrial protein CYCS involving apoptosis may induce immature proplatelet formation; pathogenic variants in SRC, a kinase that regulates several signalling pathways and in IKZF5, a transcriptional regulator, may disrupt megakaryopoiesis by a so far unknown mechanism.

Inherited thrombocytopenias with increased platelet size

Thrombocytopenias with increased platelet size is characterised by increased platelet volume (macrothrombocytopenia) and reduced platelet numbers, and represent the commonest inherited thrombocytopenias. Many of them have been characterised at the molecular level, whereas others still await a clear identification of the molecular defect. Giant platelets and moderate thrombocytopenia are most frequently found in certain populations of Mediterranean origin and also may be associated with other inherited or congenital syndromes, such as MYH9-related disease, Bernard–Soulier syndrome, stomatocytosis, etc.

MYH9-related disease is a rare autosomal dominant disease characterised by the presence of thrombocytopenia with giant platelets and basophilic inclusions (Dohle's bodies) within granulocytes, and despite mild neutropenia, there is no increased susceptibility to infection. About 50% of patients present significant thrombocytopenia deriving from an ineffective thrombopoiesis, but despite the impairment of platelet shape change, life-threatening haemorrhage is rare. The platelets of patients suffering from MYH9-related disease not only show a volume that can be twice as normal, but also display bizarre morphology and hyper-granularity. The condition includes a group of autosomal dominant diseases, known in the past as May–Hegglin anomaly and Sebastian, Fetchner and Epstein syndrome, according to the presence of hearing loss, glomerulonephritis and cataract. Subsequently, because of the high variability of the clinical phenotype, even in members of the same kindred, these eponyms have been abandoned and the term MYH9-related disease has been proposed independently of the presence of Dohle-like bodies and non-haematologic features. The molecular basis of these syndromes has been elucidated. All these clinical entities are caused by pathogenic variants that occur within a gene (*MYH9*) located on the long arm of the chromosome 22 (22q12-13). This gene encodes for the heavy chain of non-muscle myosin IIA (NMMHC-IIA), a protein involved in the contractile activity of the platelet cytoskeleton. On the whole, all diseases may be grouped as MYH9-related disease (Table 44.3).

The Grey Platelet syndrome (GPS) is a rare disorder inherited as an autosomal recessive trait due to pathogenic variants within the *NBEAL2* gene, although a dominant transmission has been also shown, characterised by large platelets with a selective deficiency in the number and content of α-granules (see also in disorders of platelet aggregation). Because of this, platelets are either markedly hypogranular or agranular and have subnormal levels of α-granule proteins, such as fibrinogen, von Willebrand factor, thrombospondin, β-thromboglobulin and platelet factor 4. A missense pathogenic variant at position 759 in the *GATA-1* gene, inducing an amino-acid change (Arg216Gln), which segregates in a X-linked GPS, has been recently identified, suggesting that the *GATA-1* gene is required for platelet α-granule regulation. Thrombocytopenia is usually pronounced and severe bleeding may occur.

Mediterranean macrothrombocytopenia is an asymptomatic disorder with moderate isolated thrombocytopenia and large platelets inherited as an autosomal dominant trait. The condition is characterised by mild or no clinical manifestations and

Table 44.3 Main clinical differences amongst syndromes due to pathogenic variants within the *MYH9* gene.

	Macro	Renal disease	Hearing loss	Cataract	Leukocyte
Disease	thrombocytopenia				Inclusion*

normal bone marrow megakaryocytes, platelet survival and *in vitro* platelet functions. Platelets from some patients suffering from Mediterranean macrothrombocytopenia show a reduced expression of the GPIb-IX platelet receptor, and heterozygous pathogenic variants within the *GPIbα* or *Ibβ* genes have been described. These patients with Mediterranean macrothrombocytopenia may be viewed as carrying a heterozygous form of Bernard–Soulier syndrome (see below). The remaining patients with Mediterranean macrothrombocytopenia do not show a reduction of the content of the GPIb-IX platelet receptor and the pathogenesis of this form needs further clarification.

Type 2B von Willebrand disease is a thrombocytopenia resulting from enhanced platelet destruction. Patients suffering from this syndrome show a qualitative abnormality of plasma von Willebrand factor (VWF): pathogenic variants within exon 28 of the *VWF* gene yields a VWF with an increased affinity for the platelet receptor GPIb-IX allowing for faster clearance of the resulting VWF-platelet complexes that leads to thrombocytopenia and to the selective loss of the largest VWF multimers from plasma. In general, the degree of thrombocytopenia is moderate and the bleeding is of variable severity. A *VWF* gene pathogenic variant was identified in a Montreal kindred, previously labelled as Montreal platelet syndrome, a very rare platelet disorder characterised by giant platelets, reduced platelet count and spontaneous *in vitro* platelet aggregation: this kindred has now been reclassified as type 2B von Willebrand disease. Type 2B von Willebrand disease should be distinguished from the rare pseudo-von-Willebrand disease (or platelet-type von Willebrand disease). The defect in this autosomal dominant condition results from gain of function pathogenic variants in the gene encoding for the GPIb-subunit of the platelet receptor, increasing the affinity for VWF resulting in spontaneous binding of platelets to VWF with shortened platelet survival and thrombocytopenia. The reasons why most patients suffering from platelet-type von Willebrand disease show variable enlarged platelets remain unclear.

Jacobsen and Paris–Troussau syndromes are other very uncommon causes of macrothrombocytopenia. The Jacobsen syndrome is a contiguous gene syndrome inherited as an autosomal dominant trait characterised by a chromosomal deletion encompassing the long arm of the chromosome 11 (11q23.3–11q24.2). Paris–Trousseau syndrome identifies patients who present with macrothrombocytopenia, abnormal platelet function and morphologically abnormal megakaryocytes in the bone marrow. A heterozygous deletion of the *FLI1* gene has been described in unrelated children with deletions of 11q23 and Paris–Trousseau thrombocytopenia. Interestingly, in patients suffering from Jacobsen syndrome without thrombocytopenia, the chromosomal deletion did not include the *FLI1* gene, suggesting that deletion of this gene is specific for the thrombocytopenia that occurs in most patients with Jacobsen and Paris–Trousseau syndromes.

Pathogenic variants in GFI1b, a transcriptional factor involved in haematopoietic stem cells homeostasis and megakaryocyte maturation leads to thrombocytopenia, as well as defects of the Mg^{2+} channel TRPM7, a possible modulator of cell survival, that causes alterations in the cytoskeleton preventing proplatelet formation. In this respect, the cytoskeleton remodelling that leads to megakaryocyte maturation and proplatelet formation is under the control of several genes: *DIAPH1, ACTN-1, TUBB-1*, that code for tubulin beta 1, a major component of microtubules, *TPM4*, that codes for tropomyosin 4, FLNA that codes for filamin A: pathogenic variants in any of these lead to defective proplatelet formation hence thrombocytopenia.

Thrombocytopathies

Platelets participate in haemostasis by adhering to exposed elements of the subendothelial matrix. Once adhered onto the subendothelial surface they activate and secrete the proteins contained in their granules and aggregate with each other. Abnormalities in any of these stages, adhesion, activation, secretion and aggregation may give rise to a functional inherited platelet disorder. Patients suffering from any of these

diseases usually show a bleeding diathesis with a prolonged bleeding time, abnormal PF100 closure times in the presence of a normal platelet count. The most accurate test for evaluating platelet activation is light transmission aggregometry, which uses platelet-rich plasma or washed platelets, and monitors the change in light transmission upon agonist addition and simultaneously dense granule secretion. However, diagnosing a platelet function defect can be difficult, because of need for specific expertise, and skilled investigators are required. A further major challenge is the wide overlap with the response of healthy subjects. Up to 40% of patients presenting with a platelet function defect, light transmission aggregometry fails to correctly identify the thrombocytopathy.

Disorders of platelet adhesion

The interaction of platelet receptors with blood components, collagen and fibronectin in the sub-endothelium layer allows platelet adhesion to the same, aided by the bridging effect of VWF (Figure 40.2). The platelet surface is equipped with a series of receptors that interact with one or more of the previous sub-endothelial factors. The most important receptors are the GPIb-IX and the α2-β1 (previously known as GPIa-IIa). The α2-β1 is a member of the integrin β-1 subfamily that binds collagen alongside GPIV and GPVI. Sequential and multiple receptor-ligand binding reinforces adhesion and provides the simultaneous stimuli that are required to mobilise intracellular calcium and induce protein phosphorylation. Bernard–Soulier Syndrome (BSS) is a bleeding disorder characterised by giant platelets, mild or moderate thrombocytopenia and prolongation of the skin bleeding time of PF100 closure times, disproportionate to the degree of thrombocytopenia. BSS is a recessively inherited autosomal disorder due to abnormalities of the GP Ib-IX-V receptor complex and consanguinity is common in reported kindreds. The frequency of BSS has been estimated to be approximately 1 case in one million people. Bleeding may be severe and fatal haemorrhages may occur. Cutaneous bleeding, muscular and internal organ haemorrhages are common. Epistaxis and menorrhagia may be difficult to control, and hemarthroses have also been reported. Platelet counts range from as low as 20×10^9/L to near normal and, on the peripheral blood film, over 80% of the platelets are usually larger than 2.5 µm, often up to 8.0 µm, in diameter. The number of bone marrow megakaryocytes is usually normal. Patients presenting with BSS show an absent platelet agglutination in response to ristocetin (in the presence of human VWF), normal aggregation, ATP secretion and thromboxane (TX) B_2 formation in response to a variety of aggregating agents, and delayed response to thrombin. Because of the defective binding to VWF, platelets in BSS have substantial reduction in their ability to adhere to sites of vascular injury where subendothelial VWF becomes exposed. As a consequence, the primary hemostatic response, plug formation, is impaired, and prolonged bleeding occurs. Variable levels of the glycoprotein (GP) Ib-IX-V complex have been detected on the platelet surface of patients with BSS, some patients exhibiting near normal GP Ib-IX-V amounts (variant type of BSS). In spite of the differences in glycoprotein content, clinical bleeding and platelet functional and morphologic abnormalities, these patients are indistinguishable from the classical BBS phenotype. The entire cDNA encoding the protein chains comprising the GP Ib-IX-V receptor complex has been sequenced, clarifying the molecular basis of the syndrome. This complex consists of four proteins: the disulfide-linked α- (135 kD) and β-chains (25 kD) of GPIb, and the non-covalently associated subunits GPIX (22 kD) and GPV (82 kD). They all share structural and functional features suggesting a common evolutionary origin. Different transcripts encode the four polypeptide chains and, with the exception of that of GPIbβ, genes show continuous (intron-depleted) open reading frames. In addition, each element contains one or more homologous 24-amino-acid leucine-rich glycoprotein repeats. The genetic heterogeneity in the glycoprotein content of BSS patients shows that multiple molecular abnormalities may lead to a similar clinical disorder and implies that BSS may be the result of defects within the subunits that hamper the coordinated expression of the complex on the platelet membrane. In this respect, BSS would resemble abnormalities of other multi-subunit complexes, in which a defect in a single subunit prevents the assembly and the surface expression of the other sub-units and

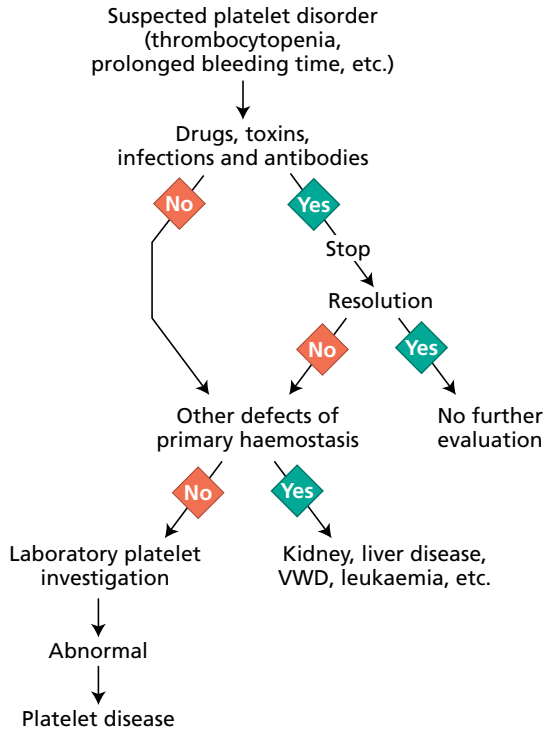

Figure 44.2 Flowchart for the investigation of a suspected platelet disorder.

therefore of the full complex. In addition to quantitative and qualitative abnormalities of the *GPIbα* gene, the recognised BSS phenotype has also been documented in patients with detrimental pathogenic variants within platelet *GPIX* and *GPIbβ* genes.

A defect of one of the platelet collagen receptors has been described in very few patients. These patients showed mild bleeding disorders and a selective but varied impairment to collagen induced adhesion to subendothelial surfaces and to collagen-induced platelet aggregation. Platelets have two major receptors for collagen; α2β1 integrin, with a major role in adhesion of platelets to subendothelial surfaces, and GPVI, mainly involved in platelet activation. Thus, it is conceivable that collagen binding to platelets is a multistep mechanism, involving first the binding of platelets to exposed collagen at the flowing blood/sub-endothelium interface by means of the α2β1 receptor and then platelet activation through a second receptor GPVI.

Disorders of platelet signalling transduction

Once adhered to the subendothelial factors, the platelet membrane transduces to the intracellular environment the signals required for platelet activation, such as calcium mobilisation, protein phosphorylation and the generation of arachidonic acid (AA). Activated platelets release the molecules stored in their granules, some of which aid in the recruitment of additional platelets and lead to the formation of the platelet plug typical of primary haemostasis (Figure 44.1). The signalling events involved in platelet activation, aggregation and secretion are multiple. Any abnormalities in platelet signalling may underlie a platelet dysfunction. The term platelet signalling disorders defines a group of heterogeneous abnormalities in signal transduction and platelet secretion. Congenital defects of platelet signalling mechanisms are put together for convenience of classification rather than on the basis of knowledge in the pathophysiology of specific diseases. Patients suffering from these defects represent the vast majority of subjects presenting with inherited thrombocytopathies. Many platelet receptors are coupled to G-proteins. P2Y1 and receptors for thromboxane A2, and thrombin act via Gαq. Receptors for prostaglandins activate, whereas P2Y12 inhibits adenylate cyclase through Gs and Gi2, respectively. Platelet activation by means of binding to receptors gives rise to hydrolysis of phosphoinositide by phospholipase C, leading to the formation of inositol triphosphate, which in turn, functions as a messenger to release calcium from intracellular stores. In addition, hydrolysis of phosphoinositide leads to the formation of diacylglycerol, which activates protein kinase C. The activation of the protein kinase C is thought to play a major role in platelet secretion and in the activation of the αIIb-β3 complex. Although defects in phospholipase C activation, calcium mobilisation and protein phosphorylation have been suggested in several patients, few patients have been reported with deficiency in platelet Gαq, Gs hyperfunction and reduced expression of phospholipase C-β2. Following stimulation, platelet phospholipase A2 mobilises the AA from the phospholipid pool. Then, the AA is metabolised by cyclo-oxygenase and thromboxane synthase to form thromboxane A2, a strong platelet-aggregating agent, which is necessary for a secretion response. A defect in AA mobilisation and thromboxane A2 production has been identified in some patients. Individuals with this defect showed an abnormal aggregation and secretion in response to a series of stimulating factors, but a normal production of thromboxane A2 in response to AA. Several patients presenting on the clinical side with a variable bleeding diathesis and on the laboratory side with a slightly prolonged bleeding time and an impaired platelet aggregation were diagnosed with a deficiency of cyclo-oxygenase and a defect in thromboxane A2 formation.

Disorders of platelet aggregation

Circulating epinephrine, ADP and collagen at the site of vessel injury, as well as thrombin deriving from coagulation activation, are the exogenous platelet agonists that promote an increase of the intracytoplasmic platelet concentration of Ca^{2+} followed by the release of the content of the α and δ granules alongside the generation of thromboxane A_2, all endogenous platelet agonists. Whether exogenous or endogenous, all platelet agonists, induce the inside-out expression of membrane GPIIb/IIIa, the fibrinogen receptor: the binding of soluble fibrinogen to GPIIa/IIIb favours platelet-platelet interaction and allows increased strength in the resulting aggregate.

Accordingly, the lack of GPIIb/IIIa expression represents the most severe platelet aggregation disorder whereas the selective impairment of platelet receptors (ADP, epinephrine, thromboxane and collagen) and storage pool disease represent less severe platelet function defects. To discriminate amongst disorders of these pathways, a series of substances are employed to challenge platelets *in vitro* and the manner they respond to these stimuli helps to identify specific thrombocytopathies (Table 44.4).

Glanzmann's thrombasthenia (GT) is a bleeding diathesis marked by a prolonged bleeding time, a normal platelet count and the absence of aggregation in response to ADP, collagen, arachidonic acid and thrombin. Platelet agglutination induced by ristocetin and VWF is normal. This congenital bleeding disorder is associated with an impaired or absent clot retraction. GT is one of the less common congenital bleeding disorders (prevalence 1/1,000,000) and is transmitted as an autosomal recessive trait with consanguinity reported in affected kindreds. The clinical features are those expected with platelet dysfunction: easy and spontaneous bruising, mucosal membrane bleeding, subcutaneous haematomas and petechiae; occasionally. Patients suffer from intra-articular bleeding causing hemarthroses and fatal haemorrhages have been described. Quantitative or qualitative (variant GT forms) abnormalities of

Thromboxane receptor defect	Impaired	Impaired	Impaired	Impaired	Present

the platelet αIIbβ3 integrin (previously known as the glycoprotein complex IIb/IIIa) have been shown to be responsible for this disorder. αIIb and β3 subunits are prominent integral components of the platelet membrane that form heterodimers containing specific sites for platelet-to-platelet cohesion. The αIIbβ3 integrin serves as platelet receptor for fibrinogen, fibronectin, vitronectin and VWF. In addition, the $\alpha IIb\beta_3$ integrin modulates, to some extent, calcium influx, cytoplasmic alkalinisation, tyrosine kinase phosphorylation and clot retraction. Clinical heterogeneity of GT has been assessed on the basis of platelet function testing or using crossed immune-electrophoresis, Western blot, flow cytometry and fibrinogen binding. Type I GT is characterised by the lack of surface-detectable αIIbβ3 complex and a profound defect in platelet aggregation and clot retraction. Type II GT is characterised by markedly reduced, amounts of the αIIbβ3 receptor on the surface, usually from 10 up to 20% of normal values. Therefore, platelets have enough receptors to allow the formation of micro aggregates but are still profoundly unable to form large aggregates. The clot retraction is only moderately impaired. In addition, a series of patients presented with a variant form with almost normal levels of the αIIbβ3 complex, which is dysfunctional in that platelets, when activated, can neither aggregate nor bind fibrinogen. An extreme variability in the clinical symptoms is present, even amongst patients with similar degrees of platelet abnormality and prolongation of the bleeding time. In general, no aggregation abnormalities are detected in heterozygotes, but a decreased amount of the αIIbβ3 integrin has been reported, platelet content being approximately one-half of the normal amount.

A pathogenic variant in the *FERMT3* gene is responsible for the recessive leucocyte adhesion deficiency type-III; the impairment of the actin function within the cytoskeleton prevents the proper inside-out GpIIb/IIIa activation leading to a GT phenotype. A pathogenic variant within *RASGRP2*, the gene coding for a nucleotide exchange factor in the monomeric GTPase Rap1 conducive to the inside-out signalling pathway of the GP IIb/IIIa, prevents the GTPase to respond to the increase in Ca^{2+} following platelet stimulation, hence the pathogenic variant is associated with reduced platelet response to multiple activators.

Defects of platelet ADP receptors have been characterised in a few patients and all suffered from a bleeding diathesis. On the platelet surface, different types of ADP receptors have been identified, two G-protein-coupled receptors, P2Y1 and P2Y12. The P2Y1 receptor is responsible for the shape change of platelets and transient platelet aggregation, giving rise to centralisation of platelet granules and formation of filopodia, while the P2Y12 receptor is involved in the amplification of the response and in the stabilisation of platelet aggregates through the full activation of the αIIbβ3 integrin. The P2Y12 receptor defect is inherited as an autosomal recessive trait and most patients so far identified were born from consanguineous parents. In these patients, a blunted platelet aggregation in response to ADP, with a retained shape change, has been reported. Only one patient has been briefly reported with a defect of the P2Y1 receptor. This patient showed impaired platelet aggregation in response to ADP and other agonists The selective impairment of epinephrine receptors, α2 adrenergic receptors (α2AR), has been associated with bleeding. A number of individuals with an impaired aggregation response to epinephrine and a congenital defect of platelet α2AR receptors have been described, and some of them presented a history of easy bruising. A selective impairment of the thromboxane A2 receptor has been described in several patients with a mild lifelong disorder, consisting of mucosal bleeding and easy bruising, and a defective platelet aggregation in response to several agents, but not thrombin. An autosomal dominant inheritance has been suggested in some cases.

Defects of endogenous agonists are more frequent than GT and the most common are the storage pool deficiency (SPD) syndromes that may be classified according to the decreases of the content of α-granules, dense (δ) granules or both (Figure 44.1). Partial or total deficiency of α-granules with normal amounts of δ granules typify the GPS.

The GPS is caused by a homozygous or compound heterozygous pathogenic variant in the neurobeachin-like 2 (*NBEAL2*) gene that codes for the NBEAL2-protein, member of a family of proteins that includes also the Beige and Chediak-Higashi (BEACH) domains involved in vesicle trafficking that is critical for the development of α granules. The GPS is autosomal recessive, affected people suffer mucocutaneous bleeding in the presence of moderate thrombocytopenia and large and pale platelets are seen on blood film. The syndrome is progressive, in that thrombocytopenia can worsen towards adolescence and adulthood, accompanied by a degree of myelofibrosis and occasionally splenomegaly. Additional genes (*GATA1, VPS33B, VIPAS39, GFI1B* and *PLAU*) are involved in congenital α-granule deficiency, but it is not distinguishable whether α-granule deficiencies are a single phenomenon of unknown genetic cause or as a component of multisystemic diseases involving all lysosome-like organelles.

Deficiency of δ granules typify Hermansky–Pudlak syndrome (HPS) and Chediak´-Higashi syndrome (CHS). HPS is characterised by oculocutaneous albinism, the absence of platelet dense granules and infiltration of ceroid-pigmented reticuloendothelial cells in the lung and the colon, leading to pulmonary fibrosis and inflammatory bowel disease. The causative genes encode dysfunctional proteins that impair the trafficking of lysosomes and vesicles. The genetic heterogeneity of HPS is quite wide and so far, pathogenic variants in several orthologous genes associated with different protein-associated complexes (HPACs) have been found in HPS patients: *BLOC1S3, BLOC1S5, BLOC1S6, DTNBP1* (HPAC BLOC-1 Deficiency); *HPS3, HPS5, HPS6* (HPAC BLOC-2 Deficiency); *HPS1, HPS4* (HPAC BLOC-3 Deficiency); *AP3B1, AP3D1* (HPAC AP-3 Deficiency). Carriers of pathogenic variants in genes associated with a HPAC BLOC-3 Deficiency exhibit a severe form of oculocutaneous albinism, progressive restrictive lung disease, and bleeding diathesis, whereas individuals with pathogenic variants in genes associated with a HPAC BLOC-2 Deficiency show a milder phenotype. Finally, carriers of pathogenic variants in AP3B1 or AP3D1 exhibit immunodeficiency.

The rare CHS presents with a variable degree of oculocutaneous albinism and a poor resistance to respiratory and cutaneous infections. The infections are generally fatal during infancy or in early childhood, but patients may also die of a chronic lymphohistiocytic infiltration known as the accelerated phase during the second or third decades of life. Unlike HPS, CHS does not seem to display locus heterogeneity and the only gene proved to cause CHS (*LYST*) is sited on chromosome 1q42.1–42.2; *LYST* codes for the lysosomal trafficking regulating protein CHS1 that is dysfunctional in CHS. The δ-SPDs mentioned are inherited in an autosomic recessive pattern, including thrombocytopenia with absent radius that may associate with a SPD. Instead, the deficiency of δ granules coincidental with Wiskott Aldrich syndrome is inherited in an X-linked recessive manner. The bleeding phenotypes of SPD are those expected from a platelet function defect and consist of easy and spontaneous bruising, mucocutaneous haemorrhages, haematuria and epistaxis. Patients with GPS, with δ-SPD or αδ-SPD usually have absent ADP and epinephrine-induced secondary aggregation waves, although the primary waves are present. Collagen-induced aggregation is absent or markedly reduced, whereas ristocetin-induced agglutination is normal.

Quebec platelet disorder is a rare autosomal dominant bleeding disease associated with abnormal proteolysis of α-granule proteins; platelets show increased stores of urokinase plasminogen activator and genetic studies show a tandem duplication of the urokinase plasminogen activator gene, PLAU. Intraplatelet generation of plasmin is thought to trigger degradation of stored α-granule proteins, increasing risks for a number of bleeding symptoms, including delayed-onset bleeding after haemostatic challenges that responds only to anti-fibrinolytic therapy.

Treatment

As a rule, there is no specific treatment for the vast majority of congenital platelet disorders. In congenital thrombocytopenias due to maternal use of drugs or chemical agents, thrombocytopenia recovers after few days to few weeks, as in the case of thiazide drugs. In surviving thrombocytopenic newborns infected with rubella or cytomegalovirus, platelet levels may return to normal after several months. In newborns with alloimmune congenital thrombocytopenia, platelets return to normal values in 14–21 days. Only severe cases need to be treated with washed platelets, corticosteroids or exchange transfusions. In general, principal treatments in patients with congenital platelet diseases are general measures aiming at avoiding bleeding and the use of supportive therapeutic approaches for controlling haemorrhages. However, since types and severity of bleeding vary in different patients, therapeutic approaches have to be individualised.

General measures

Patient education of patients is of great importance: patients and their parents have to be instructed to avoid trauma. Regular dental care may be helpful to prevent gingival bleeding. Drugs that impair platelet functions, such as acetylsalicylic acid-containing medications, should be avoided. In women, the use of oral contraceptives may be employed to prevent menorrhagia. Local measures, such as the application of firm pressure in the case of epistaxis, will usually suffice in the event of mild bleeding.

Drugs

Antifibrinolytic agents are useful as an adjunctive measure to prevent and control mild or moderate bleeding and may stop menorrhagia and other mild bleeding manifestations from mucous membranes, such as epistaxis: tranexamic acid, either orally at a dose of 15–25 mg/kg t.d.s. or intravenously at a dose of 10 mg/kg t.d.s. in the case of more serious bleeding. Antifibrinolytic agents represent the specific treatment for Quebec platelet syndrome.

Desmopressin (1-desamino-8-D-arginine vasopressin or DDAVP) is a mainstay of the therapy of patients with congenital platelet defects. Depending on platelet defect, administration of desmopressin may shorten the bleeding time. Intravenous, subcutaneous or intranasal administration of desmopressin increases factor VIII and VWF transiently by releasing them from storage sites and supporting platelet function. The drug is usually administered at a dosage of 0.3 μg/kg in 50 mL of saline by slow intravenous infusion (over 30 min to avoid possible hypotensive effects) or subcutaneously. In general, since the response to desmopressin varies amongst patients, but is constant in each patient, normalisation or improvement of the closure times of the PF100 or of bleeding time pre and post a test dose of desmopressin may identify those patients who may benefit from the drug. Recombinant activated factor VII (rFVIIa) has proven effective in the treatment of bleeding in haemophilic patients with inhibitors. The administration of rFVIIa in patients with congenital platelet disorders, such as BSS, SPD and Glanzmann's Thrombasthenia may stop spontaneous bleeding and/or may prevent bleeding during and after surgical procedures, though arterial and venous thromboembolism have been described after its use. Recombinant FVIIa is currently approved in Europe for prophylaxis and treatment of bleeding in patients with Glanzmann's thrombasthenia with antibodies to GP IIb-IIIa and/or HLA, and past or present refractoriness to platelet transfusion. The recommended dose is 90 μg/kg as a minimum of three intravenous boluses at 2-hour intervals.

With regards to the thrombopoietin agonists, a clinical trial has demonstrated the efficacy of eltrombopag in reducing the bleeding risk in the MYH9-related disease, in ANKRD26-related thrombocytopenia, in WAS, in the monoallelic BSS and in the ITGB3-related thrombocytopenia whereas the benefit of romiplostin in WAS derives from an observational study. Both agents provided pre-operative support in patients requiring surgery, minimising the use of platelet support hence of allo-immunisation.

Platelet transfusions

Platelet transfusions are employed to control severe haemorrhage in patients with thrombocytopenia or thrombocytopathies. Spontaneous as well as post-traumatic bleeding is common at a platelet count below 20×10^9/L and is extremely likely at a platelet count below 5×10^9/L. Extensive clinical experience has shown that control of bleeding is possible upon achievement of an adequate increase in the circulating platelet count. However, the coexistence of platelet dysfunctions has to be taken into account to correctly calculate the dosage of platelets required. Platelet transfusions are effective in controlling bleeding but may be responsible for transmission of infectious diseases, febrile reactions or development of alloimmunisation. Use of the thrombopoietic agents may substitute the need for peri-operative platelet support. In patients with thrombocytopathies, platelet transfusions should be employed only for the treatment of severe bleeding because of the risk of alloimmunisation.

The occurrence of platelet alloimmunisation is more frequent in patients lacking a membrane glycoprotein, such as in BSS and GT: indeed, the infusion of normal platelets into a donor with BBS or GT may stimulate the emergence of alloantibodies in the donor that may recognise the relevant platelet receptors in subsequent platelet transfusions causing platelet refractoriness. Similarly, a pregnant woman with BSS or GT may conceive a heterozygous fetus: If there is contamination of maternal blood with fetal blood, the mother could become sensitised to the relevant receptors and develop platelet refractoriness when given subsequent platelet transfusions.

Other measures

Splenectomy has generally no effect in congenital thrombocytopathies and in thrombocytopenias but has proven to be effective in some patients with inherited thrombocytopathies. Allogenic bone marrow transplantation may provide, in theory, an effective cure for inherited disorders involving platelet count or functions restoring a normal megakaryocytopoiesis. Indeed, it represents the only definitive therapy for patients with CAMT and remains the therapeutic modality of choice for classic WAS. Allogeneic bone marrow transplants have been successfully performed with complete correction in patients with amegakaryocytic thrombocytopenia with radioulnar synostosis, BSS and severe Glanzmann's thrombasthenia. However, the risks of an allogeneic bone marrow transplant are superior to those related to a bleeding tendency and, therefore, a transplant procedure is rarely required in patients suffering from congenital platelet disorders.

Conclusions

Over the recent years, a series of studies and reports have improved our understanding of the pathogenesis of congenital platelet disorders: new responsible genes have been identified and some patients have been characterised at the molecular level, allowing a deeper insight into the pathogenesis of inherited thrombocytopenias and thrombocytopathies (Table 44.5). Careful personal and family history taking, coupled with an

accurate physical examination are of major value for the evaluation of a patient presenting with bleeding due to congenital platelet disorders and are crucial in the selection of the appropriate laboratory tests (Figure 44.2). In most cases, this approach will allow the correct identification of the platelet defect. However, despite recent advances in knowledge, the molecular mechanisms underlying most of the congenital bleeding disorder remain unclear. The challenge to further our understanding of congenital platelet disorders must continue in order to design specific tools for their diagnosis, treatment and prevention. Gene therapy may represent a successful curative modality for congenital platelet disorders, whereas further trials with thrombopoietic agents will inform us about their efficacy and safety. Hopefully, refinements in such approaches will help provide targeted management for the majority of bleeders due to severe congenital platelet disorders.

CHAPTER 45

Primary immune thrombocytopenia

45

Nichola Cooper and Drew Provan

Imperial College, London, UK and Queen Mary University of London, London, UK

Introduction

Primary immune thrombocytopenia (ITP) is an autoimmune bleeding disorder that affects both children and adults. Until recently, it was considered an autoantibody disorder in which platelets, opsonised with antiplatelet antibody, were removed prematurely by the reticuloendothelial system. More recent studies have shown that there is a relative platelet under-production in some patients, and there may be a role for CD8+ T cell mediated destruction of platelets and/or megakaryocytes.

Many patients have no clinical problems, but bleeding may occur. Other features of ITP are fatigue and an increased rate of thrombosis. ITP is unpredictable in its clinical course. Treatment is aimed at either reducing the platelet destruction through immunosuppression or increasing platelet production using thrombopoietin receptor agonists (TPORAs).

Clinical features

Paediatric and adult ITP have some differences in their underlying cause and presentation. In children, ITP often follows a viral illness or immunisation. The profound thrombocytopenia may be associated with extensive petechiae, purpura and bruises. There may also be bleeding from mucous membranes such as the nose or mouth. Despite the severity of the clinical features, many children do not need treatment and most will undergo spontaneous remission. Around 15% of children will develop chronic ITP, although this is higher in those presenting during adolescence, and may be more like 50%.

In adults, there is generally no prodromal illness and the patient may become aware of petechiae or excessive bruising and seek medical attention. ITP is often diagnosed by chance, for example during hospital admission for surgery or when a full blood count (FBC) is checked for other reasons.

ITP is heterogeneous. Many patients suffer few clinical problems related to their thrombocytopenia, while others have major bleeding from the outset. Although patients usually only bleed if the platelet count is less than 30×10^9/L, the platelet count alone is an unreliable predictor of outcome, and the clinical symptoms and signs of ITP are influenced by patient age, general health, comorbidities, medication and many other factors. In addition, there may rarely be an acquired platelet dysfunction caused by antibody binding to an important region of the glycoprotein molecules on the platelet surface. Autoantibodies reacting with glycoprotein (GP)IIb/IIIa may affect platelet aggregation, and anti-GPIb/IX autoantibodies can impair platelet adhesion to von Willebrand factor, causing unexpectedly severe bleeding for the level of platelet count. Other autoantibodies such as antiphospholipid antibodies, occur in up to 30% of patients with ITP, and these may affect platelet and vascular function, increasing rates of thrombosis. However, in general, unlike the thrombocytopenia that accompanies bone marrow failure, serious bleeding is not common in patients with ITP.

Reaching a consensus on terminology

Terminology for ITP was established by group of experts during a consensus meeting in order to help stratify disease and enable the comparison of different clinical trials. The key terminologies

Table 45.1 Consensus Terminology definitions.

Phenomenon	Terminology and definition
Otherwise, idiopathic thrombocytopenia likely due to immunological mechanism	Immune thrombocytopenia
Type	Primary Secondary (SLE, HIV, hepatitis B, etc.)
Diagnostic criterion	Requires isolated platelet count $<100\times10^9$/L
'Acute' and 'chronic' categories	'Newly diagnosed' (0–3 months), 'Persistent' (3–12 months) 'Chronic' (>12 months)
Severe ITP	Where there is clinically relevant bleeding irrespective of platelet count

are listed in Table 45.1. With an increasing repertoire of new medications, refractory disease still needs to be better defined. Chronic ITP implies disease that has been present for 12 months or more from diagnosis.

Pathophysiology

ITP is thought to be a classic organ-specific autoimmune disease and, in common with other autoimmune diseases, there is a skewing of the Th1/Th2 response towards Th1 (proinflammatory). These are disorders in which there are antibodies or cells (B cells, T cells, antigen-presenting cells or others) that react against self-antigens. These may cause disease if the target tissue is damaged. The binding of antibodies to target cells results in clearance of the antigen from the body. The normal adaptive response, such as that seen in microbial infection, results in complete removal of the non-self-antigen. In autoimmune disease, however, there is continual production and incomplete clearance of the antigen, leading to perpetuation of the immune attack. In ITP the antigen is usually a platelet glycoprotein, found on megakaryocytes and platelets.

Antiplatelet antibodies and their targets

The autoantibodies involved in ITP are generally IgG, but IgA and IgM autoantibodies have also been reported. Opsonised platelets are removed prematurely by the reticuloendothelial system via an Fc-dependent mechanism. In addition, the autoantibodies may impair megakaryocyte growth and development, platelet release and may also induce apoptosis of megakaryocytes. The overall result of this is failure of platelet production.

There are various assays for measuring antiplatelet antibodies. Looking for the presence of platelet-associated IgG is of no value since this is found in non-immune as well as immune thrombocytopenia. More sophisticated assays, such as the monoclonal antibody-specific immobilisation of platelet antigens (MAIPA) assay, has greater specificity (90%) albeit with low sensitivity (50–65%). Using MAIPA, platelet-associated IgG and antigen capture assays, several platelet antigens have been characterised. These include GPIIb/IIIa (integrin αIIbβ3 and the fibrinogen receptor) and GPIb/IX (the von Willebrand factor receptor), which appear to be the most frequently involved. Less commonly, GPIa/IIa, GPIV and GPV are involved.

However, in many patients auto-antibodies are not detected, and responses to antibody depletion treatment are inconsistent suggesting there are other mechanisms of thrombocytopenia.

T cell involvement

The role of T cells in the development of ITP is becoming clearer. That T cells are involved has been known for some time, since the autoantibodies in ITP are predominantly of the IgG subclass, and isotype switching from IgM to IgG requires T-cell help. However, some 40% of patients with chronic ITP have no detectible autoantibodies yet are thrombocytopenic and appear to have true ITP. CD8+ T cells have been linked to the pathogenesis of many autoimmune diseases, such as type 1 diabetes. Studies by Wadenvik's group first showed that in some patients with ITP, T cells interact directly with platelets, inducing platelet lysis (Figure 45.1). We have recently confirmed this and shown that expanded CD8 T cell clones are present in patients with more refractory disease. These cells could also target megakaryocytes reducing platelet production. However, it is not yet clear how cell-mediated platelet destruction contributes to the severity of disease or to the difficulty of treatment in some patients with ITP.

Thrombopoietin levels in ITP

Thrombopoietin (TPO) is the principal growth factor involved in platelet production. Plasma TPO levels are elevated in patients with aplastic anaemia, chemotherapy-induced thrombocytopenia and other marrow failure syndromes. However, in ITP, levels of TPO are normal or only modestly elevated (Figure 45.2).

The liver produces TPO and this binds to TPO receptors on platelets and megakaryocytes. The free (unbound) TPO is able

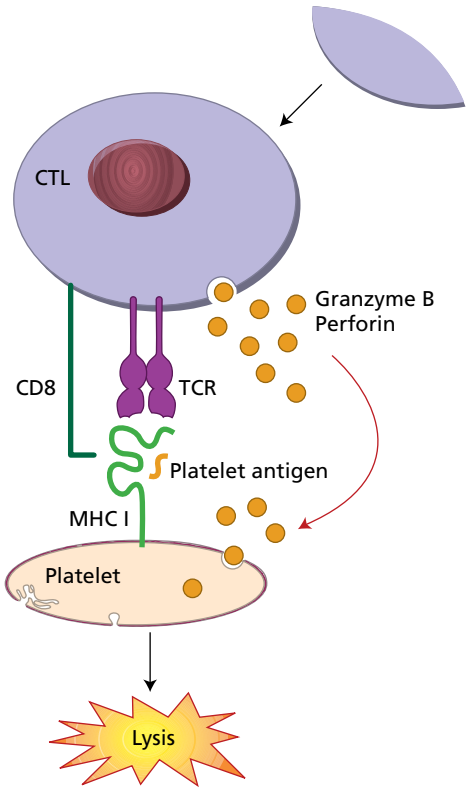

Figure 45.1 Model of cell-mediated cytotoxicity in chronic ITP. In the case of chronic ITP in the active phase, cytotoxic lymphocytes release toxic contents, such as granzyme B and perforin, and platelet lysis occurs.

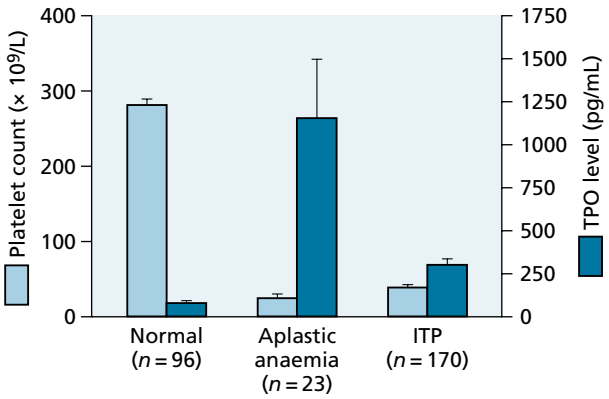

Figure 45.2 Thrombopoietin levels are usually normal or only slightly raised in patients with ITP, while in aplastic anaemia they are very raised, which can be an important test to distinguish between increased platelet destruction (such as ITP) or reduced platelet production (such as aplastic anaemia).

to stimulate the bone marrow to generate sufficient platelets to counterbalance the natural daily platelet losses through platelet senescence. If the megakaryocyte mass and platelet turnover are increased, such as in ITP, TPO is bound to the receptors on these cells, leaving little free TPO to stimulate undifferentiated bone marrow cells in patients with ITP. In addition, when older, desialylated platelets are removed in the liver, this triggers more TPO production. In ITP, there is a relative lack of TPO, which compounds the platelet losses that occur through increased destruction of platelets by the reticuloendothelial system.

Small studies also suggest that TPO levels can be used to predict response to thrombopoietin receptor agonists (TPORAs) but these assays are not widely available yet.

ITP is multifactorial

ITP has a multifactorial basis. Like other autoimmune diseases, loss of tolerance to a self-antigen alone is not sufficient to generate the autoimmune disorder. Patients probably require: (i) a specific set of genetic determinants, such as polymorphisms within major histocompatibility complex (*MHC*), *CTLA4* or other genes, (ii) dysregulation of the immune response (involving dendritic cells, T or B cells or all three) and (iii) an environmental 'trigger', which may be infectious, for example, a viral infection. Autoimmune disease arises only when all these determinants are present in an individual at the same time. This is further reinforced by the observation that self-reactive lymphocytes are commonly found in normal individuals.

In summary, ITP is much more complex than originally believed, with several mechanisms leading to thrombocytopenia (Table 45.2).

Possible triggers of ITP

The role of *Helicobacter pylori* in the development of ITP

This Gram-negative microaerophilic bacterium, the main cause of gastritis and peptic ulcer disease, has also been implicated in the development of gastric adenocarcinoma and mucosa-associated lymphoid tumours, and in some autoimmune disorders. Some studies have shown improvement in platelet counts in ITP patients positive for *H. pylori* following eradication of the bacterium. However, the data from different studies are

Table 45.2 Potential causes of thrombocytopenia in ITP.

- Autoantibody opsonisation of platelets leading to destruction by the reticuloendothelial system
- Autoantibody opsonisation of megakaryocytes, with inhibition of megakaryocyte growth, differentiation and platelet release
- Autoantibody-induced direct platelet or megakaryocyte apoptosis
- Relative thrombopoietin deficiency
- Molecular mimicry and immune complex formation
- T-cell mediated lysis of platelets

conflicting, with some centres showing a very high rate of response to eradication, while others have a low rate.

How *H. pylori* may initiate or perpetuate ITP is not known. Possibilities include molecular mimicry, where there is cross-reactivity between the antibody, the bacterium and platelet antigens.

COVID-19 and vaccine-induced ITP

During the pandemic, it became apparent that both SARS-CoV2 infection and the COVID-19 vaccines can precipitate ITP. Viral infection and the mRNA vaccines Pfizer-BioNTech usually cause transient ITP with spontaneous recovery. The ChAdOx1 nCoV-19 vaccine has been associated with more severe ITP, including haemorrhagic ITP although the number of cases per vaccine remain very rare. This is not unique to COVID-19 vaccines, as other vaccines and viral infections are also associated with ITP.

Natural history of ITP

The natural history of ITP is heterogeneous with some patients going into an early remission after steroid use, others responding to second-line therapy, and a smaller proportion developing refractory disease. There are no biomarkers to predict what type of ITP a patient will develop. While current treatments increase the platelet count, and improve the HRQoL, it is not known whether patients live longer on treatment or whether treatment alters the natural history of the disease. For many patients, ITP is a fairly minor disorder. Serious bleeding is not common and clinical sequelae of the disease are generally absent in patients with platelet counts above 30×10^9/L. There have been a few studies published looking at clinically relevant bleeding and platelet count. In normal individuals, there is a correlation between the platelet count and bleeding. The lower the platelet count, the more likely bleeding is to occur. In ITP most patients show little bleeding until the platelet count drops below 20×10^9/L. One study showed that no grade 4 bleeding occurred in patients with platelets greater than 10×10^9/L. A recent study of occult cerebral microbleeds was consistent with these findings, with patients only developing cerebral microbleeds if they had the lowest count less than 15×10^9/L.

ITP is not only a bleeding disorder. The Nordic registry has shown increased mortality in patients with ITP irrespective of bleeding. Patients with ITP also have an increased risk of developing thrombosis, and although uncommon this causes significant morbidity and mortality. Patient-reported outcome studies also report that fatigue and other HRQoL are impaired in ITP.

Diagnosis

Despite significant advances in our understanding of ITP, the diagnosis remains one of exclusion. A thorough history should be obtained, looking for diseases that might cause thrombocytopenia. The patient should be asked about bleeding during previous surgery or dentistry. The sites of bleeding should be determined.

A full physical examination should be normal, apart from the expected clinical signs associated with thrombocytopenia. In addition to the 'dry purpura' of ITP, there should be an examination of the mucous membranes, including the mouth and optic fundi looking for the presence of retinal haemorrhage. Enlargement of the liver, spleen or lymph nodes suggests an alternative diagnosis.

The laboratory investigation of ITP is straightforward. The FBC should confirm the isolated thrombocytopenia. There may be a degree of iron deficiency anaemia, but this should be in proportion to the clinical history. There should be no abnormal white blood cells or red cell fragments in ITP. If the latter are found, the underlying diagnosis may be thrombotic thrombocytopenic purpura, a disorder that is far more serious than ITP and which requires urgent treatment. Table 45.3 outlines the most useful tests in the diagnosis of ITP, along with other tests that are either of limited or no value.

Table 45.3 Investigation of suspected ITP.

Basic evaluation of ITP
- Patient history
- Family history
- Physical examination
- Full blood count
- Peripheral blood film
- Blood group (Rh) and reticulocyte count
- Direct antiglobulin test
- Quantitative immunoglobulin measurement
- Bone marrow examination*
- *Helicobacter pylori*
- HIV
- HCV

Tests that may be useful in selected cases
- Antiphospholipid antibody (including anticardiolipin and lupus anticoagulant)
- Antithyroid antibody and thyroid function
- Pregnancy test
- Antinuclear antibodies
- Viral PCR for parvovirus and cytomegalovirus
- Immunoglobulins and Lymphocyte

Tests of unproven or uncertain benefit
- Glycoprotein-specific antibody
- Thrombopoietin assay
- Reticulated platelet count
- Indirect platelet-associated IgG
- Platelet survival study
- Serum complement levels

* The need for bone marrow remains contentious and the indications for performing this test are discussed in Table 45.4.

Table 45.4 Indications for bone marrow examination in ITP.

- Failure to respond to, or relapse following, first-line therapy
- Presence of atypical clinical or laboratory features
- Before splenectomy (but see text)

Bone marrow examination

Previously, one of the mainstays of diagnosis was assessment of the bone marrow. The rationale behind this was the possibility of a patient having a marrow disorder such as leukaemia, lymphoma or infiltration. However, studies to date have shown that in patients with isolated thrombocytopenia, and with no atypical symptoms or signs, no cases of bone marrow pathology were detected. For this reason, recent guidelines do not recommend performing a bone marrow examination in all patients with ITP. If patients have unusual features such as multiple cytopenias, hepatomegaly, splenomegaly, lymphadenopathy, any clinical features suggesting the presence of a disease other than ITP, or they do not respond adequately to ITP treatments, then a bone marrow examination should be performed (Table 45.4).

Cytologically, the bone marrow in ITP generally shows normal development and maturation of all cell lines. Megakaryocyte numbers are typically normal or increased. During the clinical trials of the TPORAs, some patients developed increased reticulin fibrosis in the bone marrow. Subsequent reviews of patients with ITP who have not received any treatment have shown that bone marrow reticulin is increased in around two-thirds of patients. The increased reticulin seen in the TPORA studies is most likely due to stimulation of pre-existing reticulin.

Management

The two major international guidelines for the management of patients with ITP were updated in 2019. Both show that there are still limited data to help guide management.

In general, management is aimed to prevent major haemorrhage, the most feared event in patients with ITP. However, catastrophic bleeding is not common, and historically patients were over-treated, and the adverse effects of treatment, such as infection, were more common than bleeding symptoms. The main aim of treatment has therefore shifted away from trying to normalise the platelet count towards finding a strategy that will allow the patient to achieve a 'safe' platelet count. What constitutes a safe platelet count will vary from patient to patient, and also each patient with ITP will have differing requirements throughout their disease history. For example, a young patient with platelet count of 20×10^9/L should be safe to work and carry out normal day-to-day activities but would not be deemed safe if he or she wished to ski or undergo surgery. The safe platelet count would therefore be higher during these haemostatic challenges. The one-size-fits-all approach has failed to work over the years and has caused increased morbidity and mortality in patients due to the adverse effects associated with many of the treatments in current use.

There are many current treatments for ITP, although only a few have been approved (licensed) for this indication. Those that do have a license for ITP include corticosteroids, intravenous immunoglobulin (IVIg), intravenous anti-D, the thrombopoietin receptor agonists (TPORAs) eltrombopag, romiplostim and avatrombopag and the Spleen Tyrosine Kinase inhibitor (SYKi) fostamatinib. Rituximab also has considerable evidence in ITP but has not been submitted for licensing.

Initial treatment

First-line therapies comprise corticosteroids, IVIg and anti-D. These three treatments work fairly quickly (within 24–48 hours) and their efficacy rates are high at around 70–80% and are considered short-term treatment. The disadvantage of these and most of the other treatments is that the platelet count generally drops once the treatment is stopped. These treatments are seldom curative and must be considered palliative therapies. In addition, IVIg and anti-D are pooled blood products with their associated risks.

Second-line treatment

If patients fail to respond to first-line treatment, they may then be given a second-line drug, such as immunosuppression with azathioprine, mycophenolate mofetil or rituximab, or increasing the platelet count using a TPORA (Table 45.5).

Table 45.5 Treatment options after first-line therapy.

Non-approved second-line treatments
- Azathioprine
- Dexamethasone
- Methylprednisolone
- Ciclosporin
- Mycophenolate mofetil
- Cyclophosphamide
- Danazol
- Dapsone
- Vincristine
- Rituximab

Surgical second-line treatment
- Splenectomy

Approved second-line treatments
- Romiplostim
- Eltrombopag
- Avatrombopag
- Fostamatinib

Table 45.6 Target platelet counts for procedures.

Procedure	Target platelet count
Dentistry (non-invasive)	Any
Dentistry (fillings, local anaesthesia)	$\geq 30 \times 10^9$/L
Minor surgery	$\geq 50 \times 10^9$/L
Major surgery	$\geq 80 \times 10^9$/L

Short-term treatment

This refers to treatments lasting 2 weeks or more, which can be used when patients have a sudden drop in their platelet count leading to an unacceptably low platelet count, or when patients face haemostatic challenges such as planned surgery or dentistry, or other high-risk activity, where the main risk is excessive bleeding. Patients are generally started on treatment 1 or 2 weeks prior to the event, with regular monitoring of platelet counts. Table 45.6 shows the target platelet counts for the most common procedures.

Long-term treatment

This is required when patients have an unsupported platelet count that is too low for normal day-to-day activities. Generally, these patients will have failed other therapies or, if they responded to corticosteroids, they require unacceptably high doses to maintain a safe count. In this setting, the aim is not to achieve a specific count, but rather to move the platelet count into a 'safe' zone. This will vary from patient to patient. In general, once platelets exceed $15–20 \times 10^9$/L the risk of bleeding is low. Older individuals, or those with comorbidities or previous bleeding, will generally require a higher platelet count.

Many of the existing treatments used for long-term platelet control have known toxicities. The aim with long-term treatment is to use a treatment that has acceptable levels of toxicity, but which achieves the desired platelet count.

Thrombopoietin receptor agonists

Three TPORAs are now approved for ITP: romiplostim, a peptibody given as a weekly injection and eltrombopag and avatrombopag small molecules given as daily oral tablets. Romiplostim, eltrombopag and avatrombopag have undergone rigorous trials in adult patients with ITP both before and after splenectomy. Romiplostim and eltrombopag are also licensed for ITP in children – avatrombopag is currently in clinical trials, and met its primary end point in paediatric clinical trials. The study enrolled 75 subjects between 1 and <18 years. The primary endpoint of durable platelet response (6 out of 8 weekly platelet counts $\geq 50 \times 10^9$/L in the absence of rescue medication during weeks 5–12), was met in 28% of patients who received avatrombopag subjects in comparison with 0% of patients on the placebo arm ($p = 0.0077$, 95% CI 15.8–39.7). The efficacy rates for TPORAs are encouraging in all patients, and since they do not involve immunosuppression and are not corticosteroid-based, they appear to offer many advantages over other drugs.

From pivotal randomised clinical trials, responses to romiplostim were seen in 88% of non-splenectomised patients and in 79% of splenectomised patients. Concomitant ITP medication was reduced or stopped in 79% of subjects and there was a reduction in rescue medication. From clinical trials of eltrombopag, efficacy was reported at 79%, again with a reduction or cessation of concomitant medication in 59%, with reduction in bleeding reported at 76%. Both of these agents are now licensed for use as second-line treatment for ITP and are recommended second-line treatments in both International Consensus Guidelines and the American Society of Haematology Guidelines from 2019.

They are mostly very well tolerated. In some of the clinical trials, thrombotic events were reported in up to 6% of cases. Whether this is a treatment effect, or the increased risk of ITP is not clear. Initial concerns about the effect of long-term TPORAs on the bone marrow have not been realised.

In addition to the high efficacy, around 30% of patients treated with TPO-RAs may be weaned off the TPO-RA after 6 months if their platelet counts are stable and safe. This is termed 'treatment-free remission or TFR'. The mechanism for the TFR is not understood but there appears to be a reduction in inflammatory cytokines towards a more anti-inflammatory state.

Rituximab

This chimeric monoclonal antibody targets the CD20 antigen on B cells and is licensed for B-cell non-Hodgkin lymphoma and rheumatoid disease. Although it has not been submitted for licensing, there have been several studies of its use in ITP and other autoimmune haematological disorders including randomised controlled studies showing its efficacy in ITP. The largest review of rituximab in ITP was conducted by Arnold and colleagues, whose data suggest that around 60% of patients will respond to rituximab and approximately 40% of all patients will achieve a complete response. The responses are bimodal, with an early phase within 1–2 weeks and a second peak at about 6–8 weeks. Response duration varies from 2 months in partial responders to 5 years or more in about 15–20% of initially treated patients. A randomised controlled trial of rituximab versus placebo did not show any reduction in the rate of long-term treatment failure with rituximab, despite higher response rates and longer duration of response. A number of studies have suggested that women with a shorter duration of disease have better responses.

There are some safety concerns with rituximab and it should be used with caution in any patient who has positive hepatitis B core antibody status, since hepatitis B may be re-activated, and anti-viral prophylaxis is recommended for these patients. Adverse events associated with rituximab are usually mild or moderate, with a low incidence of infections. Severe infectious complications have been reported, although they are rare.

Fostamatinib: spleen tyrosine kinase inhibitor

Fostamatinib is the first spleen tyrosine kinase inhibitor to be licensed for use in ITP in the US in 2017 and in Europe in 2019 for the treatment of patients with ITP who have failed prior treatments. In the randomised controlled studies, the primary endpoint of stable platelet count $>50\times10^9$/L on 4 of 5 visits during weeks 14–24 was achieved in 18% of patients on fostamatinib and in 2% of patients on placebo; an overall response rate (a platelet count $\geq50\times10^9$/L on one or more visits in the first 3 months) was achieved in 43% of patients on fostamatinib and in 14% of patients on placebo. Platelet responses were long-lasting in the long-term extension study. Patients in these studies were mostly refractory to many other therapies. Ad-hoc analysis of the clinical trial showed higher response rates in patients who were within the first year of diagnosis. Interestingly there were no thrombotic events in the clinical trials. Adverse effects of treatment included gastrointestinal effects and hypertension.

Mycophenolate mofetil

Mycophenolate (MMF) is the most commonly used non-licensed immunosuppressive treatment in ITP. Most chronic studies show about 30% efficacy. A recent open-label randomised study showed lower relapse rates in patients who were randomised to receive MMF in addition to steroid therapy. Further studies are needed to compare immunosuppression with TPORAs as second-line therapy. MMF is contraindicated in pregnancy due to fetal toxicity.

Novel therapies in development

A number of classes of therapy are in late-stage clinical development. These target specific cells or molecules involved in ITP pathogenesis (see Figure 45.3). These agents include: anti neonatal Fc receptor drugs, Bruton tyrosine kinase inhibitors and anti-complement agents.

Anti-FcRn

The neonatal Fc receptor modulates the half-life of IgG and albumin by binding to IgG and releasing it from endothelial endosomes. As well as recycling normal IgG, the FcRn also recycles pathologic IgG. Blocking the FcRn causes IgG breakdown within the endosomes.

From recent clinical studies efgartigimod was well tolerated with a response rate of around 38%. Data thus far would appear to indicate that although the IgG levels fall this does not to increase the risk of infection.

Bruton tyrosine kinase inhibitors

Bruton tyrosine kinase, like syk, is involved in Fcγ signalling and is another potential target for ITP therapy. BTK is necessary for B cell development, function and antibody production. Several BTKIs have been developed for diseases such as chronic lymphocytic leukaemia (91). However, BTKIs have been reported to inhibit platelet aggregation which may result in bleeding, which is a concern in ITP. Although this was reported with ibrutinib it is not the case with rilzabrutinib.

Results from a recent Phase 2 study of rilzabrutinib in adult patients with relapsed or refractory ITP have been published. Fifty-nine adults, who had at least one prior response to treatment and a platelet count $\leq30\times10^9$/L, were given oral rilzabrutinib at 200 or 400 mg daily or 300 or 400 mg twice daily. The highest response rate was seen in the 400 mg twice daily group. Of 44 patients on this dose, 39% achieved the primary endpoint (two or more platelet counts $\geq50\times10^9$/L without the use of rescue therapy). Of the 33 patients who completed the study for more than 12 weeks, 17 of these (52%) responded. Of the responders half of these (50%) achieved a platelet count $\geq30\times10^9$/L by day 8. Rilzabrutinib was well tolerated with adverse events of Grade 1 or 2 only.

Anti-complement agents

Complement is believed to be involved in the pathogenesis of ITP for some patients. However, the contribution made by complement to ITP is not clearly understood. Early phase studies with sutimlimab, a monoclonal IgG C1s inhibitor, have been conducted. The patients treated were adults with ITP for >1 year and an inadequate response to ≥2 prior treatments. A total of 12 patients were treated of which 42% responded (platelet count $\geq50\times10^9$/L). Four patients (33%) achieved a platelet count of $\geq50\times10^9$/L for ≥70% of their study visits. One-third of patients responded in 2 days or less. No treatment-related adverse events were noted. Another complement inhibitor, iptacopan, a selective Factor B inhibitor, is currently undergoing Phase 2 clinical trials in ITP.

Other treatments in development

A number of other molecules are being developed. This includes other TPO receptor agonists lusutrombopag and heterombopag, as well as an anti-CD 38 molecule (daratumumab), and others. Anti-CD38 treatment may be useful for some with refractory ITP which may be caused by long-lived plasma cells. The proteasome inhibitor, bortezomib, has been used anecdotally in refractory ITP with variable results. However, this agent is not currently licensed for this indication.

Splenectomy

Splenectomy is a surgical option for patients who have relapsed after treatment with first- and second-line drugs. All guidelines recommend deferring splenectomy until at least 12 months from diagnosis. The procedure increases the lifespan of

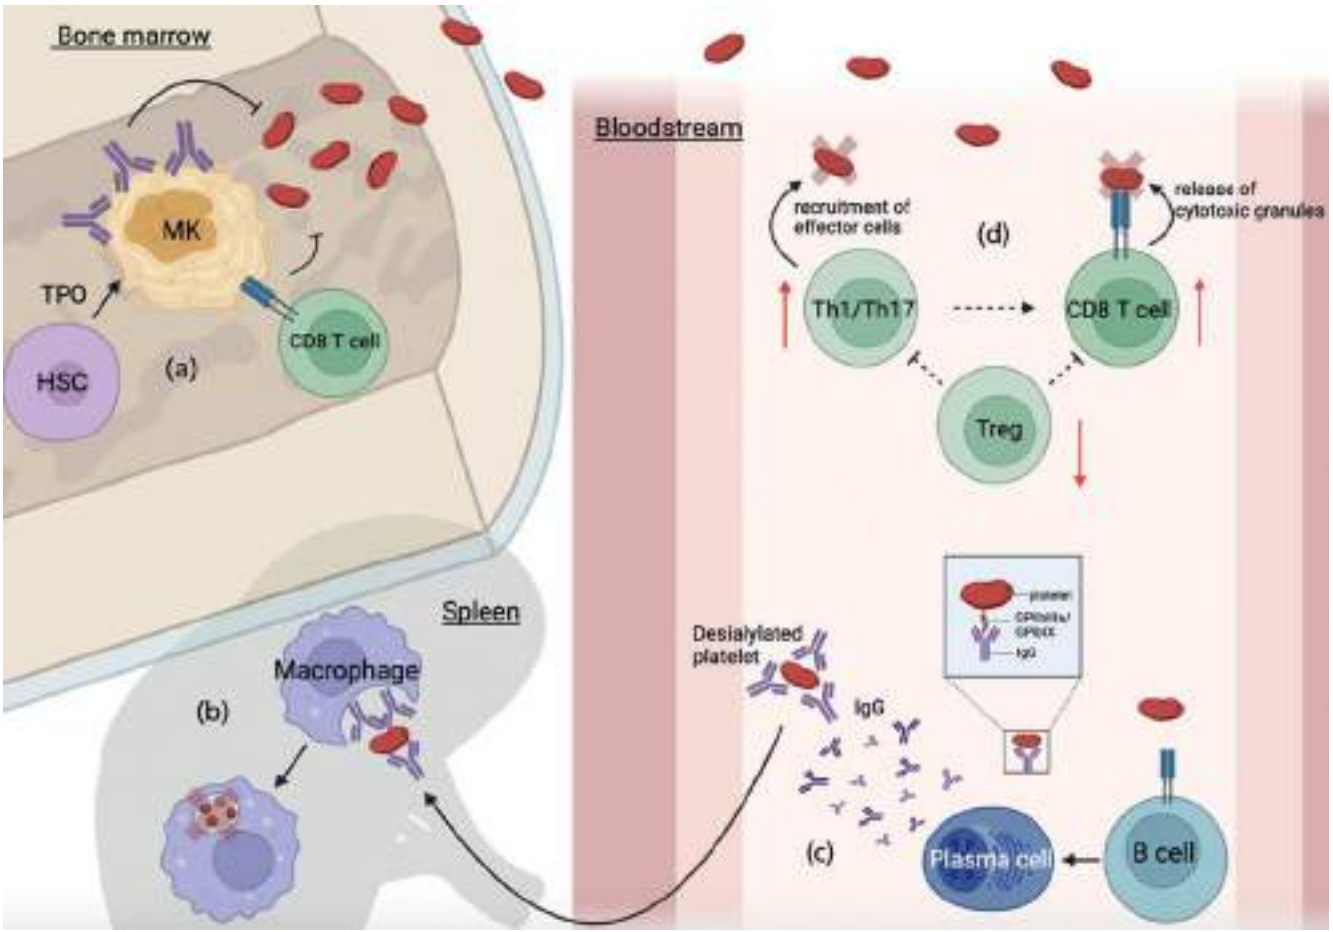

Figure 45.3 Pathogenesis of ITP. (a) Platelets are produced by megakaryocytes (MKs), which are derived from haematopoietic stem cells (HSCs) in the bone marrow. The process of thrombopoiesis is regulated by growth factors and cytokines, primarily thrombopoietin (TOP). (b) As platelets age, they become desialylated, marking them for clearance by the reticuloendothelial system, primarily in the spleen and liver. (c) In conditions like immune thrombocytopenia (ITP), platelets are destroyed due to autoantibodies that bind to abundant glycoproteins, particularly (GPIIb/IIIa and GPIb/IX) on both platelets and MK. The coating of autoantibodies on MKs interferes with their maturation, leading to impaired platelet release. Meanwhile, autoantibody-opsonised platelets are desialylated and subsequently phagocytosed by splenic macrophages via their Fcγ receptors (FCγRs). (d) In addition to autoantibody-mediated platelet destruction, abnormal T cell responses have been reported in patients with ITP. CD4+ T cell responses are skewed towards effector T helper (Th)1 and TH17 lineages and away from regulatory T cells (Tregs), leading to the breakdown of immune tolerance. Elevated levels of cytotoxic CD8+ T cells in ITP can directly induce platelet and MK apoptosis through T cell receptor (TCR)-mediated release of cytotoxic granules. (*Source:* Created with BioRender.com).

antibody-coated platelets and may reduce antibody production. Responses are seen in about two-thirds of patients, who achieve a normal platelet count, and the response is often sustained with no additional therapy for at least 5 years. Even patients who do not have a complete response may still expect a partial or transient increase in platelet count. Around 14% of patients do not respond and approximately 20% of responders will relapse months or years later.

Splenectomy has a low but definite peri- and post-operative morbidity and mortality but the rates have been much reduced by the use of laparoscopic splenectomy.

Predicting the response to splenectomy

Clinicians have long sought possible predictors of response to splenectomy. Potential predictors have included response to oral corticosteroids, IVIg and others. Indium-labelled autologous

platelet scanning appears to be the most sensitive predictor of response to splenectomy. However, indium scanning is not available in every hospital and is limited to only a few centres worldwide.

Prevention of infection after splenectomy

Splenectomised patients are at long-term risk for opportunistic postsplenectomy infection (OPSI) with encapsulated bacteria (see also Chapter 5). OPSI is often rapidly progressive and has a poor outcome. The main organisms responsible for sepsis in splenectomised patients are pneumococci (50%), meningococci and *Haemophilus influenzae*.

In order to prevent OPSI, patients should be given prophylactic polyvalent pneumococcal vaccine at least 4 weeks prior to, or 2 weeks after, splenectomy, with re-vaccination according to local guidelines. *H. influenzae* b and meningococcal C conjugate vaccinations should also be administered prior to splenectomy. Re-vaccination in susceptible individuals for *H. influenzae* should be administered according to local guidelines.

In the UK, the Chief Medical Officer advises the long-term use of oral antibiotics in the form of phenoxymethylpenicillin 250 mg twice daily, or equivalent, or erythromycin 250 mg twice daily if the patient is allergic to penicillin. However, the need for lifelong antibiotic prophylaxis remains unproven.

Patients with refractory ITP

The Terminology Consensus document published in 2009 defines refractory ITP as that where the patient has undergone splenectomy which has failed or relapsed, and who has 'severe' ITP (clinically relevant bleeding) or a risk of bleeding. Some 20% or more of adult patients fall into this category. Clinically, patients with refractory ITP pose a major challenge since, by definition, they are resistant to many of the treatments in current use. They often have low platelet counts, in addition to bleeding that is difficult to control since the disease is unresponsive to conventional therapies.

Possible options for patients with refractory ITP are combinations of treatment including TPORAs and immunosuppression and combined chemotherapy – although this is often poorly tolerated. Many patients may not need treatment, even with low platelet counts.

ITP in children

Children with ITP are treated based on clinical bleeding, quality of life and not just platelet count. Severe bleeding is uncommon in children with ITP, even when the platelet count is very low ($<10\times10^9$/L). The incidence of intracranial haemorrhage (ICH) in children with ITP is around 0.1–0.5%. As with adult ITP, there is no method to predict which children will develop ICH. In general, however, ICH is commoner in patients with refractory or resistant disease than at initial presentation. Investigation of childhood ITP is similar to that in adults, although the incidence of *H. pylori* infection is much lower and there is no need to screen for this.

'Watch and wait' policy

Around 70% of children with acute ITP do not have significant bleeding symptoms and can be managed without drug therapy. Admission to hospital should be reserved for children with clinically significant bleeding, such as severe epistaxis or gastrointestinal or other bleeding. Most children with minor, mild or moderate symptoms can be safely managed in the outpatient setting. The emphasis is towards treating symptoms rather than platelet counts, since the platelet count is a surrogate marker and does not accurately predict clinical outcome.

General measures for persistent and chronic ITP in children

Many children stabilise with an adequate platelet count and have no symptoms unless injured. In children who are less than 10 years of age at diagnosis, spontaneous remission is very likely to occur, and expectant management can continue depending on the risk of bleeding and the degree of activity restriction of the child. The onset of menstruation may be problematic and can be managed with antifibrinolytic agents and the combined contraceptive pill.

Management of chronic ITP in childhood should be tailored to each individual child and situation, and therapy should be effective and it should not carry more risk than the untreated condition.

Treatment options in childhood ITP

Children with severe bleeding symptoms should be treated. Treatment should also be considered in children with moderate bleeding or those at increased risk of bleeding and for patients whose lifestyle is restricted due to ITP.

First-line treatment in children

If treatment is deemed to be required, options include IVIg, IV anti-D and corticosteroids.

IVIg raises the platelet count in more than 80% of children and does so more rapidly than steroids or no therapy. Transient side-effects are seen in 75% of children. Intravenous anti-D immunoglobulin can be given to Rh(D)-positive children as a short infusion and is useful in the outpatient setting. Mild extravascular haemolysis is common, with a mean drop in haemoglobin of 10 g/L. Like IVIg, anti-D is a pooled blood product, but it is derived from a smaller donor pool. The safety profile of anti-D is good with no reported transmission of infection to date. However, there have been reports of severe intravascular haemolysis leading to disseminated intravascular coagulation, most of which have been fatal. Prednisolone at a dose of 1–2 mg/kg daily for a maximum of

14 days is effective in around 75% of children (platelet count $>50\times10^9$/L) within 72 hours. More prolonged high-dose corticosteroid regimens are associated with increased toxicity.

Second-line treatment for paediatric ITP

Thrombopoietin receptor agonists (TPORAs) are the recommended next line of treatment for children who have significant bleeding, or who develop chronic ITP. Immunosuppressive treatments including rituximab and MMF can be considered in those who are refractory to TPORAs and continue to have symptoms.

ITP in pregnancy

Thrombocytopenia occurs in 5% of pregnancies, but most of these cases are gestational rather than immune-mediated (see also Chapter 53). The diagnosis of ITP involves the exclusion of other causes of thrombocytopenia during pregnancy. Patient history, physical examination, blood count and blood film examination are used in non-pregnant patients. The work-up of a pregnant patient with ITP is essentially the same as that of a non-pregnant patient. There are some conditions specific to pregnancy and these should be considered when investigating a pregnant patient with thrombocytopenia (Table 45.7).

Laboratory investigation of ITP in pregnancy

ITP in pregnancy, as with other types of ITP, is a diagnosis of exclusion. All investigations carried out in pregnancy are aimed at excluding conditions that may result in thrombocytopenia. Some disorders such as thrombotic thrombocytopenic purpura and HELLP syndromes require urgent diagnosis and treatment since the mortality rates are high (Table 45.8).

Management of ITP in pregnancy

There should be close collaboration between the obstetrician, haematologist, obstetric anaesthetist and neonatologist. Treatment is largely based on the risk of maternal haemorrhage. Throughout the first two trimesters, treatment is initiated when the patient is symptomatic and/or when platelet counts fall below 20×10^9/L, or when it is necessary to produce an increase in platelet count to a level considered safe for procedures such as obstetric delivery or epidural anaesthesia. Patients with platelet counts of $20–30\times10^9$/L or more do not require routine treatment.

Table 45.7 Causes of maternal thrombocytopenia in pregnancy.

- Gestational thrombocytopenia
- Pre-eclampsia, HELLP syndrome and disseminated intravascular coagulation
- Folate deficiency
- Massive obstetric haemorrhage
- Acute fatty liver

HELLP, haemolysis, elevated liver enzymes and low platelets.

Table 45.8 Investigation of suspected ITP in pregnancy.

- Coagulation screening (prothrombin time, PT)
- Activated partial thromboplastin time (APTT)
- Fibrinogen assay
- Liver function tests including bilirubin, albumin, total protein, transferases, γ-glutamyl transferase and alkaline phosphatase
- Antiphospholipid antibodies, including anticardiolipin antibodies and lupus anticoagulant
- SLE serology
- Review of the peripheral blood film
- Reticulocyte count
- Bone marrow examination: not required to make the diagnosis of ITP in pregnancy

Delivery

A platelet count above 50×10^9/L is generally acceptable for standard vaginal or caesarean delivery. For epidural anaesthesia, a platelet count of 75×10^9/L is required, although this is not evidence-based.

Treatment options in pregnancy

First-line treatment options for ITP in pregnancy are similar to those of other adult ITP patients, namely corticosteroids and IVIg. There is limited evidence for the use of intravenous anti-D, splenectomy, azathioprine, rituximab and TPORAs.

Other agents, such as mycophenolate should not be used in pregnancy because of known teratogenicity.

Corticosteroids

These are the most cost-effective option. Prednisolone is initially given at a dose of 10–20 mg/day and may then be adjusted to the minimum dose that produces a haemostatically effective platelet count. At least 90% of the administered dose of prednisolone is metabolised in the placenta by 11β-hydroxlase, but high doses may have an effect on the fetus.

Intravenous immunoglobulin

If prolonged high-dose steroid therapy is required or significant side-effects occur, or a rapid platelet increase is required, IVIg should be considered. The conventional doses of IVIg and likely response rates are similar to those seen in non-pregnant patients.

Options for maternal ITP refractory to first-line treatment

As with non-pregnant adults, combining first-line treatments in the refractory patient may be appropriate in the weeks prior to delivery. High-dose methylprednisolone (1000 mg), possibly in

combination with IVIg or azathioprine, has been suggested as a treatment for pregnant patients' refractory to oral corticosteroids or IVIg. Azathioprine has been used for many years in the post-transplant setting and this drug appears to be safe in pregnancy, though the response is generally slow. Splenectomy in pregnancy is rarely required, but if essential is best carried out in the second trimester.

Rituximab has been used during pregnancy in patients with ITP and with other autoimmune disorders and appears safe when used in the second trimester. Both azathioprine and rituximab can help to reduce the amount of steroids used.

Increasing case reports have shown safety and efficacy of TPORAs in the third trimester in patients with very refractory disease but should be used with caution.

Management of the neonate (of mothers with ITP)

Thrombocytopenia in the neonate (from mothers with ITP) accounts for 3% of all cases of thrombocytopenia at delivery. The fetal or neonatal platelet count cannot be reliably predicted from the maternal platelet count. After delivery, a cord blood platelet count should be determined in all cases. Intramuscular injections (such as vitamin K) in the fetus should be avoided until the platelet count is known. Those infants with subnormal counts should be observed clinically and haematologically, as the platelet count tends to fall further to a nadir between days 2 and 5 after birth.

CHAPTER 46

Thrombotic thrombocytopenic purpura (congenital and acquired) and haemolytic–uraemic syndrome

46

Pier Mannuccio Mannucci, Massimo Cugno and Flora Peyvandi

Angelo Bianchi Bonomi Hemophilia and Thrombosis Center, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Università degli Studi di Milano, Milan, Italy

Thrombotic thrombocytopenic purpura (TTP) was first described in 1924 by Moschcowitz in a 16-year-old girl who died after an acute illness presenting with a pentad of signs and symptoms (anaemia, thrombocytopenia, fever, hemiparesis and haematuria). At postmortem examination disseminated thrombi, principally made of platelets, were found in the terminal circulation of multiple organs. Over the next three decades, other cases were described, more frequently but not exclusively in women, occurring alone (idiopathic) or in association with other diseases of autoimmune, infectious or neoplastic nature or with drug intake and during pregnancy. It was also understood that thrombocytopenia was caused by platelet consumption due to the widespread deposition of thrombi in the microcirculation and that anaemia was due to intravascular haemolysis following the mechanical fragmentation of red cells (schistocytes) in blood forced to flow through partially occluded vessels.

Thirty-one years after Moschowitz, Gasser described a syndrome called haemolytic–uraemic syndrome (HUS). In common with TTP, HUS was characterised by mechanical haemolytic anaemia, consumptive thrombocytopenia and microvascular thrombosis, but differed because there were minimal neurological symptoms but severe renal damage with uraemia, often heralded by episodes of bacterial haemorrhagic enterocolitis. Subsequently, it became apparent that a clear distinction between the two syndromes was difficult. Although thrombocytopenia, anaemia and multiorgan ischaemic symptoms due to disseminated thrombus formation in the terminal circulation were common features, the prevalence of neurological over renal symptoms could not clearly differentiate TTP from HUS and vice versa. The term thrombotic microangiopathy (TMA) was then proposed, meant to emphasise the common pathology of the two syndromes with no implication of the prevalence of neurological or renal symptoms.

Even though it had been postulated that in TTP disseminated thrombus formation in the microcirculation was due to the presence of substance(s) that aggregated platelets intravascularly, the putative aggregating agent remained elusive until 1982, when Moake and colleagues demonstrated that the plasma from 4 patients with TTP contained ultralarge, highly thrombogenic forms of the multimeric glycoprotein von Willebrand factor (VWF), a major adhesive moiety contained in endothelial cells, platelets and plasma. VWF multimers of particularly high molecular weight (ultralarge) bind avidly to the platelet receptor glycoprotein (GP)Ib-IX-V and aggregate platelets in conditions of high shear stress such as those occurring in the microvascular beds. Accordingly, ultra-large VWF was postulated to be the aggregating agent involved in the formation of thrombi in the microcirculation of TTP patients.

It remained to be explained why normally absent ultra-large multimers were present in the plasma of TTP patients. Even though the deficiency or dysfunction of one or more enzymes physiologically disposing of them had been postulated, it was

not until the late 1990s that the research groups led by Furlan and Tsai independently showed that the link between ultra-large VWF multimers and TTP was a metal ion-dependent plasma metalloproteinase of 190 kDa, identified in 2001 by Zheng and colleagues as a new member (the 13th) of the ADAMTS (*A* *D*isintegrin *A*nd *M*etalloprotease with *T*hrombo*S*pondin type-1 repeats) family of metalloproteinases (Figure 46.1).

The physiological function of this protease, contained in plasma and platelets, is to reduce the size of VWF by cleaving ultra-large multimers as soon as they are secreted from endothelial cells (Figure 46.2), thereby avoiding their presence in plasma leading to *in vivo* platelet aggregation and heightened thrombus formation. Most importantly, both the investigators made the seminal and still cogent observation that ADAMTS13 was deficient in the plasma of TTP patients but not in those with HUS. This observation challenged the unitarian theory of TTP and HUS as different clinical manifestations of the same disease mechanism (TMA) and generated the current views that TTP is due to very low plasma levels of the VWF-cleaving protease whereas HUS, characterised by moderately reduced to normal plasma levels of the protease, is often mechanistically related to alterations of components of the complement system. Thus, TTP and HUS are different diseases, even though there is some degree of overlap of signs and symptoms owing to the common pathology of disseminated thrombotic microangiopathy. Accordingly, an accurate differential diagnosis is warranted, because different first-line therapies are currently employed for these life-threatening diseases (plasma exchange and the VWF inhibitor caplacizumab for TTP and the complement inhibitor eculizumab for the atypical, complement-mediated forms of HUS).

Thrombotic thrombocytopenic purpura

TTP is a rare disease with an estimated yearly incidence of approximately five cases per million, even though greater awareness and improved diagnostic facilities give the impression that incidence is currently increasing. *Congenital TTP*, also known as Upshaw–Schulman syndrome, caused by mutations in the gene encoding ADAMTS13 and transmitted as an autosomal recessive trait, is often but not exclusively clinically manifested at birth or during childhood. *Acquired TTP* (preferably identified as immune-mediated TTP) is due to the development of autoantibodies that inactivate or bind ADAMTS13. Mortality of both TTP types was very high (80–90%) until plasma exchange

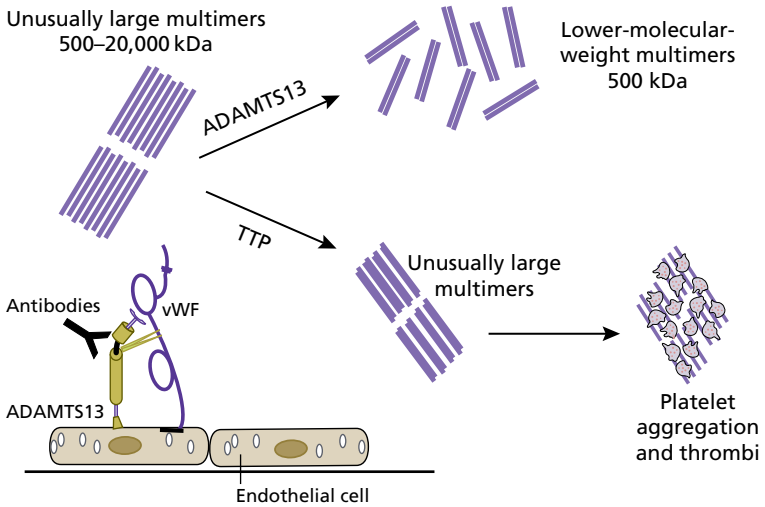

Figure 46.2 Pathophysiology of TTP. VWF is secreted from endothelial cells in the form of ultra-large multimers that anchor to endothelial cell surfaces but are also released into the circulation. ADAMTS13 cleaves a Tyr–Met bond in the A2 domain of VWF, thus severing the ultra-large multimers. The inherited or acquired deficiency of ADAMTS13 leads to failure of VWF cleavage and thus to the persistence in plasma and onto endothelial cells of ultra-large multimers, which aggregate platelets, especially in conditions of high shear forces.

(PEX) was introduced for treatment but is still high (10–20%), despite the dramatic improvements recorded after the adoption of this procedure. Because of the wide spectrum of presenting symptoms and associated comorbid conditions, cases of TTP may be initially seen by a variety of physicians other than haematologists – such as neurologists, nephrologists, oncologists and gynaecologists – and this sometimes hinders the prompt recognition of the disease.

Pathology and mechanism of TTP

The pathological basis of both congenital and acquired TTP is the disseminated formation in the microcirculation of platelet thrombi, associated with relatively little endothelial cell injury and fibrin content but abundant intrathrombus VWF. Microthrombi are found in multiple organs (mainly brain, kidney, in myocardium causing sudden death, adrenal gland, digestive tract and pancreas) and lead to multiorgan failure, whereas thrombi in large arterial and venous blood vessels are usually lacking. The current mechanistic model implies that endothelial cells, perturbed in the context of varied triggering conditions (Table 46.1), secrete greater amounts of ultra-large VWF multimers that, in situations of congenital or acquired ADAMTS13 deficiency, remain uncleaved and aggregate platelets in conditions of high fluid shear stress, resulting in massive microvascular thrombosis, ischaemic organ damage, consumptive thrombocytopenia and mechanical haemolytic anaemia (Figure 46.2).

Congenital TTP

Congenital TTP is very rare and represents no more than 4% of all TTP cases with an annual incidence of less than 1 per million. It more often occurs early after birth or during infancy, although the disease may become clinically manifest in adulthood at the time of infections or pregnancy. Congenital TTP is caused by homozygous or more frequently double heterozygous biallelic mutations in the *ADAMTS13* gene (located on chromosome 9q34) that affect protein secretion or function. According to the International Hereditary TTP Registry, more than 200 mutations have been identified to date. Their location on *ADAMTS13* reveals no common hotspots, even though 75% of the missense mutations are in the gene portion that encodes the N-terminal domain of the molecule. The majority of mutations are missense and the remaining are nonsense, splice-site and frameshift variants that lead to the formation of truncated forms of the protease. Of the mutations characterised by means of *in vitro* expression studies, the majority affect ADAMTS13 biosynthesis, intracellular trafficking and secretion and/or proteolytic activity.

Notwithstanding the consistent hallmark of severe ADAMTS13 deficiency unaccompanied by inhibitory antibodies, clinical presentation is variable, with between-patient differences in terms of age of onset, severity, number of relapses and need for long-term prophylactic replacement therapy (see more below). The type of gene mutation may account for some of this heterogeneity and influence phenotype severity: mutations in the portion of the gene encoding the N-terminal domains of the protease may be associated with more severe disease in terms of earlier age at first episode and higher rate of recurrence. Pertaining to the potential triggers of acute episodes, conditions such as pregnancy and infections are believed to act by inducing an increase in VWF levels exceeding the levels that tiny residual amounts of protease activity are normally able to dispose, leading to the precipitation of acute TTP episodes.

Table 46.1 Underlying conditions and diseases associated with immune-mediated TTP.

- Pregnancy and postpartum
- Infections (particularly HIV)
- Drugs (quinine and quinidine, clopidogrel, cyclosporin, interferon-α, statins)
- Chemotherapy (mitomycin, cisplatin, gemcitabine)
- Organ transplantation
- Autoimmune disease (lupus erythematosus, rheumatoid arthritis, scleroderma)
- General and cardiac surgery

Acquired TTP

Immune-mediated TTP accounts for the great majority of clinical cases and occurs mainly in adults, often as a primary disease in the absence of any obvious trigger or comorbidity. However, it can also arise in association with such conditions as immune-mediated diseases, infections, drug intake, pregnancy, sepsis, tumours and organ transplantation (Table 46.1). Acquired TTP is due to the development of autoantibodies that inhibit the enzymatic activity of ADAMTS13 and/or bind the protease, thus leading to its accelerated plasma clearance through opsonisation and/or other mechanisms. Anti-ADAMTS13 autoantibodies are usually of the IgG class, although in a few cases, they are of the IgA and/or IgM isotype. Epitope mapping of anti-ADAMTS13 showed that in the majority of cases they are polyclonal antibodies of the IgG4 subclass, with a primary epitope in the Cys-rich spacer domain of the protease that is essential for efficient VWF-cleavage activity and crucial for the interaction between the protease and its substrate. However, cases of autoimmune TTP are also observed in patients with IgG molecules that react with the TSP1 2–8 and CUB domains of ADAMTS13 (Figure 46.1). Ultra-large VWF multimers are not constantly detected in patient plasma, perhaps because of an imbalance between their release in plasma from endothelial cells and heightened binding to platelets, so that larger multimers may be even lacking in plasma.

Clinical and laboratory findings in TTP

The presence of both consumptive thrombocytopenia and mechanical haemolytic anaemia is essential for a clinical diagnosis of both congenital and acquired TTP. Platelet count is very low in the acute phase, with values of 30×10^9/L or less. Signs of mechanical haemolytic anaemia (haematocrit usually <20%) include the presence of schistocytes on peripheral blood smears, reticulocytosis (>2.5%), high indirect bilirubin (>2mg/dL), very low or unmeasurable haptoglobin and negative direct Coombs test. High serum lactate dehydrogenase (LDH), usually in excess of 1000 U/L, is a sensitive albeit non-specific sign of red cell destruction and tissue necrosis due to microthrombotic organ ischaemia and is useful to monitor disease evolution. The main presenting clinical features and signs in acute TTP are in Table 46.2. Neurological symptoms (coma, stroke, seizures or focal signs such as motor deficits and aphasia) typically fluctuate in presentation and severity as a result of the ongoing formation/clearance of thrombi in the cerebral microcirculation. Other neurological symptoms (such as headache, blurred vision, ataxia or mental status changes) are less typical. Chest and abdominal pain are also frequent. However, in the majority of cases disease onset is characterised by non-specific signs and symptoms such as fatigue, nausea and fever. Even though the majority of patients with TTP have serum creatinine levels no higher than 2.0 mg/dL, signs of renal involvement such as microscopic haematuria and mild proteinuria are frequent. There is little or no alteration of the coagulation and fibrinolysis systems, even though D-dimer plasma levels may be moderately increased.

ADAMTS13 laboratory testing

Measuring ADAMTS13 in plasma is currently possible owing to the availability of laboratory assays of enzyme activity. These were initially based on the degree of degradation of plasma-derived or recombinant VWF by ADAMTS13 contained in test plasma, but now the most widely used assays are based upon synthetic VWF peptides containing the protease cleavage site. All available assays measure ADAMTS13 activity in static conditions and thus fail to reflect the *in vivo* physiological blood flow conditions necessary for optimal protease activity.

- The current use of peptides as FRET (fluorescence resonance energy transfer) substrates instead of full-length VWF in enzyme immunoassays may fail to detect a few ADAMTS13 deficiencies, since these assays measure the metalloprotease activity independently of the exosite interactions with other VWF domains. Similar problems may occur when ADAMTS13 autoantibodies develop against these exosites.
- Activity assays are often available only in specialised laboratories and usually not in an emergency time frame.
- Immunoenzymatic assays which measure plasma ADAMTS13 antigen usually give low levels, but are of limited clinical value, because they measure only the immunoreactive protein and not the protease functional activity.
- With regard to the laboratory detection of autoantibodies, most of them inhibit the enzymatic activity of ADAMTS13, so that they can be titrated *in vitro* by classical mixing studies, using dilutions of mixtures of serially diluted plasma from patients and normal individuals. Direct antibody Western blotting and ELISA are also available.

Clinical applications of ADAMTS13 assays

Unmeasurable or very low plasma levels of enzymatic activity (<10%) are required to unequivocally establish a diagnosis of inherited or acquired TTP (Table 46.3). The detection of anti-ADAMTS13 helps to distinguish congenital from acquired TTP and offers a guide to disease prognosis and treatment of the immune-mediated forms with immunosuppressive drugs. After remission from an acute TTP episode approximately one-third or more patients develop chronic recurrent disease, particularly those who present with unmeasurable ADAMTS13 activity (Table 46.3) and still detectable anti-ADAMTS13 autoantibodies during first remission.

Table 46.2 Presenting clinical symptoms and signs in acute TTP.

Thrombocytopenia	Epistaxis, bruising, petecchiae, microscopic haematuria
Neurological symptoms – often fluctuating	Confusion, headache, paresis, seizures and aphasia, dysarthria, visual problems, fatigue
Fever (>37.5 °C)	Not constantly present
Jaundice	Resulting from mechanical haemolytic anaemia
Renal	Proteinuria, microhaematuria
Cardiac	Chest pain, heart failure, hypotension
Gastro-intestinal tract	Abdominal pain, nausea

Table 46.3 Clinical applications of *ADAMTS13* testing in acute TTP and aHUS.

Stage	ADAMTS13 deficiency (<10%)	Diagnostic implications
Acute phase	Yes	TTP is confirmed
	No	TTP is excluded, suspect aHUS or other TMAs
Remission	Yes	Risk of relapse

Recently the International Society on Thrombosis and Haemostasis (ISTH) developed TTP guidelines which apply rigorous methodologic standards to the diagnosis and management of adult patients with a suspected TTP. In particular, the ISTH guidelines on TTP diagnosis pointed out the importance of ADAMTS13 testing, emphasising that the use of the clinical scores (such as the French and PLASMIC scores) supports clinical judgement in differential diagnosis and decision for treatment but cannot replace *ADAMTS13* testing. The ISTH guidelines also emphasise the importance of providing clinicians with a timely access to measurement of plasma ADAMTS13 activity (and inhibitor or anti-ADAMTS13 IgG) for the optimal management of newly diagnosed patients with TTP. They also concluded that the management of TTP relapses in a previously diagnosed patient could be safely undertaken on clinical grounds with no need for a confirmatory *ADAMTS13* test.

Differential diagnosis with HUS

Typical HUS is usually easily distinguishable from TTP owing to the occurrence of diarrhoeal prodromes and the presence of more frequent and severe symptoms of renal impairment. It is sometimes more difficult to distinguish TTP from atypical HUS, notwithstanding the higher prevalence of neurological symptoms in the former and more severe renal failure in the latter (see more below). However, reliance on prevalent organ symptoms is misleading, because approximately half of cases with atypical HUS have neurological symptoms and a few of them may present, at least initially, with normal creatinine. Other issues of differential diagnosis materialise with conditions that present themselves as TMAs, all being characterised by consumptive thrombocytopenia and mechanical haemolytic anaemia (Table 46.4)

A severe deficiency of ADAMTS13 unequivocally distinguishes TTP from HUS and other TMAs (Table 46.3). However, because results of *ADAMTS13* testing often have a turnaround time incompatible with the early application of a life-saving therapy such as PEX, efforts were made to identify simple laboratory data that predict before PEX which subjects are more likely to be severely deficient in ADAMTS13 activity and thus have TTP. Pre-treatment platelet count lower than 30×10^9/L and creatinine less than 2.3 mg/dL predict severely deficient ADAMTS13 activity (<10%) with a sensitivity of 98%, specificity 48%, positive predictive value 85%, negative predictive value 93%. These criteria led to the development of the so-called French Score, widely used in clinical practice for its simplicity and clinical value to proceed to implement PEX. More recently, the PLASMIC score added to these simple biomarkers other positive or negative data recorded at presentation, such as the degree of haemolysis epitomised by unmeasurable haptoglobin, a mean corpuscular volume lower than 90 fL, a prothrombin time INR <1.6, no active cancer or history of organ transplantation. The ensuing scores are used to define cases at higher, intermediate or low risk of being TTP (Table 46.5). A PLASMIC score of 5 or more has a diagnostic sensitivity of 99% and specificity of 57%. On the other hand, moderate or mild thrombocytopenia and severe renal insufficiency almost eliminate the likelihood of severe ADAMTS13 deficiency, indicate that the diagnosis is not TTP and lead to suspicion of HUS in patients presenting with TMA. However, as emphasised in the ISTH guidelines, the final confirmation of TTP diagnosis requires *ADAMTS13* testing. Even though a dysregulation of the complement system is the main disease mechanism in atypical HUS, low C3 and normal C4 serum levels are seldom detected in these patients, thus limiting the diagnostic usefulness of these simple and largely available tests. The identification of mutations in the genes encoding complement proteins (factor H, factor I, membrane cofactor protein (MCP) and other rarer proteins) is not necessary to diagnose atypical HUS, not only because gene analysis is time-consuming and of limited availability, but also because no mutation is identified in at least half of cases.

Table 46.4 Clinical conditions presenting as thrombotic microangiopathies (TMAs) requiring the differential diagnosis with TTP and HUS.

- Disseminated intravascular coagulation
- Pre-eclampsia/HELLP syndrome
- Scleroderma/systemic lupus erythematosus
- Catastrophic antiphospholipid antibody syndrome
- Disseminated malignancy

Table 46.5 Components of the PLASMIC score.

	Points
Platelet count <30.000	1
Bilirubin >2 mg/dL, reticulocytes >2.5%, undetectable haptoglobin	1
No active cancer	1
No history of organ transplantation	1
MCV <90 fL	1
INR <1.6	1
Creatinine <2 mg/dL	1

Score 6–7: high risk of TTP.
Score 5: intermediate TTP risk.
Score 0–4: low TTP risk.

Differential diagnosis of TTP from other thrombotic microangiopathies

Acquired TMAs can also be observed in syndromes such as disseminated intravascular coagulation (DIC), the HELLP (*H*aemolysis, *E*levated *L*iver enzymes and *L*ow *P*latelets) syndrome in pregnant women, the catastrophic antiphospholipid antibody syndrome, pre-eclampsia and eclampsia, cancer and stem cell transplantation.

DIC can be distinguished from TTP by more markedly increased plasma levels of D-dimer, hypofibrinogenaemia and prolonged prothrombin and activated partial thromboplastin times. Because pregnancy is one of the most frequent clinical associations of TTP, differential diagnosis also involves other pregnancy-related TMAs such as pre-eclampsia and eclampsia. In the latter, hypertension is more frequent and renal damage is not as severe, whereas the degree of anaemia and thrombocytopenia is usually more severe in TTP. Tests of coagulation and fibrinolysis are usually abnormal in pre-eclampsia or eclampsia, albeit less markedly than in DIC. Very high serum transaminases differentiate HELLP from TTP in pregnancy. Disorders such as systemic lupus erythematosus, rheumatoid arthritis, scleroderma and the so-called catastrophic antiphospholipid antibody syndrome that sometimes present acutely with widespread microvascular thrombosis, mechanical haemolytic anaemia and consumptive thrombocytopenia, may be distinguished from TTP because laboratory tests such as antinuclear and antiphospholipid antibodies and the detection of the lupus anticoagulant give positive results. Another element of differential diagnosis is the presence of venous and arterial thromboses in large blood vessels, at variance with TTP.

Evans syndrome, due to the concomitant presence of antiplatelet and antierythrocyte autoantibodies, is distinguished by a positive Coombs test, lack of schistocytes and the usual absence of end-organ ischaemic symptoms. At variance with TTP thrombus formation in large venous or arterial vessels are frequent features of heparin-induced thrombocytopenia (HIT) and the recently described Vaccine-Induced Thrombotic Thrombocytopenia (VITT), but TTP can be differentiated not only by lack of exposure to heparin or anti-SARS-CoV-2 vaccines but also by the presence of haemolytic anaemia and schistocytosis. Disseminated malignancy is sometimes associated with consumptive thrombocytopenia and haemolytic anaemia. Until further investigations exclude or confirm the presence of metastatic cancer, it is not easy to distinguish TTP from this TMA. ADAMTS13 plasma levels have been measured in these TMAs and several other unrelated conditions and physiological states, such as the neonatal state, pregnancy, localised and metastatic cancer, liver cirrhosis, inflammatory states, postoperative period, uraemia, sepsis and autoimmune diseases. In the majority of these instances ADAMTS13 activity was lower in patients than in controls but, in contrast to TTP, at plasma levels of 10% or more.

Natural history

In approximately two-thirds of cases TTP occurs only once (acute sporadic TTP). However, in at least one-third, the disease recurs at varying time intervals after remission from the acute episode. Recurrence is not easily predictable but occurs more often during the first year and in patients who have persistently low levels of ADAMTS13 during regular monitoring after first remission (Table 46.3). Recurrences may comprise single or several episodes and usually present with less severe clinical manifestations, perhaps because patients have become alert to the first signs and symptoms of their disease.

Treatment

The efficacious management of TTP began with the serendipitous observation that plasma infusion improved the clinical course. Plasma exchange (PEX) subsequently appeared to be more effective than infusion. In 1991, the results of a seminal randomised clinical trial established the greater efficacy of PEX over infusion, the clinical response rate being 78% in the former compared with 49% in the latter (mortality rates, 22% and 37%, respectively). Only after the discovery of the mechanistic role of VWF and its cleaving protease ADAMTS13 have these empirical treatments found a rationale. PEX acts by removing circulating disease-causing autoantibodies, the most frequent mechanism of acquired TTP but also by replacing the protease in cases of congenital and acquired deficiency.

In congenital TTP, ADAMTS13 replacement therapy is the essence of management and can be achieved by infusion of fresh-frozen plasma and also of some virally inactivated, intermediate-purity plasma factor VIII-VWF concentrates that contain relatively large amounts of ADAMTS13, such as 8Y (BPL; BioProducts Laboratory, Elstree, Herts) and KoateVR-DVI (Kedrion Biopharma, USA). The advantage of these products is that they can be administered with a small infusion volume in the outpatient or home setting (6). BPL 8Y has been used with success at a dosage of 15–30 U/kg, although there is no standardised content of ADAMTS13 in this or other plasma-derived products. Despite the fact that ADAMTS13 has a half-life of 2–3 days, the clinical effect of plasma (20–30 mL/kg) or 8Y are such that infusions every 2 weeks are usually sufficient to supply enough ADAMTS13 to maintain low but measurable plasma levels of the protease and avoid platelet consumption and related clinical symptoms. Since recurrence is not a constant finding and is not accurately predictable, it is not firmly established which patients should undergo regular prophylaxis and which peak and trough

ADAMTS13 levels are necessary, either to attain remission of the acute episode or to prevent recurrences. There is as yet no definite evidence that patients with congenital ADAMTS13 deficiency treated with plasma or plasma products develop alloantibodies toward the protease. The recent ISTH guidelines on treatment of congenital TTP suggest prophylactic plasma infusion or a watch and wait strategy (a conditional recommendation in the context of very low level of certainty) and suggest against the use of FVIII-VWF concentrate versus a watch and wait strategy (a conditional recommendation in the context of very low certainty). A recombinant preparation of ADAMTS13 improves defective proteolysis of VWF *in vitro*, but this product is still in a Phase 3 clinical trial and not yet licensed for clinical use as replacement therapy in congenital TTP.

Acquired TTP. A simple scheme summarising the steps to be followed in the acute management of acquired immune-mediated TTP is in Table 46.6. Treatment with PEX should be initiated as soon as the clinical diagnosis of TTP is suspected. However, plasma infusion is still the only therapy with nearly global availability and critically ill TTP patients are often first admitted to hospitals without facilities for PEX. In these circumstances, daily infusion of large amounts of fresh-frozen plasma (FFP) (30 mL/kg) should be promptly started (Table 46.6), implementing at the same time measures to perform PEX. Patients are best admitted to intensive care units, where coma, seizures and such severe side-effects of PEX as congestive heart failure, catheter-related bleeding, thrombosis and infections can be optimally managed. At least 1–1.5 plasma volumes should be exchanged daily until platelets rise and a clinical response is obtained, defined as platelet count $>150 \times 10^9$ IL sustained for 3–4 days, Daily treatment with PEX must be continued for at least 3–4 days even after attaining a clinical response (Table 46.6). Tapering PEX (over 1–2 weeks) seems to reduce the risk of early relapse. Even though a clinical response is usually achieved after 5–10 days, daily PEX for up to 1 month is sometimes necessary. Fresh-frozen plasma treated with virus-inactivation methods (e.g. solvent/detergent) should be preferred if possible in the context of PEX, because it decreases the risk of infections associated with patient exposure to plasma from a large number of donors.

Table 46.6 Steps in the acute management of acquired, immune mediated TTP.

- Clinical suspicion (based on severe thrombocytopenia, mechanical haemolytic anaemia, presence of schistocytes in the blood film, high serum LDH) and the use of the French and PLASMIC scores.
- Plasma exchange (PEX) should be started as soon as possible.
- Daily plasma exchanges (1–1.5 plasma volumes) until platelets are higher than 150×10^9/L for at least 3–4 days and LDH is normal.
- Immunomodulation: prednisone 1–2 mg/kg for at least 15 days, then tapering over 30 days.
- Immunomodulation anti-CD20 (rituximab, 375 mg/m^2 weekly for 4 weeks)
- Anti-VWF caplacizumab: 10 mg upfront intravenously, then 10 mg/day subcutaneously for at least 20 days.

The immune-mediated mechanism of acquired TTP must be tackled by means of immunomodulating agents but always in association to PEX, which is the primary weapon. Corticosteroids are usually the first choice at the time of acute presentation (Table 46.6). A recommendation from the ISTH guidelines in the context of very low certainty enlists the addition of corticosteroids over PEX alone for patients with immune mediated TTP experiencing a first acute event. For those patients experiencing a relapse, the ISTH guidelines recommend addition of corticosteroids to PEX over PEX alone (a recommendation in the context of very low level of certainty).

Another immunomodulating medicine currently recommended as an adjunct to standard PEX in the acute management of immune-mediated TTP is the anti-CD20 humanised monoclonal antibody rituximab, that blocks the production of anti-ADAMTS13 antibodies through the depletion of B lymphocytes. Rituximab is generally administered once weekly at 375 mg/m^2 for four consecutive weeks immediately after the end of each PEX procedure (Table 46.6). The plasma levels of ADAMTS13 need to be checked after 2 weeks and if levels are not satisfactorily increased prolongation of this therapy until 6 weeks should be considered (personal experience). For patients experiencing their first acute event or relapse, ISTH guidelines suggest the addition of rituximab to corticosteroids and PEX over corticosteroids and PEX alone (a conditional recommendation in the context of very low level of certainty). For prophylaxis of patients in remission who still have low plasma ADAMTS13 activity but no clinical signs/symptoms, a conditional recommendation in the context of very low level of certainty suggests the preferred use of rituximab over its non-use. Many other immunomodulatory agents used in the past (vincristine, cyclosporin, cyclophosphamide) are no longer considered valid options due to the risk of adverse effects coupled with less efficacy than corticosteroids and rituximab. The clinical efficacy of antiplatelet agents in TTP is unproven and platelet transfusion is generally ineffective.

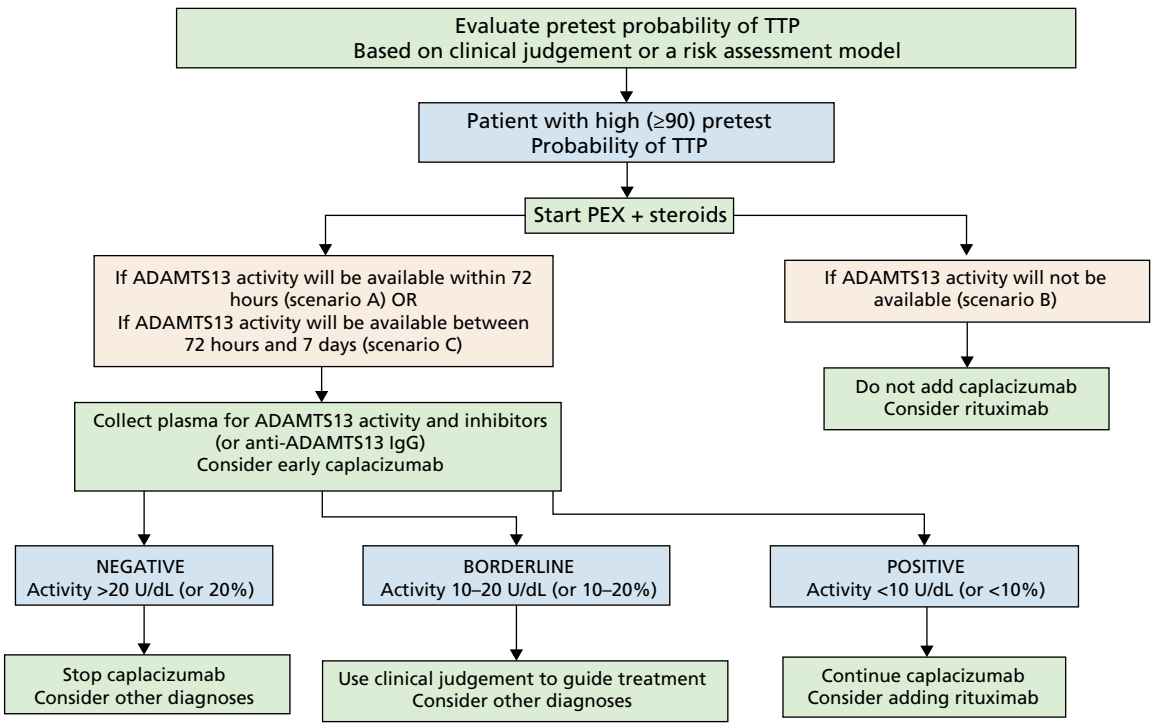
A new therapeutic agent acting upon the VWF disease pathway has been licensed in 2018 by the FDA and EMA for the management of acute TTP. Caplacizumab is a first-in-class humanised nanobody which binds the A1 domain of VWF and prevents platelet aggregation and thrombus

formation in the microcirculation by blocking the interaction between ultra-large VWF and the platelet glycoprotein Ib-IX-V. This agent, which targets VWF and thus does not address the underlying autoimmunity and the anti-ADAMTS13 autoantibody, gave good clinical results as an adjunct to PEX and immunomodulation in the frame of the two randomised trials TITAN and HERCULES. A faster reversal of thrombocytopenia (within a median time of 3 days) was obtained with a 74% reduction of a combined endpoint (death, recurrence and major thromboembolic events) and also a shorter duration of PEX and hospitalisation. The approved daily dose of caplacizumab is 10 mg according to EMA and 11 mg for FDA, first intravenously and then subcutaneously (Table 46.6), and it should be continued until ADAMTS13 levels are kept above 20% for at least 2 weeks. According to the ISTH guidelines, caplacizumab should be preferred over not using this drug in those patients with immune-mediated TTP who experience an acute event (first event or relapse). The data informing this recommendation were of moderate certainty.

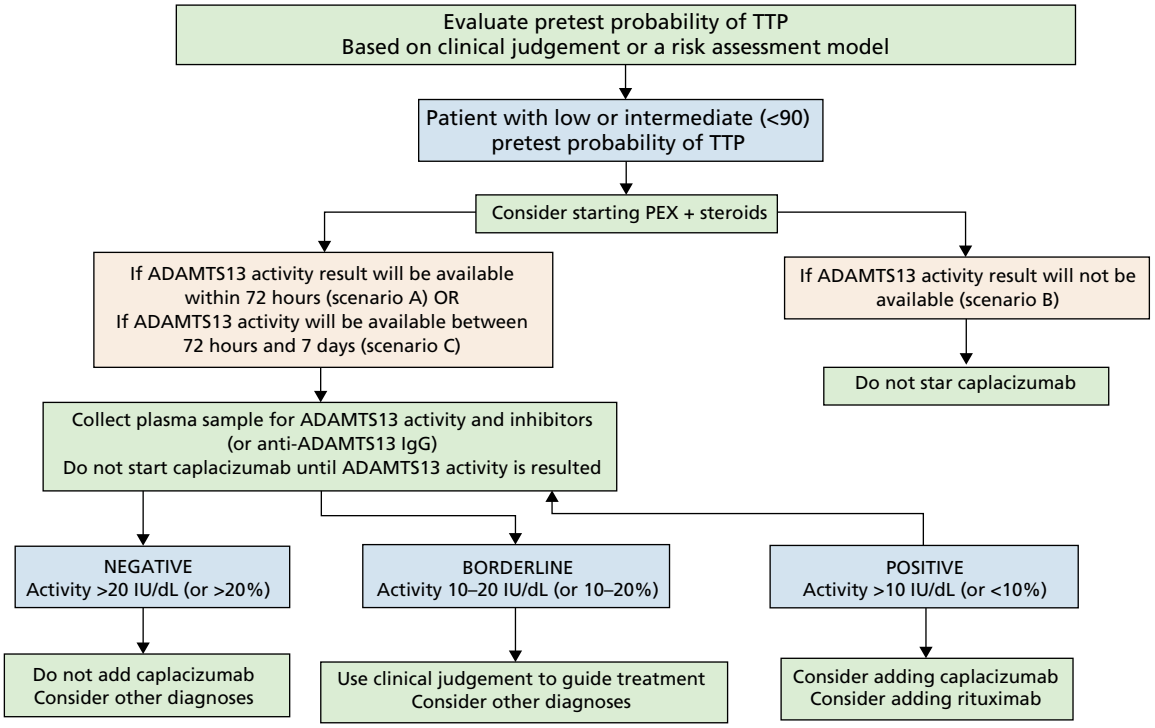
The benefit of caplacizumab is accrued if started in the early phase of an acute TTP event i.e. at the time when a diagnosis is confirmed. Therefore, caplacizumab use should be conditional on the capacity to accurately identify patients with a high clinical suspicion of TTP, evidence of severe deficiency of plasma ADAMTS13 activity and presence of anti-ADAMTS13 IgG. In settings characterised by no access to *ADAMTS13* testing, caplacizumab should not be used, regardless of the pretest probability of TTP. Major hurdles to its widespread use are cost and accessibility in various parts of the world. Moreover, caplacizumab should only be given under the guidance of clinicians experienced in TTP and with the required level of knowledge on the use of this drug.

Out of the acute phase, some patients with immune mediated TTP need to continue immunomodulation to prevent recurrences. In the remission phase, this approach is usually implemented in those who had recurrences (usually after intervals ranging from as little as 1 month from the first acute episode) but also upfront after first remission in the presence of clinical conditions associated with a high risk of recurrence (pregnancy, elective surgery, active autoimmune disorders) and with evidence of persistent severe deficiency of ADAMTS13 and presence of anti-ADAMTS13 antibodies. In these cases, the first choice is usually rituximab or lower doses of corticosteroids than those used in the acute phase. Second-choice drugs in unresponsive patients are cyclosporine or azathioprine.

To sum up, the enclosed flow chart summarises the management of patients with immune-mediated TTP according to the ISTH guidelines. In settings characterised by a timely access to *ADAMTS13* testing and for patients with a high clinical suspicion (≥90% pretest probability) of immune-mediated TTP (as based on clinical assessment or a formal clinical risk assessment scores), the following strategy is suggested:



In settings with a timely access to *ADAMTS13* testing but for patients with intermediate or low clinical suspicion of immune-mediated TTP (e.g. based on clinical assessment or a formal clinical risk assessment scores), the following strategy is suggested:



Haemolytic uraemic syndrome

The most typical and frequent forms of HUS are acquired and occur acutely and sporadically, particularly in infants and young children, after gastrointestinal infections associated with bacteria as Escherichia coli that produce the Shiga-like toxin, so that it is called *S*higa-like *T*oxin-producing *E*scherichia *C*oli (STEC) HUS. More seldom, 10% of HUS are cases of the so-called atypical HUS (aHUS) that can be familial, due to the inherited dysfunction of complement proteins and may have a sporadic or chronic recurrent course. It occurs mainly in infants or young children, but at least one-third of cases develop in adulthood, often in association with triggers such as delivery or drug intake.

STEC HUS

This acute syndrome almost always presents as a single sporadic episode heralded by bloody diarrhoea from 2 days to 2 weeks before the onset of symptoms. Besides consumptive thrombocytopenia and mechanical haemolytic anaemia in common with TTP, the most typical symptoms are severe renal failure with oligo-anuria. Serum creatinine is much more abnormal than in TTP, thrombocytopenia is usually less severe. Signs of compensated DIC, with relatively high plasma levels of D-dimer, are another distinctive feature. Neurological involvement is less common than in TTP, but coma and seizures may occur in association with uraemia and severe hypertension.

Aetiology

The most common bacterial agents that cause the prodromal gastrointestinal infection are *Escherichia coli* type 0157:H7 or O:104 or, more seldom, *Shigella dysenteriae* serotype I. These and other less frequently involved infectious agents such as pneumococci produce exotoxins called verocytotoxin, Shiga toxin or Shiga-like toxins, that can be detected on stool samples by culture methods or polymerase chain reaction (PCR) assays. These toxins, after absorption from the gastrointestinal tract into the blood, bind to the glycosphingolipid membrane receptor globotriaosylceramide, which is particularly dense in the kidney glomerular capillary endothelial cells. The toxin–receptor complex is endocytosed and thereby causes cytolysis and extensive endothelial swelling and desquamation, which in turn engenders the formation of microthrombi in the renal microvasculature, mainly composed of platelets but also rich in fibrin (Figure 46.3).

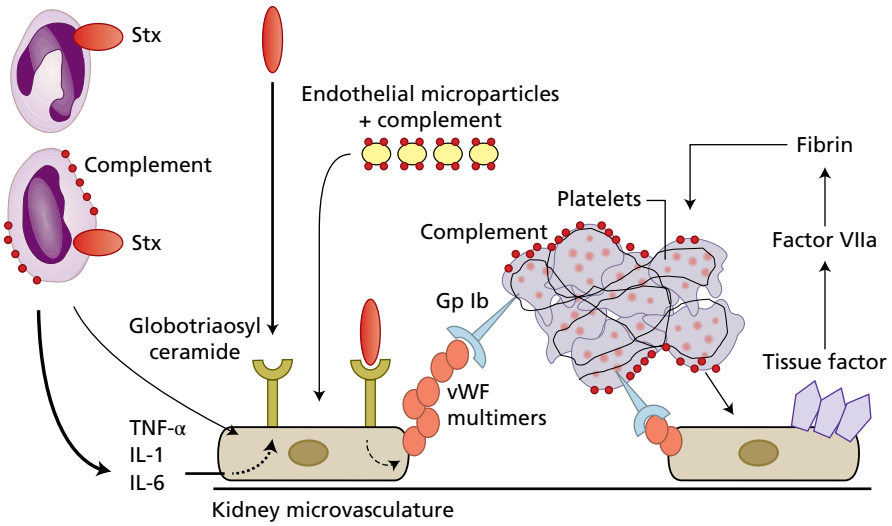


Figure 46.3 Pathophysiology of STEC HUS. Verocytotoxin, Shiga toxin or Shiga-like toxins, after absorption from the gastrointestinal tract into the blood, bind to the glycosphingolipid membrane receptor globotriaosylceramide on the glomerular capillary endothelial cells. The toxin–receptor complex is endocytosed and causes cytolysis, endothelial swelling and desquamation, which leads to massive formation of microthrombi in the renal microvasculature, mainly composed of platelets but also rich in fibrin. Gp Ib: platelet glycoprotein Ib; IL: interleukin; Stx: Shiga toxin; TNF: tumour necrosis factor.

Pathology and pathogenesis

The pathology of STEC-HUS is characterised by more extensive endothelial damage than TTP but less VWF and more fibrin are detected in microvascular thrombi. Plasma VWF levels are often very high but ultra-large multimers are not detectable during the acute phase of the disease, perhaps because these multimers leak in excess into plasma from damaged endothelial cells bind avidly to GPIb on the platelet membrane and are thus removed from plasma. As forementioned, ADAMTS13 is normal or only mildly reduced in the plasma of these patients (Table 46.3), this finding at variance with TTP being crucial for the differential diagnosis.

Natural history

In the great majority of cases, STEC-HUS is a self-limiting disease, with little tendency to early or late relapses. The acute episode is often accompanied by severe renal failure, so that haemodialysis may be required. Residual renal dysfunction is common after the acute episode and end-stage renal disease requiring maintenance dialysis or kidney transplantation is needed in approximately one-quarter of patients.

Treatment of STEC HUS

During the diarrhoeal prodrome, antimotility agents are contraindicated, because they favour the persistence of bacterial toxins in the gastrointestinal lumen and their passage into blood. The role of antibiotics is controversial, but in practice, they are often used, with a strong indication at least for patients with evidence or suspicion of sepsis or *Shigella dysenteriae* infection. In addition, the optimal management of STEC HUS includes intravenous hydration and monitoring renal function. In cases of severe renal failure, early institution of dialysis is essential in order to reduce sequelae and death. PEX is not recommended in patients with STEC HUS. A possible forthcoming approach to prevention is vaccination against vero/Shiga toxins in children living in endemic areas.

Atypical HUS

The term atypical HUS (aHUS) is used for TMAs characterised by severe renal failure often associated with the dysregulation of the alternative complement pathway. Given the key role of complement in aHUS, the term complement-mediated HUS (cHUS) is now more often preferred. In the disease, there is an excessive activation of C3 convertase, its partial consumption and production of C3a and C3b, resulting in increased formation of the C5b-9 terminal complement complex (also called the membrane-attack complex [MAC]) that directly damages vascular endothelial cells. C3a and C3b also activate other cells, such as platelets and leucocytes, causing inflammation and thrombosis (Figure 46.4). In aHUS, kidney glomeruli are particularly affected due to the formation of microvascular thrombi. However, microvascular thrombosis may occur almost everywhere but particularly in organs such as the brain, lung and gastrointestinal tract. The acute attacks can be triggered by infections, pregnancy, drugs or trauma in the presence of dysregulation of complement factors and inhibitors, mainly but not exclusively of genetic origin. Approximately half of the patients have loss-of-function mutations of the genes encoding complement inhibitors (factor H, factor I and membrane cofactor protein [MCP]) or gain-of-function mutations in the genes encoding complement activators (complement component 3 [C3] and factor B) (Table 46.7) resulting in excessive C3 activation with the consequences described above. The type of mutation impacts prognosis, patients with mutations in the factor H gene having the poorest prognosis in terms of short- and long-term

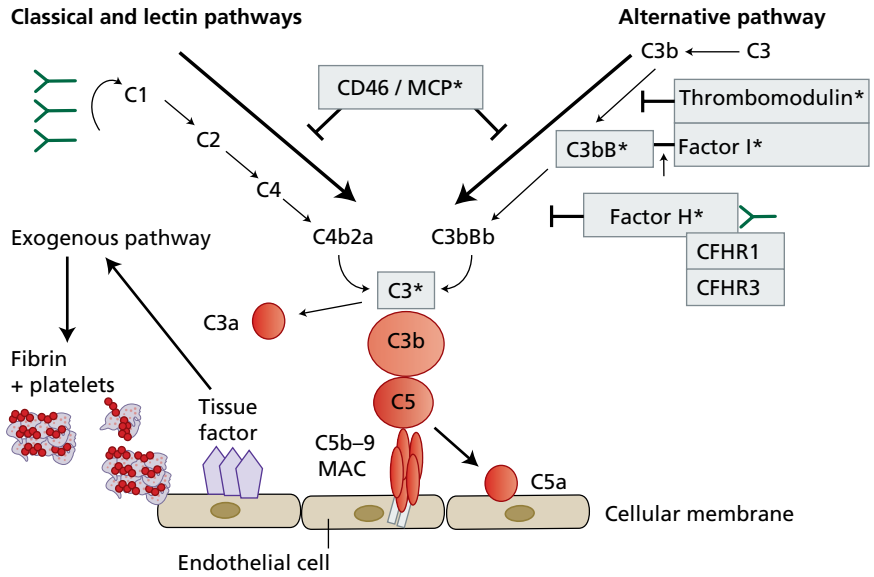

Figure 46.4 Pathophysiology of aHUS. An excessive activation of C3 convertase and its partial consumption with production of C3a and C3b results in the increased formation of the C5b-9 terminal complement complex (also called the membrane-attack complex [MAC]), that in turn causes the damage of vascular endothelial cells. C3a and C3b also activate platelets and leucocytes, causing inflammation and thrombosis. CFHR, complement factor H-related; MAC, membrane attack complex; MCP, membrane cofactor protein. *mutations are reported in genes encoding these complement factors.

Table 46.7 Main complement factors and regulators with their function and frequency of alteration.

Complement factor or antibody	Function	Percentage frequency of gene mutations/antibodies
CFH	• Recognises C3 and mediates cofactor activity for CFI • Accelerates the decay of C3 convertase	20–30
CFI	• Plasma serine protease • Cleaves C3b into inactive C3b	4–10
C3	• Its activation is required for both classical and alternative complement activation pathways • Its proteolytic cleavage produces C3a and C3b; C3a is an anaphylatoxin and the precursor of some cytokines and C3b serves as an opsonising agent	5–10
Thrombomodulin	• Transmembrane protein • Involved in the generation of TAFI, which cleaves C3 and C5a	5
CFB	• Plasma serine protease • Its proteolytic cleavage produces the noncatalytic chain Ba and the catalytic subunit Bb • The active subunit Bb associates with C3b to form the alternative pathway C3 convertase • Bb is involved in the proliferation of preactivated B lymphocytes, while Ba inhibits their proliferation	1–2
MCP	• Integral transmembrane protein that binds C3b and serves as a cofactor for CFI	10–15
CFH antibodies		3–6

CFB, complement factor B; CFH, complement factor H; CFI, complement factor I; MCP, membrane cofactor protein; TAFI: thrombin activatable fibrinolysis inhibitor.

renal function and relapse risk, even after kidney transplantation (see below). On the other hand, patients with MCP mutations have a better prognosis. A few cases of aHUS have also been described in association with the development of acquired autoantibodies against factor H that can be of the IgG class when associated with genetic abnormalities of the factor H-related antigens or of the IgM class in absence of such abnormalities. Given that nearly half of patients with aHUS have no identified complement abnormalities, much remains to be learned pertaining to disease mechanisms and causes other than complement defects may be the culprit. Other TMAs with a clinical presentation of acute kidney injury may be: (i) metabolism-mediated, such as homozygous mutations in the gene encoding the methylmalonic aciduria and homocystinuria type C (MMACHC) protein; (ii) haemostasis-mediated, such as homozygous mutation in the genes encoding thrombomodulin, plasminogen or diacylglycerol kinase ε [DGKE]); (iii) drug-mediated, by an immune reaction (quinine) or a toxic reaction (calcineurin inhibitors such as cyclosporine or tacrolimus).

Laboratory diagnosis

As mentioned above, low serum C3 levels are a simple and widely available method for diagnosing affected patients, but more than 50% of those diagnosed with aHUS have normal levels. Similarly, mutations in complement proteins are important but not sufficient in the development of aHUS, because carriers are often asymptomatic and actual disease precipitation requires triggering factors such as infections, surgery, pregnancy or immune-mediated diseases that activate the complement alternative pathway. It must be reiterated that for the diagnosis it is of paramount importance to measure ADAMTS13 activity to rule out TTP when higher than 10% and look for E. coli-producing Shiga-like toxin in stool samples to rule out STEC HUS if negative. While ADAMTS13 results are awaited, a platelet count >30000/mm^3 and/or a serum creatinine level >2.0 mg/dL strongly suggest a diagnosis of aHUS (Figure 46.5).

Natural history

Until recently HUS was a disease with a poor prognosis with a fatality rate of between 10 and 20% and rate of progression to end-stage renal insufficiency of 50% or more despite the use of PEX. aHUS is often a chronic ongoing systemic disease, because even after recovery from the acute illness patients may suffer from additional episodes if exposed to clinical triggers (infection, surgery, pregnancy) owing to their persistent inability to regulate complement activity.

Treatment

Until the first decade of the 2000s, aHUS was treated with plasma therapy, mainly PEX but also infusion only. The rationale of this approach was the replacement of deficient or dysfunctional complement proteins, but also the removal of activated complement factors and anti-factor H autoantibodies when present. Plasma therapy had to be often combined with haemodialysis to control oligo-anuria and uraemia. Despite poor outcomes (10–20% case fatality rate and 50% or higher rate of progression to stage renal disease) plasma infusion or PEX still remain important treatment weapons. The response to PEX is typically re-assessed at days 2–3, with the goal to establish whether or not there is improvement of anaemia and thrombocytopenia, as well as improvement or at least stabilisation of end-organ damage. In the few patients responding optimally to PEX, this therapy is continued daily until normalisation of surrogate markers of ongoing microthrombotic disease such as platelet count, haemoglobin and LDH and then stopped without prolonged tapering. Markers of kidney damage (high serum creatinine and proteinuria) and neurologic findings and symptoms when present and persistent are of high significance for the clinical management of these patients. A poor response to PEX can be defined as lack of haematological response, but also by worsening kidney insufficiency despite daily PEX. In these cases, PEX should be discontinued and therapy with eculizumab considered.

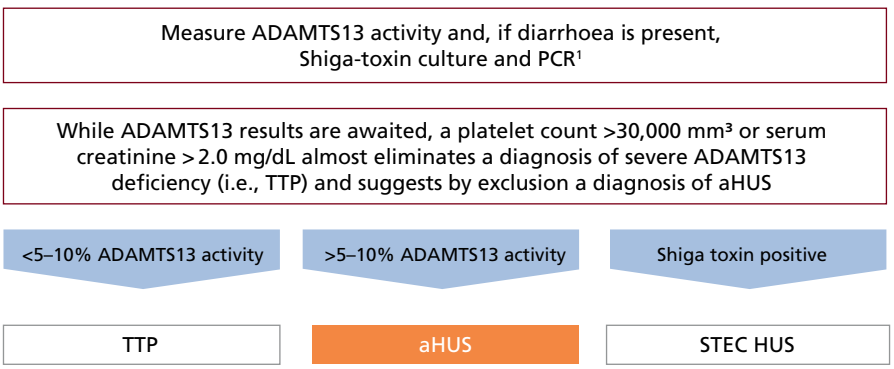

Figure 46.5 Differential diagnosis of patients with a suspected aHUS, TTP or STEC HUS.

Eculizumab, a humanised monoclonal antibody approved in 2011 for the treatment of aHUS, binds to complement protein C5 and blocks the formation of the end product membrane attack complex and thus stands as an effective life- and kidney-sparing therapy for patients with aHUS. This product has been prospectively evaluated for efficacy and safety in aHUS patients with a broad spectrum of disease features (those recently diagnosed or with long disease duration but also those who had already undergone transplant or on continuous dialysis). Therapy often resulted not only in haematologic improvement but also and most importantly in the marked improvement of renal function, even in cases with advanced disease. There is evidence that a rapid initiation of therapy with eculizumab is associated with a greater improvement in renal function in aHUS patients. However, the initiation of eculizumab treatment prior to a window of 2–3 days of PEX is not advised when there are difficulties in differentiating with certainty aHUS from TTP at the time of presentation (Figure 46.5), but eculizumab is recommended as first-line therapy when the diagnosis of aHUS is known at the time of acute presentation (such as, for instance, for recurrences).

Even though eculizumab is usually well tolerated, all patients should receive a meningococcal vaccine owing to the increased risk to acquire this infection. Intravenous eculizumab is initiated at a dose of 900 mg weekly for the first 4 consecutive weeks and then, beginning on week 5, maintenance therapy is administered every other week at a dose of 1200 mg, usually for an indefinite treatment period. These recommended dosing schedules are extremely costly. However, indefinite therapy with eculizumab can be tailored by monitoring global complement tests in order to determine the minimal effective dose to maintain the disease in remission, but with a substantial saving of costs. Attempts have been made to discontinue this therapy in small series of patients but no general recommendation beyond individualisation can be currently offered. Eculizumab is often associated with dramatic clinical responses and, most importantly, with such a high degree of recovery of renal function that at least 80% of patients can discontinue dialysis, in contrast with the previous gloomy picture when most patients died or progressed to end-stage renal disease despite PEX. It is of extreme importance to avoid permanent dialysis and renal transplantation, because the results of the latter are often poor and appear to correlate with the cause of complement dysregulation. For instance, the disease did not recur in the transplanted kidneys of patients with *MCP* gene mutations, presumably because the new kidney produces protective levels of endogenous MCP. In contrast, kidney transplantation alone did not correct the deficiency of complement factors I and H produced by the liver, so that in patients with factor H or factor I gene mutations, outcome was poor owing to disease recurrence. However, an approach as formidable as combined liver and kidney transplantation may lead to a favourable long-term outcome for recurrent HUS associated with *factor H* gene mutations.

A long-acting C5 inhibitor with the name ravulizumab has been recently developed through minimal modifications of eculizumab and approved for the treatment of aHUS both in the US and in Europe. Clinical data in paediatric patients with aHUS have shown that ravulizumab can be safely administered and the dosing interval prolongation up to 4–8 weeks, due to a half-life 4 times longer than that of eculizumab.

Concluding remarks

In the last few years, TTP and HUS, previously known to clinicians and pathologists for their dire consequences, have witnessed spectacular improvements owing to increased mechanistic knowledge and development of new specific diagnostic criteria particularly for TTP, whereas atypical HUS still remains a diagnosis of exclusion. Most importantly, improved therapeutic options led to a marked decrease in mortality and morbidity, particularly for atypical HUS following the availability of eculizumab. In TTP, the pivotal role of VWF and the deficiency or dysfunction of its major proteolytic enzyme ADAMTS13 in inducing microvascular platelet-rich thrombi is evident. The development of laboratory methods to measure ADAMTS13 in plasma demonstrated that bona fide TTP cases have very low or unmeasurable levels of this protease. Trigger(s) are usually needed for the occurrence of full-blown TTP, because patients with congenital and immune-mediated, acquired deficiency of ADAMTS13 may not manifest clinical disease for long periods of time. The clinicians confronted with the treatment of these seriously ill patients should be cognisant that plasma therapy, mainly plasma exchange and immunomodulation with rituximab remain the treatment of choice for patients with clinically diagnosed TTP, but the anti-VWF nanobody caplacizumab is a useful adjunct to the PEX/rituximab approach. An important not completely resolved therapeutic problem is the secondary prevention of the chronic recurrent forms. Various immunomodulatory treatments have been tried with promising results, particularly rituximab.

STEC-HUS is now well characterised from an aetiological standpoint, so that it can be specifically recognised and properly treated. The dire consequences of atypical HUS, that is still lacking specific diagnostic tests, are now dramatically improved by the availability of a complement inhibition therapy with the humanised monoclonal antibody eculizumab, that is able to induce not only a dramatic therapeutic response in many patients unresponsive to plasma therapy but also the recovery of renal function, in contrast with the poor prognosis for patients treated only with plasma-based therapy. However, long-term complement inhibition comes with an immense financial burden, the inconvenience of frequent infusions and the small but real risk of meningococcal infection associated with indefinite

therapy. The problem of frequent infusions has been addressed by lengthening the dosing interval of eculizumab based on the measurement of complement activation markers and by making clinically available an extended half-life C5 inhibitor. On the other hand, the efficacy and safety of eculizumab discontinuation remains uncertain and this choice must be accurately individualised.

CHAPTER 47

Antithrombotic agents

47

Jeffrey I Weitz

McMaster University and the Thrombosis & Atherosclerosis Research Centre, Hamilton, Ontario, Canada

Introduction

Antithrombotic drugs used for the prevention and treatment of thrombosis include antiplatelet drugs, which inhibit platelet activation and aggregation; anticoagulants, which attenuate coagulation; and fibrinolytic agents, which induce fibrin degradation. With the predominance of platelets in arterial thrombi, strategies to prevent or treat arterial thrombosis focus mainly on antiplatelet agents, although anticoagulants and fibrinolytic agents are often used in the acute setting. The addition of low-dose rivaroxaban to dual antiplatelet therapy with aspirin plus clopidogrel or to single antiplatelet therapy with aspirin alone reduces the risk of recurrent ischaemic events in patients with an acute coronary syndrome (ACS) or in those with stable coronary or peripheral artery disease. These observations highlight the utility of anticoagulants on top of antiplatelet agents, so-called dual pathway inhibition, for secondary prevention in patients with atherosclerosis.

Anticoagulants are the mainstay for the prevention and treatment of venous thromboembolism (VTE), which includes deep vein thrombosis (DVT) and pulmonary embolism (PE). Antiplatelet drugs are less effective than anticoagulants for VTE prevention because of the limited platelet content of venous thrombi. Selected patients with VTE benefit from fibrinolytic therapy such as those with severe PE or extensive proximal DVT.

This chapter describes the antiplatelet drugs and anticoagulants in common use.

Antiplatelet Agents

The antiplatelet agents include aspirin, dipyridamole, inhibitors of $P2Y_{12}$, glycoprotein (GP) IIb/IIIa antagonists, and vorapaxar. Their sites of action are illustrated in Figure 47.1.

Aspirin

Mechanism of action: Aspirin produces its antithrombotic effect by irreversibly acetylating and inhibiting platelet cyclooxygenase-1 (COX-1), a critical enzyme in the biosynthesis of thromboxane A_2. At higher doses, aspirin also inhibits COX-2, an inducible COX isoform found in endothelial and inflammatory cells. In endothelial cells, COX-2 initiates the synthesis of prostacyclin, a potent vasodilator, and inhibitor of platelet activation that antagonises the effects of thromboxane A_2. Because acetylation of COX-1 by aspirin is irreversible and because anucleate platelets cannot synthesise more of the enzyme, COX-1 activity is lost for the platelet lifetime, which is 8–10 days. About 10% to 12% of circulating platelets are replaced every day; however, the recovery of platelet function is faster than that predicted by the rate of platelet turnover because aspirin-treated platelets can respond to TXA_2 generated by newly produced platelets. Consequently, stopping aspirin for 5 to 7 days is sufficient to restore normal platelet function.

Indications: Aspirin is routinely used for secondary prevention in patients with ischaemic stroke, ACS, or peripheral artery disease where it reduces the risk of recurrent ischaemic events by about 20%. Aspirin is no longer recommended for primary prophylaxis except in the highest-risk patients.

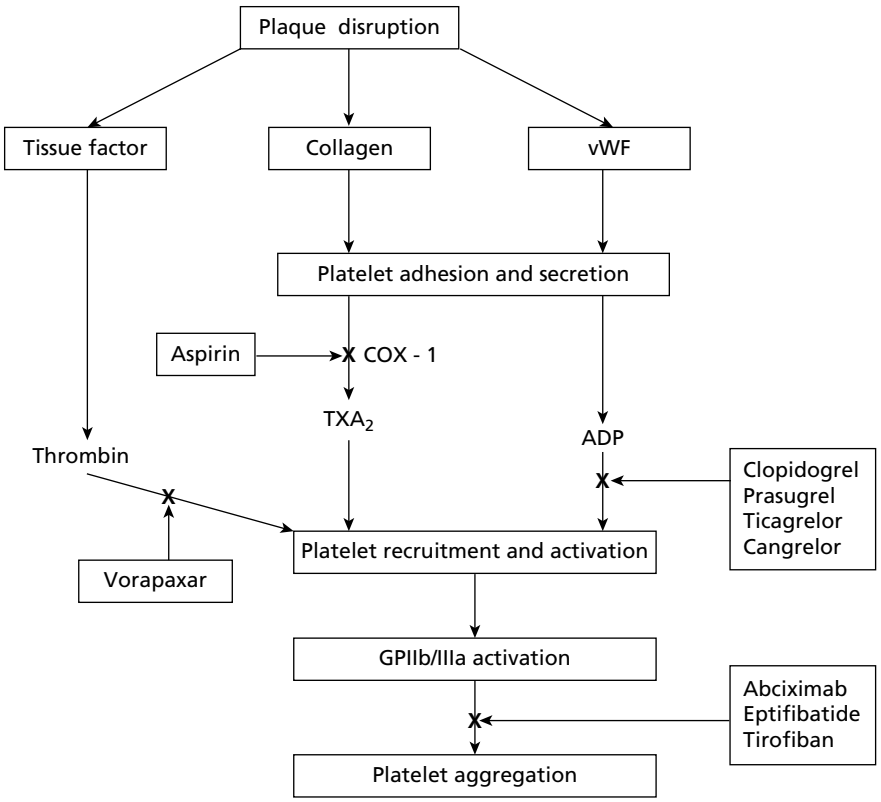

Figure 47.1 Sites of action of antiplatelet drugs. Aspirin inhibits the synthesis of thromboxane A_2 (TXA_2) by irreversibly acetylating cyclo-oxygenase 1 (COX-1). The reduced release of TXA_2 attenuates platelet activation and recruitment to the site of vascular injury. Clopidogrel, and prasugrel irreversibly block $P2Y_{12}$, a key ADP receptor on the platelet surface; cangrelor and ticagrelor are reversible inhibitors of $P2Y_{12}$. Abciximab, eptifibatide and tirofiban inhibit the final common pathway of platelet aggregation by blocking binding of fibrinogen and von Willebrand factor (vWF) to activated GP IIb/IIIa. Vorapaxar inhibits thrombin-mediated platelet activation by targeting protease-activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

Dosing: At doses of 75–100 mg/day, aspirin abolishes TXA_2 synthesis without significant inhibition of COX-2 and subsequent impairment of prostacyclin synthesis.

Side Effects: The most common side effects are gastrointestinal, which range from dyspepsia to erosive gastritis or peptic ulcers with bleeding and perforation. The use of enteric-coated or buffered aspirin in place of plain aspirin does not eliminate these side effects. The risk for major bleeding with aspirin is 1% to 3% per year; the risk is increased with the concomitant use of anticoagulants.

Aspirin allergy characterised by bronchospasm occurs in about 0.3% of the general population and is more common in patients with chronic urticaria or asthma, particularly those with nasal polyps or chronic rhinitis. Aspirin overdose is associated with hepatic and renal toxicity.

Aspirin resistance: The term *aspirin resistance* is used to describe both clinical and laboratory phenomena. Clinical aspirin resistance is defined as the failure of aspirin to protect patients from ischaemic vascular events, a diagnosis that can only be made after such events occur. This retrospective diagnosis provides no opportunity to modify therapy nor is it realistic to expect aspirin, which selectively blocks thromboxane A_2 biosynthesis, to prevent all vascular events. The biochemical definition of aspirin resistance involves the failure of the drug to inhibit thromboxane A_2 synthesis or arachidonic acid-induced platelet aggregation. Potential mechanisms for such resistance include poor adherence, reduced absorption of enteric-coated aspirin, thromboxane A_2 generation via COX-1 independent pathways, and genetic polymorphisms in *COX-1*. High body weight and increased platelet turnover after surgery or in patients with myeloproliferative disorders are associated with an increased risk for aspirin resistance. Tests used for the diagnosis of biochemical aspirin resistance include quantification of thromboxane B_2, the stable metabolite of thromboxane A_2, in serum or urine, or assessment of arachidonic acid-induced platelet aggregation using light transmission aggregometry or point-of-care devices such as the VerifyNow® system. Tests for aspirin resistance should remain research tools because there is

no evidence that they identify patients at higher risk for recurrent vascular events or that the resistance is reversed with higher doses of aspirin or the addition of other antiplatelet drugs.

Dipyridamole

Mechanism of action: Dipyridamole attenuates platelet aggregation by increasing the intracellular levels of cAMP. This occurs in two ways. First, dipyridamole increases plasma adenosine levels by blocking adenosine reuptake. Adenosine stimulates adenylyl cyclase in platelets leading to increased intracellular cAMP. Second, by reversibly inhibiting platelet phosphodiesterase, dipyridamole prevents cAMP degradation. Inhibition of phosphodiesterase in the vessel wall results in vasodilation by increasing endothelial cell prostacyclin production and by increasing cGMP levels in vascular smooth muscle cells.

Indications: Slow-release dipyridamole in conjunction with aspirin is used for secondary stroke prevention in patients with prior stroke or transient ischaemic attack (TIA). Compared with clopidogrel, this combination was no more effective and was associated with more bleeding and more discontinuations because of side effects. Therefore, dipyridamole is rarely used.

Dosing: The fixed combination, which contains 200 mg of extended-release dipyridamole and 25 mg of aspirin is given twice daily.

Side effects: Dipyridamole produces vasodilation and its major side effects include headache, facial flushing, dizziness, hypotension, and gastrointestinal complaints, symptoms that often subside with continued drug use.

P2Y12 antagonists

P2Y12 is the major ADP receptor on platelets. The P2Y12 antagonists include clopidogrel, prasugrel, ticagrelor, and cangrelor.

Clopidogrel

Mechanism of action: Clopidogrel is a prodrug that requires metabolic activation by cytochrome P450 (CYP) 2C19 to acquire activity. Consequently, its onset of action is delayed unless loading doses are given. The active metabolite has an elimination half-life of about 30 to 60 minutes, but its antiplatelet effect persists for the lifetime of the platelet because it acts by forming an irreversible disulfide bond with the receptor. Therefore, clopidogrel should be held for 5 to 7 days prior to surgery or invasive procedures associated with a high risk of bleeding.

Indications: Clopidogrel is indicated, often in combination with aspirin, for secondary prevention of atherothrombotic events in medically treated patients with ACS. For those undergoing coronary stent implantation, clopidogrel combined with aspirin is recommended for 1 year with at least 3 months of treatment for drug-eluting stents and 1 month for bare-metal stents. Clopidogrel may be added to aspirin for secondary prevention in patients with stroke or TIA; clopidogrel is stopped after 3 to 4 weeks to minimise the risk of bleeding, and patients are continued on aspirin monotherapy. Clopidogrel monotherapy can be used in place of aspirin for secondary prevention in patients with a history of ischaemic stroke, myocardial infarction, or peripheral artery disease.

Dosing: After an initial loading dose of 300 to 600 mg, clopidogrel is given at a dose of 75 mg once daily.

Side effects: The major side effect is bleeding. Concomitant administration of aspirin or an anticoagulant increases the risk of bleeding. Although platelet transfusion can overcome the antiplatelet effects of clopidogrel, it should be used with caution in patients with haemorrhagic stroke.

Clopidogrel resistance: The capacity of clopidogrel to inhibit ADP-induced platelet aggregation varies amongst subjects reflecting, at least in part, genetic polymorphisms in the *CYP2C19*, which is involved in its metabolic activation. Patients with the loss-of-function *CYP2C19*2* allele exhibit reduced platelet inhibition in comparison with those with the wild-type *CYP2C19*1* allele and are at higher risk of cardiovascular events. Up to 25% of Whites, 30% of Blacks, and 50% of Asians carry the loss-of-function allele, which may render them resistant to clopidogrel. Polymorphisms in *CYP3A4* can contribute to reduced metabolic activation of clopidogrel and polymorphisms in *ABCB1* may impair clopidogrel absorption.

Prasugrel

Mechanism of action

Like clopidogrel, prasugrel is a thienopyridine prodrug that requires metabolic activation. Prasugrel is activated more efficiently than clopidogrel, which results in more rapid, greater and more predictable inhibition of ADP-induced platelet aggregation. Therefore, prasugrel overcomes the resistance observed with clopidogrel even in subjects with loss-of-function *CYP2C19*2* alleles. Prasugrel produces irreversible P2Y12 inhibition and should be held for 5–7 days prior to surgery or invasive procedures associated with a high risk of bleeding.

Indications

Prasugrel, administered with aspirin, is indicated for the secondary prevention of ischaemic events in patients with an ACS who are managed with PCI. In this setting, prasugrel is more effective than clopidogrel but is associated with an increased risk of bleeding. Prasugrel is no more effective than clopidogrel in patients with ACS who are managed medically.

Dosing

Prasugrel is given as a loading dose of 60 mg followed by 10 mg once daily. The dose is reduced to 5 mg once daily in those over the age of 75 years or weighing less than 60 kg.

Side-effects

The major side-effect is bleeding, which can be treated with platelet transfusion. Concomitant administration of aspirin or an anticoagulant increases the risk of bleeding

Ticagrelor

Mechanism of action

An orally active agent belonging to the cyclopentyltriazolopyrimidine class, ticagrelor reversibly binds to $P2Y_{12}$ at a location distinct from the ADP binding site and blocks receptor activation via an allosteric mechanism. Because it does not require metabolic activation, ticagrelor has a more rapid onset of action than clopidogrel or prasugrel. When possible, ticagrelor should be stopped 5 days prior to surgery because its offset of action is slow.

Indications

Ticagrelor, together with aspirin, is indicated for secondary prevention of atherothrombotic events in patients with an ACS treated medically or with PCI (with or without stent implantation) or coronary artery bypass graft surgery. It is also indicated for patients with a history of MI at least 1 year ago who are at high risk of recurrent atherothrombotic events.

Dosing

For patients with ACS, a loading dose of 180 mg is followed by 90 mg twice daily for up to 1 year. For patients with a history of MI, the dose is 60 mg twice daily for up to 3 years.

Side-effects

In addition to bleeding, the most common side-effects include dyspnoea, which occurs in up to 15% of patients, and bradyarrhythmia. The dyspnoea is usually self-limited, but drug discontinuation is necessary if the dyspnoea persists or is severe in intensity.

Platelet transfusion is ineffective for ticagrelor reversal because the drug binds to P2Y12 on the transfused platelets. Bentracimab, an antibody fragment that binds ticagrelor and its metabolite with high affinity, is under development for rapid ticagrelor reversal.

Cangrelor

Mechanism of action

Cangrelor is a rapidly acting reversible inhibitor of $P2Y_{12}$. It has an immediate onset of action after intravenous administration, a half-life of 3–5 min, and an offset of action within 1 hour.

Indications

Cangrelor is indicated for patients undergoing PCI who have not received pretreatment with clopidogrel, prasugrel or ticagrelor and are not receiving a GPIIb/IIIa inhibitor.

Dosing

Cangrelor is administered as a 30 μg/kg intravenous bolus before PCI followed by an infusion of 4 μg/kg/min for at least 2 hours or for the duration of PCI, whichever is longer. When transitioning to oral $P2Y_{12}$ inhibitor therapy, ticagrelor can be given at a loading dose of 180 mg at any time during or immediately after the cangrelor infusion. Loading doses of prasugrel or clopidogrel should only be given after the cangrelor infusion is stopped because cangrelor blocks their interaction with $P2Y_{12}$.

Side-effects

The most common side-effect is bleeding.

GPIIb/IIIa antagonists

The GPIIb/IIIa antagonists include abciximab, eptifibatide and tirofiban (Table 47.1)

Mechanism of action

GPIIb/IIIa, which is found on the surface of platelets and megakaryocytes, is the most abundant platelet receptor. GPIIb/IIIa is inactive on resting platelets but undergoes conformational activation upon platelet activation. Once activated, GPIIb/IIIa binds fibrinogen and von Willebrand factor, which then bridge adjacent platelets together to induce platelet aggregation. Because they inhibit the final common pathway of platelet aggregation, GPIIb/IIIa inhibitors are the most potent of the antiplatelet agents.

Table 47.1 Features of GPIIb/IIIa antagonists.

Feature	Abciximab	Eptifibatide	Tirofiban
Description	Fab fragment of humanised mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD mimetic
Specific for GP IIb/IIIa	No	Yes	Yes
Plasma half-life	Short (min)	Long (2.5 h)	Long (2.0 h)
Platelet-bound half-life	Long (days)	Short (s)	Short (s)
Renal clearance	No	Yes	Yes

Abciximab, eptifibatide and tirofiban are structurally and pharmacologically distinct. Abciximab is a Fab fragment of a humanised murine monoclonal antibody directed against the activated form of GPIIb/IIIa, whereas eptifibatide and tirofiban are synthetic small molecules. Eptifibatide is a cyclic heptapeptide that competes with fibrinogen for receptor binding because of its Lys-Gly-Asp motif. Tirofiban is a nonpeptidic tyrosine derivative that inhibits fibrinogen and von Willebrand factor binding to GPIIb/IIIa by serving as an Arg-Gly-Asp mimetic.

Abciximab has a plasma half-life of 7 days but can be detected on the surface of platelets for up to 2 weeks. Eptifibatide and tirofiban have plasma half-lives of about 2 hours. Abciximab is cleared by proteolysis, whereas eptifibatide and tirofiban are cleared via the kidneys.

Indications

GPIIb/IIIa antagonists are used in high-risk patients undergoing PCI, particularly those with ST-segment-elevation MI who have not been adequately pretreated with antiplatelet drugs or those requiring rapid platelet inhibition. Eptifibatide and tirofiban can be started 1–2 days before and continued during PCI, whereas abciximab is only recommended during PCI.

Dosing

Abciximab is given as a 0.25 mg/kg bolus followed by a 12-hour infusion of 0.125 μg/kg/min (maximum 10 μg/min). Eptifibatide is given as a 180 μg/kg bolus followed by an infusion of 2 μg/kg/min for 18–24 hours; the dose is reduced to 1 μg/kg/min if the creatinine clearance is less than 50 mL/min. Tirofiban is given as a 0.4 μg/kg bolus followed by an infusion of 0.1 μg/kg/min for 18–24 hours; the dose is reduced by 50% if the creatinine clearance is less than 30 mL/min.

Side-effects

In addition to bleeding, thrombocytopenia is the most serious complication. Thrombocytopenia, which occurs soon after drug administration, is immune-mediated and is caused by antibodies directed against neoantigens on GPIIb/IIIa that are exposed upon antagonist binding. With abciximab, thrombocytopenia occurs in up to 5% of patients. Thrombocytopenia is severe in about 1% of these individuals. Thrombocytopenia is less common with eptifibatide and tirofiban than with abciximab, occurring in about 1% of treated patients. Platelet transfusion is indicated if there is bleeding or if the platelet count falls below 50,000/μL.

Vorapaxar

Mechanism of action

Thrombin is the most potent platelet agonist. Vorapaxar, a synthetic analogue of himbacine, is an orally active inhibitor of type 1 protease-activated receptor (PAR-1), the major thrombin receptor on platelets. Although vorapaxar inhibits platelet PAR-1 in a reversible manner, because of its long half-life (8–12 days) and its high-affinity interaction with PAR-1, vorapaxar functions as an irreversible inhibitor of PAR-1.

Indications

Vorapaxar is indicated for the reduction of thrombotic cardiovascular events in patients with a history of MI or peripheral artery disease and no history of intracranial haemorrhage, stroke or TIA. Vorapaxar is often administered in conjunction with aspirin and/or clopidogrel.

Dosing

Vorapaxar is given orally at a dose of 2.08 mg once daily.

Side-effects

The major side-effect is bleeding, including intracranial and fatal bleeding.

Anticoagulants

There are both parenteral and oral anticoagulants. Currently available parenteral anticoagulants include the heparins (unfractionated heparin [UFH], low-molecular-weight heparin [LMWH] and fondaparinux) and direct thrombin inhibitors (bivalirudin and argatroban). The oral anticoagulants include vitamin K antagonists, such as warfarin, and direct oral anticoagulants (DOACs), which are also termed non–vitamin K antagonist oral anticoagulants (NOACs). The DOACs include dabigatran, which inhibits thrombin, and rivaroxaban, apixaban and edoxaban, which inhibit factor Xa.

Heparins

The heparins include unfractionated heparin (UFH), low-molecular-weight heparin (LMWH) and fondaparinux.

Mechanism of action

UFH is a naturally occurring glycosaminoglycan synthesised by mast cells. Medicinal heparin, which is extracted from porcine intestinal mucosa, consists of polysaccharide chains of alternating uronic acid and glucosamine residues with varying degrees of sulfation. The polysaccharide chains of UFH range in molecular weight from 3000 to 30,000 with a mean molecular weight of 15,000. LMWH is manufactured from UFH by controlled depolymerisation using chemical or enzymatic methods. The LMWH preparations, which include enoxaparin, dalteparin and tinzaparin, have mean molecular weights between 4500 and 5000. Fondaparinux, a synthetic analogue of the antithrombin-binding pentasaccharide, has a

Table 47.2 Comparison of heparin, Lmwh and fondaparinux.

Features	Heparin	LMWH	Fondaparinux
Number of saccharide units	10–30	15–17	5
Catalysis of factor Xa inhibition	Yes	Yes	Yes
Catalysis of thrombin inhibition	Yes	Yes	No
Bioavailability after subcutaneous administration (%)	20	90	100
Plasma half-life (h)	1–4	4	17
Renal excretion	No	Yes	Yes
Induces release of tissue factor pathway inhibitor	Yes	Yes	No
Neutralised by protamine sulphate	Yes	Partially	No

molecular weight of 1728. Table 47.2 compares the features of LMWH and fondaparinux.

UFH and LMWH act as anticoagulants by binding to antithrombin and accelerating the rate at which it inhibits clotting enzymes, particularly thrombin and factor Xa (Figure 47.2). The interaction of UFH and LMWH with antithrombin is mediated by a unique pentasaccharide sequence, which is found on one-third of the chains of UFH and one-fifth of those of LMWH. Fondaparinux is a synthetic analogue of this antithrombin-binding pentasaccharide sequence. Once bound to antithrombin, UFH, LMWH and fondaparinux induce a conformational change in the reactive centre loop that renders it more accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude but has no effect on the rate of thrombin inhibition. To promote thrombin inhibition, UFH and LMWH serve as a template that binds antithrombin and thrombin and brings the enzyme in close apposition to the inhibitor.

Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which corresponds to a molecular weight of 5400) are of sufficient length to bridge thrombin and antithrombin together. With a mean molecular weight of 15,000 and a range of 3000–30,000, almost all the chains of UFH are long enough to provide this bridging function. By definition, heparin has an anti-factor Xa to anti-factor IIa (thrombin) ratio of 1:1. In contrast, with mean molecular weights ranging from 4500 to 5000, which correspond to 15–17 saccharide units, at least half of the pentasaccharide-containing chains of LMWH are too short to bridge thrombin to antithrombin. However, these shorter chains retain the capacity to accelerate factor Xa inhibition. Consequently, LMWH catalyses factor Xa inhibition by antithrombin relatively more than thrombin inhibition and has an anti-factor Xa to anti-factor IIa ratio that ranges from 2:1 to 4:1. Because fondaparinux is too short to bridge thrombin to antithrombin, fondaparinux only catalyses factor Xa inhibition.

Heparin and LMWH induce the release of tissue factor pathway inhibitor (TFPI) from the endothelium. Longer heparin chains induce the release of more TFPI than shorter chains; fondaparinux does not induce TFPI release. TFPI binds and inhibits factor Xa and the TFPI-factor Xa complex then inhibits tissue factor–bound factor VIIa, thereby shutting down thrombin generation via the extrinsic pathway of coagulation. Consequently, released TFPI may contribute to the antithrombotic activity of heparin and LMWH.

After entering the circulation, heparin binds to a variety of plasma proteins other than antithrombin, which decreases its anticoagulant activity. The levels of heparin-binding proteins vary between patients because some of these proteins are acute-phase reactants whose levels are elevated in ill patients, whereas others, such as high-molecular-weight multimers of von Willebrand factor and platelet factor 4 (PF4), are released when platelets or endothelial cells are activated by thrombin. The large amounts of PF4 released from platelets in the vicinity of platelet-rich arterial thrombi may locally neutralise the anticoagulant activity of heparin.

UFH is cleared through a combination of a rapid saturable and a much slower first-order mechanism. The saturable phase of UFH clearance reflects binding to endothelial cells and macrophages. Bound UFH is internalised and depolymerised. The slower, non-saturable mechanism of clearance is largely renal. At therapeutic doses, UFH is mostly cleared through the rapid, saturable and dose-dependent mechanism. The complex kinetics of clearance renders the anticoagulant response to UFH nonlinear at therapeutic doses, with both the intensity and duration of effect rising disproportionately with increasing dose. Thus, the apparent biological half-life of UFH increases from 30 minutes after an intravenous bolus of 25 U/kg, to 60 min with a bolus of 100 U/kg, to 150 min with a bolus of 400 U/kg. In contrast to UFH, LMWH and fondaparinux are cleared solely via the kidneys. Consequently, LMWH and fondaparinux are not recommended if the creatinine clearance is less than 30 mL/min.

Indications

UFH, LMWH and fondaparinux are used for thromboprophylaxis in medical and surgical patients, for prevention and treatment of arterial thrombosis, and for initial treatment of VTE. UFH is used for anticoagulation during PCI, haemodialysis, cardiopulmonary bypass and extracorporeal membrane oxygenation (ECMO). LMWH is used less frequently for these indications and fondaparinux is avoided because of the risk of catheter thrombosis or clotting of extracorporeal circuits.

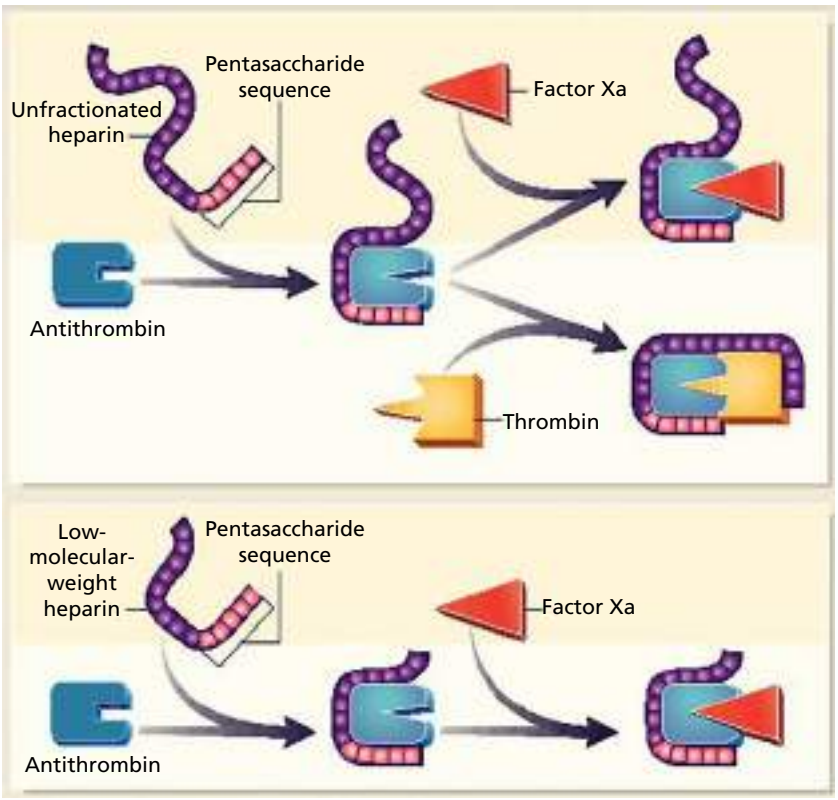

Figure 47.2 Catalysis of antithrombin-mediated inhibition of thrombin or factor Xa by unfractionated heparin (top), low-molecular-height heparin (middle) or fondaparinux (bottom). The interaction of unfractionated heparin and low-molecular-weight heparins with antithrombin is mediated by a unique pentasaccharide sequence. Binding to antithrombin induces a conformational change at the reactive centre loop of antithrombin that accelerates its interaction with factor Xa. Consequently, unfractionated heparin, LMWH and fondaparinux catalyse the inactivation of factor Xa by antithrombin. Catalysis of thrombin inhibition by antithrombin requires the formation of a ternary heparin–antithrombin–thrombin complex, which can be formed only by heparin chains at least 18 saccharide units long. This explains why LMWH has less inhibitory activity against thrombin than unfractionated heparin, and fondaparinux has none.

Dosing

When used for thromboprophylaxis, UFH, LMWH and fondaparinux are given subcutaneously in fixed doses of 5000 units subcutaneously 2 or 3 times daily, 4000–5000 units once daily and 2.5 mg once daily, respectively. For treatment, UFH is given as an intravenous bolus of 5000 units or 70–80 units/kg followed by an infusion of 15–18 units/kg/h. When used for cardiac interventions or for surgery, UFH is often given as a fixed intravenous bolus of 5000–10,000 units or as a weight-adjusted bolus dose of 70–100 units/kg. For treatment, LMWH is given subcutaneously at doses of 150–200 units/kg once daily or 100 units/kg twice daily. Fondaparinux is given subcutaneously at a dose of 7.5 mg once daily; the dose is reduced to 5 mg once daily for those weighing less than 50 kg and increased to 10 mg once daily for those weighing more than 100 kg.

Monitoring

Because the levels of heparin-binding proteins vary between patients, the anticoagulant response to fixed or weight-adjusted doses of UFH is unpredictable. Consequently, coagulation monitoring is essential to ensure that the response is therapeutic when heparin is administered for treatment purposes. The activated partial thromboplastin time (aPTT) is used for monitoring therapeutic doses of UFH, and an aPTT ratio of 1.5–2.5 was initially considered therapeutic because it, corresponded with a heparin level of 0.2–0.4 IU/mL by protamine titration or 0.3–0.7 IU/mL by anti-Xa assay. However, aPTT reagents vary in their responsiveness to UFH so local calibration of aPTT is essential to determine the therapeutic range. Direct monitoring using an anti-Xa assay has advantages over aPTT monitoring, but anti-Xa assays are not standardised and are not available in all hospitals.

LMWH and fondaparinux do not require coagulation monitoring. If monitoring is necessary, anti-factor Xa levels must be measured because LMWH has little effect on the aPTT and fondaparinux has no effect. Therapeutic anti-factor Xa levels with LMWH range from 0.5 to 1.2 U/mL when measured 3–4 hours after drug administration. When LMWH is given in prophylactic doses, peak anti-factor Xa levels of 0.2–0.5 U/mL are desirable.

Side-effects

The most common side-effect of heparins is bleeding. Other complications include thrombocytopenia, osteoporosis and elevated levels of transaminases.

Bleeding

Concomitant administration of antiplatelet or fibrinolytic agents increases the risk of bleeding with heparins, as does recent surgery or trauma.

Thrombocytopenia

A <30% reduction in the platelet count compared with baseline occurs in up to one-third of patients within the first 4 days of starting UFH. This reversible dose-dependent phenomenon is not associated with bleeding or thrombotic complications and does not require cessation of heparin. In contrast, heparin-induced thrombocytopenia (HIT) is a limb and life-threatening process that is triggered by antibodies directed against neoantigens on PF4 that are exposed when heparin binds to this protein (see Chapter 48). These antibodies, which usually are of the IgG subtype, bind simultaneously to the heparin-PF4 complex and to platelet Fc receptors. Such binding activates the platelets and generates platelet microparticles. Circulating microparticles are prothrombotic because they express anionic phospholipids on their surface and can bind clotting factors, thereby promoting thrombin generation.

Typically, HIT occurs 5–14 days after initiation of heparin therapy, but it can manifest earlier if the patient has received heparin within the past 3 months. Even a 50% decrease in the platelet count from the pretreatment value should raise the suspicion of HIT in those receiving UFH (Table 47.3). HIT occurs more frequently with UFH than with LMWH, in surgical patients than in medical patients, and, like many autoimmune disorders, in females than in males. HIT can be associated with venous or arterial thrombosis. Venous thrombosis, which manifests as deep vein thrombosis/or pulmonary embolism, is more common than arterial thrombosis. Arterial thrombosis can manifest as ischaemic stroke or acute MI. Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischaemia.

The diagnosis of HIT is established using enzyme-linked assays to detect antibodies against heparin-PF4 complexes or with platelet activation assays. Enzyme-linked assays are sensitive but can be positive in the absence of any clinical evidence of HIT. Because of its sensitivity, a negative enzyme-linked assay result excludes the diagnosis of HIT. The most specific diagnostic test is the serotonin release assay. This test is performed by quantifying serotonin release when washed platelets loaded with labelled serotonin are exposed to patient serum in the absence or presence of varying concentrations of heparin. If patient serum contains HIT antibodies, heparin addition induces platelet activation and subsequent serotonin release.

Heparin should be stopped in patients with suspected or documented HIT, and an alternative anticoagulant should be administered to prevent or treat thrombosis (Table 47.4). The agents most often used for this indication are parenteral direct thrombin inhibitors (such as argatroban or bivalirudin) or parenteral or oral factor Xa inhibitors (such as fondaparinux or rivaroxaban). The alternative anticoagulant should be continued until the platelet count is normal or the diagnosis of HIT is excluded. Warfarin should be avoided in HIT patients because it can trigger skin necrosis and thrombosis. These complications

Table 47.3 Features of heparin-induced thrombocytopenia.

Features	Details
Thrombocytopenia	Platelet count of ≤100,000/μL or a decrease in platelet count of ≥50%
Timing	Platelet count falls 5–10 days after starting heparin
Type of heparin	More common with unfractionated heparin than low-molecular-weight heparin
Type of patient	More common in surgical patients and patients with cancer than general medical patients; more common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

Table 47.4 Management of heparin-induced thrombocytopenia.

Stop all heparins.
Give an alternative anticoagulant, such as, argatroban, bivalirudin, fondaparinux or rivaroxaban
Do not give platelet transfusions.
Do not give warfarin until the platelet count returns to its baseline level. If warfarin was administered, give vitamin K to restore the INR to normal.
Evaluate for thrombosis, particularly deep vein thrombosis in the lower extremities.

INR, international normalised ratio.

occur because warfarin lowers the levels of protein C and many HIT patients already have low levels of this anticoagulant protein because of increased thrombin generation.

Osteoporosis

Treatment with therapeutic doses of UFH for more than a month can cause a reduction in bone density, which can lead to vertebral fractures. Studies *in vitro* and in mice suggest that this occurs because UFH decreases bone formation and enhances bone resorption. The risk of osteoporosis is lower with LMWH than with UFH; fondaparinux does not appear to affect bone metabolism.

Elevated levels of transaminases

Therapeutic doses of UFH or LMWH can be associated with a modest elevation in serum levels of hepatic transaminases without a concomitant increase in the level of bilirubin. Levels of transaminases rapidly return to normal when the drugs are stopped.

Reversal of heparins

In patients with serious bleeding, the anticoagulant effects of UFH can be completely reversed with protamine sulphate, which is a mixture of basic polypeptides isolated from salmon sperm. Typically, 1 mg of protamine sulphate neutralises 100 U of heparin. Protamine sulphate incompletely neutralises the anticoagulant effects of LMWH because it binds only the longer chains. Because longer chains are responsible for the catalysis of thrombin inhibition by antithrombin, protamine sulphate completely reverses the anti-factor IIa activity of LMWH, but only partially reverses its anti-factor Xa activity and has no effect on the anticoagulant activity of fondaparinux. To avoid anaphylactoid reactions, protamine sulphate is administered by slow intravenous infusion. If available, andexanet alfa reverses the anti-factor Xa activity of LMWH and can be used for fondaparinux reversal.

Parenteral direct thrombin inhibitors

Heparin and LMWH indirectly inhibit thrombin because they require antithrombin to exert their anticoagulant activity. In contrast, direct thrombin inhibitors do not require a plasma cofactor; instead, they bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include argatroban and bivalirudin. Argatroban is licenced for the treatment of HIT, whereas bivalirudin is approved as an alternative to heparin in patients undergoing percutaneous coronary intervention (PCI), including those with HIT.

Argatroban

Mechanism of action

Argatroban, a univalent inhibitor that targets the active site of thrombin, is metabolised in the liver. Consequently, it must be used with caution in patients with hepatic insufficiency but is not affected by renal impairment. The drug has a half-life of about 45 min.

Indications

Prevention and treatment of thrombosis in patients with HIT.

Dosing

Argatroban is administered by continuous intravenous infusion at a starting dose of 1 mcg/kg/min; the starting dose is decreased to 0.5 mcg/kg/min in patients with hepatic impairment. The aPTT is used to monitor its anticoagulant effect, and the dosage is adjusted to achieve an aPTT 1.5–3 times the baseline value, but not to exceed 100 s. However, responsiveness of aPTT reagents varies and some studies favour thrombin inhibition assays such as the Ecarin chromogenic assay. Argatroban also prolongs the international normalised ratio (INR), a feature that can complicate transitioning of patients from argatroban to warfarin. This problem can be circumvented by using levels of factor X in place of the INR to monitor warfarin. Alternatively, the argatroban infusion can be stopped for 2–3 hours before determination of the INR.

Side-effects

Bleeding is the main side-effect. There is no reversal agent for argatroban.

Bivalirudin

Mechanism of action

A synthetic 20–amino acid analogue of hirudin, bivalirudin is a divalent thrombin inhibitor wherein its amino-terminal portion interacts with the active site of thrombin and its carboxy-terminal tail binds to exosite 1, the substrate-binding domain on thrombin. Bivalirudin has a plasma half-life of 25 min, the shortest half-life of all the parenteral direct thrombin inhibitors. It is degraded by peptidases and partially excreted via the kidneys.

Indications

Bivalirudin is licenced for prevention and treatment of thrombosis in patients with HIT and as an alternative to heparin in patients undergoing PCI or cardiac surgery.

Dosing

In patients with HIT, bivalirudin is administered by continuous intravenous infusion at a dose of 0.15 mg/kg/h if the creatinine clearance is over 60 mL/min; the dose is reduced to 0.08 mg/kg/h

if the creatinine clearance is between 30 and 60 mL/min and to 0.05 mg/kg/h if the creatinine clearance is less than 30 mL/min. When used as an alternative to heparin in patients undergoing PCI, bivalirudin is administered as a bolus of 0.75 mg/kg followed by an infusion of 1.75 mg/kg/h for the duration of the procedure.

Monitoring

When given in high doses for PCI, the anticoagulant activity of bivalirudin is monitored with the activated clotting time. With the lower doses used for HIT, its activity can be monitored using the aPTT. The target aPTT ratio is 1.5–2.5 compared with the baseline value.

Side-effects

Bleeding is the main side-effect. There is no reversal agent for bivalirudin.

Oral anticoagulants

For over 60 years, the vitamin K antagonists, such as warfarin, were the only available oral anticoagulants. This situation changed with the introduction of the DOACs, which include dabigatran, rivaroxaban, apixaban and edoxaban.

Warfarin

A water-soluble vitamin K antagonist initially developed as a rodenticide; warfarin is the most prescribed coumarin derivative.

Mechanism of action

Warfarin interferes with the synthesis of the vitamin K–dependent clotting proteins, which include prothrombin (factor II) and factors VII, IX and X, and anticoagulant proteins, which include protein C, protein S and protein Z.

All the vitamin K–dependent clotting factors possess glutamic acid residues at their amino terminals. A posttranslational modification adds a carboxyl group to the gamma carbon of these residues to generate gamma-carboxy glutamic acid. This modification is essential for expression of the activity of these clotting factors because it enables their calcium-dependent binding to anionic phospholipid surfaces. A vitamin K–dependent carboxylase catalyses the gamma-carboxylation. Thus, vitamin K from the diet undergoes reduction to vitamin K hydroquinone by vitamin K reductase (Figure 47.3). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which in the presence of carbon dioxide, replaces the hydrogen on the gamma carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidised to vitamin K epoxide, which then undergoes reduction to vitamin K in a reaction catalysed by vitamin K epoxide reductase.

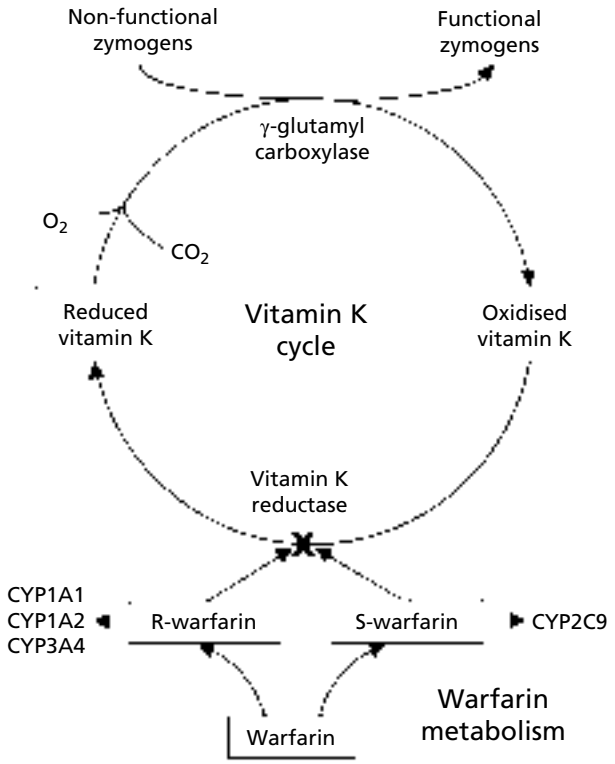

Figure 47.3 Mechanism of action of warfarin. A racemic mixture of *S*- and *R*-enantiomers, *S*-warfarin is the most active. By blocking vitamin K epoxide reductase, warfarin inhibits the conversion of oxidised vitamin K into its reduced form. This inhibits vitamin K–dependent gamma-carboxylation of factors II, VII, IX and X because reduced vitamin K serves as a cofactor for gamma-glutamylcarboxylase, which catalyses the gamma-carboxylation process, thereby converting non-functional zymogens (prozymogens) to functional zymogens capable of binding calcium and interacting with anionic phospholipid surfaces. *S*-warfarin is metabolised by CYP2C9. Common genetic polymorphisms in this enzyme can influence the metabolism of warfarin. Polymorphisms in the C1 subunit of vitamin K reductase (*VKORC1*) can also affect susceptibility of the enzyme to warfarin-induced inhibition, thereby influencing warfarin dosage requirements.

Warfarin inhibits vitamin K epoxide reductase, thereby blocking the gamma-carboxylation process. This results in the synthesis of partially gamma-carboxylated clotting proteins with little or no biological activity. Warfarin exerts its anticoagulant activity when the newly synthesised clotting factors with reduced activity gradually replace their fully active counterparts. The antithrombotic effect of warfarin requires a reduction in the functional levels of factor X and prothrombin, clotting factors with half-lives of 24 and 72 hours, respectively. Because the antithrombotic effect of warfarin is delayed, patients

with established thrombosis or at high risk for thrombosis require concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH or fondaparinux.

Warfarin is a racemic mixture of *R*- and *S*-isomers. It is rapidly and almost completely absorbed from the gastrointestinal tract. Levels of warfarin in blood peak approximately 90 minutes after administration. Racemic warfarin has a plasma half-life of 36–42 hours, and more than 97% of circulating warfarin is bound to albumin. Only a small fraction of unbound warfarin is biologically active.

Warfarin accumulates in the liver, where the two isomers are metabolised via distinct pathways. The more active *S*-enantiomer of warfarin is primarily metabolised by CYP2C9. Two relatively common variants, *CYP2C9*2* and *CYP2C9*3* encode an enzyme with reduced activity. Approximately 25% of Whites have at least one variant allele; these variant alleles are less common in Blacks and Asians. Patients with one variant allele require 20–30% lower maintenance doses of warfarin, whereas those homozygous for these alleles require 50–70% lower doses than do those with the wild-type *CYP2C9*1* alleles. Consistent with the decreased warfarin dose requirement, patients with at least one *CYP2C9* variant allele are at about a twofold higher risk for bleeding compared with individuals with no variant alleles.

Warfarin interferes with the vitamin K cycle by inhibiting the C1 subunit of vitamin K epoxide reductase (VKORCI). Polymorphisms in *VKORC1* can influence the anticoagulant response to warfarin. Several genetic variations of *VKORC1* are in linkage disequilibrium and have been designated as non-A haplotypes. *VKORC1* variants are more prevalent than variants of *CYP2C9*. Asians have the highest prevalence of *VKORC1* variants, followed by Whites and Blacks. The warfarin dose requirements for patients heterozygous or homozygous for the A haplotype are 25 and 50% lower than that needed for patients with the non-A/non-A haplotype. Polymorphisms in *CYP2C9* and *VKORC1* explain up to 25% of the variability in warfarin dose requirements. In addition to genetic factors, fluctuations in the dietary intake of vitamin K, concomitant medications and various disease states influence the anticoagulant effect of warfarin. Consequently, several computerised genotype-based warfarin dosing algorithms also include pertinent patient characteristics, such as age, body weight and concomitant medications. Although these algorithms streamline warfarin dosing, it remains unclear whether their use improves patient outcomes in terms of reducing haemorrhagic complications or recurrent thrombotic events.

Indications

Warfarin is used for the prevention and treatment of venous and arterial thromboembolism.

Dosages

Warfarin is usually started at a dose of 5–10 mg. Lower doses are used for patients with *CYP2C9* or *VKORC1* polymorphisms that affect the pharmacodynamics or pharmacokinetics of warfarin and render patients more sensitive to the drug. The dose is then titrated to achieve the desired target INR. Because of its delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH or fondaparinux. The initial increase in the INR reflects a reduction in the functional levels of factor VII. Consequently, concomitant treatment with the parenteral anticoagulant should be continued until the INR has been therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of prothrombin have fallen into the therapeutic range with warfarin.

Monitoring

Warfarin therapy is most often monitored with the prothrombin time (PT), a test sensitive to reductions in the levels of prothrombin, factor VII and factor X. The test involves the addition of thromboplastin, a reagent that contains tissue factor, phospholipid and calcium, to citrated plasma and determination of the time until clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of vitamin K–dependent clotting factors. Consequently, less sensitive thromboplastins will trigger the administration of higher doses of warfarin to achieve a target PT. This issue can cause problems because higher doses of warfarin increase the risk for bleeding.

The INR was developed to circumvent many of the problems associated with the PT. To calculate the INR, the patient's PT is divided by the mean normal PT, and this ratio is then raised to the power of the international sensitivity index (ISI), an index of the sensitivity of the thromboplastin used for determination of the PT to reductions in levels of the vitamin K–dependent clotting factors. Extremely sensitive thromboplastins have an ISI of 1.0. Most current thromboplastins have ISI values that range from 1.0 to 1.4.

Although the INR has helped standardise anticoagulant practice, problems persist. The precision of INR determination varies depending on reagent-coagulometer combinations, which has led to variability in INR results. Unreliable reporting of the ISI by thromboplastin manufacturers also complicates determination of the INR. Furthermore, every laboratory must establish the mean normal PT with each new batch of thromboplastin reagent. To accomplish this, the PT is measured in newly collected plasma samples from at least 20 healthy volunteers via the same coagulometer that is used for patient samples.

For most indications, warfarin is administered at doses that produce a target INR of 2.0–3.0. An exception is patients with mechanical heart valves in the mitral position or in patients with a mechanical heart valve in other positions who have additional risk factors for stroke, such as atrial fibrillation, in whom a target INR of 2.5–3.5 is recommended. Studies in

patients with atrial fibrillation demonstrate an increased risk for ischaemic stroke when the INR falls below 1.7 and an increase in bleeding with INR values higher than 4.5. These findings highlight the narrow therapeutic window of vitamin K antagonists.

The narrow therapeutic window of warfarin renders frequent monitoring of coagulation necessary to ensure a therapeutic anticoagulant response. Even patients with stable warfarin, dose requirements should have their INR determined every 3–4 weeks. Although some studies have raised the possibility that testing every 12 weeks may suffice in such patients, these results require confirmation in larger numbers of patients. More frequent INR monitoring is necessary with the introduction of new concomitant medications because many drugs enhance or reduce the anticoagulant effects of warfarin.

Side-effects

The major side-effect of warfarin is bleeding; a rare complication is skin necrosis. Uncommon side-effects include vascular calcification, particularly in patients with end-stage kidney disease, alopecia and purple toes. Unless a parenteral anticoagulant is given concomitantly, skin necrosis can occur with the initiation of warfarin therapy in patients with hereditary or acquired deficiency in protein C or protein S because warfarin lowers the levels of these vitamin K–dependent anticoagulant proteins even further prior to exerting its antithrombotic effects. Warfarin crosses the placenta and can cause fetal abnormalities, so it should not be used during pregnancy.

Bleeding

At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or haematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding can also occur. Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation of the cause of the bleeding.

Skin necrosis

A rare complication of warfarin, skin necrosis usually occurs 2–5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts or toes. Typically, the centre of the lesion becomes progressively necrotic. Examination of skin biopsy specimens taken from the borders of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis occurs in patients with congenital or acquired deficiencies of protein C or protein S or in patients with HIT whose heparin has been stopped but an alternate anticoagulant has not been given. Initiation of warfarin therapy in these patients produces a precipitous fall in the plasma levels of proteins C and S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect through lowering of the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis that is localised to the microvasculature of fatty tissues for unknown reasons.

Treatment of warfarin-induced skin necrosis involves discontinuation of warfarin and reversal with vitamin K if needed. An alternative anticoagulant should be given to patients with thrombosis. Protein C concentrates may accelerate healing of the skin lesions in protein C–deficient patients; fresh frozen plasma may be of value for those with protein S deficiency. Occasionally, skin grafting is necessary in those with extensive skin loss. Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when initiating warfarin therapy. Warfarin should be started at low doses in these patients, and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2–3 consecutive days. The use of rivaroxaban or apixaban in place of warfarin can simplify management of such patients.

Pregnancy

Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk for embryopathy is highest with warfarin administration in the first trimester of pregnancy. Central nervous system abnormalities can also occur with exposure to warfarin at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus that can cause bleeding. This is of particular concern at delivery when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential problems, warfarin is contraindicated in pregnancy, particularly in the first and third trimesters. Instead, heparin, LMWH or fondaparinux can be given during pregnancy for prevention or treatment of thrombosis. Warfarin does not pass into breast milk and thus is safe for nursing mothers.

Periprocedural management

There is no need to stop warfarin treatment before procedures associated with a low risk for bleeding such as dental cleaning, simple dental extraction, cataract surgery or skin biopsy. In contrast, warfarin must be stopped 5 days before elective invasive procedures associated with a moderate or high risk for bleeding to allow the INR to return to normal levels. Only patients at high risk for thrombosis while not taking warfarin (such as those with mechanical heart valves in the mitral

position or patients with atrial fibrillation with a prior history of stroke) require bridging with once- or twice-daily subcutaneous injections of LMWH when the INR falls below 2.0. The last dose of LMWH should be given 12–24 hours before the procedure, depending on whether LMWH is administered twice or once daily, respectively. Once haemostasis is secure after the procedure, warfarin can be restarted. Thromboprophylaxis with LMWH can be given starting the day after major surgery and should be continued until the INR is therapeutic

Reversal

In asymptomatic patients whose INR is between 3.5 and 9, warfarin should be withheld until the INR returns to the therapeutic range. If the patient is at high risk for bleeding, sublingual or oral vitamin K at a dose of 1–2.5 mg can be considered. Patients with serious bleeding require 10 mg of vitamin K by slow intravenous infusion with additional doses of vitamin K until the INR is in the normal range together with four-factor prothrombin complex concentrate to replace the missing vitamin K–dependent clotting proteins. Prothrombin complex concentrate is preferred over fresh frozen plasma for warfarin reversal because it normalises the INR more rapidly and because the volume of administration is much smaller.

Direct oral anticoagulants (DOACs)

Mechanism of action

The DOACs include dabigatran, which inhibits thrombin, and apixaban, edoxaban and rivaroxaban, which inhibit factor Xa. These agents, which are small molecules that bind reversibly to the active site of their target enzyme, have a rapid onset of action after oral administration and have half-lives that permit once- or twice-daily administration (Table 47.5). Designed to produce a predictable level of anticoagulation, the DOACs are more convenient than warfarin because they can be given in fixed doses without routine coagulation monitoring.

Indications

All four DOACs are licenced for stroke prevention in patients with non-valvular atrial fibrillation, which encompasses patients without mechanical heart valves or severe rheumatic mitral valve disease, and for treatment of venous thromboembolism (VTE). For these indications, guidelines give preference to DOACs over VKAs such as warfarin for most patients. Exceptions are patients with (i) end-stage kidney disease and a creatinine clearance below 15 mL/min, (ii) triple positive antiphospholipid syndrome (i.e. lupus anticoagulant and elevated levels of anticardiolipin and anti-beta2-glycoprotein I antibodies) and (iii) cancer-associated thrombosis at high risk for bleeding such as those with an unresectable intraluminal gastrointestinal or gastroesophageal tumour or transitional cell cancer of the bladder, and patients with multiple brain metastases.

Dabigatran, rivaroxaban and apixaban are licenced for thromboprophylaxis after elective hip or knee arthroplasty; edoxaban is only licenced for this indication in Japan. Very low dose rivaroxaban is licenced for use with aspirin for secondary prevention in patients with coronary or peripheral artery disease.

Dosing

For prevention of stroke in patients with nonvalvular atrial fibrillation, rivaroxaban is given at a dosage of 20 mg once daily, with a reduction to 15 mg once daily in patients with a creatinine clearance of 15–49 mL/min; dabigatran is given at a dosage of 150 mg twice daily with a reduction to 110 mg twice daily in patients over 80 years of age or over 75 years of age with a risk factor for bleeding such as a creatinine clearance between 30 and 50 mL/min or concomitant use of an antiplatelet agent; the 110 mg dabigatran dosage is not available in the United States where a dosage of 75 mg twice daily is used for patients with a creatinine clearance of 15–30 mL/min and the 150 mg twice daily dose for those with a creatinine clearance over 30 mg/mL; apixaban is given at a dosage of 5 mg twice daily, with a reduction to 2.5 mg twice daily for patients with at least two of the

Table 47.5 Comparison of the pharmacologic properties of the direct oral anticoagulants.

Characteristic	Rivaroxaban	Apixaban	Edoxaban	Dabigatran
Target	Factor Xa	Factor Xa	Factor Xa	Thrombin
Prodrug	No	No	No	Yes
Bioavailability	80%	60%	50%	6%
Dosing	qd (bid)	bid	qd	bid (qd)
Half-life (hours)	7–11	12	9–11	12–17
Renal excretion	33% (66%)	25%	50%	80%
Interactions	CYP3A4/P-gp	CYP3A4/P-gp	P-gp	P-gp

bid, twice a day; CYP, cytochrome P450; P-gp, P-glycoprotein; qd., once a day.

'ABC' criteria (i.e., age over 80 years, body weight under 60 kg and creatinine over 1.5 g/dL); and edoxaban is given at a dosage of 60 mg once daily for patients with a creatinine clearance of 50–95 mL/min and with a reduction to 30 mg once daily for patients with any one of the following criteria: creatinine clearance 15–50 mL/min, a body weight of 60 kg or less, or use of potent P-glycoprotein inhibitors, such as verapamil or quinidine.

For treatment of VTE, dabigatran and edoxaban are started after patients have received at least a 5-day course of treatment with a parenteral anticoagulant such as LMWH; dabigatran is given at a dose of 150 mg twice daily provided the creatinine clearance is over 30 mL/min, and the dosage regimen for edoxaban is identical to that used in patients with atrial fibrillation. In contrast, rivaroxaban and apixaban can be given in all-oral regimens; rivaroxaban is started at a dose of 15 mg twice daily for 21 days and is then reduced to 20 mg once daily thereafter, whereas apixaban is started at a dose of 10 mg twice daily for 7 days and is then reduced to 5 mg twice daily thereafter. For long-term secondary prevention, the dosage of apixaban can be lowered to 2.5 mg twice daily and the dose of rivaroxaban can be lowered to 10 mg once daily, doses that have safety profiles similar to those of placebo and aspirin, respectively.

Dabigatran, rivaroxaban and apixaban are licenced for thromboprophylaxis after elective hip or knee replacement surgery; edoxaban is not licenced for this indication except in Japan. Thromboprophylaxis is started after surgery and is often continued for 30 days in patients undergoing hip replacement and for 10–14 days in patients undergoing knee replacement. In lower-risk patients undergoing hip or knee replacement surgery, a 5-day course of rivaroxaban followed by a 30-day course of aspirin at a dose of 81 mg daily appears to be as effective and safe as extended thromboprophylaxis with rivaroxaban. Dabigatran is given at a dose of 220 mg once daily, whereas rivaroxaban and apixaban are given at doses of 10 mg once daily and 2.5 mg twice daily, respectively.

For secondary prevention in patients with stable coronary or peripheral artery disease, very low dose rivaroxaban (2.5 mg twice daily) is combined with aspirin (81–100 mg once daily) to lower the risk for major adverse cardiovascular or limb events. None of the other DOACs is approved for this indication.

Monitoring

Although administered without routine monitoring, it is helpful to determine the anticoagulant activity of the DOACs in some situations, such as assessment of adherence, detection of accumulation or overdose, identification of bleeding mechanisms and determination of activity before surgery or intervention. For qualitative assessment of anticoagulant activity, the PT can be used for factor Xa inhibitors and the aPTT for dabigatran. However, the PT and aPTT may be normal even in the presence of relevant concentration of drug. Rivaroxaban and edoxaban prolong the PT more than apixaban does. In fact, because apixaban has such a limited effect on the PT, anti-factor Xa assays are needed to assess its activity. The effect of the drugs on tests of coagulation varies depending on the reagents used to perform the tests. Chromogenic anti-factor Xa assays and the diluted thrombin clotting time or ecarin clotting or chromogenic assays with appropriate calibrators provide quantitative assays to measure plasma levels of the factor Xa inhibitors and dabigatran, respectively.

Side-effects

As with any anticoagulant, bleeding is the most common side-effect of the DOACs. Although the risk of intracranial bleeding is lower with the DOACs than with warfarin, the risk for gastrointestinal bleeding is higher with dabigatran (at the 150 mg twice-daily dose), rivaroxaban and edoxaban (at the 60 mg once-daily dose) than with warfarin. Dyspepsia occurs in up to 10% of patients treated with dabigatran; this problem improves with time and can be minimised by taking the drug with food. As small molecules, the DOACs can pass through the placenta. Consequently, these agents are contraindicated in pregnancy, and when used by women of childbearing potential, appropriate contraception is important. Small amounts of rivaroxaban pass into breast milk. Therefore, DOACs should not be used by nursing mothers.

Periprocedural management

Like warfarin, the DOACs must be stopped before surgical procedures associated with a moderate or high risk for bleeding. The drugs should be withheld for 1–2 days or longer if renal function is impaired. After surgery, patients should receive thromboprophylaxis with LMWH until haemostasis is restored, at which point the DOACs can be restarted.

Cardiac procedures such as atrial fibrillation ablation or pacemaker implantation can safely be performed without interruption of the DOACs. However, it may be prudent to hold the dose on the morning of the day of the procedure to avoid intervention at peak drug levels.

Management of bleeding

With minor bleeding, withholding one or two doses of drug is usually sufficient. With more serious bleeding, the approach is like that with warfarin, except that vitamin K administration is of no benefit; the anticoagulant and any antiplatelet drugs should be withheld, the patient should be resuscitated with fluids and blood products as necessary, and the bleeding site should be identified and managed. Coagulation testing will determine the extent of anticoagulation, and renal function should be assessed so that the half-life of the drug can be estimated. Timing of the last dose of anticoagulant is important, and oral activated charcoal may help prevent absorption of drug administered in the past 4 hours, particularly in cases of overdose. If bleeding continues or is life-threatening or if it occurs in a critical organ (e.g. the eye) or in a

closed space (e.g. the pericardium or retroperitoneum), reversal of the anticoagulant should be considered.

Reversal

The pharmacological features of the agents available for DOAC reversal are described in Table 47.6 available for DOAC reversal, and idarucizumab is licenced for dabigatran reversal in patients with serious bleeding or those requiring urgent surgery or intervention. A humanised antibody fragment, idarucizumab binds dabigatran with 350-fold higher affinity than that of dabigatran for thrombin to form an essentially irreversible complex that is cleared by the kidneys. Idarucizumab, which is given intravenously as a 5-g bolus, rapidly reverses the anticoagulant effects of dabigatran and normalises the aPTT, diluted thrombin time or ecarin clot time.

Andexanet alpha is available, depending on local approval, for reversal of rivaroxaban, apixaban and edoxaban. A recombinant variant of factor Xa without catalytic activity, andexanet serves as a decoy to sequester oral factor Xa inhibitors until they are cleared from the circulation. Low or high-dose intravenous andexanet regimens are used. The low-dose regimen starts with a bolus of 400 mg followed by an infusion of 4 mg/min for up to 120 min, whereas the high-dose regimen starts with a bolus of 800 mg followed by an infusion of 8 mg/min for up to 120 min. The low-dose regimen is used for reversal of doses of rivaroxaban or apixaban of 10 mg or 5 mg or less, respectively, or for any dose of rivaroxaban or apixaban if the last dose was taken more than 8 hours prior to presentation. The high dose regimen is used to reverse rivaroxaban or apixaban doses over 10 and 5 mg, respectively, if the last dose was taken less than 8 hours since the presentation, or for reversal if the dose of rivaroxaban or apixaban or the timing of the last dose is unknown. Andexanet alfa is expensive and is not available in all countries and in all hospitals. Because of its cost, andexanet alfa is often reserved for reversal in patients with intracranial bleeds or for bleeds into a closed space such as retroperitoneal or pericardial bleeds. If andexanet is unavailable, the results of prospective cohort studies suggest that four-factor prothrombin complex concentrate (25–50 units/kg) also is effective at restoring haemostasis. If there is continued bleeding, activated prothrombin complex concentrate (50 units/kg) or recombinant factor VIIa (90 μg/kg) can be considered.

Neither andexanet alfa nor prothrombin complex concentrate has been evaluated for reversal in patients requiring urgent surgery or intervention. Furthermore, andexanet alfa not only reverses oral factor Xa inhibitors but also reverses heparin and LMWH. This could be problematic in patients who require cardiac surgery or vascular surgery, procedures where heparin is used routinely. To circumvent this problem, most surgical procedures and interventions can be done without reversal and four-factor prothrombin complex concentrate can be given if necessary. For patients requiring surgery to stop bleeding such as those with a ruptured aortic aneurysm or with bleeding secondary to polytrauma, upfront four-factor prothrombin concentrate administration can be considered.

At an earlier stage of development than andexanet, ciraparantag is a synthetic, cationic small molecule that binds rivaroxaban, apixaban and edoxaban, as well as dabigatran, heparin, LMWH and fondaparinux. When given as an intravenous bolus to volunteers who took rivaroxaban, apixaban or edoxaban, ciraparantag reduced the whole-blood clotting time in a concentration-dependent manner. Additional studies are needed before ciraparantag will be approved.

Table 47.6 Reversal agents for direct oral anticoagulants.

Feature	Idarucizumab	Andexanet Alfa	Ciraparantag
Structure	Humanised antibody fragment	Recombinant human factor Xa variant	Synthetic, small cationic molecule
Mass (Da)	47,776	39,000	573
Mechanism of action	Binds dabigatran with high affinity	Competes with factor Xa for binding	Binds via hydrogen bonds
Target	Dabigatran	Rivaroxaban, apixaban, edoxaban and heparins	Dabigatran, rivaroxaban, apixaban, edoxaban and heparins
Administration	Intravenous bolus	Intravenous bolus followed by a 2-hour infusion	Intravenous bolus
Measurement of reversal	Activated partial thromboplastin time, diluted thrombin time, ecarin clotting time or chromogenic assay	Calibrated anti-factor Xa assays	Whole-blood clotting time
Elimination	Renal (catabolism)	Not reported	Not reported
Cost	Moderate	High	Likely low

Novel anticoagulants in development

Although the DOACs are a major advance over warfarin, the search for more effective and safer anticoagulants continues. Evidence that factor XII and factor XI, components of the contact system, are important for thrombosis but less so for haemostasis has prompted the development of anticoagulants that target these factors. Ongoing studies are evaluating antisense oligonucleotides, inhibitory antibodies and small molecule inhibitors of factor XI.

CHAPTER 48

Pathogenesis of venous thromboembolism

48

Henry G Watson

School of Medicine and Dentistry, University of Aberdeen, Scotland, UK

Introduction

Epidemiology of venous thromboembolism (VTE)

Deep vein thrombosis (DVT) is common, principally affecting the lower limbs. In western populations, the annual incidence is around 1–1.5 per 1000 population. Incidence is age-dependent, being exceptional in childhood and increasing with age with an incidence of around 1 per 10,000 population per annum in young adults, and 1 per 100 per annum in the very elderly. The incidence of pulmonary embolism is lower, at around 1 per 3000 population annually, although subclinical pulmonary embolism occurs frequently in subjects with proximal lower limb DVT. Of patients who die in hospital, there is evidence of pulmonary embolism in up to 20% of cases and in many, it contributes to the cause of death. In some cases pulmonary embolism presents without identifiable DVT, reflecting that 80% of DVT are clinically silent. Venous thrombosis can of course develop in any part of the circulation and indeed in certain conditions, there is a predilection for specific sites such as in the splanchnic circulation in patients with myeloproliferative neoplasms or in the cerebral veins in patients with the rare vaccine induced thrombocytopenia and thrombosis syndrome (VITT).

Virchow's triad, described in 1859, postulates that venous thrombosis may result from changes in blood flow, hypercoagulability of the blood or abnormalities of the blood vessel wall. Each of these features could arise from genetic or acquired conditions and acquired conditions may be persistent or transient. Venous thrombosis should be viewed as a multicausal disease in which genetic and acquired risk factors interact synergistically. This effect may be additive or multiplicative. The interaction between combined oral contraceptive preparations and factor V Leiden is probably the best-documented description of this synergistic relationship between inherited and acquired risk factors (Rosendaal Diagram as Figure 48.1). Understanding gene–environment interactions and the concept of multiple coinciding risk factors is necessary to recognise periods of increased thrombosis risk for patients. Modern management of proven episodes of VTE emphasises the detection, or not, of risk factors that might determine the duration of anticoagulation and the use of validated scoring systems to predict the risk of recurrence of thrombosis following withdrawal of anticoagulant therapy in those sustaining otherwise 'unprovoked' episodes of VTE. Conditions deemed to be risk factors for VTE are shown in Table 48.1.

Hereditary thrombophilia

Familial thrombophilia is likely a multiple-gene disorder. Family members of 'thrombosis-prone families' may have one or more defects some of which will be identifiable in the laboratory whilst others are not.

In most instances, heritable thrombophilia is a late-onset genetic disease with low penetrance. There is no internationally accepted definition of thrombophilia. A clinical definition of heritable thrombophilia describes an inherited tendency for venous thrombosis.

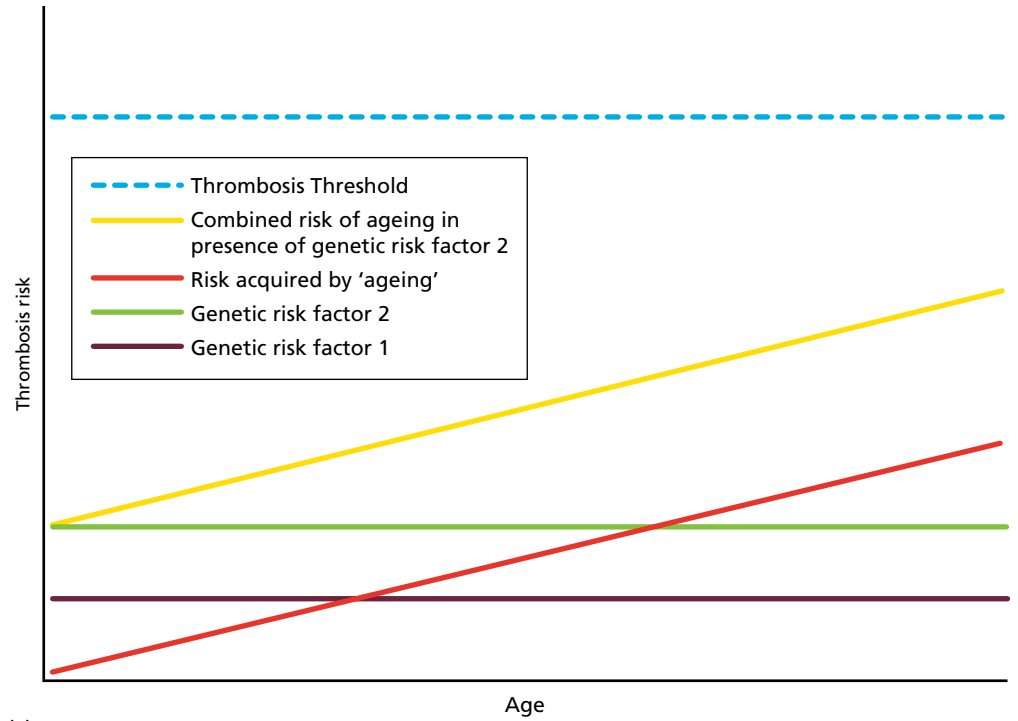

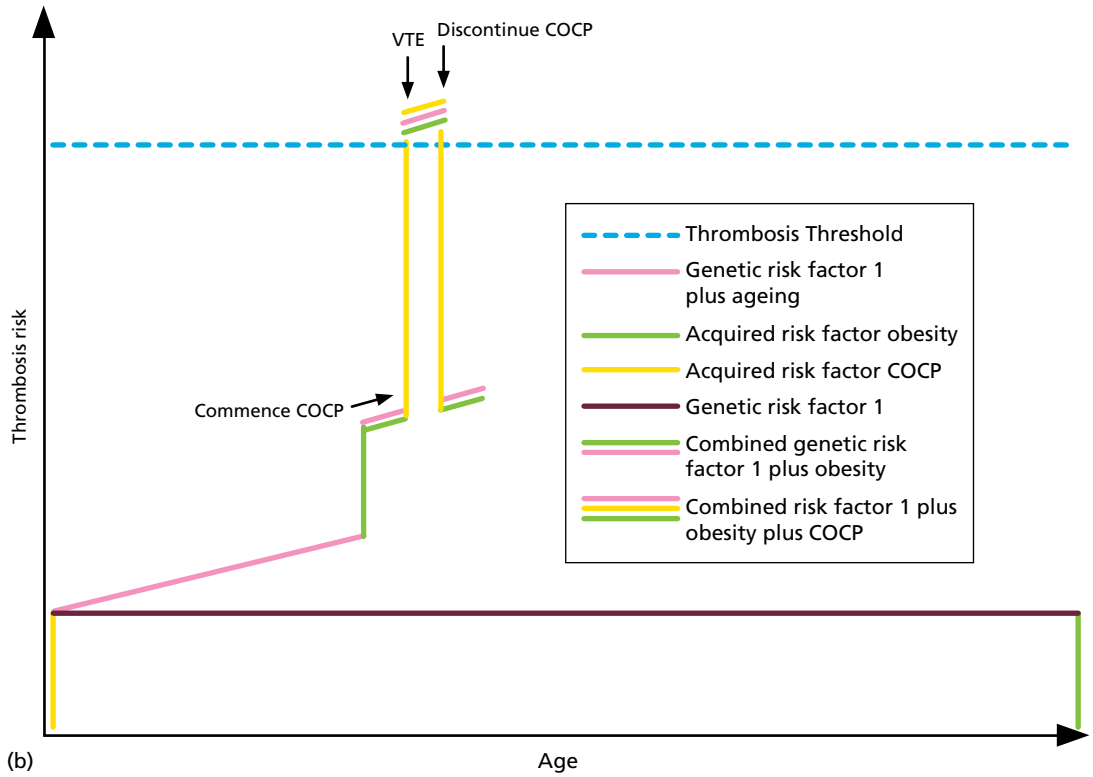

Figure 48.1 (a) The model assumes that there is a thrombosis threshold that, when breached may result in the development of VTE. Numerous risk factors, inherited and acquired, permanent and temporary can contribute to the risk of developing thrombosis. It is well recognised that thrombosis risk increases with age probably due to the acquisition of factors that result in vascular degeneration and hypercoagulability. Thrombosis-prone families, such as those with factor V Leiden have an inherited risk of thrombosis which is constant in

Deficiencies of the natural anticoagulants antithrombin, protein C and protein S have been linked with familial thrombosis. The causal association between these heritable thrombophilias and venous thrombosis has been confirmed by comparing the prevalence of defects in patients with venous thrombosis and controls. In recent years, several other potential thrombophilic risk factors have been investigated but only the *F5*G1691A (FVR506Q, FV Leiden) and the *F2*G20210A gain of function gene mutations have been shown to be unequivocally associated with an increased risk of thrombosis, that is an odds ratio (OR) of ≥2. The prevalence of the heritable thrombophilias varies across populations and the relative risk (RR) for thrombosis development (the probability of the disease in those with the risk factor divided by the probability of the disease in those without the risk factor) or the odds ratio (OR) (the odds of the disease in those with the risk factor divided by the odds of the disease in those without the risk factor) ranges from around 2, for the *F2*G20210A, to 20 for antithrombin deficiency.

It was hoped that the availability of laboratory tests for these conditions would significantly help to inform clinical decision-making within families and also in patients with a first episode of unprovoked VTE. It is now apparent that testing for heritable thrombophilia typically does not predict the likelihood of recurrence in the majority of unselected patients with symptomatic venous thrombosis (Figure 48.2). Furthermore, testing for inherited thrombophilia has not been shown to reduce recurrence of venous thrombosis in clinical studies. There is a low risk of thrombosis in affected asymptomatic relatives of patients with thromobophilic defects followed prospectively and the results of thrombophilia tests are, as such, frequently given undue weight resulting in dubious clinical decision-making with regard to the management of periods of risk and exposure to risk factors. Given these considerations, the clinician must consider the potential clinical utility of testing for heritable thrombophilic defects in each individual patient or family affected by venous thrombosis.

Heritable thrombophilia is subject to a strong gene–environment interaction. For example, there is a synergistic increase in the risk of venous thrombosis due to an interaction between the factor V Leiden mutation and oestrogen exposure and obesity. Similar observations have been made in antithrombin-deficient families where venous thrombosis frequently occurs when an affected individual is exposed to an environmental risk. This was evident in a study of families with type 1 antithrombin deficiency, where the incidence of venous thrombosis was 20 times greater in affected family members, but was strongly dependent on the presence of concurrent acquired risk factors. In this study, the annual incidence of venous thrombosis in affected family members in any year in which they were exposed to surgery, trauma, plaster cast immobilisation or hospitalisation was 20% (provoked venous thrombosis). However, in any year in which there was no exposure the incidence of VTE was only 0.3% (i.e. unprovoked venous thrombosis rate). This is very much in keeping with the multicausal model for VTE described by Rosendaal shown in Figure 48.1.

Antithrombin deficiency

The gene for antithrombin (*SERPINC1* and previously termed antithrombin III) is located on the long arm of chromosome 1 and contains seven exons spanning 13.5 kb encoding a glycoprotein of 464 amino acids, 58 kDa and plasma concentration 2–3 μmol/L. Antithrombin is a serpin (serine protease inhibitor) and its primary targets are thrombin, factor Xa and factor IXa. Its molar concentration in the circulation is higher than that of prothrombin, and as only a fraction of prothrombin is converted to thrombin during coagulation, antithrombin is present in vast excess over the protease, although the site will determine the local concentrations of the enzyme and inhibitor. The plasma half-life of antithrombin is about 90 hours.

The serpin mechanism was confirmed following resolution of a crystal structure of the final serpin–protease complex in 2000. In contrast to the classical lock-and-key mechanism of protease inhibition, serpins form a stable covalent complex in which there is a

level over time (genetic risk factor 1). Some genetic factors are associated with a higher risk than others (genetic risk factor 2). The combined effect of genetic risk factor 2 and increasing age is shown). The model shows the increasing risk of thrombosis with age and also the increased thrombosis risk associated with the combined effects of an inherited and acquired risk factors. (b) This figure demonstrates the effect on thrombosis of combinations of risk factors. The figure assumes a thrombosis threshold and that thrombosis risk increases with age as outlined in (a). The level of risk of thrombosis associated with genetic risk factor 1, use of the combined oral contraceptive and with obesity are all similar as shown in the figure. The figure demonstrates the effect of the concurrence of risk factors in the development of VTE. In some situations the concurrence of risk factors, such as genetic risk factor 1 and obesity results in an additive effect while the concurrence of genetic risk factor 1 and the COCP has a multiplicative effect on thrombosis risk. The temporary and reversible nature of thrombosis risk factors, which may result in recommendations of finite periods of anticoagulation are also demonstrated. In the figure, the effect of ageing combined with genetic risk factor 1 is shown. The patients thrombosis risk increases as obesity develops. The addition of the COCP to genetic risk factor 1 combined with obesity results in clinical VTE. When the patient develops VTE, the COCP is stopped and the risk of thrombosis returns to that associated with the combination of genetic risk factor 1 and obesity.

Table 48.1 Risk factors for venous thromboembolism.

Familial thrombophilia
- Antithrombin deficiency
- Protein C deficiency
- Protein S deficiency
- FVR506Q (Factor V Leiden)
- F2G20210A (Prothrombin mutation)

Inevitable/environmental
- Increasing age
- Pregnancy and puerperium
- Prolonged immobility, e.g. long-haul travel
- Obesity
- Trauma

Iatrogenic
- Surgery
- Indwelling venous devices
- Pharmacological
- Oestrogen-related: combined oral contraceptive, hormone-replacement therapy, tamoxifen
- Ovarian stimulation regimens
- Chemotherapy and radiotherapy
- Heparins (immune reaction)

Disease-related
- Antiphospholipid syndrome
- Cancer
- Myeloproliferative neoplasms
- Acute promyelocytic leukaemia
- Chronic inflammatory states e.g. nephrotic syndrome, Behcet's syndrome, inflammatory bowel disease, connective tissue disorders
- Acute inflammatory disorders e.g. pneumonia, sepsis.
- Stroke
- Paroxysmal nocturnal haemoglobinuria
- Thrombotic thrombocytopenic purpura
- Sickle cell disease and other sickling syndromes
- Congestive cardiac failure

dramatic conformational change in both the inhibitor and the inhibited protein that alters the properties of each, resulting in rapid clearance from the circulation. Antithrombin consists of three β-sheets and nine α-helices organised into an upper β-barrel domain and a lower helical domain. These two domains are bridged by the main structural feature of a serpin, the central A sheet. The flexible reactive centre loop (RCL) contains the scissile bond formed by the P1 arginine and P1′ serine. Amino acids in the RCL are designated P1, P2 and so forth, moving towards the N-terminus of the peptide sequence and P1′, P2′ and so forth moving towards the C-terminus of the sequence. The length and flexibility of the loop render it highly susceptible to proteolysis. Cleavage of the RCL by thrombin, FXa or FIXa produces a conformational change during which the RCL inserts as the central strand of the expanded central A sheet. This results in translocation of the protease to the opposite pole of the serpin. The incorporation of the RCL as the central strand produces a hyperstable molecule such that the protease is crushed by intermolecular clashes with the hyperstable serpin. Distortion of the active site architecture disrupts the catalytic triad and results in disorganisation of almost 40% of the protease architecture. The poor inhibitory activity of the circulating native form of antithrombin is conferred by intramolecular contacts that restrain the RCL and orientate the P1 arginine away from attacking proteases. Activation via release of the RCL is favoured by binding of glycosaminoglycans to the 'heparin-binding site' located in the region of the D-helix. An initial low-affinity interaction induces high-affinity binding (referred to as an induced fit mechanism) and this produces a conformational change in the antithrombin that releases the RCL for protease attack. Activation increases the rate of protease inactivation 1000-fold. Successful inhibition of the protease depends on a race between complete proteolysis of the RCL with release of the regenerated protease from the cleaved loop (the substrate pathway) and incorporation of the cleaved loop into the central A-sheet with resultant capture and crushing of the tethered protease (the inhibitory pathway). Some mutations in the *SERPINC1* gene produce a dysfunctional antithrombin molecule in which the insertion of the RCL into the central A-sheet is retarded, turning the molecule into a substrate rather than an inhibitor. This is an example of how this highly regulated mechanism of thrombin or FXa inhibition renders antithrombin susceptible to dysfunction through genetic mutation.

Two laboratory phenotypes of heritable antithrombin deficiency are recognised. Type 1 is characterised by a quantitative reduction of antithrombin, with a parallel reduction in function and the level of protein in the plasma measured immunologically as the antigenic level. Type 2 deficiency is due to the production of a qualitatively abnormal antithrombin protein. The functional activity is discrepantly low compared with the antigenic level. Type 2 deficiency is subclassified according to the nature of the functional defect:

- Type 2 reactive site (*RS*): mutations alter the sequence of the RCL, reducing the ability to inhibit thrombin or FXa in the presence or absence of heparin in a laboratory assay.
- Type 2 heparin-binding site (*HBS*): mutations affect the ability of antithrombin to bind to and be activated by glycosaminoglycans and therefore result in reduced ability to inhibit thrombin or FXa only in the presence of heparin in a laboratory assay. These mutations are typically located in the designated 'heparin-binding site' in the region of the D helix of the molecule.
- Type 2 pleiotropic (*PE*): a single mutation produces multiple effects on the structure–function relationship of the molecule, particularly the interaction between heparin binding and RCL, often associated with low plasma levels due to either effects on secretion or instability.

Approximately 100-point mutations (missense, nonsense or insertions or deletions causing frameshifts) and several whole

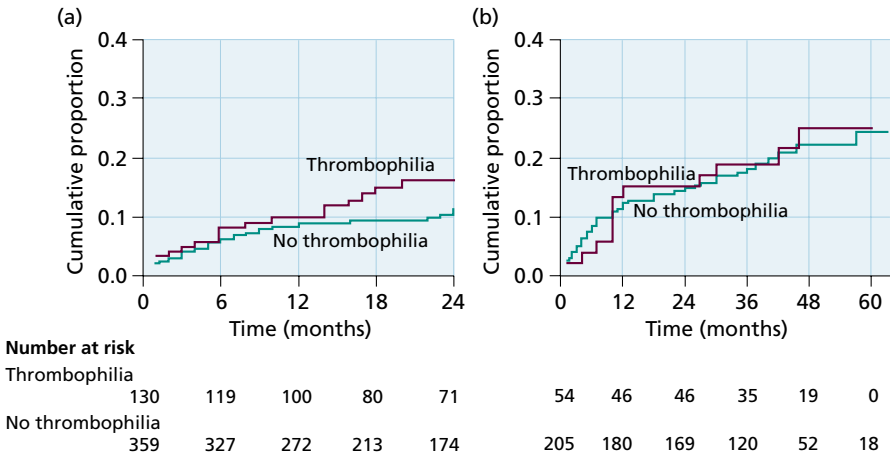

Figure 48.2 Cumulative recurrence of venous thrombosis in consecutive patients with and without heritable thrombophilia followed from the end of anticoagulation after a first episode of venous thrombosis in the first (a) and second (b) Cambridge cohort studies. The hazard ratio for recurrence in patients with thrombophilia compared with those without was 1.3 (95% CI 0.8–2.0) and 1.0 (95% CI 0.5–2.1), respectively. In the second cohort, patients with postoperative thrombosis were excluded, which may account for the slightly higher recurrence rate. (Source: For related publications on these cohorts, see Baglin *et al.* (2003) and Baglin T, Palmer CR, Luddington R, Baglin C (2008) Unprovoked recurrent venous thrombosis: prediction by D-dimer and clinical risk factors. *J. Thromb. Haemost.* **6:** 577–82.)

or partial gene deletions have been identified as causes of type 1 deficiency. Numerous point mutations causing qualitative type 2 deficiency have been identified. Homozygous type 1 deficiency and probably homozygous type 2 *RS* mutations are incompatible with life. Homozygous type 2 *HBS* and *PE* mutations are compatible with life but are associated with increased risk of thrombosis and adverse pregnancy outcome.

Protein C deficiency

The gene for protein C (*PROC*) is located on chromosome 2 and contains nine exons spanning 11 kb. Protein C is a vitamin-K-dependent glycoprotein synthesised in the liver (419 amino acids, 62 kDa, plasma concentration 65 nmol/L). Its concentration in plasma is about 100 times less than that of antithrombin. The plasma half-life of protein C is about 6 hours.

Protein C is the zymogen precursor of activated protein C (APC). Protein C is activated by thrombin bound to thrombomodulin on the endothelial surface. This is facilitated by the endothelial protein C receptor (EPCR). APC acts as a physiological anticoagulant by cleaving the cofactors FVa and FVIIIa so reducing thrombin generation. Protein S is a cofactor for APC-mediated inactivation of FVa and FVIIIa. APC has an anti-inflammatory effect on endothelium via cleavage of PAR1 and also reduces pro-inflammatory cytokines such as IL-6, IL-8 and TNFα and upregulates anti-inflammatory cytokines such as IL-10. These actions may also be relevant to thrombosis risk.

Protein C deficiency is classified into type 1 and 2 defects on the basis of functional and antigenic assays. The relative risk of thrombosis in relation to type 1 and the various type 2 defects has not been characterised. Most heritable protein C deficiency is due to type 1 deficiency. The majority of type 1 defects are due to point mutations. Multiple type 2 defects have been reported involving the catalytic active site, the phospholipid-binding Gla domain, the propeptide cleavage activation site and sites of interaction with substrates or cofactors.

Protein S deficiency

The gene for protein S (*PROS*) is located on chromosome 3 and contains 15 exons spanning 80 kb. A pseudogene with approximately 95% homology is located adjacent to *PROS* and this can cause difficulty in the identification of mutations within *PROS*.

Protein S is a vitamin-K-dependent glycoprotein produced in the liver, endothelial cells and megakaryocytes (676 amino acids, 69 kDa, plasma concentration of free protein 145 nmol/L). Protein S is a non-enzymatic cofactor for APC-mediated inactivation of FVa and FVIIIa. Approximately 60% circulates bound to C4b-binding protein and this portion is inactive. The remaining 40%, designated free protein S, is uncomplexed and is the active form. Free protein S increases the affinity of APC for negatively charged phospholipid surfaces on platelets or the endothelium and increases complex formation of APC with the activated forms of FV (FVa) and FVIII (FVIIIa). The binding of protein S by C4b-binding protein is very strong and free protein S is essentially the molar excess of protein S over C4b-binding protein. In addition to APC cofactor activity, protein S has an independent anticoagulant effect by acting as a cofactor for TFPI (tissue factor pathway inhibitor that inhibits FVIIa and FXa).

Protein S defects have been divided into three types. In type I deficiency, both total and free protein S antigen levels are low (and functional activity is low if measured). A type III deficiency

characterised by a normal level of total protein S, but a reduced level of the free protein S has been described. This may be a phenotypic variation resulting from the same genetic mutations associated with type I deficiency (not recognised with the less sensitive assay for total protein S), but many patients with an apparent type III phenotype do not have heritable protein S deficiency and this may be related to the increase in C4b-binding protein levels with age. Type II defects are characterised by reduced activity in the presence of normal total and free levels of protein S. Type II deficiency is difficult to diagnose because functional protein S assays are imprecise.

FVR506Q (FV)

The gene for FV is located on chromosome 1. It contains 25 exons spanning 80 kb. FV (2196 amino acids, 330 kDa, plasma concentration of free protein 30 nmol/L) is the cofactor for activation of prothrombin by FXa in the prothrombinase complex. The plasma half-life is 15 hours. Factor V has no cofactor activity until cleaved by thrombin or FXa at Arg709, Arg1018 and Arg1545. In 1993, the phenomenon of resistance to APC in patients with venous thrombosis was described. Patient plasma was resistant to the anticoagulant effect of added exogenous APC. The effect was measured by dividing the activated partial thromboplastin time (APTT) in the presence of added APC by the APTT in the absence of added APC. APC resistance was defined as a ratio less than 2.0. Increased APC resistance was shown to cosegregate with thrombosis in families with familial venous thromboembolism and it was reported that the majority of patients with familial APC resistance have a point mutation, guanine to adenine transition at nucleotide 1691, in exon 10 of the *F5* gene. This encodes what is known as the FV Leiden variant (FVR506Q). FV Leiden has normal procoagulant activity, but slower inactivation by APC. Prothrombinase activity is dependent on FVa maintaining the integrity of the enzymatic complex on a phospholipid surface. Thus thrombin generation is limited by FVa, and the normal inactivation of FVa by APC attenuates thrombin generation. Inactivation of FVa occurs through cleavage of the proteins at positions Arg306, Arg506 and Arg679 by APC. Initial cleavage at R506 is necessary for subsequent cleavage at R306 and R679. Mutation of these residues (*F5*G1691A, *FV*R506Q or FV Leiden; *F5*G1091C, *FV*A306T or FV Cambridge) results in resistance to inactivation by APC. The *FV*R506Q variant is present in about 5% of Caucasians with highest rates in white Northern Europeans. The mutation is far less frequent in Africans, Asians and races of Asian ancestry. The high prevalence suggests positive selection but could also be a founder effect.

APC resistance in the absence of *FV*R506Q is found in about 5% of patients with a history of venous thrombosis. This is often related to high FVIII levels or low FV levels, which may be found in association with the *F5*HR2 haplotype. There is evidence that APC resistance in the absence of *FV*R506Q is also associated with venous thrombosis, but defining the cause of resistance in individual patients has no clinical utility. Acquired APC resistance is commonly observed in pregnancy and combined oral contraceptive users.

*F2*G20210A

The gene for prothrombin is located on chromosome 2 and contains 14 exons spanning 21 kb. Prothrombin is a vitamin-K-dependent protein synthesised in the liver (579 amino acids, 72 kDa, plasma concentration 2 μmol/L). Prothrombin is the zymogen precursor of thrombin.

A single nucleotide change, guanine to adenine at position 20210 in the 3′ untranslated region of the prothrombin gene (*F2*G20210A), is associated with elevated plasma prothrombin levels and an increased risk of venous thrombosis. The prevalence of the *F2*G20210A variant is about 2% of whites, with a higher prevalence in southern compared with northern Europeans. The mutation increases the plasma level of prothrombin by about 30%, but the mechanism has not been explained. No specific clotting test for the presence of the mutation has been described and diagnosis depends on DNA analysis.

Other natural anticoagulants

Tissue factor pathway inhibitor (TFPI) is an inhibitor of FXa and tissue factor-bound FVIIa. TFPI knockout is embryonically lethal in mice. TFPI is predominantly on the vascular wall and so measurement in plasma samples is not representative of total TFPI availability. In a few studies, plasma TFPI levels were slightly lower in patients with venous thrombosis than in normal individuals but it is not clear that low levels are a risk factor for venous thrombosis. Protein Z is a vitamin-K-dependent protein that circulates in complex with PZI (protein-Z-dependent protease inhibitor) and catalyses the inhibition of FXa. A causal relationship between PZI and/or PZ deficiency and venous thrombosis has not been demonstrated. Heparin cofactor II, a serpin with a similar structure–function relationship to antithrombin, inhibits thrombin when activated by glycosaminoglycans. Heparin cofactor II knockout mice are healthy and do not develop spontaneous thrombosis, but do have a shorter time to thrombosis in an arterial injury model. A relationship between heparin cofactor II deficiency and thrombosis in humans is uncertain. A relationship between thrombosis and mutations affecting thrombomodulin or EPCR has not been established.

Other procoagulant factors

Increased levels of factors VIII, IX and XI have been associated with an increased risk of VTE. The observed association between elevated VIII levels and VTE are possibly accounted for by the effect of ABO blood group on von Willebrand factor

levels. Recent GWAS however, describe an association between thrombosis risk and rs11420917, which is located upstream from the factor VIII gene on the X chromosome. GWAS studies also identify associations between VTE and loci near the factor 5, 2, 11 and *FGA::FGG* genes. Several genes that do not code for coagulation factors have recently been described in association with thrombosis on chromosome 19 with SLC44A2, a choline transmembrane transporter, ILF3, an interleukin enhancer binding factor, and AP1M2, a subunit of the heterotetrameric adaptor related protein complex, the most plausible candidate genes.

There is equivocal evidence for a causal relationship between fibrinogen levels and venous thrombosis. Elevated fibrinogen levels per se are associated with thrombosis and *FGA::FGG* does show a significant signal in GWAS studies. In addition, approximately 300 examples of heritable dysfibrinogenaemia have been reported. These are suspected when there is a significant discrepancy between the functional Clauss assay and a clot weight or antigen assay. Further investigation is by genetic analysis. The majority of dysfibrinogenaemias are asymptomatic or associated with increased bleeding and very few examples are considered to be clearly associated with an increased tendency to thrombosis, which may be arterial, venous or a combination. Dysfibrinogenaemia has been found in less than 1% of patients with a history of venous thromboembolism and under 10% of patients with dysfibrinogenaemia will sustain a thrombosis. It is associated with postpartum thrombosis and an increased risk of pregnancy loss. The identification and characterisation of rare dysfibrinogenaemias associated with thrombosis is beyond the capability of most coagulation laboratories. Polymorphisms in the prothrombin gene that may further increase the risk of venous thrombosis associated with the *F2*G20210A mutation have been described but their effect is mild. A polymorphism in the *FXIII* gene (*FXIIIV341L*) is significantly less common in patients with coronary heart disease than in control subjects, and a protective effect for venous thromboembolism has been reported.

Fibrinolysis

A causal relationship between levels of individual specific proteins involved in regulating fibrinolysis has not been established. However, a global measure of fibrinolytic potential as measured by a plasma-clot lysis assay was associated with an approximately twofold increased risk of venous thrombosis in patients with clot lysis times above the 90th percentile of controls in the Leiden Thrombophilia Study. Analysis of the MEGA (Multiple Environmental and Genetic Assessment) study confirmed this finding and demonstrated that hypofibrinolysis in combination with established acquired and genetic risk factors, such as *FV*R506Q, had a synergistic effect on venous thrombosis risk. A genetic basis for hypofibrinolysis in these patients was not investigated. Genetic mutation in the thrombin-activatable fibrinolytic inhibitor (*TAFI*) gene has not been linked to thrombosis risk, although plasma TAFI levels appeared to be weakly linked to thrombosis risk in some studies.

Treatment of patients with venous thrombosis and heritable thrombophilia

There is no evidence that the presence of heritable thrombophilia should influence the intensity of anticoagulation or thromboprophylaxis. In patients with antithrombin deficiency, heparin resistance is infrequent and recurrence or extension of thrombosis while on treatment is no greater than that observed in individuals without antithrombin deficiency. Warfarin-induced skin necrosis is extremely rare, even in patients with protein C or S deficiency. The intensity of maintenance therapy with warfarin should not be influenced by laboratory evidence of inherited thrombophilia. There is no evidence that recurrence on treatment is more likely in patients with heritable thrombophilia.

Long-term prospective cohort outcome studies have shown that finding a heritable thrombophilia does not usefully predict recurrence in unselected patients after an episode of venous thrombosis. However, these studies were not powered to exclude an increased risk of recurrence in relation to the rare thrombophilias, such as antithrombin or protein C deficiency. Therefore, it remains uncertain if mutations in *SERPINC1*, *PROC* or *PROS* causing deficiency of the corresponding protein sufficiently predict a high enough risk of thrombosis to justify lifelong anticoagulation. Studies in thrombosis-prone families indicate a risk of recurrence that would justify long-term anticoagulation, but these studies may not be representative of risk associated with the *SERPINC1*, *PROC* and *PROS* mutations per se, but may be influenced by additional defects in the thrombosis-prone family members. Further studies are required to define the relative risk of recurrent events associated with the actual *SERPINC1*, *PROC* and *PROS* mutations.

Systematic reviews indicate a relative risk of 1.4 for recurrent venous thromboembolism in patients heterozygous for the *FV*R506Q mutation and 1.2–1.7 for the *F2*G20210A mutation compared to other patients with idiopathic VTE. The authors concluded that the magnitude of the increase in risk was modest and by itself did not justify an extended duration of anticoagulation. An analysis of the MEGA study showed that testing for inherited thrombophilia did not reduce recurrence of venous thrombosis.

In addition, three key studies, to guide clinical practice, have attempted to determine the risk factors and rates of recurrence of thrombosis following a first unprovoked event. In the DASH study, HERDOO2 and the Vienna prediction model for Thrombosis recurrence, routine testing for familial thrombophilia and antiphospholipid syndrome was not carried out but patients known to have 'strong thrombophilia' were excluded.

Based on the size of these studies and the rarity of 'strong thrombophilia', it was felt unlikely that routine testing would have been of value. Based on these and the results of the Cambridge study above (Figure 48.2), the following conclusions seem reasonable:

- Indiscriminate testing for heritable thrombophilias in unselected patients presenting with a first episode of venous thrombosis is not indicated.
- Decisions regarding duration of anticoagulation (lifelong or not) in unselected patients should be made based on whether an episode of venous thrombosis is provoked or unprovoked, independent of thrombophilia status. The use of the predictive scoring systems above should be considered in all patients with unprovoked events.
- Testing for heritable thrombophilias in selected patients, such as those with a strong family history of unprovoked recurrent thrombosis, may influence decisions regarding duration of anticoagulation and the information given to the patient. Unfortunately, in this regard, identifying patients for testing is not straightforward, as criteria for defining thrombosis-prone families have not been validated and the association between family history of thrombosis and detection of inherited thrombophilia is weak.

Case finding in heritable thrombophilia and thrombosis-prone families

Testing for heritable thrombophilias in patients presenting with venous thrombosis theoretically allows case finding of affected asymptomatic family members. The rationale for this is that it permits avoidance of future environmental risks (e.g. use of the combined oral contraceptive pill) or provides an opportunity for targeted thromboprophylaxis at times of high risk (such as surgery). This rationale assumes, however, that such action would not be taken for family members tested and found not to have the thrombophilic abnormality found in their kin. It also does not account for a situation where a young individual family member who suffers from an unprovoked event at a young age has negative thrombophilia tests. Individual risk is affected by multiple genetic and environmental factors that are different, even amongst first-degree relatives. Prospective cohort studies have determined the annual risk of venous thrombosis in asymptomatic family members identified after testing unselected patients presenting with venous thrombosis. The annual risk of venous thrombosis in asymptomatic family relatives of index patients was 0.1% for those with *F2*G20210A, 0.6% for those with *FV*R506Q, about 2% for protein C and protein S deficiency, and 4% for antithrombin deficiency. Identifiable high-risk periods contributed to approximately half of all events in patients with *FV*R506Q and thromboprophylaxis appears to reduce risk. However, it is the case that during many high-risk periods individuals with a family history of thrombosis are routinely offered thromboprophylaxis independent of thrombophilia test results.

Given the uncertainty, some experts argue that it is reasonable to perform testing if it is anticipated that clinical management will be influenced, for example an intensified or extended period of prophylaxis during a high-risk period. If a family history suggests a high degree of genetic penetrance, then it might be reasonable to test an asymptomatic patient and then their relatives with a view to enhanced prophylaxis at times of high risk in affected members. In all cases, the risks, benefits and limitations of testing should be discussed in the context of explained inheritance and disease risk. The importance of this is demonstrated by reported anxiety after testing positive and an overestimated perception of risk in tested individuals. Simple methods for quantifying a positive family history do not discriminate patients with and without thrombophilia and therefore the decision to test for inherited thrombophilia cannot be accurately guided by the presence or absence of a family history of thrombosis.

Purpura fulminans

Purpura fulminans is a rare syndrome characterised by progressive haemorrhagic skin necrosis that occurs in neonates with congenital severe protein C or S deficiency at birth or in the first few days of life, and in association with infection in children and adults. The condition may occur in children without congenital anticoagulant deficiency following viral infections, with an onset within 10 days of infection. Acquired severe protein S deficiency has been reported in purpura fulminans following chickenpox infection. With bacterial infections, disseminated intravascular coagulation (DIC) is often present, for example meningococcal infection. In patients with very severe skin necrosis, testing for acquired protein C or S deficiency should be considered, as plasma exchange may be beneficial. Neonates homozygous for protein C or S deficiency may be born with skin necrosis and extensive thrombosis.

Vitamin K antagonist-induced skin necrosis

Vitamin K antagonist-induced skin necrosis, such as that seen with warfarin or other coumarins, is extremely rare, even in patients with protein C or S deficiency, such that most individuals with protein C or S deficiency do not develop skin necrosis. However, a high proportion of patients with vitamin K antagonist-induced necrosis have heritable protein C deficiency. The condition has been described in patients with other heritable thrombophilias. Vitamin K antagonist-induced necrosis associated with heritable thrombophilias tends to involve a central distribution especially targeting the buttocks and thighs.

Neonatal stroke (see also Chapter 50)

Heritable thrombophilic defects are associated with perinatal brain injury. The pathogenesis is thrombosis in either cerebral arteries or cerebral veins or sinuses. Thrombophilia is not a significant risk factor for ischaemic stroke in adults, as it does

not increase the risk of arterial thrombosis. Cerebral vein thrombosis can present clinically as stroke and this should be borne in mind but is usually obvious on imaging of the patient. In the neonate, the pathophysiology of stroke is quite different and thrombophilia may increase the risk of arterial thrombosis and stroke in the neonate or fetus.

Laboratory methods and testing strategy for heritable thrombophilia

The laboratory diagnosis of heritable thrombophilia is difficult as the tests are subject to considerable preanalytical variables. Low levels of antithrombin, protein C and protein S occur in a variety of circumstances and test results and the clinical implications of both positive and negative results may be misinterpreted.

A full blood count and routine screening coagulation tests may be helpful. The APTT may detect some lupus anticoagulants (LAs), but only if a lupus-sensitive reagent is used. The thrombin time will detect heparin contamination and the prothrombin time (PT) is useful as an indicator of liver synthetic function for the interpretation of protein C and protein S levels. Testing is usually delayed until at least 1 month after completion of a course of anticoagulation with a vitamin K antagonist or DOAC. Testing should be avoided during intercurrent illness and use of COCPs or HRT should be noted. Sometimes testing is performed during pregnancy and so interpretation must be made with this in mind.

Functional assays should be used where the accuracy and precision are acceptable. However, no single method will detect all defects. For example, a protein C chromogenic assay will not detect a dysfunctional protein C molecule with impaired phospholipid binding due to a mutation in the Gla domain. A clot-based protein C assay would be sensitive to this defect, but imprecision of the assay would result in reduced sensitivity and specificity for other defects compared with a chromogenic assay. Using APTT-based assays will result in erroneous low protein C levels in the presence of factor V Leiden and other causes of activated protein C resistance. Similarly, the performance of antithrombin assays will be influenced by heparin concentration, the preincubation time with heparin, use of FXa or bovine or human thrombin as a substrate. For example, an assay utilising a short heparin incubation time will detect heparin binding-site defects, which may not be associated with an appreciably increased risk of venous thrombosis.

Even in families with characterised defects, a phenotypic assay may fail to accurately discriminate affected and non-affected individuals.

Preanalytical variables

Most assays are affected by clots in the sample. Antibody assays may be affected by atypical antibodies such as paraproteins, rheumatoid factor and heterophile antibodies. Chromogenic assays are subject to interference by lipaemia and haemolysis. Clot-based assays are subject to imprecision due to variation in the baseline clotting time and the levels of other coagulation or anticoagulant factors.

Low levels of antithrombin, protein C or protein S may relate to age, sex, acquired illness or drug therapy. Interpretation of results in children must be with reference to the normal range for age.

Low levels of antithrombin, protein C or protein S suspected to be the result of heritable mutations should be confirmed on one or more separate samples. Demonstrating a low level in other family members supports a diagnosis of heritable deficiency and characterisation of the genetic mutation can confirm the diagnosis and give some indication of thrombosis risk, particularly in the case of antithrombin deficiency.

Antithrombin assays

Activity assays typically use a chromogenic substrate in which a synthetic peptide is linked to *p*-nitroaniline. Cleavage of the peptide releases the *p*-nitroaniline with a resultant colour change. Patient plasma is incubated with heparin and then an excess of thrombin or FXa is added. The heparin-activated antithrombin is complexed and neutralises some of the thrombin or FXa. The remaining free protease quantified by cleavage of the appropriate chromogenic substrate is inversely proportional to the antithrombin level in patient plasma.

Interference by other proteases and inhibitors in the plasma sample is a potential problem. Interference by heparin cofactor II, another heparin-activated serpin, can be eliminated by using FXa or bovine thrombin as the target protease, as heparin cofactor II only inhibits human thrombin. The effect of other proteases in the patient plasma can be minimised by addition of a protease inhibitor such as aprotonin.

The total amount of antithrombin protein can be measured immunologically, for example by ELISA. As antithrombin antigen levels may be normal or near normal in type II deficiency, immunological assays may fail to identify patients with these variants.

Antithrombin levels are slightly reduced in infants, during pregnancy, in women taking oestrogen preparations, and in some patients during heparin therapy. Levels also decrease with age and acquired low levels occur in liver disease, DIC, nephrotic syndrome, during L-asparaginase therapy, and in protein malnutrition and cachexia.

Protein C assays

Protein C defects are divided into type 1, with a reduced amount of functionally normal protein, and type 2, where there is reduced activity due to a dysfunctional protein. In type 2 cases, there is discordance between the functional and antigenic levels. The laboratory diagnosis of protein C deficiency is based on a functional assay. Most commercially available functional assays of protein C employ the specific activator Protac, a

protein C activator derived from the venom of the southern copperhead snake (*Agkistrodon contortrix*). Chromogenic assays using a synthetic substrate for APC are simple to perform and can detect all type 1 defects and also type 2 defects affecting the catalytic site. A chromogenic assay will not detect most other type 2 defects. Clotting assays utilising the prolongation of either the PT or APTT after Protac activation have the capacity to detect other, but not all, type 2 defects, but are subject to imprecision due to variation in the baseline clotting time and the levels of other factors, for example if there is a short APTT due to a high FVIII level, or the presence of the factor V Leiden mutation which results in a falsely low protein C activity due to APC resistance, or in the presence of a LA. The diagnosis of protein C deficiency is problematic because of the wide overlap in protein C activity between heterozygous carriers and unaffected individuals. Protein C levels are not affected by pregnancy or oestrogen exposure. Acquired low levels of protein C occur during anticoagulant therapy with oral vitamin K antagonists, vitamin K deficiency, DIC and liver disease.

Protein S assays

Protein S is usually quantified immunologically rather than measured functionally. Originally, free protein S was measured in plasma supernatant after precipitation of C4b-bound protein S by polyethylene glycol (PEG). Nowadays PEG precipitation is not required as monoclonal antibodies that detect only free protein are used. Functional protein S assays are imprecise and are not used in the majority of coagulation laboratories.

Protein S levels are significantly lower in premenopausal females, so much so that different reference ranges are required for males and females and if this is not done there is a significant risk of a false-positive diagnosis of protein S deficiency in women. Protein S levels fall progressively during normal pregnancy and are reduced by oestrogens. Acquired low levels of protein S occur during anticoagulant therapy with oral vitamin K antagonists, vitamin K deficiency, DIC and liver disease.

FVR506Q and APC resistance

Nowadays, the *FV*R506Q mutation is usually detected by direct genetic analysis. APC resistance assays typically utilise the APTT. Samples are tested with and without an added fixed concentration of APC. The clotting times are expressed as a sensitivity ratio, i.e. the APTT (seconds) of patient plasma plus APC divided by the APTT (seconds) of patient plasma without added APC; the lower the ratio, the greater the APC resistance. Platelet contamination and activation must be avoided as this will lead to apparent APC resistance. The APC resistance assay is abnormal not only in the presence of *FV*R506Q, but with all other causes of heritable and acquired APC resistance and in individuals with a prolonged baseline APTT due to clotting factor deficiencies or anticoagulant therapy. It is therefore not specific for *FV*R506Q. Modification of the test by a one in four predilution of the test plasma in FV-deficient plasma increases the sensitivity and specificity of the assay for *FV*R506Q to almost 100% and this test is reliable if genetic analysis is not available.

*F2*G20210A

A laboratory clotting test with sensitivity and specificity for this mutation is not available and so detection is by direct genetic analysis.

General recommendations for laboratory tests and interpretation

- Testing at the time of acute venous thrombosis is not indicated.
- Testing is most easily interpreted when the patient does not have any circulating anticoagulant. Oral vitamin K antagonists cause a reduction in protein C and S levels. Dabigatran results in overestimation of AT, PC and PS levels and variable observations have been made around the effect of rivaroxaban, apixaban and edoxaban on different types of antithrombin, protein C and protein S assay.
- Functional assays should be used to determine antithrombin and protein C levels.
- Chromogenic assays of protein C activity are less subject to interference than clotting assays and are preferable.
- Immunoreactive assays of free protein S antigen are preferable to functional assays.
- If an APC resistance assay is performed to detect *FV*R506Q, the modified APC sensitivity test should be used. If positive, the mutation should be confirmed by a direct genetic test. An APC resistance assay is unnecessary if a direct genetic test for FV Leiden is used initially.
- Repeat testing for identification of deficiency of antithrombin, protein C and protein S is indicated and a low level should be confirmed on more than one sample. Deficiency should not be diagnosed on a single abnormal result.
- Thrombophilia testing must be performed by experienced laboratories with appropriate quality control and assurance. Results should be interpreted by an experienced clinician considering the clinical circumstances and all relevant factors that may influence individual test results.

Acquired risks for thrombosis

Pregnancy and venous thromboembolism

Around 1 in 1000 pregnancies is complicated by DVT or pulmonary embolism. Widespread use of thromboprophylaxis in at-risk pregnancies has contributed to massive pulmonary embolism no longer being the leading cause of pregnancy-related death in the UK. However, it still remains a major cause of death in the Triennial Confidential Enquiry. Although

the postpartum phase is the time of highest risk, it is shorter and overall at least as many episodes of VTE occur antepartum, including some in the first trimester. There are notable clinical features in pregnancy-related DVT: around 70% of thromboses affect the deep veins of the left lower limb and involve the iliofemoral vein from the time of presentation; thrombosis restricted to the deep veins of the calf is uncommon in pregnancy. The left-sided predominance may relate to the anatomical relationship between the iliac artery and vein on that side. Many affected women develop post-thrombotic syndrome.

The pathogenesis of pregnancy-related VTE is multifactorial. Pre-existing patient factors, such as age and obesity, along with specific pregnancy-related changes in coagulation such as suppressed systemic fibrinolytic capacity and the progressive increase in plasma concentrations of coagulation factors from early pregnancy including factor (F)VIII and fibrinogen, along with the fall in plasma concentration of the anticoagulant cofactor protein S all contribute to thrombosis risk. Complications of pregnancy such as multiple pregnancy, hyperemesis gravidarum and pre-eclampsia along with operative delivery, especially emergency caesarean section also contribute to the risk.

Diagnosis of VTE in pregnancy is dependent on imaging in all cases because the use of pre-test probability scores, such as the Wells score combined with D-dimer assays, has not been validated in pregnancy. In cases of suspected pulmonary embolism, the use of bilateral Doppler ultrasound of the legs negates the need for radiation exposure such as V/Q or CTPA scanning if it is positive. This is relevant as CT pulmonary angiography is associated with an increased risk of breast cancer in the mother of around 10%. V/Q scanning delivers a lower dose of radiation to the mother but may carry a slight increased risk of childhood cancer; in both situations, the absolute risk is very small. V/Q SPECT has a similar sensitivity and specificity to CTPA.

The treatment of choice for pregnancy-associated VTE is with low-molecular-weight heparin (LMWH). This is based on the low rate of complications and side effects and the comparative ease of administration. Dosing should be based on the woman's booking or early pregnancy weight. There is insufficient evidence to recommend whether the dose of LMWH should be given once daily or in two divided doses. Treatment with therapeutic doses of subcutaneous LMWH should be continued during the remainder of the pregnancy and for at least six weeks postnatally and until at least 3 months of treatment has been given in total. Once labour is established LMWH should be discontinued; where delivery is planned, either by elective caesarean section or induction of labour, the last therapeutic dose of LMWH should be at least 24 hours prior to planned delivery. Regional anaesthesia and analgesic methods should not be undertaken until at least 24 hours have elapsed after a therapeutic dose of LMWH. In addition, LMWH should not be recommenced for at least 4 hours after the use of spinal anaesthesia or after epidural catheter removal, and epidural cannulae should not be removed within 10–12 hours of the most recent dose of LMWH.

There is evidence of an association between heritable thrombophilia and pregnancy morbidity, including pregnancy loss, pre-eclampsia and intrauterine growth retardation. It has been shown however that antepartum prophylactic dalteparin does not reduce the occurrence of pregnancy loss or placenta-mediated pregnancy complications in pregnant women with thrombophilia at high risk of these complications and is associated with an increased risk of minor bleeding. Routine use of LMWH as VTE prophylaxis in all women with positive thrombophilia testing is of dubious benefit and should be confined to those with previous or family history of VTE.

Immobility and venous thromboembolism

It is likely that venous stasis contributes to the pathogenesis of some cases of VTE. Sitting still for 90 min reduces the flow through the popliteal vein by 50%. Immobility is probably one of many contributors to hospital-acquired VTE and is almost certainly a factor in the pathogenesis of DVT in paralysed and immobilised limbs.

There has been considerable interest in the relationship between VTE and prolonged immobilisation during travel. The term 'economy class syndrome' has been coined to encompass the occurrence of VTE during and after air travel. Epidemiological data suggest a relative risk of around twofold, which persists for 2–6 weeks after the index journey. A similar level of risk applies to other modes of powered travel, including by road. The incidence of fatal pulmonary embolism induced acutely by air travel is less than one in a million journeys. In addition, there is little evidence for any increased thrombosis risk in journeys of less than 4 hours of continuous travel. Unsurprisingly older travellers with recent surgical or medical admission and those with a previous history of VTE or other known risk factors for VTE are at highest risk. The contribution of hypobaric hypoxia to hypercoagulability is not proven and as such it appears that for travel-associated VTE immobility is the key risk factor. It is reasonable to assume that any form of long-distance powered travel carries a low, but slightly increased, risk of VTE and to recommend simple precautionary measures such as maintenance of mobility in order to maintain venous flow in the lower limbs. In patients with overt risk and in those with a previous travel-associated thrombosis pharmacological thromboprophylaxis may be considered for journeys over 4 hours.

Hospital-acquired thrombosis

VTE is common in patients in hospital and in those who have been recently hospitalised. One of the best illustrations of this comes from the Million Women's Study 2009 which demonstrated a 70-fold increased risk of subsequent VTE in women undergoing surgery and a 10-fold increased risk of thrombosis in

patients undergoing more minor day procedures compared with no procedure. Patients admitted to medical wards also have a higher thrombosis risk during and post-discharge. This has led to the widespread adoption of thromboprophylaxis in this group. This intervention has significantly reduced thrombosis occurrence. Hospital-acquired thrombosis (HAT) may occur up to 90 days after admission, with the highest incidence of DVT in the first week and highest incidence of PE in the second to third week after discharge. The pathogenesis is multifactorial, immobility, active malignancy and the acute phase response seen in patients with inflammatory disorders and sepsis all contribute. The highest incidence of VTE follows major lower limb orthopaedic surgery. In hip replacement and knee replacement surgery, subclinical DVT is frequently detectable by imaging, although there is evidence that clinically significant VTE may be becoming less common due to improvements in surgical techniques and materials, as well as wider use of thromboprophylaxis. Extended prophylaxis for up to 28–35 days has been shown to reduce VTE in those undergoing hip replacement and abdominal or pelvic surgery for cancer. Patients undergoing total knee replacement benefit from 14 days of pharmacological prophylaxis. For those undergoing hip or knee replacement, several direct oral anticoagulants (DOACs) along with unfractionated and low molecular weight heparins are licenced for thromboprophylaxis. Several studies have shown good prevention of VTE post orthopaedic surgery using an initial period of either a DOAC or LMWH followed by oral aspirin and aspirin monotherapy is advised post-total knee replacement by NICE in England.

Indwelling venous devices

The use of indwelling venous catheters is common in patients with malignancy, acute renal failure and those requiring total parenteral nutrition and critical care. Thrombosis of these lines is common with a higher incidence observed in patients with large-diameter lines and those with a tip positioned distal to the superior vena cava. A number of other factors contribute to the thrombosis risk, including infection, extrinsic compression, the use of certain types of chemotherapy and a previous history of VTE. Many studies have tried to address the role of thromboprophylaxis in prevention of catheter-associated thrombosis. Systematic reviews remain vague on the benefits of thromboprophylaxis with slight reductions in thrombotic events being off-set by bleeding. Treatments include local thrombolysis and anticoagulation with or without line removal.

Pharmaceuticals and vaccines

Combined oral contraceptive

VTE associated with use of the combined oral contraceptive (COCP) is well documented. The overall risk of VTE in a COCP user is around four to fivefold higher than in a non-pill user but this is affected by the progestogen content of the preparation. The risk is increased by a family history of thrombosis, obesity, thrombophilia and older age (see Figure 48.1). Fortunately, the absolute thrombosis risk remains acceptable due to the low background incidence of thrombosis in women of childbearing age. Combined pills induce a state of activated protein C resistance, and this appears to be more marked with the third-generation contraceptives than second-generation preparations. Most preparations in current use contain an equivalent dose of oestrogen, usually 30–35 μg of ethinylestradiol. However, the progestogen content varies. In second-generation pills, this is levonorgestrel, whereas in third-generation products it is desogestrel, gestodene or norgestimate. There is convincing epidemiological evidence that third-generation pills carry a greater risk of clinical VTE. Progestogen-only oral contraceptives appear to carry a lower risk of VTE such that their use can be considered in women in whom the COCP is contraindicated.

Hormone-replacement therapy

Oral hormone-replacement therapy (HRT) is also associated with a VTE risk. The relative thrombosis risk is equivalent to second-generation COCPs, but the absolute risk is greater due to the higher background incidence of VTE in older women. Observational data indicate a very high rate of VTE in women with a previous history of venous thrombosis who subsequently embark upon HRT. Such is the level of risk that HRT is generally contraindicated in such women. If there are overwhelming indications for HRT (disabling menopausal symptoms or gender reassignment) some clinicians consider anticoagulation alongside HRT in high-risk situations. The thrombosis risk associated with oral HRT is not apparent with transdermal preparations. It is suggested that this is due to the avoidance of the first-pass effect in the liver. Studies also suggest a higher thrombosis risk associated with the use of oral conjugated equine oestrogen compared with oestradiol.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is an important diagnosis because failure to recognise the syndrome carries a high risk of morbidity and mortality. It is due to development of antibodies directed against a complex of heparin and platelet factor 4. It is more commonly seen with unfractionated heparin (UFH) than LMWH and in surgical rather than medical or obstetric patients. Typically, the platelet count begins to fall between 5 and 10 days after first exposure to heparin. In subjects with previous recent exposure, it may occur earlier and very occasionally the thrombocytopenia develops after heparin has been discontinued. The condition may complicate heparin administered at any dose. In contrast to other drug-related immune thrombocytopenias, the degree of thrombocytopenia is rarely severe ($<20\times10^9$/L), and bleeding is not a common feature. There may be systemic symptoms, including fever and a local reaction at the heparin injection site, such as erythema or even skin necrosis after subcutaneous

administration. Because of platelet activation, there is often new thrombosis, and this may manifest before the platelet count reaches thrombocytopenic levels. When heparin has been administered to treat arterial disease the new thrombosis is most commonly arterial, and in treatment of DVT, there is usually extension of the presenting thrombus, often with pulmonary embolism. Thrombotic stroke, myocardial infarction, visceral ischaemia and DIC have all been reported.

Confirmatory laboratory tests are not entirely satisfactory. Immunoassays for heparin/platelet factor 4 are sensitive, but lack specificity because a significant proportion of subjects treated with heparin have positive antibody tests, but neither thrombocytopenia nor thrombosis. In contrast, bioassays are specific, but high sensitivity is difficult to achieve. Few centres provide a reliable bioassay for routine diagnosis.

The most practical approach to diagnosis outside the intensive care unit, where thrombocytopenia is common due to the other causes that may coexist with HIT, is the use of a pre-test probability scoring system based on the timing of onset of thrombocytopenia, presence or absence of new thrombosis, presence or absence of other potential cause of thrombocytopenia, and the degree of thrombocytopenia (the four Ts score). If the probability score is high or intermediate, heparin should be stopped and an alternative non-cross-reacting anticoagulant commenced while further investigation is carried out. An alternative anticoagulant such as argatroban, danaparoid or fondaparinux must be administered immediately as the risk of thrombosis persists for several days after heparin withdrawal. There are small case series where DOACs have been used in patients who can swallow. The outcomes as might be predicted have been satisfactory. When a high or intermediate score is combined with the results of an immunoassay including high-dose heparin neutralisation, this results in improved sensitivity and specificity for the diagnosis of HIT. The antibody may cross-react with low-molecular-weight heparins and they should be avoided. The pathogenic antibodies tend to become unmeasurable in the ensuing few months, but further exposure to heparin should be avoided in the long term. Patients with a diagnosis of HIT who present without a thrombotic event should be anticoagulated with a non-heparin anticoagulant for at least 30 days.

Vaccine induced immune thrombocytopenia and thrombosis

Vaccine induced immune thrombocytopenia and thrombosis (VITT) was first described early in 2021 when the vaccination programme for SARS-CoV2 started to take place on a large scale. The details around this condition and its management are still emerging. VITT describes an aberrant immune response to vaccines against SARS CoV2 which results in the formation of anti-PF4/vaccine antibodies. In a similar fashion to HIT, the antibodies bind to and activate platelets through their Fc receptor and this results in a catastrophic pro thrombotic illness. In distinction to HITT, these antibodies are not heparin dependent. The incidence of VITT is around 14 per million vaccine doses. The key features are thrombosis at unusual sites with associated features of a consumptive coagulopathy including thrombocytopenia, hypofibrinogenaemia and high levels of D-dimers. The most commonly affected sites are the cerebral veins but thrombosis is also observed in the splanchnic circulation as well as in heart, lungs and limbs. Thrombosis may be arterial or venous. Suspected cases are identified from their history of vaccination, with most patients presenting between 5 and 40 days after a first dose of vaccine. The complication is much more common in recipients of the two adeno-associated virus (AAV) vaccines (Astrazeneca ChAdOx1 nCoV-19 and Johnson and Johnson Ad26.COV2.S) but has been reported following receipt of non-AAV vaccines. Following clinical suspicion, based on the presentation and vaccine history it is usual for blood testing and scanning to be performed. The presence of thrombosis along with thrombocytopenia, hypofibrinogenaemia and very elevated D-dimers increase the likelihood of VITT. The majority of cases will have a positive anti-PF4 ELISA which may remain elevated for some time. It is worth noting that there is variability in the sensitivity of different anti-PF4 assays to VITT antibodies.

Treatment of VITT includes early therapy with IVIgG, high-dose steroids and anticoagulation with a non-heparin anticoagulant. Plasma exchange and rituximab have been used. The optimal duration of anticoagulation in these cases is not currently known. The mortality rate for this condition is high at around 25% with many patients succumbing very rapidly following diagnosis to a thrombotic or haemorrhagic death but may be falling with improved awareness and experience.

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is an acquired thrombophilic condition. The essential features are arterial or venous thrombosis or recurrent pregnancy loss or placental dysfunction occurring in a subject in whom laboratory tests for antiphospholipid antibody are persistently positive. Diagnostic criteria have been established in order to standardise diagnosis for the purposes of clinical studies (Table 48.2).

DVT, pulmonary embolism and ischaemic stroke are the principal thrombotic manifestations, but any vessel may be involved, including the microvasculature. The full range of clinical features is not necessarily present. For example, women can have severe thrombotic events without pregnancy complications whilst those with pregnancy complications commonly have no other manifestation. In addition to thrombosis and pregnancy failure, additional clinical and laboratory features are variably present in APS. These include mild thrombocytopenia and livedo reticularis. Cardiac valvular abnormalities occur in up to

30% of patients but are usually subclinical. Exceptionally, the syndrome may manifest as widespread multiorgan microvascular occlusion, with multiorgan failure, so-called catastrophic APS.

In primary APS, the syndrome presents in isolation while APS may occur in association with other chronic systemic autoimmune diseases, usually systemic lupus erythematosus (SLE) when it is termed secondary APS.

Antiphospholipid antibodies

Antiphospholipid antibodies (APA) react with proteins that bind negatively charged phospholipids. These may be detected in solid-phase ELISA assays or in coagulation-based tests. The most important is β_2-glycoprotein I (β_2-GP1), as pathogenic antibodies are most frequently reactive with this protein. β_2-GPI is a member of the complement control protein family. It has five domains but antibodies reactive to a specific epitope on domain I are most pathogenic.

The LA is an *in vitro* phenomenon in which the presence of the APA slows phospholipid-dependent coagulation tests. This is probably due to impaired assembly of the components of the prothrombinase complex. LA antibodies are usually reactive to β_2-GPI/phospholipid or to prothrombin/phospholipid. LA due to prothrombin-reactive antibodies may be negative in anticardiolipin assays. Subjects with APS may have any combination of LA and anticardiolipin positivity.

Pathogenic mechanisms in APS

Important candidate mechanisms for thrombosis are antibody-induced enhanced thrombin generation, interference with the activated protein C anticoagulant pathway, and increased monocyte and endothelial tissue factor expression. Platelet activation and inhibition of fibrinolysis by antiphospholipid antibodies have also been proposed. In relation to pregnancy failure, it is noteworthy that early miscarriage before full placentation is common. This may be attributed to antiphospholipid antibodies causing inhibition of early trophoblast growth. A role for complement activation in pregnancy loss has also been proposed. Placental dysfunction is the hallmark of the second- and third-trimester complications of intrauterine fetal death, intrauterine growth restriction, pre-eclampsia and placental abruption.

Diagnosis of antiphospholipid syndrome

As indicated in Table 48.2 the diagnosis of APS is based on the presence of a qualifying event combined with the demonstration of a persistently positive APA test over a period of at least 12 weeks. Transient antibodies may occur after infection, syphilis being the prime example, and may be seen in association with several drugs particularly chlorpromazine.

Laboratories should perform both solid phase and coagulation-based assays in the assessment of suspected cases of APS. Overall, it appears that LA is associated most strongly with clinical events. In relation to solid-phase assays, high-titre antibodies and IgG antibodies associate more strongly with clinical manifestations than do IgM and lower-titre antibodies. Patients who are positive for LA, anticardiolipin and anti-β2 GP1 form a group termed triple positive APS. Emerging data indicate a more severe disorder with higher rates of thrombosis recurrence. Anticoagulation of this group is discussed below.

Table 48.2 Diagnostic criteria in APS.

*Clinical criteria**
- Thrombosis: arterial, venous or microvascular thrombosis in any tissue or organ

Pregnancy complications
- Unexplained death of morphologically normal fetus at or beyond 10 weeks of gestation
- Three or more unexplained consecutive miscarriages before 10 weeks
- One or more premature births of a morphologically normal fetus before 34 weeks of gestation due to pre-eclampsia, eclampsia or severe placental insufficiency

*Laboratory criteria**
- Antiphospholipid antibody
- IgG or IgM anticardiolipin antibodies at moderate or high concentration†; IgG or IgM anti-β_2-GPI >99th percentile *and/or*
- Lupus anticoagulant

* There must be at least one clinical and at least one laboratory criterion present. The laboratory test must be consistently positive on at least two occasions 12 weeks apart as transient antibodies may occur, for example in infection. Such antibodies are not usually associated with clinical events.

† Evidence of the definition of moderate/high concentration. In general, values of IgG anticardiolipin >40 GPLU are considered to be moderate-titre antibodies; >99th percentile has been employed also. The significance of low-titre antibodies is less clear.

Lupus anticoagulant tests

The characteristics of LA are that they produce prolongation of phospholipid-dependent tests that are not due to factor deficiency or specific factor inhibitors. These features are determined by repeating abnormal phospholipid-dependent tests in the presence of normal plasma and in the presence of excess phospholipid. Lupus inhibitors will produce prolongation of the test which is not corrected by normal plasma but is corrected by an excess of phospholipid. Other inhibitors, like the Xa inhibitors and anti-factor VIII inhibitors, will not correct with addition of plasma or phospholipid. The tests most frequently employed to detect LA are the activated partial thromboplastin time (APTT), the dilute Russell's viper venom time (DRVVT) and, less frequently the kaolin clotting time (KCT) or silica clotting time (SCT).

Because no LA test shows 100% specificity and sensitivity, more than one test system should be used for the detection of LA. The PT and thrombin time should also be performed as

they are not usually affected by the presence of LA and the results assist in the interpretation of LA tests.

APTT reagents have varied sensitivity to LA and are often labelled as LA sensitive or not by manufacturers. The specificity of the APTT for inhibitor detection is improved by inclusion of a mixing study with platelet-free normal pooled plasma but very few labs routinely do this. Inhibitors to coagulation factors, usually FVIII, also cause prolongation of the APTT which may not be corrected by addition of normal plasma. Typically, FVIII inhibitors are time and temperature-dependent, unlike LA. Diagnostic confusion may arise due to LA that prolongs the APTT, causing erroneously low results in all APTT-based coagulation factor assays.

Russell's viper venom directly activates factor X and in the presence of Factor V, prothrombin, calcium and phospholipid leads to cleavage of fibrinogen to form a fibrin clot. As such, inhibition of the phospholipid, along with various factor deficiencies and the presence of acquired and pharmacological inhibitors of the pathway will produce prolongation of the coagulation time. The process of repeating the tests in the presence of normal plasma and in excess of phospholipid allows interpretation of the assay. As with all coagulation tests, because of variations in reagents and techniques, it is essential that laboratories derive local normal ranges and participate in external quality assessment.

The SCT is used in some centres as a screening test for LA. Assays with low levels of phospholipid appear to be the most sensitive and positive results can be confirmed by using an excess of phospholipid to demonstrate phospholipid dependency of the test. The KCT is like an APTT with no additional phospholipid however there is no phospholipid correction test. The test is affected by clotting factor deficiencies and anticoagulants but is rarely used partly due to problems with automation of the assay.

Alternative tests for LA may be employed. They include the tissue thromboplastin inhibition test and clotting tests that use venoms other than Russell's viper venom. An example is the Taipan venom: this test has been shown to have a strong positive predictive value in patients receiving warfarin.

Solid-phase assays (for anticardiolipin and anti-β_2-GP1 antibodies)

The other methods for detecting antiphospholipid antibodies involve solid phase assays such as anticardiolipin and more specific anti-β_2-GP1 assays. The introduction of international standards has allowed the calculation of anticardiolipin results in IgG or IgM antiphospholipid units (GPLU and MPLU, respectively) related to a given concentration of affinity-purified anticardiolipin immunoglobulin. Despite this, issues remain around the precision, and accuracy of these assays. Interpretation of the anticardiolipin assay is not straightforward and in patients positive for LA and anticardiolipin assays the tests may not be identifying the same antibodies. The clinical significance of low-titre anticardiolipin is doubtful but may be difficult to interpret in patients who have a qualifying clinical event for APS.

Specific assays for anti-β_2-GPI antibodies have been developed, and several commercial kits are available. Anti-β_2-GPI antibody assays may show higher precision and better correlation with the thromboembolic complications in APS and SLE than assays for anticardiolipin and are less likely to give transient positive results in association with infection.

Management of APS

Thrombosis

Data from observational studies suggest that the recurrence rate, following a first episode of otherwise unprovoked VTE, in an individual who is diagnosed with APS is high enough to warrant long-term anticoagulation. In patients at equipoise post-VTE, investigation into APS is probably the single most relevant 'thrombophilia test'. Previously, higher INR targets had been set for these patients but it has been shown that an INR target of 2.5 is suitable for most APS patients. The anticoagulant of choice in APS-related thrombosis has become much debated following changes to the SPC of the DOACs in relation to their use in patients with APS. Expert groups continue to debate the interpretation of the statement in SPCs that 'DOACs are not recommended for patients with a history of thrombosis who have a diagnosis of APS' which evolved following a 2019 study, TRAPS, that showed an excess of thrombotic events in patients with APS randomised to rivaroxaban as opposed to warfarin with an INR target of 2.5. Whether the results of this study, where most of the thrombosis was arterial, commute to patients with venous thrombosis is the issue. Clinical trials in patients with arterial thrombosis and APS have been smaller and less convincing as a result.

Immunosuppressive therapy is not indicated in primary APS. An exception may be catastrophic APS when combination treatment with antithrombotics, corticosteroids and other immunomodulatory therapies such as immunoglobulin and plasma exchange is administered as a potentially life-saving emergency measure.

Pregnancy

It is important that the criteria in Table 48.2 are adhered to when dealing with obstetric APS. Miscarriage is a common occurrence and up to 3% of women of childbearing age will have antiphospholipid antibodies which, in most are of no known relevance. In women with recurrent first-trimester miscarriage as defined, around 15% will have APA although the pathogenicity of these is not wholly clear. A small proportion of women with antiphospholipid antibodies also have anti-Ro antibodies. Their detection is important as anti-Ro is associated with a 2% risk of complete heart block in the fetus and a 10% chance of neonatal lupus.

The management of a pregnancy in a mother with obstetric APS includes enhanced ante-natal care with increased surveillance

by ultrasound scanning and in most cases the use of the antithrombotics LMWH and aspirin. The use of aspirin and LMWH has become usual practice in many centres and countries despite the lack of convincing evidence for its benefit. Many women who present to obstetric clinics have a pre-formed opinion on what their management should be based on their own initial research and many feel that the addition of antithrombotic therapy may improve their chances of a live birth.

Thromboprophylaxis for those with APS and a previous history of thrombosis is based on the use of LMWH, although there is no international consensus on dosing.

Venous thromboembolism and cancer

The association between cancer and venous thromboembolism is well established. Thrombotic events are common and rank second only to the direct effects of the cancer as a cause of death in cancer patients. In addition to intrinsic biological features of the primary disease, there are other factors, including surgery, chemotherapy, radiotherapy, hormonal therapies and the use of indwelling central lines that increase thrombosis risk in this group of patients. The development of venous thromboembolism in the context of malignancy is generally a poor prognostic feature often being indicative of advanced and aggressive disease. Several mechanisms may contribute to the propensity to develop venous thromboembolism in the context of active cancer and some of these may also arise as consequences of the use of some forms of chemotherapy. Proposed mechanisms include activation or disruption of endothelial function, activation of coagulation and platelets and inhibition of natural anticoagulants. Amongst the best-documented mechanisms are the expression of tissue factor and cancer procoagulant on tumour cells and the prothrombotic properties of mucins secreted by adenocarcinomas. There is evidence that tissue factor expression, which may result from proto-oncogene expression and tumour-suppressor gene inhibition, confers a proangiogenic state, which may enhance the aggressiveness and invasiveness of cancers. Several tumour types including lung, brain, pancreas, stomach, ovary, renal and lymphoma have the strongest reported association with thrombosis development. Whether this is related to the direct effects of thrombosis or reflects inherent tumour aggressiveness is not clear. Cancer chemotherapy may result in an excess of both venous and arterial thrombosis. An excess of VTE is seen with the use of platinum-based drugs cis- and carboplatin, with the iMIDs, thalidomide, lenalidomide and pomalidomide, with anti EGFR antibodies cetuximab, panitumumab and necitumumab and with the CDK inhibitors palbociclib, abemaciclib and ribociclib. Use of bevacizumab and the VEGFR TKIs sunitinib, sorafenib and axitinib is associated with an excess of arterial thrombosis, while the *BCR::ABL* TKIs dasatinib, nilotinib and ponatinib are associated with an excess of both arterial and venous thrombosis.

Cancer patients with VTE have poorer outcomes in terms of the need for hospital admission and higher rates of major bleeding and thrombosis recurrence on anticoagulant therapy, compared with patients who do not have cancer. It is now usual practice for the majority of patients with active cancer who are admitted to hospital in the UK to receive thromboprophylaxis during their stay. The role of routine thromboprophylaxis in ambulatory cancer patients receiving chemotherapy is less clear. A Cochrane review of nine RCTs involving 3538 patients, which compared patients receiving thromboprophylaxis (eight LMWH and one warfarin) with control groups found a reduction in VTE risk without a significant increased risk of bleeding. However, the number needed to treat to prevent one episode of thrombosis was 60, suggesting that further stratification to identify those individuals at the highest risk was needed. In a more recent Cochrane review in 2021 of 10 RCT, 6 on the use of VKA and 4 on the use of DOACs there was no reduction in mortality in the treated groups. Risk assessment scores such as that developed by Khorana, which identified patients with stomach, pancreas, lung, lymphoma, gynaecologic, bladder and testicular cancer combined with a platelet count $>350 \times 10^9$/L, haemoglobin <100 g/L, leucocyte count $>11 \times 10^9$/L and a body mass index of >35 kg/m^2 may or may not be helpful.

The initial management of established venous thromboembolism in patients with active cancer differs from usual therapy. Several studies have shown that continuous treatment with LMWH at therapeutic doses compares favourably with the use of coumarins with reduced thrombosis recurrence without any increase in major bleeding. The reasons for this difference in efficacy of LMWH are not clear, but it has been suggested that better compliance with therapy, lower rates of drug interactions and less interference around times of poor or limited oral intake (when vitamin K intake is variable) may contribute. The management of patients with cancer with an ongoing indication for anticoagulation after 6 months is less clear and a variety of options, including LMWH, warfarin and DOACs are used. Patients, however, find ongoing compliance with parenteral therapy difficult and uncomfortable. Two studies have investigated the option of replacing LMWH with a DOAC after an initial period of treatment. SELECT D compared rivaroxaban with LMWH showing a reduced rate of recurrent VTE but a slight excess of bleeding while ADAM VTE compared LMWH with apixaban showing a significant reduction in VTE recurrence with no excess of bleeding in favour of apixaban. Although it has been suggested that heparins improve life expectancy through an anti-cancer effect, recent data do not support this suggestion.

Because of the association between cancer and thrombosis various studies have investigated the potential benefit of extensive cancer screening in patients with, what appear to be, unprovoked events. This has included the use of tumour biomarkers

and extensive CT scanning. Most studies show that while extensive investigation may lead to slightly earlier cancer diagnosis in some patients, it does not affect outcomes of the cancer. This is reflected in many subsequent guidelines.

Thrombotic risk in myeloproliferative disease (polycythaemia rubra vera and essential thrombocythaemia) (see also Chapter 35)

Untreated, polycythaemia vera (PV) affects life expectancy, with the majority of patients dying of vascular occlusion, which may involve large vessels or the microvasculature. There is clearly significant overlap between PV and essential thrombocythaemia (ET), and thrombosis may involve both arterial and venous circulation. There does appear to be a predisposition towards thrombosis in the cerebral circulation, but events occur elsewhere and notably involve the splanchnic vessels. A well-described entity is the development of unprovoked intra-abdominal venous thrombosis in individuals who have the *JAK-2* V617F mutation without the typical peripheral blood phenotype of MPD.

In PV there is good evidence that the incidence of vascular occlusion is positively related to the packed cell volume, with the lowest incidence in patients with good control of haematocrit. The role of thrombocytosis in risk of thrombosis in PV is controversial. The risk of thrombosis in PV increases with advancing age, a past history of thrombosis, and presence of other risk factors for thrombosis. Thrombosis risk is reduced by control of haematocrit and antiplatelet therapy.

The risk of thrombosis in ET is related to patient age and the presence of other risk factors for thrombosis. Recent data indicate an increased thrombosis risk in patients with ET who are *JAK-2* V617F positive and in those with elevated white cell counts. Platelet count appears more closely related to bleeding than thrombosis.

The microvascular events and vasomotor manifestations of both PV and ET may relate to quantitative and qualitative changes in red cells and platelets, as they are not seen in other forms of polycythaemia or in reactive thrombocytosis. The role of white cells and endothelial cells that form part of the clone is not clear. It is possible that similar small-vessel occlusive and vasomotor changes seen in the feet and hands may also occur in other parts of the body. Erythromelalgia, a syndrome consisting of painful burning red extremities with normal peripheral pulses, is the characteristic vasomotor disturbance. Livedo reticularis is occasionally seen. In the digital vessels, the development of thrombosis can lead to ischaemia and gangrene. In relation to the cerebral circulation, a range of symptoms and signs, including transient cerebral ischaemia, transient monocular blindness, migraine, headaches and seizures are seen. Both the cerebrovascular complications and erythromelalgia of myeloproliferative disease may respond promptly to low-dose aspirin and/or cytoreduction.

Inflammation and thrombosis

The activation of the coagulation system is appropriate as a defence mechanism in the context of bacterial and viral infection where clot formation can limit the dissemination of pathogens via the bloodstream. In terms of evolution, it is therefore not surprising that there are numerous interactions and 'cross talk' between infection, inflammation and thrombus formation pathways. However, the aberrant or excessive activation of so-called thromboinflammation resulting in immunothrombosis may result in pathological clot formation in both the venous and arterial systems. Evidence for this association is supported by the increased number of cardiovascular events seen in patients with inflammatory disease and following both serious and apparently more minor infection. It is quite likely that this activation of inflammatory pathways (Table 48.3) underlies the observation of many hospital-acquired thromboses, discussed earlier. The main cellular drivers of immunothrombosis are innate immune cells, especially monocytes and neutrophils. These drive a process of cell activation that results in activation of inflammatory cytokines (interleukin-6 and 1β), the coagulation cascade and complement. Inflammation upregulates procoagulant factors, downregulates physiological anticoagulants and inhibits fibrinolytic activity and ultimately when defence systems such as DNase 1 and activated protein C are swamped, thrombosis results. It is likely that there are differences between the process of thrombosis formation as a result of thromboinflammation in venous and arterial vessels. However, it does seem that the activation of both platelets and neutrophils and their subsequent interaction is required for both. Nuclear extracellular traps (NETs) are found in both arterial and venous thrombi. They are formed in response to microbial

Table 48.3 Effects of inflammation on haemostasis.

Increased

- Fibrinolytic activity
- Endothelial glycosaminoglycans

infection and to other endogenous danger signals such as those resulting from inflammation. They have a significant role in clearing large pathogens but may also result in the formation of thrombi in the vascular bed. NETs formation, NETosis, has many triggers but the binding of P-selectin to P-selectin glycoprotein ligand-1 (PSGL1) on neutrophils is one of the best recognised and may represent a potential therapeutic target. NETs can activate the coagulation cascade by providing a negatively charged surface to allow contact activation and by inhibition of the natural anticoagulant TFPI.

The protein C anticoagulant pathway appears to be highly influenced by inflammation. Thrombomodulin and endothelial cell protein C receptor are both downregulated by inflammatory cytokines and the overcoming of the protective effect of the aPC pathway may result in thrombosis formation.

Endothelial cell activation causes multiple prothrombotic changes, including downregulation of fibrinolysis by increased production of plasminogen activator inhibitor (PAI-1) which may be one of the key factors in the prothrombotic state associated with COVID-19.

An excess of venous thrombosis is seen in patients with chronic inflammatory conditions including inflammatory bowel disease, Behçet disease, rheumatoid, SLE and diabetes. The exact pathogenesis of VTE is not clear in these conditions but almost certainly involves some of the mechanisms discussed above. In patients with SLE, NETs degradation is impaired resulting in persistent activation of complement.

Atherosclerosis can be considered an inflammatory state and the recent description of atherosclerotic plaque formation associated with clonal haematopoiesis of indeterminant potential (CHIP), allows an explanation of the possible mechanisms involved. The acquired myeloid gene mutations, *DNMT3A*, *TET2*, *ASXL1* and *JAK2* are all associated with an increased rate of coronary artery disease. It is likely that the expression of these pro-inflammatory mutations in monocytes results in the formation of active plaque.

The recognition of the associations between inflammation and thrombosis has triggered an appropriate interest in exploring the potential for immunosuppression and anti-inflammatory drugs as an intervention to prevent thrombosis. Several studies involving canakinumab, methotrexate and colchicine have reported with the key issue being the balance between a reduced rate of thrombosis and increased rates of infection associated with the intervention.

Haematological prothrombotic states due to non-malignant diseases of the blood and bone marrow

Paroxysmal nocturnal haemoglobinuria (see Chapter 31)

Paroxysmal nocturnal haemoglobinuria is a rare acquired disorder that results from mutations in the phosphatidylinositol glycan class A (*PIG-A*) gene. This results in the production of blood cells that lack the normal mechanisms to regulate the effects of complement. As many as 40% of patients with an eventual diagnosis of PNH will have suffered a venous thrombosis prior to diagnosis and 30–45% will suffer from an event in the course of their disease. Thrombosis is the commonest cause of death, accounting for 40–65% of PNH deaths. Thrombosis occurs at many sites, but there is an excess of events in the splanchnic circulation and in the cerebral veins. Occasionally, painful discoloured skin lesions occur when superficial dermal veins are affected. These lesions rarely ulcerate. Occasionally, skin lesions can resemble purpura fulminans; these can affect large areas of skin with necrosis and demarcation. In pregnancy, PNH is associated with an increased risk of fetal loss (40%) as a result of thrombosis and haemorrhage. The prothrombotic state in PNH is complex and multifactorial. This includes platelet activation, the effects of intravascular red cell haemolysis and neutrophil and monocyte activation. Platelet and endothelial microparticles from activated cells along with oxidative stress may also be relevant. Impaired fibrinolysis has also been observed and may be caused by interactions between complement activation, coagulation and fibrinolysis. Anticoagulation of patients with PNH has typically been with a VKA but there is no obvious reason why DOACs could not be used in this regard. There is ongoing discussion around the need for anticoagulation when the PNH clone size has been minimised, which can occur in patients treated with eculizumab or ravulizumab.

Thrombotic thrombocytopenic purpura

See Chapter 46.

Sickle cell disease (see Chapter 15)

Sickle cell disease is complicated by microvascular and macrovascular occlusion with resultant tissue ischaemia distal to the sickling. Venous thromboembolism is a problem in patients with sickling conditions. Several studies have shown a cumulative incidence of VTE between 11 and 17% by the age of 40 years. Recurrence rates are also high at around 35% at 5 years. The rate of VTE in patients with sickle cell disease is higher than that seen in other frequently hospitalised patients with other chronic disorders. The exact mechanisms that result in an excess of VTE in patients with sickle cell disease are not clear and are likely multiple. There is evidence of a prothrombotic state shown by increased levels of prothrombin fragment 1 + 2 and thrombin–antithrombin complexes. Sickled erythrocytes adhere more readily to vascular endothelium and strongly accelerate coagulation due to abnormal exteriorisation of procoagulant anionic membrane phospholipids. Recently the P-selectin inhibitor Crizanlizumab has been shown to reduce vaso-occlusive crisis in patients with sickle cell and it will be interesting to see whether this will translate into a reduced incidence of VTE. Other interventions between P-selectin and P-selectin glycoprotein ligand are current causes of interest.

CHAPTER 49

Prevention and management of venous thromboembolism

49

Nicola Curry and Susan Shapiro

Oxford University Hospitals NHS Foundation Trust, Oxford University, Oxford, UK

Introduction

Venous thromboembolism (VTE), which comprises deep vein thrombosis (DVT) and pulmonary embolism (PE), has an incidence of about 1 per 1000 per annum, with two-thirds presenting as DVT and one-third as PE. Approximately half of VTEs are associated with hospital admissions, and hospital VTE prevention programmes are important to help reduce this risk. The case fatality of VTE is approximately 5%, but there is also major morbidity caused by post-thrombotic syndrome (PTS) of the leg and chronic thromboembolic pulmonary hypertension (CTEPH). Anticoagulants are highly effective in secondary prevention, but leave the patient at risk of bleeding. The risk of recurrence is considerable and patients need to be assessed to identify those who require long-term anticoagulation as secondary prevention. This chapter covers primary VTE prevention (risk assessment and thromboprophylaxis), VTE diagnosis and acute treatment, and secondary VTE prevention.

VTE prevention

Approximately half of VTEs are associated with hospital admissions. Thromboprophylaxis has been shown in clinical trials to reduce the risk of VTE by approximately 50% for medical inpatients and up to 70–80% following orthopaedic surgery.

A national VTE prevention programme was launched in England in 2010 to reduce this hospital associated morbidity and mortality. The foundation of the programme was national guidance and standards for VTE prevention (National Institute of Clinical Excellence, NICE, guidance). This guidance requires all adults (over the age of 16 years) to be VTE risk assessed on admission to hospital using a standardised risk assessment tool. If a patient is assessed to be at increased risk of VTE without significant bleeding risks, the patient is advised to have pharmacological thromboprophylaxis daily whilst an inpatient. Surgical patients have historically been additionally considered for mechanical thromboprophylaxis; however, recent clinical trial evidence from the GAPS trial challenges this concept as it demonstrated that anti-embolism stockings did not provide additional reduction in VTE compared to low molecular weight heparin alone in elective surgical patients. A few select groups of patients are also considered for extended thromboprophylaxis on discharge (total hip and knee replacement, major abdominal cancer surgery).

England's VTE prevention programme requires hospitals to record the number of patients who have a VTE risk assessment on admission to hospital (target greater than 95%); and to review all cases of hospital-associated-thrombosis (defined as VTE occurring within 90 days of hospitalisation) to check whether or not the patient received appropriate thromboprophylaxis daily. If on review it is considered that the patient did not receive appropriate thromboprophylaxis each day, then the hospital-associated-thrombosis is reported as 'potentially preventable'. A 'potentially preventable' hospital-associated-thrombosis reflects that an error occurred. Formal root cause analysis of 'potentially preventable' thromboses is recommended in order to identify the causes of the error and

Hoffbrand's Postgraduate Haematology, Eighth Edition. Edited by Adam J Mead, Michael A Laffan, Graham P Collins, Deborah Hay, and A Victor Hoffbrand (Consulting Editor).

Companion website: www.wiley.com/go/mead/HPH8e

then action changes to reduce the risk of such an error occurring again. Evaluating the impact of this national VTE prevention programme is challenging but there is evidence of a reduction in 'potentially preventable' hospital-associated-thromboses and mortality associated with VTE since it was introduced.

Choice of VTE risk assessment

All VTE risk assessments are based on both VTE risk factors and bleeding risk factors. If a person is identified as being at risk of VTE without bleeding risk factors, then pharmacological thromboprophylaxis is prescribed. If a significant bleeding risk factor is identified then pharmacological thromboprophylaxis is not offered, and mechanical thromboprophylaxis alone may be considered.

The majority of hospitals in the UK currently use the National VTE risk assessment tool (Department of Health) 2010 although this tool has not been validated in randomised clinical trials. In this tool, the presence of a single additional VTE risk factor in a surgical patient or in a medical patient with reduced mobility is considered to indicate a high VTE risk, with the presence of any bleeding risk factor indicating a high bleeding risk (see Table 49.1). Pharmacological thromboprophylaxis is recommended for those with a high VTE risk and low bleeding risk, with consideration of mechanical thromboprophylaxis alone in those with both high VTE risk and high bleeding risk.

Various VTE risk assessment tools have been reported in the literature including the Padua Prediction score, the predictive (four factor) IMPROVE score, the Geneva risk score, the Khorana score and the Caprini risk assessment model. The Padua Prediction Score is currently the best-validated score for inpatients. It gives a weighted score and patients who score 4 or more are considered at high risk of VTE and considered for pharmacological thromboprophylaxis (see Table 49.2)

Choice of anticoagulant and dose

The initial landmark trials of thromboprophylaxis in medical inpatients (MEDENOX, PREVENT) used a prophylactic dose of low molecular weight heparin (LMWH). This remains the recommended pharmacological thromboprophylaxis for medical inpatients. For people with a contraindication to heparin such as a history of heparin-induced thrombocytopenia, allergy or those who refuse medications of porcine origin, alternatives such as fondaparinox can be used. There is evidence to suggest that the dose of LMWH should be increased in obesity, and so many hospitals advise weight-based prophylactic LMWH regimens.

Prophylactic doses of the Direct Oral Anticoagulants (DOACS) Apixaban and Rivaroxaban were shown to be safe and effective alternatives to LMWH following total hip and knee replacement and are licenced as an alternative pharmacological prophylaxis agent following these operations.

Duration and extended thromboprophylaxis

The majority of guidelines currently advise to consider pharmacological thromboprophylaxis only as an inpatient except after certain high VTE risk operations: 10–14 days post total knee

Table 49.1 Table of additional VTE risk factors and bleeding risk factors, based on the National VTE risk assessment (Department of Health).

Additional VTE risk factors	Bleeding risk factors
• Age over 60 years, • Active cancer or cancer treatment • Critical care admission • Dehydration • Known thrombophilia • Obesity (BMI over 30 kg/m^2) • One or more significant medical comorbidities (for example): heart disease, metabolic endocrine or respiratory pathologies, acute infectious diseases and inflammatory conditions • Personal history of VTE or first- degree relative with a history of VTE • Use of hormone replacement therapy • Use of oestrogen-containing contraceptive therapy • Varicose veins with phlebitis • Pregnancy or less than 6 weeks postpartum	• Active bleeding • Acquired bleeding disorder (such as acute liver failure) • Concurrent use of anticoagulants known to increase the risk of bleeding (such as warfarin with an INR 2 or more; direct/novel oral anticoagulants such as apixaban, rivaroxaban, edoxaban, dabigatran; or fondaparinux) • Acute stroke • Thrombocytopenia (platelets less than 75×10^9/L) • Uncontrolled systolic hypertension (230/120 mmHg or higher) • Untreated inherited bleeding disorder (such as haemophilia and von Willebrands disease) • Lumbar puncture/epidural/spinal anaesthesia within the next 12 hours • Lumbar puncture/epidural/spinal anaesthesia within the previous 4 hours • Other high-risk bleeding procedure such as neurosurgery, spinal surgery or eye surgery

Table 49.2 Padua VTE risk assessment model (high risk of VTE: ≥4).

Score	Baseline characteristic
3	Active cancer*
3	Previous VTE (with the exclusion of superficial vein
3	thrombosis)
3	Reduced mobility**
2	Already known thrombophilic condition***
1	Recent (<1 month) trauma and/or surgery
1	Elderly age (≥70 years)
1	Heart and/or respiratory failure
1	Acute myocardial infarction or ischaemic stroke
1	Acute infection and/or rheumatologic disorder
1	Obesity (BMI ≥30)
	Ongoing hormonal treatment

* Patients with local or distant metastases and/or in whom chemotherapy or radiotherapy had been performed in the previous 6 months.
** Bedrest with bathroom privileges (either due to patients' limitations or on physicians' order) for at least 3 days.
*** Carriage of defects of antithrombin, protein C or S, factor V Leiden, G20210A prothrombin mutation, antiphospholipid syndrome.

replacement; 28–35 days post total hip replacement, and 28 days following major abdominal cancer surgery.

In order to reduce the burden of VTE associated with hospitalisation, large randomised controlled trials have looked at prophylactic LMWH or low-dose DOAC as extended thromboprophylaxis following medical hospitalisation (for 28–35 days post-discharge). Meta-analysis of these trials showed a reduction in symptomatic VTE or VTE death (0.8 versus 1.2%, $p = 0.002$) but with increased major or fatal bleeding (0.6 versus 0.3%, $p < 0.001$). Given this balance of risk and benefit, the American College of Chest Physician Guidelines do not currently recommend extended thromboprophylaxis for medical patients.

Ambulatory thromboprophylaxis

Patients with certain cancers, particularly pancreatic cancer, have a greatly increased risk of thrombosis. All patients should be advised of the signs and symptoms of VTE and to seek medical attention early if they experience them. Risk stratification tools have been designed with the aim of risk stratifiying ambulatory patients who are at very high risk of VTE, and offering thromboprophylaxis. However primary thromboprophylaxis in this setting is generally not currently recommended.

Compared to when the original landmark trials of medical and surgical thromboprohylaxis were performed, the average duration of medical and surgical hospitalisations have become shorter. This combined with advances in surgical techniques and support of early mobilisation post-operatively may have reduced the baseline risk of thrombosis, changed the balance of risk/benefit, and is an area for further research. Furthermore, medicine in the UK is increasingly moving towards ambulatory, same-day emergency care with supported early discharge; research is required to examine the VTE risk in this relatively new and expanding medical cohort in order to ascertain whether or not (a subgroup of) these patients may benefit from thromboprophylaxis.

Diagnosis of VTE

Diagnosis of deep vein thrombosis

It is difficult to diagnose a deep vein thrombosis (DVT) by clinical means alone. A patient can present in a 'classical' way – with a unilateral swollen, hot and painful calf. However, symptoms and signs are highly variable and the contemporary diagnostic pathway for a patient who presents with symptoms suggestive of a deep vein thrombosis (DVT) is to follow a diagnostic algorithm (see Figure 49.1), in recognition of this diagnostic uncertainty, which combines clinical, laboratory and radiological tools.

Algorithms for the diagnosis of a deep vein thrombosis

The objective diagnosis of DVT depends on diagnostic imaging, using either a three-point compression or a duplex ultrasound scan (USS). These methods are reported to have a 97–98% sensitivity. However, because of the increasing number of negative tests, strategies have been developed that can exclude the diagnosis in some patients without the need for imaging. These strategies rely on the use of information from the clinical history and examination to estimate a pretest probability (PTP) and assays to detect D-dimers. The commonest PTP probability assessment tool is the Wells score (see Table 49.3). An 'unlikely' PTP score is not on its own enough to rule out a DVT, but an unlikely score can be used to rule out the diagnosis if the D-dimer test is also negative (Figure 49.1).

Thrombus formation is followed by a fibrinolytic response, which releases fibrin degradation products (containing the D-dimer motif) into the circulation. It follows that absence of a rise in D-dimers implies that thrombosis is not occurring. The strategy for using D-dimer assays in the diagnosis of DVT is to employ a sensitive test with a high negative predictive value. Fully quantitative, laboratory D-dimer tests are recommended above point-of-care D-dimer tests in the UK, but point-of-care tests can be used where laboratory testing is not available, to speed up diagnosis. The specificity of the assays for DVT is poor and false positive results are common.

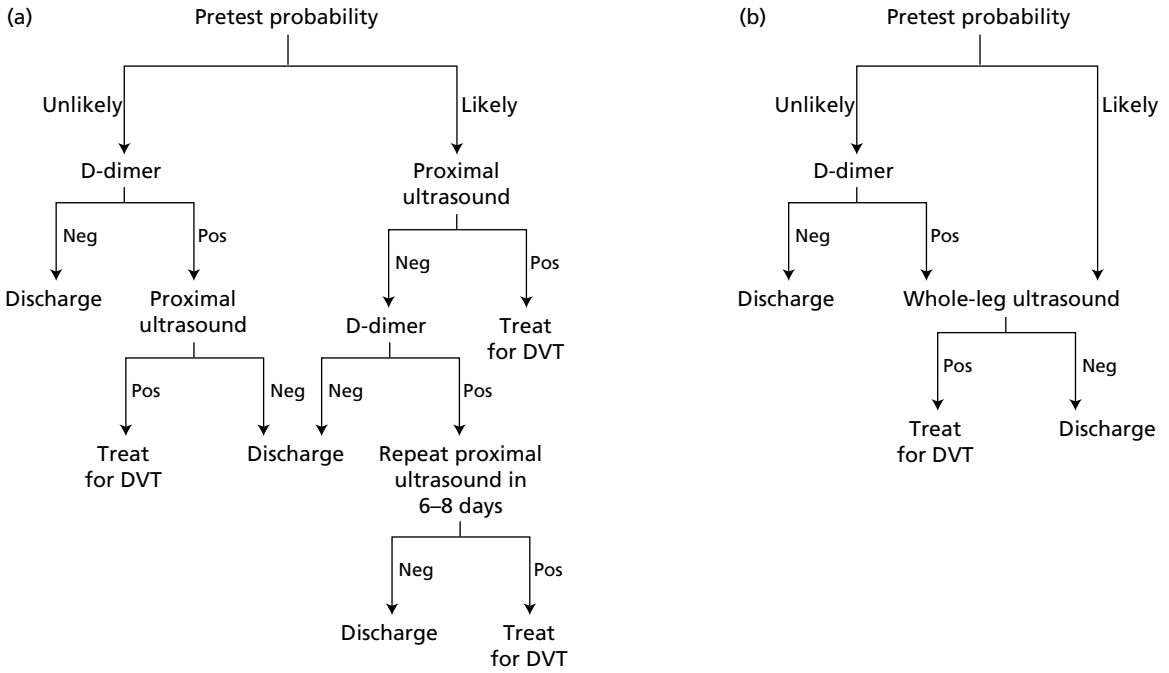

Figure 49.1 (a) Diagnostic algorithm for DVT with scanning of proximal veins only. (b) Diagnostic algorithm for DVT with scanning of whole leg.

Table 49.3 Wells clinical score used for predicting the probability of DVT prior to further testing.

Risk factors, symptoms or signs	Points
Active cancer (patient receiving treatment for cancer within the previous 6 months or currently receiving palliative treatment)	1
Paralysis, paresis or recent plaster immobilisation of the lower extremities	1
Recently bedridden for 3 days or more, or major surgery within previous 12 weeks	1
Localised tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than the asymptomatic leg (measured 10 cm below tibial tuberosity)	1
Pitting oedema confined to the symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Previously documented deep vein thrombosis*	1
Alternative diagnosis at least as likely as deep vein thrombosis	−2

Score ≥2 points, likely pretest high probability; score ≤1-point, unlikely pretest probability.
* The authors give a point for previous DVT or PE.

All patients who have a 'likely' PTP or who have a raised D-dimer need to proceed to diagnostic imaging. This is illustrated in Figure 49.1a, b.

There are two accepted algorithms where a patient who requires an USS either undergoes a whole leg scan or has a proximal scan only – which looks only at the venous system as far as the popliteal veins. A whole leg scan needs to be performed only once, whereas if a patient has a first proximal scan that is negative, but has a raised D-dimer, they will need a repeat scan a week later, principally to exclude proximal extension of a distal DVT. If only the proximal veins are scanned, we know that patients with an 'unlikely' PTP and those with a normal D-dimer do not need a second scan. Scanning the calf veins (e.g. in a whole leg scan) increases the complexity of the scan and the duration of the procedure. The evidence on whether, or not, to treat distal DVTs is uncertain (see below).

There is some debate about which cut-off to use for the D-dimer value within the DVT diagnostic algorithm. Traditionally, the manufacturer's cut-off has been used. However, it is well known that D-dimer levels rise with age and there are prospective observational data for DVT, and retrospective data for PE, that support the use of age-adjusted D-dimer cut-offs, without reducing sensitivity of the diagnostic algorithms. In the UK, the National Institute for Clinical Excellence (NICE) provided a recommendation in 2020

suggesting that age adjustments in D-dimer test thresholds could be used for people aged over 50. (An age-adjusted D-dimer is calculated as follows: Age (years) × 10 for patients >50 years. For example, for a patient aged, 76 – a threshold of 760 ng/mL FEU would be applied).

Isolated calf DVT

DVT usually starts in the calf, but by the time symptoms develop most patients have thrombus in the proximal veins. If isolated calf DVT is left untreated, extension into the proximal veins has been reported in 3–18%, usually within one week. Isolated calf DVTs that do not extend rarely lead to clinically significant emboli and it is safe to withhold anticoagulant treatment from patients with clinically suspected DVT who have normal compression ultrasonography of the proximal veins at the time of presentation and one week later. This led to the two different ultrasound strategies for DVT diagnosis set out above (Figure 49.1). If the whole leg is scanned and an isolated calf DVT found, it is oftentreated, though, in the absence of severe symptoms or risk factors for extension, the American College of Chest Physicians suggests serial imaging instead of initial anticoagulation – which in practical terms involves an USS weekly for a further two weeks after diagnosis, and if no proximal extension is seen, then anticoagulation is not required. However, these recommendations do have caveats and if a patient has any of the following higher risks, standard anticoagulation is recommended by the American College of Chest Physicians: elevated D-dimer, severe pain, known history of cancer or previous VTE, the patient is hospitalised, or the DVT is more than 5 cm long or is unprovoked.

High-quality evidence to support treatment for distal DVT is weak. The only RCT looking at distal DVT evaluated 259 patients and was terminated early due to slow recruitment with only 50% of the required sample size. Patients were randomised to 6 weeks of treatment dose nadroparin or placebo. There was no difference (3% nadroparin versus 5% placebo) in the composite endpoint of extension to proximal DVT, presence of contralateral DVT or symptomatic PE within 42 days of study start. There was in addition a greater risk of bleeding (4 versus 0% patients) with treatment.

It must be remembered that the diagnostic algorithm is heavily based on the results of a D-dimer test. Therefore, the algorithm is useful only in the out-patient setting, since D-dimers will be elevated in most in-patients. The limitations of USS must also be recognised. USS are excellent tools for diagnosing DVT in the leg but are more limited for DVT that are more proximal: e.g. the iliac veins and indeed the inferior vena cava (IVC). If a patient presents with a significantly swollen leg, up to the groin and the USS is negative – a CT venogram should be considered to rule out a more proximal clot. In a similar way, if a patient complains of bilateral swollen legs, a CT venogram can diagnose an IVC clot.

Diagnosis of pulmonary embolism

Clinical presentation of PE depends on the size, location and number of emboli, and the patient's underlying cardiorespiratory reserve. The classic triad of chest pain, haemoptysis and dyspnoea is present in less than 20% of patients, but nearly all will have at least one of pleuritic chest pain, dyspnoea or tachypnoea.

Diagnostic imaging is necessary to make the diagnosis and CT pulmonary angiography (CTPA) and ventilation–perfusion (V/Q) lung scanning are both used. Perfusion scanning with technetium-99-labelled albumin macroaggregates is a sensitive, but not very specific, method. The specificity is improved by adding ventilation scanning in which a gaseous radionuclide such as xenon-133 or technetium-99 diethylenetriaminepentaacetic acid (DTPA) is inhaled in an aerosol form, looking for a V/Q mismatch (no perfusion in ventilated lung). However, V/Q scanning is often non-diagnostic, resulting in a non-informative 'intermediate probability' scan report. CTPA, which may also identify alternative diagnoses, is most commonly used.

In order to reduce the need for diagnostic imaging a similar strategy to that used for DVT is applied. The initial step for patients presenting with a possible PE is also to assess them for their pretest probability using a scoring system such as the Wells PE score (Table 49.4). Patients scoring as 'unlikely' can have the diagnosis excluded without the need for diagnostic imaging if they also have a negative D-dimer. If, however, the D-dimer is positive, the patient should be sent for diagnostic imaging, as should all patients who have a 'likely' PTP (Figure 49.2). Similarly, to DVT, an age-adjusted D-dimer may be used for patients over the age of 50 years.

Table 49.4 Wells clinical score used for predicting the probability of PE prior to further testing.

Risk factors, symptoms or signs	Points
Signs and symptoms of DVT	3
Alternative diagnoses less likely than PE	3
Heart rate >100	1.5
Immobility or surgery within 4 weeks	1.5
Previous DVT/PE	1.5
Haemoptysis	1
Active cancer	1

Score >4 points, likely pretest probability; score ≤4 points, unlikely pretest probability.

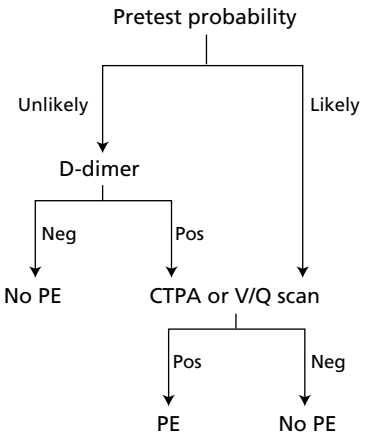

Figure 49.2 Diagnostic algorithm for PE.

Treatment of VTE

The majority of deaths (>90%) due to PE occur in untreated patients in whom the diagnosis is not made in life. Treatment with therapeutic dose anticoagulation reduces the mortality to approximately 2%, with half of deaths directly attributable to PE rather than comorbidity, such as cancer. Patients with symptomatic PE are 5 times more likely to die of fatal PE than patients with symptomatic DVT and patients with massive PE with systemic hypotension (high-risk PE) are 10–20 times more likely to die. Rapid commencement of anticoagulation, and thrombolysis in patients with high-risk PE, is therefore required to prevent death. In patients presenting with DVT without symptomatic PE, death is unusual once treatment with anticoagulation has started.

Blood samples for haemoglobin, platelet count, PT and APTT, serum creatinine and liver function should be taken. A group and save should also be ordered for patients who will be treated with thrombolysis. Thrombophilia testing is of no utility at this stage, as the results do not affect immediate patient management with any drug. Only those patients who offer a history, or have clinical signs, suggestive of an underlying malignancy should be referred for further appropriate investigation.

Initial anticoagulant therapy

Once a diagnosis of DVT or PE is made, or strongly suspected, a rapidly acting anticoagulant should be started immediately. The most commonly used anticoagulants are the direct oral anticoagulants (DOACs) which include the anti-Xa inhibitors (e.g. apixaban and rivaroxaban) and the direct thrombin inhibitor, dabigatran. The advantage of two of the anti-Xa inhibitors, namely apixaban and rivaroxaban, is that they can be given without any concomitant low-molecular-weight heparin (LMWH) in the first days after diagnosis. All other DOACs require a cross-over treatment period of at least 5 days with LMWH followed by continuation of the DOAC alone.

Not all patients with a diagnosis of VTE can be treated with a DOAC. Care should be taken using DOACs in patients with renal impairment, and depending on the specific drug, a DOAC should not be used when the creatinine clearance falls below 15–30 mLs/minute. A patient's weight should be considered – the clinical trial data for DOACs did not include a large number of overweight patients (weight greater than 120 kg, or BMI greater than 40 kg/m^2). However, recent guidance in 2023 from the ISTH supports the use of DOACs in patients weighing more that 120 kg due accumulating real-world data supporting their clinical effectiveness in this group. Patients with triple positive antiphospholipid syndrome should be offered warfarin as their first-line treatment option.

Another area of some uncertainty is the use of DOACs for unusual site VTE. The clinical trial data mostly relates to the efficacy of DOACs for DVT and PE treatment and therefore some clinicians are more hesitant using DOACs for other indications. As is often the case, not only are real-world data emerging but also, as confidence grows in the use of DOACs, many clinicians do opt for oral medications.

For those patients who are unable to have a DOAC, a vitamin K antagonist (VKA) such as warfarin or treatment dose LMWH alone can be used. The LMWH dose is based on weight and the total daily dose is given as a single or two divided subcutaneous injections without the need for monitoring or dose adjustment. LMWH should continue for at least 5 days and until the International Normalised Ratio (INR) has been greater than 2.0 for two consecutive days when it is used in combination with warfarin.

When initiating rapid loading with warfarin, a loading nomogram should be used, as individual warfarin dose requirements vary considerably. The advantages of using a dosing nomogram are:

- A therapeutic intensity of anticoagulation is reached in the shortest possible time without an excessive risk of over-anticoagulation.
- The daily maintenance warfarin dose, which will be required after the initial loading, is predictable. This reduces the risk of over-anticoagulation and hence bleeding following initial loading, and increases the likelihood of maintaining a therapeutic level of anticoagulation.

In patients with VTE who stop anticoagulant therapy after 3–6 months, the incidence of subsequent fatal PE is approximately 0.25 per 100 patient years.

Thrombolytic therapy

Streptokinase and recombinant tissue plasminogen activator (rtPA) are widely available fibrinolytic agents. Streptokinase, a glycoprotein purified from the supernatant of β-haemolytic streptococci, in complex with plasminogen, cleaves other

Table 49.5 Stratifying pulmonary embolism by risk of death.

Haemodynamically unstable PE = high risk
Systolic blood pressure <90 mmHg or a pressure drop of ≥40 mmHg for >15 min if not caused by an arrhythmia, hypovolaemia or sepsis
About 5–10% of patients are in this high-risk group and have a risk of early death of >15%
Haemodynamically stable PE
Intermediate risk
These patients are haemodynamically stable but with evidence of right heart strain or myocardial injury. Early mortality is 3–15%
Low risk
Haemodynamically stable without evidence of right heart strain or myocardial injury. Early mortality is <1%

plasminogen molecules to plasmin. This indirect action results in complex pharmacokinetic characteristics. Furthermore, streptokinase is immunogenic, which may cause allergic reactions, as well as a reduced or absent response on repeated use or after a recent infection with streptococci. tPA has a direct enzymatic effect on plasminogen that is strongly enhanced by the presence of fibrin. Guidelines on the management of acute PE now recommend stratifying patients into high, intermediate and low risk (Table 49.5). Low-risk patients can be considered for home treatment. Patients with intermediate- and high-risk PE require hospitalisation and patients with high-risk PE should be considered for immediate thrombolytic therapy as this may reduce mortality. Whilst life-saving in the acute phase, the haemodynamic benefit of thrombolysis compared to heparin is lost after the first few days. At the present time, patients with intermediate-risk are not given thrombolytic therapy, but they should be monitored, as 25% of patients deteriorate and may require urgent escalation to thrombolytic therapy. Escalation of patients to thrombolysis in clinical trials probably explains why there has been no difference in mortality in randomised trials of thrombolysis in intermediate-risk patients. In routine clinical practice, the opportunity for escalation is lost if patients are not monitored, resulting in avoidable fatal PE.

Up to 5% of patients have massive PE with hypotension at presentation. Fatal PE occurs in >15% of patients presenting with high-risk (massive) PE, 3–15% of patients with intermediate-risk PE, and in less than 1% of patients with low-risk PE or DVT alone. Right ventricular dysfunction (RVD) is present in up to 40% of patients with acute PE and normal blood pressure, and fatal PE is twice as likely in those with RVD. In patients with RVD, biomarkers such as troponin may identify those patients at greatest risk, but the clinical utility of these measurements is not yet known. Death due to acute PE results from an acute fall in cardiac output. In patients without pre-existing heart or lung disease, the haemodynamic disturbance correlates with the extent of obstruction of the pulmonary circulation.

Contraindications to thrombolysis include active internal bleeding, a stroke within 2 months, and an intracranial process such as neoplasm or abscess. Relative contraindications include surgery within 10 days, uncontrolled hypertension and pregnancy. Haemorrhagic complications are higher in patients with a recent invasive procedure such as pulmonary angiogram or placement of an inferior vena cava (IVC) filter. There is a reported incidence of intracranial haemorrhage of approximately 2%, with higher rates in the elderly and those with poorly controlled hypertension. Up to 20% of patients suffer major bleeding. If heparin is being given, it should be stopped. Heparin therapy is started 2 hours after administration of thrombolysis.

Thrombolytic therapy after DVT increases the rate of early recanalisation but is associated with a higher risk of bleeding than with anticoagulant therapy. In clinical studies, venographic obstruction and PTS were less frequent in patients treated with streptokinase compared with anticoagulation alone, but PTS assessments in these studies were not performed using any validated instrument, and bleeding complications were much more frequent in patients treated with streptokinase. Consequently, systemic streptokinase infusions are no longer used for DVT treatment. Systemic infusion of recombinant tissue plasminogen activator (rt-PA) has limited efficacy. Clinical studies suggest that the systemic administration route may not reliably achieve a therapeutic rt-PA concentration at its target sites within the thrombus. However, major bleeding is more frequent than with anticoagulant therapy. Catheter-directed intrathrombus thrombolysis (CDT) refers to the infusion of a fibrinolytic drug directly into the venous thrombus via a multisidehole catheter, which is embedded in the thrombus using imaging guidance. This is the preferred treatment currently if thrombolytic treatment is given. However, even with low-dose rt-PA (0.5–1.0 mg/h) major bleeding occurs in about 4% of patients. The long-term benefits remain unclear and so thrombolytic therapy is not recommended routinely in patients with DVT. However, it may be considered in individual patients with symptomatic iliofemoral DVT who have all of the following:

- symptoms of less than 14 days' duration;
- good functional status;
- a life expectancy of 1 year or more;
- a low risk of bleeding.

Long-term complications of VTE

Post-thrombotic syndrome (PTS)

Following acute DVT, recanalisation occurs slowly. Residual vein occlusion is present in 50% of patients at 6 months and remains present in 25% after 3 years. Clot resolution is identical in patients with and without thrombophilia. Because of frequent incomplete clot resolution, the diagnosis of recurrent ipsilateral DVT is problematic. Of particular, clinical value in this regard is

the demonstration that in patients with previous DVT, a negative high-sensitivity D-dimer assay result safely excludes recurrence. Post-thrombotic syndrome (PTS) is chronic pain and swelling, which occurs in up to one-half of patients who have a DVT; it is typically worse at the end of the day or with prolonged sitting or standing, and better after a night's rest and leg elevation. Patients may describe heaviness in the leg, cramps, pruritis and paraesthesia. There may be oedema, induration of the skin, reddish-brown hyperpigmentation and venous ectasia. Severity of PTS can be quantified using the Villalta score. PTS can occur early or, more unusually, have a latency of up to 10 years; the cumulative frequency has been estimated as 23% at 2 years and 28% at 5 years; in 5–10%, PTS is classed as severe (this includes all those with ulcers).

A major risk factor for PTS is recurrent ipsilateral DVT. During anticoagulant treatment after DVT patients with prolonged periods of subtherapeutic anticoagulation are more likely to develop PTS. There is no evidence that prolonged anticoagulant therapy reduces the risk of PTS. This indicates that early suboptimal anticoagulation rather than duration of anticoagulation influences the development of PTS and that thrombin generation may contribute to ongoing valvular damage immediately after DVT.

Early walking after acute DVT and continued high levels of physical activity appear to reduce the likelihood of clot progression and reduce the risk of PTS. Initial randomised trials demonstrated a 50% reduction in PTS with compression stockings used for up to 2 years. However, the large SOX trial failed to show a benefit when compression stockings were used for 50% of the time compared to 'sham' stockings. Consequently, any benefit of stockings in reducing the incidence and severity of PTS after DVT is now contentious, although many patients use them for symptomatic relief early after acute DVT.

Chronic thromboembolic pulmonary hypertension (CTEPH)

Following treatment of acute symptomatic PE with either thrombolysis or anticoagulation, 85% of patients still have partial occlusion of the pulmonary circulation after 1 week. At 6 months more than 50% of patients have persistent follow-up scan defects and complete resolution does not occur in the majority of patients by 1 year. Consequently, there is the difficulty of confirming or excluding recurrent acute PE in patients who do not have a follow-up scan at completion of initial treatment. Less than 5% of patients with persistent occlusion of the pulmonary circulation after 6 months will develop CTEPH. Recurrent and previous multiple PE are significant risk factors for CTEPH, but heritable thrombophilia defects are not associated with an increased risk.

Common symptoms of CTEPH include progressive shortness of breath on exertion and marked fatigue. It is important to ask patients at their 3-month anticoagulation review whether they have persistent or worsening dyspnoea and consideration should be made for further investigation if CTEPH is suspected. Diagnosis of CTEPH can be made using a combination of assessments. A V/Q scan is the preferred screening test, where a diagnosis of CTEPH can be supported by the presence of a mismatched wedge-shaped perfusion defect. An echocardiogram can also be used as part of the screening process – looking for evidence of right heart strain. Right heart catheterisation is also used to confirm the presence of pulmonary hypertension. Patients with confirmed CTEPH should be cared for by pulmonary hypertension specialists and anticoagulation continued.

Risk of recurrence and duration of anticoagulant therapy

It is important to identify an underlying clinical condition that might have caused VTE, such as cancer, by careful history, examination and appropriate investigations. Overweight patients should be advised to lose weight and smokers advised to stop. The preferred anticoagulant treatment options for patients with active malignancy and those receiving treatment for cancer are either continued LMWH or more recent data now support the use of anti-Xa inhibitors such as apixaban or edoxaban. These medications have been shown in RCTs to be slightly better than LMWH in treating, and preventing, VTE but at the cost of conferring a higher risk of bleeding for patients. Care should be taken when considering using a DOAC for gastrointestinal or urothelial tract cancers, as these patients are at greater risk of bleeding with DOAC when compared to LMWH.

If isolated calf DVT is diagnosed it is usually treated for 3 months but 6 weeks may be sufficient for isolated calf DVT following surgery. Patients with proximal DVT or PE should be treated for at least 3 months. The decision as to whether to continue anticoagulant treatment indefinitely after a first proximal DVT or PE is dependent on the risk of recurrence without continued treatment and the perceived risk of bleeding on anticoagulation. Long-term anticoagulation is usually given after recurrent unprovoked VTE. For patients who receive long-term anticoagulation, the risk-benefit ratio of continued treatment should be reassessed at regular intervals, e.g. annually or following an episode of severe over-anticoagulation (INR >8) or bleeding.

Recurrent DVT or PE is associated with a risk of death and a greatly increased likelihood of PTS and CTEPH, respectively. Secondary prevention of VTE significantly reduces the burden of disease, but recurrent VTE is only prevented for as long as anticoagulation is continued. Therefore, there is a need to improve risk stratification for both recurrent VTE and anticoagulant-related bleeding. Following an episode of venous thrombosis, patients are 40 times more likely to suffer an event in the future than patients who have not previously suffered from venous thrombosis. However, risk varies between patient groups. Patients with VTE provoked by surgery have an

annualised recurrence rate of <1%. Patients with VTE provoked by a non-surgical factor have an annualised risk of 4% and patients with unprovoked VTE have an annualised event rate of 7%. Many experts consider an annual rate higher than 5% justification for long-term anticoagulant therapy, as the risk of future fatal PE is then likely greater than the risk of fatal bleeding on long-term anticoagulation.

Decisions regarding duration of anticoagulation should be made with reference to whether or not a first episode of VTE was provoked or unprovoked (Table 49.6). Current guidelines recommend that patients with provoked VTE receive anticoagulant therapy for 3 months. For patients with unprovoked VTE, a decision should be made after 3 months as to whether the patient should continue on anticoagulation or stop. In patients with an unprovoked first event, male sex, a high D-dimer on completion of initial anticoagulant therapy and possibly younger age predict higher rate of recurrence. Decision rules for stopping anticoagulation, which include testing for D-dimer, have been evaluated. Increased D-dimer levels following completion of anticoagulant therapy after DVT are associated with residual vein obstruction (RVO) and likelihood of recurrence is not determined by RVO when adjusted for D-dimer level. Testing for heritable thrombophilia has little, if any, clinical utility in deciding whether a patient should remain on anticoagulant therapy or not, and routine testing in order to determine the duration of anticoagulant therapy is not recommended. If it is planned to stop anticoagulation treatment in a patient who has had unprovoked proximal DVT or PE, then testing for antiphospholipid antibodies should be offered, as a positive result would argue for reconsidering long-term treatment.

A further consideration when deciding whether a patient should continue anticoagulation or not after an initial 3 months of treatment is whether the first presentation was with symptomatic PE or DVT without symptoms of PE. Whilst the risk of recurrence is the same, patients who present with an initial PE are 3 times as likely to suffer from PE if they suffer a recurrence, as compared to those whose first event is a DVT.

Table 49.6 Suggested duration of anticoagulation.

3 months	3 months then consider for long-term	Usually long-term
• First proximal DVT or PE associated with a transient risk factor* • First unprovoked isolated calf DVT (consider 6 weeks if post-surgery)	• First unprovoked proximal DVT or PE**	• Recurrent unprovoked DVT or PE • Proximal DVT or PE with a significant continuing risk factor (e.g. active cancer, antiphospholipid antibodies) and no other cause

* Transient risk factors: surgery, significant trauma e.g. fracture, plaster cast; combined pill/hormone replacement therapy; pregnancy/puerperium.
** A stronger case for continuing in: males; those with raised D-dimers after completing anticoagulation; those with PE.

Other treatments

Vena caval filters

Vena caval filters are prosthetic devices that are deployed to prevent PE in patients at high risk, but in whom standard anticoagulant therapy is contraindicated, or in selected patients with PE despite therapeutic anticoagulation. Contraindications to anticoagulation insertion might be:

- central nervous system haemorrhage;
- overt gastrointestinal bleeding;
- retroperitoneal haemorrhage;
- massive haemoptysis;
- stroke in the last 14 days;
- central nervous system trauma;
- severe thrombocytopenia.

Filter placement is associated with potential complications. Because anticoagulation is usually contraindicated, at the time of filter insertion, there is a risk of thrombosis at the vascular access site. However, most of these are asymptomatic. There are no data on the long-term consequences of this complication. Mechanical problems such as caval penetration, filter migration, tilting and filter fracture are infrequent asymptomatic events with symptomatic events occurring in about 1% of patients.

With or without subsequent anticoagulation, there is a significant incidence of subsequent thrombosis in the vena cava or leg veins resulting in PTS in approximately 20%. This is not significantly different from the incidence of PTS following DVT treated with anticoagulant therapy, but due to incomplete follow-up of IVC filter patients this figure may be an underestimate. Filters are associated with a lower incidence of early PE, but there is a higher incidence of recurrent DVT and the thrombus frequently involves the inferior vena cava. Case series have not demonstrated a benefit from introducing anticoagulation for the sole purpose of preventing filter-related thrombotic events and anticoagulant therapy for patients with IVC filters should be guided by an assessment of the patient's risk of recurrent VTE and major bleeding, and not the presence of the filter alone. All efforts should be made to remove an IVC filter once a patient is able to receive anticoagulation, to minimise long-term side effects.

Thrombectomy

Thrombectomy is rarely performed in patients with massive PE but is an option in cardiothoracic centres in patients with life-threatening PE. Thrombectomy is not recommended in patients with DVT. There are insufficient data to evaluate the long-term benefit of surgical removal of the thrombus in patients.

Venous thrombosis in unusual sites

Cerebral vein thrombosis

Cerebral venous sinus thrombosis (CVST) most often affects young adults, with approximately three-quarters of patients being female. Obstruction of cerebral veins causes cerebral oedema and venous infarction, while occlusion of venous sinuses cause intracranial hypertension. It can present with recent unusual headache or stroke-like symptoms. The most sensitive diagnostic test is magnetic resonance venography. If MRI is not available, then high-resolution CT venography is useful but can be normal initially. Recognised underlying causes include infection, myeloproliferative disorders and leukaemia (especially with asparaginase treatment) and use of oestrogen-containing oral contraceptives. Mortality in the first month is approximately 5%, but 80% of surviving patients recover completely or have only a mild functional or cognitive deficit. Anticoagulant therapy was associated with a pooled relative risk of death of 0.33 (0.08–1.21) and of death or dependency of 0.46 (0.16–1.31), based on two small studies and it is recommended that patients with CVST without contraindications to anticoagulant therapy should be treated with therapeutic-dose heparin. The optimal duration of anticoagulation is unknown, but it is suggested that a minimum of 3-months treatment is given. Long-term anticoagulation has been suggested for patients with 'severe' thrombophilia and in patients with unprovoked CVST with incomplete recanalisation, but with no evidence.

Retinal vein thrombosis

Retinal vein occlusion (RVO) is predominantly a disorder of the elderly. The prognosis depends on the development of macular oedema and neovascularisation and standard therapy has been laser photocoagulation. The role of anticoagulant therapy is unclear. For branch RVO, antiplatelet or anticoagulation therapy is not recommended. Patients with acute central RVO are considered for a short course of anticoagulation with LMWH or with low-dose tPA, but routine therapy with warfarin, DOAC or antiplatelet agents is not recommended.

Upper limb DVT

Upper extremity DVT may involve the axillary, subclavian and brachial veins and may be associated with thoracic outlet syndrome, or with strenuous effort, or with placement of a central venous catheter. Compression ultrasound is an acceptable alternative to venography in the investigation of suspected upper limb DVT. PE occurs in up to 30% of cases and PTS of the arm is a risk. Recurrence is less common than in lower limb DVT. The majority of patients are managed with anticoagulation for 3 months. Those patients with a high clot burden, with a DVT involving the subclavian and axillary veins, may be considered for catheter-directed thrombolysis.

Intra-abdominal vein thrombosis

Portal vein thrombosis

The portal vein is formed from the superior mesenteric and splenic veins. The most common underlying aetiology of portal vein thrombosis is cirrhosis; other causes are intra-abdominal infection, inflammation or malignancy and blunt trauma or surgery. Myeloproliferative disorders account for up to a quarter of cases and all patients should be assessed for the *JAK2* V617F mutation. Paroxysmal nocturnal haemoglobinuria is another important cause of intra-abdominal thrombosis. Presentation can be acute, with abdominal pain, fever and nausea, or chronic, with symptoms of portal hypertension. The diagnosis can be made by CT, MRI or Doppler ultrasound. In patients with cirrhosis, the risk of anticoagulation-related bleeding is high, and anticoagulation may be regarded as too high risk. In acute portal vein thrombosis without cirrhosis, anticoagulation is usually given. There is no evidence to guide duration of anticoagulation. Although it has been suggested that anticoagulation should be given long-term in the presence of heritable thrombophilia, or if there is a failure of recanalisation, this is not based on any evidence.

Hepatic vein thrombosis

The usual presentation is with abdominal pain, ascites and hepatomegaly (Budd–Chiari syndrome). Many patients have a myeloproliferative disorder and a large proportion of patients are JAK2 positive. The diagnosis can be made with Doppler ultrasound, CT or MRI. Most patients are anticoagulated and in one-third, this is followed by transjugular intrahepatic portal-systemic shunting (TIPSS).

Mesenteric vein thrombosis

The most common causes are cancer, intra-abdominal infection, cirrhosis and surgery. Presentation is with abdominal pain and diarrhoea or peritonitis. Diagnosis is with CT or MRI. Surgery is required in patients with peritonitis, but otherwise anticoagulation is the treatment of choice.

Splenic vein thrombosis

Isolated splenic vein thrombosis is rare, and pancreatic disease is the most common aetiology. It can present with variceal bleeding and splenomegaly.

Superficial thrombophlebitis

Superficial venous thrombosis (SVT) of the lower limb, involving long or short saphenous veins or their branches, has the same risk factors as DVT. SVT was considered to be a benign and self-limiting condition; however, it is now appreciated that a significant proportion of those presenting with SVT will have concomitant DVT or PE, or are at significant risk of developing DVT or PE. SVT within 3 cm of the sapheno-femoral junction has such a high risk of progression to DVT that such patients are given therapeutic anticoagulation as for DVT. In other cases, non-steroidal anti-inflammatory drugs (NSAIDs) and heparin have been used as treatment. A Cochrane review concluded an intermediate dose of LMWH (125 units/kg) might be appropriate and for SVT ≥5 cm in length this or a prophylactic dose of fondaparinux (2.5 mg daily) for 45 days should be used, the latter reducing symptomatic DVT or PE by 82%. Rivaroxaban 10 mg daily is an alternative treatment option.

List of Abbreviations

ACS	acute coronary syndrome
ADP	adenosine diphosphate
AF	atrial fibrillation
aPC	activated protein C
APS	antiphospholipid syndrome
APT	antiplatelet therapy
ATP	adenosine triphosphate
CABG	coronary artery bypass grafting
CAD	coronary artery disease
CYP	cytochrome
DAPT	dual antiplatelet therapy
DES	drug eluting stents
DIC	disseminated intravascular coagulation
DOAC	direct oral anticoagulant (also known as NOAC; non-vitamin K dependent oral anticoagulant)
EPCR	endothelial protein C cell receptor
ESC	European Society of Cardiology
GP	glycoprotein
HITT	heparin induced thrombocytopenia and thrombosis
HTPR	high on-treatment platelet reactivity
INR	international normalised ratio
LEAD	lower extremity artery disease
LMWH	low molecular weight heparin
MACE	major adverse cardiovascular events
MI	myocardial infarction
NO	nitrous oxide
NSAIDs	non steroid anti-inflammatory drugs
NSTEMI	Non ST-segment elevation myocardial infarction
OAC	oral anticoagulant
PAD	peripheral artery disease
PAI-1	plasminogen activator inhibitor 1
PAR	protease activated receptor
PCI	percutaneous coronary intervention
PCORI	Patient-Centred Outcomes Research Institute
PFO	patent foramen ovale
PPI	proton pump inhibitors
ST	stent thrombosis
STEMI	ST-segment elevation myocardial infarction
TAFIa	thrombin-activatable fibrinolysis inhibitor
TIA	transient ischaemic attack
TM	thrombomodulin
tPA	tissue plasminogen activator
TXA2	thromboxane
UFH	Unfractionated heparin

The impact of arterial thrombosis on cardiovascular disease

The majority of acute arterial cardiovascular diseases, like myocardial infarction and ischaemic stroke, are caused by thrombosis or thromboembolism of one or more arterial branches that provide the organ with oxygen and nutrients. Arterial thrombosis typically starts at the surface of a damaged atherosclerotic plaque and may inflict more distal obstruction through dislodgement or embolisation of thrombus material. Another distinct type of arterial thrombosis originates in association with atrial fibrillation, where thrombi form in the left atrial appendix and embolise to the brain (embolic stroke). Atherothrombotic and embolic stroke from the heart are distinctly different pathologies requiring different management strategies, discussed in the next sections.

In addition, arterial thrombosis may occur in the context of systemic hypercoagulable diseases. These include coagulopathies related to antiphospholipid syndrome (APS), malignancy and other less frequent disorders including thrombotic thrombocytopenic purpura, heparin-induced thrombocytopenia and thrombosis (HITT) or in the course of disseminated intravascular coagulation (DIC), related to systemic thrombo-inflammatory disorders, including infections like Covid-19. Finally, arterial thromboembolisation may also be a consequence of paradoxical embolisation from the venous circulation, through a patent foramen (PFO) in the heart (with a recent study suggesting such thrombi may also form within the PFO); discussion of pathogenesis and management of these less frequent conditions is beyond the scope of this chapter.

Globally, myocardial infarction and ischaemic stroke, of either origin, are the most frequent causes of cardiovascular morbidity and mortality, in either sex and in all ethnicities. Importantly, not just the primary ischaemic event, but also the consequences such as heart failure, contribute to the worldwide large-scale morbidity, characteristic for many ischaemic cardiovascular diseases.

In this chapter, we will focus on the major classes of arterial thrombotic disease, the origin of thromboembolism and their antithrombotic management.

The physiological defence against atherosclerosis

Physiologically, the vascular endothelium has important protective anticoagulant and anti-inflammatory properties. Platelets – anucleate, discoid cells produced by megakaryocytes – circulate in a non-activated state, not engaging in platelet-platelet contact. To prevent unwanted and uncontrolled platelet activation and subsequent thrombus formation, the endothelial lining of the blood vessels actively produces and secretes platelet inhibitors. Endothelial cells exposed to shear stress secrete nitric oxide (NO) continuously. Also, they produce prostaglandin I_2, a product from arachidonic acid metabolism. Both compounds provide a strong platelet inhibitory influence by elevating intracellular levels of cGMP (NO) and cAMP (PGI_2). Additionally, endothelial cells express the ectonuclease CD39, which degrades the platelet agonists ATP and ADP present in the plasma to AMP. CD73, also associated with the vasculature, subsequently converts AMP to adenosine, another platelet inhibitor that results in elevated intracellular cAMP levels. Besides the production and secretion of platelet inhibitors, the glycocalyx of the endothelium, consisting of proteoglycans and glycoproteins, provides an additional means to prevent platelet adhesion as it covers prothrombotic proteins and its negative charge repels cells.

In addition, coagulation proteases like factor (F) Xa and thrombin interact with cellular receptors. These receptors include thrombomodulin (TM) and endothelial protein C cell receptor (EPCR). Binding of thrombin to TM generates a complex that converts protein C to activated protein C (aPC), which slows down coagulation by degradation of FVa and FVIIIa and also displays anti-inflammatory and cell protective properties. The thrombin-TM complex also converts plasma pro-carboxypeptidase B2 (proCPB2 or thrombin-activatable fibrinolysis inhibitor, TAFI) to activated TAFI (TAFIa), which inhibits plasmin formation. Plasmin will normally limit fibrin clot formation and prevent thrombosis, thus TAFI formation also requires regulation to limit fibrin deposition. At the same time, TAFIa has several anti-inflammatory properties including the inactivation of pro-inflammatory mediators like bradykinin, anaphylatoxins C3a and C5a and thrombin-cleaved osteopontin (OPN). This way, physiologically, low levels of thrombin support endothelial cell integrity through endothelial cell-mediated APC-protease activated receptor (PAR) signalling and TAFIa generation.

Platelets and the pathophysiology of atherosclerosis and atherothrombosis

Endothelial cell dysfunction refers to functional endothelial impairment in response to triggers of vasodilation, but also refers to diminished anti-inflammatory and anticoagulant properties. Upon inflammatory challenge of the endothelium, PARs that physiologically help to translate the cell protective effects of low amounts of FXa and thrombin, can divert their cell signalling functions towards damaging actions, depending on cell receptor density and configuration, the concentration of coagulation factors, as well as the endothelial configuration of PARs and their cofactors. Inflammation can also result in (local) loss of TM and EPCR due to proteolysis or membrane shedding, which may (locally) diminish cell protective properties and allow endothelial cell perturbation to occur (Figure 50.1a, b).

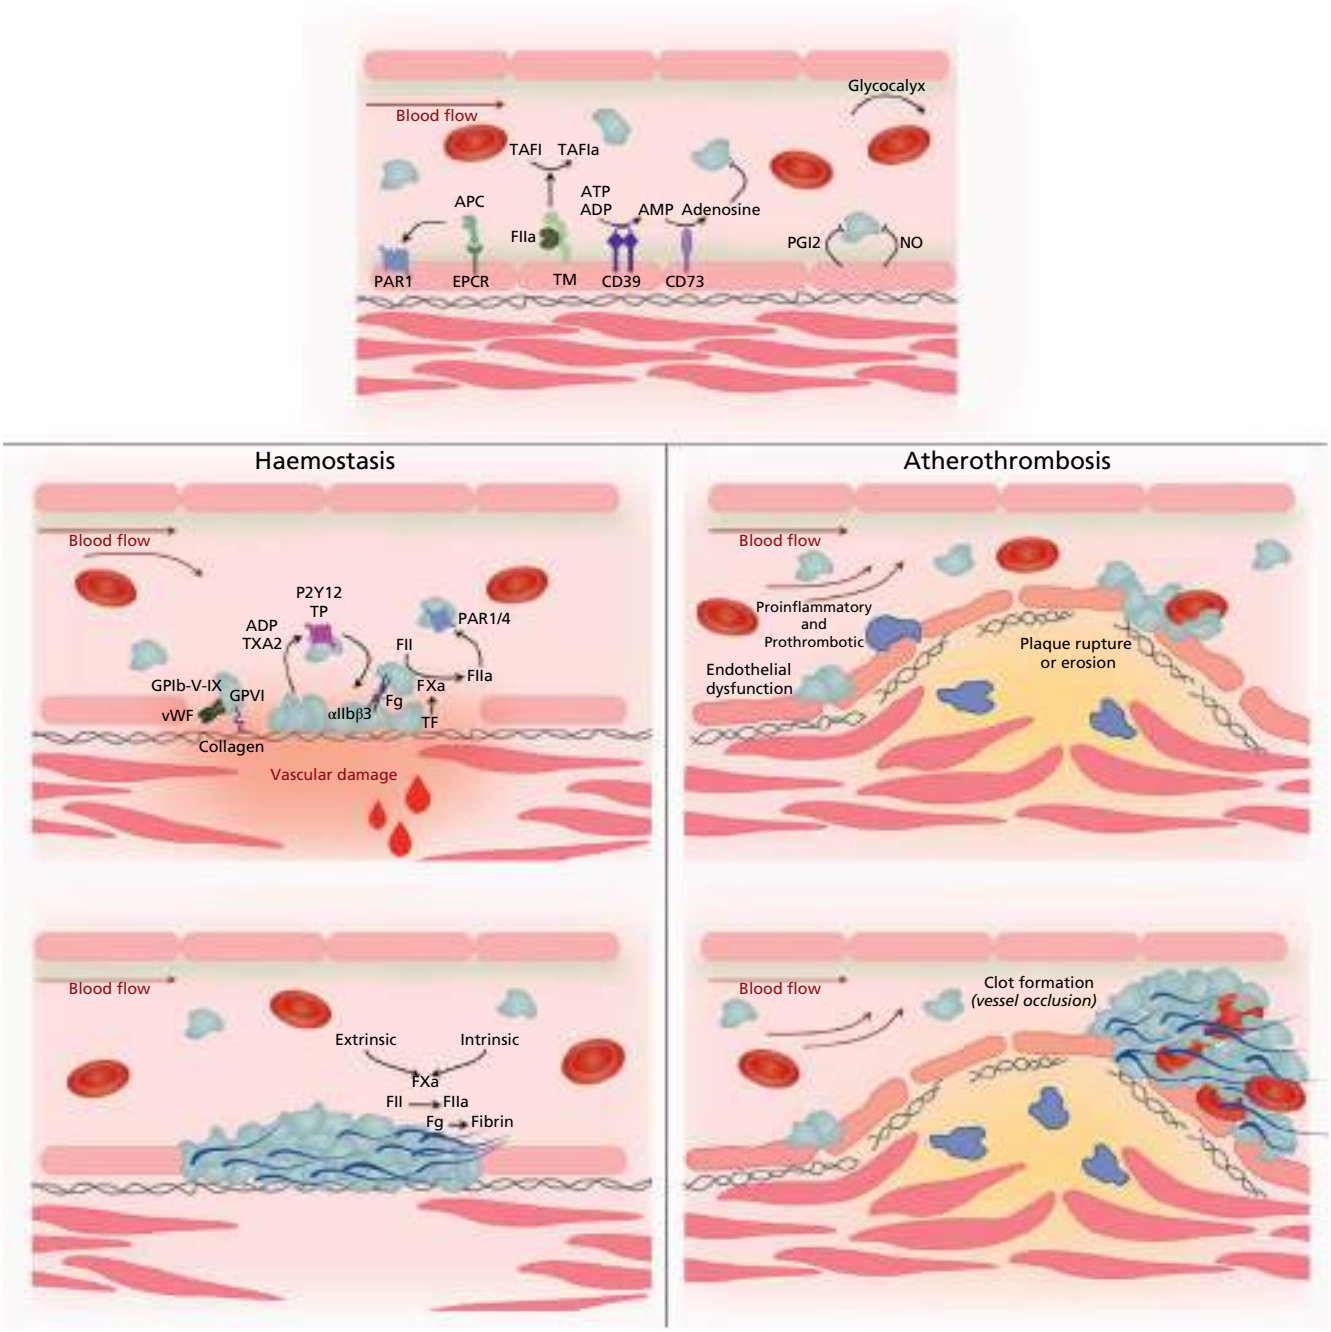

Figure 50.1 upper panel: physiological defence mechanisms of the vascular endothelium against thrombosis, showing protease-activated receptor 1 (PAR-1) and endothelial protein C receptor (EPCR) as receptors for thrombin and activated protein C, directing anticoagulant and anti-inflammatory activities. Thrombomodulin (TM) links thrombin to protein C activation as well as thrombin activatable fibrinolysis inhibitor (TAFI) activation, balancing coagulation and fibrinolysis. CD39 and CD73 direct ADP, AMP and adenosine mediated platelet reactions, while endothelial prostacyclin (PGI2) and nitrous oxide production further prevent platelet activation and act anti-inflammatory. Left middle and lower panel: the process of haemostasis occurring upon damage to the vessel wall; collagen and other platelet adhering and activating proteins allow platelet adhesion and concurrent thrombin generation further amplifies platelet activation and aggregation and thrombus formation to heal the wound bed. Right upper and lower panel: illustrate atherothrombosis occurring at the surface of a damaged atherosclerotic plaque with endothelial activation and dysfunction as early-stage events, triggering inflammation and eventually thrombosis.

When endothelial cells are activated or damaged, von Willebrand Factor (vWF) stored within the Weibel Palade bodies is released. This triggers rolling of platelets onto the damaged vascular site mediated through shear-dependent vWF – glycoprotein (GP) Iba interactions, providing platelets with the opportunity to stably adhere to other matrix components within the injured vessel or atherosclerotic plaque. Stable platelet adhesion is brought about by binding of the integrin $\alpha_2\beta_1$ and GPVI receptors to the collagen present within extracellular matrix. While platelet adhesion to collagen is widely studied, other components of the extracellular matrix, like laminin, fibronectin, vitronectin and thrombospondin, are also capable of supporting platelet adhesion and contributing to thrombus formation. Upon platelet rolling and subsequent stable adhesion to the damaged vessel wall, intracellular signalling pathways are stimulated and platelet activation is triggered resulting in secretion of the α and dense (δ) granule contents. The extent to which platelets release their granular cargo depends on the strength and type of stimulus. Whereas large molecules such as fibrinogen, factor V, P-selectin and multiple chemo- and cytokines are stored in the α granules, the dense granules contain amongst others ATP, ADP and polyphosphates. Along with thromboxane A2 (TXA2) generated by the cyclooxygenase/thromboxane synthase enzymes, ATP and ADP serve as important autocoids that upon release activate nearby platelets and as such promote the incorporation of more platelets from the circulation into the growing platelet plug. ATP signals via the purinergic receptor P2X1, while ADP activates P2Y1 and P2Y12. Within the growing platelet plug, platelet aggregation is dependent on integrin $\alpha_{IIb}\beta_3$, a glycoprotein abundantly expressed on the platelet surface. Upon platelet activation, integrin $\alpha_{IIb}\beta_3$ changes its confirmation and is thereby able to bind fibrinogen and to support platelet-platelet interactions. Concurrently, thrombin generated by the coagulation cascade additionally enhances platelet activation through activation of the PAR-1 and PAR-4 receptors present on the platelet membrane. Upon strong activation with sustained high intracellular Ca^{2+} levels, platelets become procoagulant. By exposing phosphatidyl serine on their outer leaflet of the plasma membrane, this subpopulation of procoagulant platelets provides a negatively charged surface for the assembly of the tenase and prothrombinase complexes and thus supports coagulation. Further crosstalk between the coagulation cascade and platelets occurs upon the formation of fibrin as fibrin can interact with the GPVI receptor on platelets, enabling platelets to bind to fibrin within the clot.

Different types of atherothrombosis

In accordance with Virchov's triad, thrombosis typically involves three elements, including blood flow, blood composition and vessel wall. The weight of each Virchov element may vary depending on the underlying disease: Commonly, an interaction between blood and the damaged atherosclerotic vessel wall triggers arterial thrombosis (Figure 50.1c).

Already in the early stages of atherosclerotic plaque development endothelial cell dysfunction occurs; platelets adhere to the dysfunctional endothelium and as such are able to deposit their granular cargo and release platelet microparticles. They thereby add to the endothelial cell dysfunction, mediated by amongst others CCL5/RANTES, CXCL4/platelet factor 4 and IL-1 and contribute to plaque development. Subsequently, plaque development gradually progresses and more pro-inflammatory and prothrombotic properties accumulate, until in the final stages of atherosclerosis, plaque rupture or erosion occurs. The resulting exposure of highly thrombogenic plaque material to the circulation triggers the formation of (occlusive) thrombi. Interestingly, plaque erosion and plaque rupture are associated with the formation of distinct types of thrombi. Whereas occlusive, luminal thrombi that are exposed to the necrotic core can be found on plaques that have ruptured, thrombi that are mural and non-occlusive typically form on eroded plaques. Furthermore, clot composition is different. Ruptured plaques support the formation of fibrin-rich thrombi (fibrin area: 75%, platelet area: 35% in thrombi), whereas thrombi formed on eroded plaques are rich in platelets (platelet area: 70%, fibrin area: 51% in thrombi). These thrombi enriched in platelets appear to be more prevalent in patients with non-ST segment elevation myocardial infarction (NSTEMI), while fibrin, erythrocyte-rich thrombi are more frequent in patients with acute myocardial infarction (MI). At this stage, these apparent histological differences do not yet translate into specific antithrombotic strategies for the different subtypes of MI.

Antithrombotic treatment for primary prevention of atherothrombosis

Single antiplatelet agents: mode of action, side effects

Aspirin is the common name for acetylsalicylic acid, a compound that acts by inhibiting prostaglandin synthesis in different cells; the relevant antithrombotic effect is thought to be mostly based on inhibition of the cyclooxygenase-1 production of TXA2 in platelets (Figure 50.2). It is prescribed at doses between ±75 and 325 mg od, mostly dependent on regional differences (US more commonly higher doses than Europe). Its intake results in irreversible inhibition of platelet activation and aggregation. To achieve sustained effect, daily intake of aspirin is needed to suppress newly formed platelets, about 10% per day.

Clopidogrel is a prodrug that needs metabolisation in the liver. It is ingested as a single dose of 75 mg/day and the active metabolite shows a large interindividual variation in blood. This variability is partly explained by genetic polymorphisms encoding cytochrome P450 (CYP) 2C19, the hepatic enzyme involved in biotransformation of the prodrug clopidogrel to its active metabolite. The active metabolite interferes with the binding of ADP to the platelet P2Y12 receptor. This

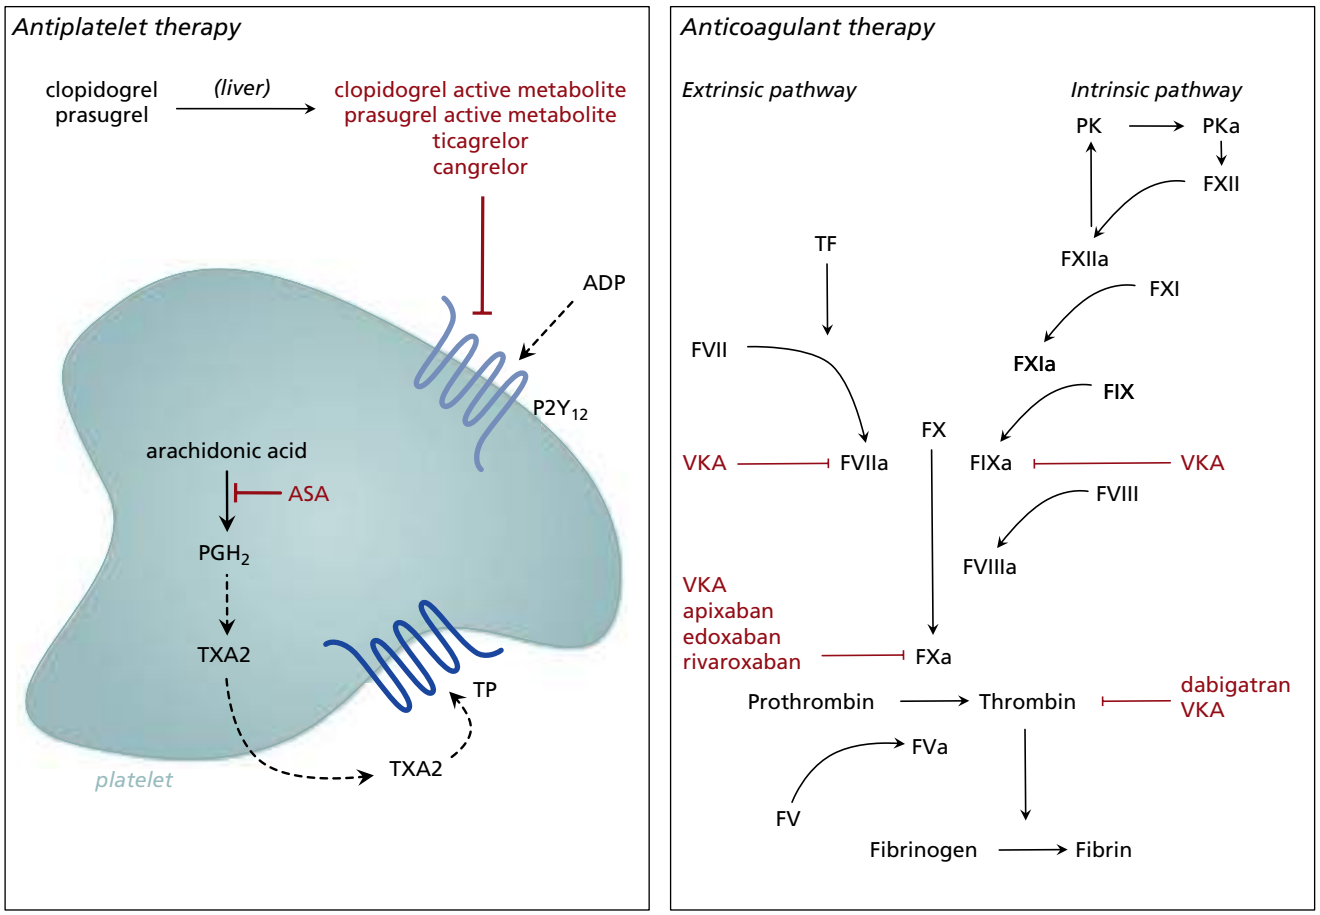

Figure 50.2 Left panel shows sites of interaction and mechanistic pathways involved in the action of aspirin and P2Y12 inhibitors; right panel illustrates the mode of action of current anticoagulants, with vitamin K antagonists (VKA) targeting the carboxylation of vitamin K-dependent proteins by the liver and direct oral anticoagulants (DOAC), directly targeting activated factor X or thrombin.

pharmacodynamic variation translates into variation in clopidogrel effectiveness after percutaneous coronary intervention (PCI). The interindividual variation in response to clopidogrel, inappropriately referred to as clopidogrel "resistance," was first identified in patients with coronary disease, occurring up to 25% of cases in platelet function testing (depending on the test used). These patients have less active metabolite and high on-treatment platelet reactivity (HTPR) while on clopidogrel; this is associated with increased incidence of major adverse cardiovascular events (MACE). Several studies addressed the question of whether clopidogrel dose adjustment based on platelet function testing, would correct this problem, but the outcome of such studies was consistently negative. However, more recent studies showed that when clopidogrel is prescribed based on the genetic profile of *CYP2C9* metabolism (translating into poor, intermediate, good or strong metabolisers), it is possible to achieve appropriate efficacy with this drug, in high-risk coronary patients (see further).

Another option is to use more potent P2Y12 inhibitors, which are either not hindered by this CYP2C9 metabolism such as prasugrel, or are not pro-drugs (ticagrelor) and therefore have a more predictable pharmacodynamic profile. Clopidogrel and prasugrel are irreversible platelet inhibitors, while ticagrelor binds reversibly.

The principal side effect of aspirin is bleeding and the regular use of aspirin increases the risk of gastro-intestinal bleeding twofold. Risk factors for bleeding should therefore be taken into account, including (recent) gastrointestinal (GI) ulcer (H. pylori infection may be a modifiable risk factor), old age, use of interacting medication including other antiplatelet therapy (APT), non steroidal anti-inflammatory drugs (NSAIDs), COX-2 selective inhibitors, oral anticoagulants, corticosteroids. In general, the risk of GI bleeding with aspirin can be effectively reduced with proton pump inhibitors (PPI), better than with histamine-2 receptor antagonists. The introduction of a PPI increases costs and also has potentially relevant side effects in the long run. Alternative options may be phospholipid-coated

aspirin preparations that in contrast to enteric-coated aspirin, have equivalent efficacy for inhibiting TXA2 formation as compared to aspirin.

Although clopidogrel does not interfere with prostaglandins in gastric mucosal tissue, its use is also associated with an increased risk of bleeding, of which GI bleeds are the most common type. The benefit of standard use of a PPI in patients on clopidogrel has been disputed, in fact, there is evidence that its concomitant use is associated with an increased risk of MACE. Compared to clopidogrel, the newer and more potent P2Y12 inhibitors prasugrel and ticagrelor are associated with a further increase in the risk of major bleeding (see also Section "Antithrombotic therapy in patients with acute coronary syndrome"). These agents are generally not prescribed as single APT, although ticagrelor may be used as a single agent in selected patients. Although the thienopyridine prasugrel is a prodrug like clopidogrel, it only requires a single oxidation step to form its active metabolite, and it seems to be not affected by genetic variations in CYP enzymes. Compared to clopidogrel, its use is associated with an increase in the risk of major bleeding, especially amongst those with age ≥75 years or body weight <60 kg such that its use is contraindicated in patients with prior stroke. Ticagrelor, a reversible P2Y12 receptor antagonist, provides faster and stronger platelet inhibition with less patient-to-patient variation. In most instances, ticagrelor and prasugrel will be prescribed as part of dual APT (DAPT) to be discussed in later sections. In order to reduce the risk of GI bleeding while on DAPT, PPI's will be additionally prescribed in most cases.

Primary prevention in subjects without apparent CVD

Given the efficacy/safety profile and the low costs, *primary* prevention with aspirin has been extensively studied. Recent studies and meta-analyses of large trials refute a major role for aspirin in primary prevention. In subjects with a specific risk factor like diabetes, aspirin can be considered in those with ≥1 organ damage or ≥3 major risk factors, or any risk factor and ≥10-year disease duration without organ damage, based on a meta-analysis of 12 randomised controlled trials, including the recent ASCEND trial that showed that aspirin reduced MACE by 11% compared with placebo. In conditions with high platelet turnover, twice daily administration of aspirin may be more effective and can be considered in specific conditions, such as subjects with myeloproliferative disease and high platelet production and turnover.

Primary prevention in subjects with documented atherosclerosis; general considerations

Primary lifelong prevention (of MACE) with aspirin or clopidogrel is indicated in all persons with *symptomatic* atherosclerotic disease, including angina and symptomatic PAD, as the benefits outweigh the bleeding risk. The benefit of aspirin has not yet been established for subjects with *asymptomatic* lower extremity artery disease (LEAD), although mortality is comparable to patients with symptomatic disease. In patients with symptomatic PAD, clopidogrel is preferred over aspirin based on the PAD subgroup analysis of the CAPRIE trial showing superior antithrombotic efficacy of clopidogrel at comparable bleeding risk. However, both aspirin and clopidogrel are still used for this indication.

Single APT, either with aspirin or clopidogrel, is also recommended in carotid artery disease with carotid artery stenosis >50%.

Stronger acting APT like ticagrelor may be used as alternative in patients with PAD in case of failure, allergy or "resistance" to aspirin or clopidogrel, based on the Euclid trial showing non-inferiority of ticagrelor versus clopidogrel.

Since the residual risk of atherothrombotic complications including mortality remains at around 10% annually in PAD patients, more intensive antiplatelet regimens have been assessed as well. Importantly, the efficacy benefits of DAPT were first established in a population with coronary artery disease in the PCI-CURE study (DAPT is further discussed in section "Antithrombotic therapy in patients with acute coronary syndrome"). Assuming similar benefits could be achieved in other high-risk for thrombosis populations, DAPT was tested in large trials like CHARISMA but with negative outcomes; no gain in efficacy and more bleeding. Consequently, in patients with non-acute, symptomatic atherosclerotic disease, DAPT with aspirin and clopidogrel is only recommended following surgical intervention of the carotid arteries (at least 1 month), or after percutaneous intervention in peripheral arteries of the legs for 1 month, followed by single APT.

The use of oral anticoagulants (mostly vitamin K antagonists) in therapeutic intensity is not indicated in patients with PAD, except for those who undergo venous bypass grafting. The most recent regimen studied in the COMPASS study involving patients with high-risk arterial vascular disease, including PAD, is the combination of the anticoagulant rivaroxaban 2.5 mg bd (Figure 50.2), and low-dose aspirin, which reduced cardiovascular mortality as well as major acute limb events in patients with PAD (patients with LEAD or carotid artery disease).

Primary prevention in patients with stable, symptomatic coronary artery disease

All patients with symptomatic coronary artery disease require APT and, in most cases, aspirin will be prescribed lifelong; clopidogrel is an alternative option. Aspirin is prescribed in a relatively low dose of 75–100 mg, either as acetylsalicylic acid or as calcium-carbasalate, although in the USA higher doses of 325 mg/day of acetylsalicylic acid may be used. Pharmacologically, there is not

much evidence for a benefit of higher doses of aspirin as compared to low doses of 75–100 mg od.

Many patients with angina will at some stage undergo vascular imaging to determine the cause of complaints and in case of significant atherosclerotic lesions, PCI and stenting is a next management step. Upon stenting, these patients will be treated with DAPT for a period of usually up to 6 months, depending on estimated risks of thrombosis and bleeding. Hence, in case of a bleeding risk, duration of DAPT after elective PCI in patients with chronic CAD may be limited to 1–3 months. Obviously, risk factors for bleeding should always be addressed and if possible managed. Alternatively, in those at high risk of recurrent thrombosis, continued DAPT may be considered; however, this policy has no favourable effect on mortality while bleeding risk doubles as compared to single APT. Combining conventional oral anticoagulants with APT in patients with stable CAD (and without AF) is not cost effective, but low-dose rivaroxaban (2.5 mg bd) plus aspirin may provide a useful strategy in particular CAD patients with an estimated high risk of thrombosis.

For the long term, in high risk for thrombosis CAD patients, the choice of single APT, or DAPT, or rivaroxaban plus aspirin (dual pathway inhibition) must be carefully balanced. A network meta-analysis of randomised controlled trials suggests an efficacy benefit for any combination with aspirin at the price of an increased bleeding risk. Taking into account outcomes of all ischaemic and bleeding events and all-cause mortality, rivaroxaban plus aspirin appeared to be the preferred long-term antithrombotic regimen for patients with chronic coronary syndrome and high-risk factors.

In patients with CAD requiring coronary artery bypass grafting (CABG), aspirin will be continued during surgery (supported with systemic heparinisation during the extracorporeal bypass procedure). Following surgery, the patient will usually continue with single APT, lifelong, because of underlying atherosclerosis.

Antithrombotic therapy in patients with acute coronary syndrome

Aspirin (bolus 150–300 mg orally or 75–250 mg i.v. loading dose, followed by low dose 75–100 mg QD) is indicated as soon as possible in all forms of acute coronary syndrome (ACS) based on the ISIS-2 trial. Aspirin halves the risk of recurrent myocardial infarction (MI, 1.0 versus 2.0%) and reduces vascular mortality (Figure 50.3). The downside of aspirin treatment is an increased bleeding risk, which is predominantly gastro-intestinal of origin.

Parenteral anticoagulation is also indicated in the acute phase of all forms of ACS. Unfractionated heparin (UFH) or the low molecular weight heparin (LMWH) enoxaparin is indicated in STEMI, while the factor Xa-inhibitor fondaparinux is not indicated due to more thrombotic complications in patients

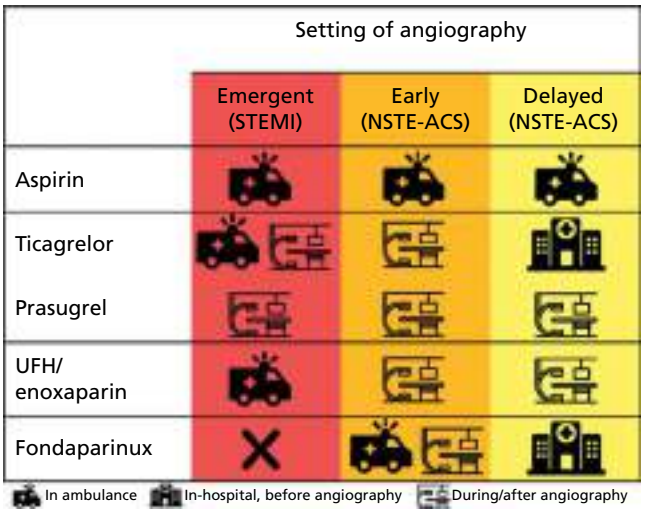

Figure 50.3 Timely use of antithrombotic therapy in the acute phase of ACSACS: acute coronary syndrome; STEMI: ST-segment elevation myocardial infarction; NSTE-ACS: non-ST-elevation ACS i.e. non-ST-elevation myocardial infarction or unstable angina pectoris; UFH: unfractionated heparin.

undergoing primary PCI. In NSTEMI the preferred agent is UFH when an early invasive strategy is chosen or fondaparinux when a conservative or delayed invasive strategy is preferred. Even when the patient is treated with fondaparinux, during coronary angiography and PCI, additional UFH is indicated as fondaparinux does not prevent catheter thrombosis, which may inflict myocardial infarction. In ACS (STEMI and NSTEMI), it is advised to administer anticoagulation until PCI or for 5 days or until discharge.

In addition to aspirin, P2Y12 inhibition is indicated in ACS. In all ACS patients, the stronger – and faster-acting agents ticagrelor or prasugrel are preferred over clopidogrel as they demonstrated superiority in the pivotal trials TRITON and PLATO, together containing over 30,000 patients. However, both ticagrelor and prasugrel increase bleeding risk, and this risk has been shown to be associated with increased morbidity and mortality for more severe bleeding.

As the thrombotic risk in ACS is highest in the early hours, it is preferred to load the patient with STEMI with one of the stronger agents, while de-escalation in-hospital is an option in those patients with a high bleeding risk. There is still controversy about when to load the STEMI patient with oral P2Y12 inhibition, whether this is in the ambulance or after coronary angiography when the coronary anatomy is known. Benefit from in-ambulance administration may be limited by slow onset of action of oral P2Y12 inhibition (2–4 hours) through gastro-intestinal absorption, even more, delayed when morphine is co-administered. Several studies found faster platelet inhibition with chewed or crushed rather than integral administered P2Y12 inhibitors; however in the COMPARE

CRUSH trial, this was not translated into improved coronary flow or ST-segment resolution.

Another option to reach rapid platelet inhibition in the early phase of STEMI is the use of intravenous platelet inhibitors. Glycoprotein IIb/IIIa inhibitors have been shown to improve pre-pPCI target vessel patency, post-pPCI ST-segment resolution and patient outcomes. However, because of slow offset of action, bleeding risk and thrombocytopenia and introduction of the more potent P2Y12 inhibitors for these patients, they are mainly used for bail-out purposes in case of suboptimal stenting or high thrombus load. Another intravenous agent, the P2Y12 inhibitor cangrelor, which has a fast on- and off-set, might also be considered for patients who have no or suboptimal P2Y12 inhibition when PCI is performed. It reduces thrombotic complications 48 hours after PCI, 3.8 versus 4.7% compared with clopidogrel (odds ratio [OR] 0.81 [95% CI 0.71–0.91]); but also comes with increased mild bleeding complications in around 6% of cases.

In NSTEMI, the choice and timing of P2Y12 inhibition depend on the preferred management (invasive or conservative) and, if coronary angiography is preferred, when this is performed (early or delayed). Loading with P2Y12 inhibitors before coronary anatomy (thus before coronary angiography) is known, is referred to as pre-treatment. Pre-treatment with half-dose prasugrel did not reduce thrombotic events but increased major bleeding in the ACCOAST trial, where all patients underwent early coronary angiography. In the ISAR REACT 5 trial, prasugrel started after coronary angiography was superior to ticagrelor before angiography in ACS patients. Bleeding events did not differ between groups. Based on the ACCOAST and ISAR-REACT 5 trials, the ESC guidelines advise, if an early invasive strategy is preferred, to wait with loading until the coronary anatomy is known and the patient is to proceed to PCI. In patients in whom a conservative or delayed invasive strategy is preferred, pre-treatment remains an option in patients with a higher thrombotic risk and ticagrelor is preferred unless the patient has a higher bleeding risk, then clopidogrel is a safer option. In patients treated conservatively, the ESC guidelines advise to use ticagrelor, while prasugrel is contraindicated. In patients with a high bleeding risk especially in the elderly, clopidogrel may be a better option.

Antithrombotic treatment at discharge

Most patients with ACS undergo PCI with stenting. In these patients, DAPT is essential to prevent ST but also spontaneous MI and stroke. When determining the most suitable P2Y12 inhibitor as well as the duration of DAPT, the associated bleeding risk has to be balanced against the reduced thrombotic risk. The 12-month duration of DAPT in ACS is based on the TRITON and PLATO trials. Since then, the newer generations drug-eluting stents (DES) that are used and also better implantation techniques have led to lower rates of stent thrombosis, challenging the need for long duration of DAPT.

Several RCTs tested a shortened (1–6 months as compared to 12 months) duration of DAPT. All of these trials have shown reduced bleeding, while only a few demonstrated a higher thrombotic risk with a shorter DAPT duration. Based on the results of these trials, in line with the ESC guidelines, we consider 1-year DAPT to be recommended in ACS. However, a shorter course could be considered in patients at higher risk of bleeding complications.

When DAPT is discontinued, patients are usually treated with lifelong aspirin monotherapy to prevent recurrent atherothrombotic events. A recent study, the HOST EXAM trial, randomised Korean patients in their chronic maintenance period after PCI to clopidogrel or aspirin monotherapy. It showed that clopidogrel might be a favourable option both with regards to thrombotic (3.7 versus 5.5%, HR 0.68 [95% CI 0.52−0.87]) and bleeding complications (2.3 versus 3.3%, HR 0.70 [95% CI 0.51–0.98]). Several trials had already tested P2Y12 inhibitor monotherapy after 1–3 months of uneventful standard DAPT, similar to the trials studying a shortened DAPT as described above. In general, these trials found P2Y12 inhibitor monotherapy (mostly ticagrelor) equally effective as compared to standard DAPT, whilst reducing bleeding (but not major bleeding) complications. Based on these results, P2Y12-inhibitor monotherapy after an initial short course of DAPT should be an alternative for standard DAPT in patients undergoing PCI without high ischaemic risk. Based on the HOST EXAM trial, also clopidogrel might be preferred over aspirin after one-year DAPT post-ACS.

Risk scores or criteria such as PRECISE-DAPT and ARC-HBR may aid decision-making. They should be applied at the time of PCI to guide DAPT duration. The PRECISE-DAPT score is a five-item risk score to predict out-of-hospital bleeding after PCI. Amongst patients with a high bleeding risk (PRECISE-DAPT score $\geq$25), standard DAPT was associated with no reduction in ischaemic events, but a strong increase in bleeding with a number needed to harm of 38. In contrast, standard treatment in patients without high bleeding risk (PRECISE-DAPT score <25) was associated with significant reductions in the combined ischaemic endpoint, without an increase in bleeding, with a number needed to treat of 65. Thus, by upfront deciding on a short course of DAPT in patients at high bleeding risk, a substantial proportion of excess bleeding events might be prevented, while patients without high bleeding risk benefit from standard or extended DAPT. Noteworthy, in five out of eight RCTs included in the PRECISE-DAPT derivation cohort, exclusion criteria such as thrombocytopenia, anaemia or history of bleeding were applied. In the derivation cohort, the incidence of bleeding was relatively low (1.5 and 0.8% for major and minor and major bleeding events, respectively) suggesting that patients at highest risk of bleeding were not included. The expert consensus-derived ARC-HBR criteria are relatively new and not extensively studied yet. It should be noted that

risk-score-guided DAPT duration has never been compared to not risk-score guided decision-making in a randomised fashion.

Antithrombotic therapy in ACS patients with concomitant indication for OAC

A special population of interest is patients that have a concomitant indication for oral anticoagulants (OAC; mostly atrial fibrillation), since combination therapy with antiplatelet therapy increases bleeding risk significantly. It is known from the AFIRE and the OAC-ALONE trials, that in stable CAD combination therapy of OAC and antiplatelet therapy should be avoided for its clear harm with regards to bleeding complications, without antithrombotic benefit. The occurrence of an ACS however, demands temporary use of APT to prevent recurrent MI and ST. Combination therapy of OAC, P2Y12 inhibitor and aspirin is referred to as triple therapy, whereas combination therapy with OAC and P2Y12 inhibitor without aspirin is referred to as dual therapy (in contrast to dual antiplatelet therapy [DAPT]). The pivotal WOEST trial was the first to show that, omitting aspirin (thus dual therapy) reduced bleeding from 44.4 to 19.4% (HR 0.36, 95% CI 0.26–0.50) without increased MACE. The PIONEER, RE-DUAL, ENTRUST and AUGUSTUS trials confirmed this. The AUGUSTUS trial showed in addition, that DOAC should be preferred over VKA, both for bleeding reduction and antithrombotic efficacy (patients with mechanical heart valve prosthesis or other contra-indication to DOAC were not included). Post-hoc analysis also found, that if aspirin was used, its benefit was only observed in the first 30 days after PCI. Therefore, in patients with a high thrombotic risk, aspirin could be used but its duration should be limited to the in-hospital phase, with extension to 30 days only in rare high-thrombotic risk cases. Duration of P2Y12 inhibition has not been the subject of study in patients with dual therapy and should be similar to those without OAC. The choice of P2Y12 inhibitor is usually clopidogrel for its more favourable bleeding risk as compared to ticagrelor or prasugrel, however not backed by sound evidence with regards to antithrombotic efficacy.

Guided and non-guided de-escalation

Switching from the potent P2Y12 inhibitors ticagrelor or prasugrel to the weaker clopidogrel for its more favourable bleeding profile is referred to as de-escalation. De-escalation can be guided or unguided. Unguided de-escalation is initiated after a certain period of time in a population at higher bleeding risk such as the elderly. Guided de-escalation can be based on platelet function testing or genetic profile and is usually initiated soon after PCI; current guidelines advice this strategy for selected patients ineligible for 12 months of potent P2Y12 inhibition.

Unguided de-escalation

Two trials have investigated unguided de-escalation from ticagrelor or prasugrel to clopidogrel after one month of uncomplicated DAPT. The TOPIC and TALOS-AMI trials both found de-escalation to reduce bleeding (4.0 versus 14.9%, HR 0.30 [95% CI 0.18–0.50]; and 3.0 versus 5.6%, HR 0.52 [95% CI 0.35–0.77], respectively) without an increase in thrombotic events or MACE at 12 months. The HOST-REDUCE-POLYTECH-ACS randomised ACS patients after one month to half or full dose prasugrel in a Korean population. The reduced dose was associated with less bleeding (2.9 versus 5.9%, HR 0.48 [95% CI 0.32–0.73]), and no increase in efficacy events. Finally, the POPular AGE trial randomised patients aged ≥70 years of age about one day after ACS to clopidogrel or ticagrelor. The use of clopidogrel reduced bleeding complications (18 versus 24%, HR 0.71 [0.54–0.94]) without difference in MACE. Thus, unguided de-escalation after one month to clopidogrel or half-dose prasugrel reduces bleeding and seems as effective as maintained potent P2Y12 inhibition. Immediate unguided de-escalation has been studied in elderly and may also be an option for selected patients.

Platelet function guided de-escalation

The TROPICAL ACS trial investigated platelet function-guided de-escalation from prasugrel to clopidogrel after 1 week of prasugrel treatment. The investigational study arm was treated with clopidogrel for 1 week, and patients then demonstrating high-platelet reactivity switched back to prasugrel, while the patients with normal platelet reactivity remained on clopidogrel until 12 months after MI. Patients in the control arm were treated with prasugrel for 12 months. The platelet function-guided strategy did not significantly reduce bleeding complications, nor MACE. However, as this strategy poses no benefit with regard to bleeding reduction, its value may be less clear than other de-escalation strategies.

Genotype guided de-escalation

The POPular Genetics trial investigated genotype-guided P2Y12 inhibitor de-escalation in STEMI patients. As clopidogrel is a prodrug that becomes active through CYP2C19 which has several common loss-of-function alleles, it might be appropriate to prescribe the generally weaker clopidogrel if absence of these alleles can be confirmed. The study randomised patients 1–3 days after STEMI to genotype-guided clopidogrel (61% of the population) or to potent P2Y12 inhibitor in carriers of a loss-of-function allele. The control group consisted of potent P2Y12 inhibition. The genotype strategy significantly reduced bleeding complications (9.8 versus 12.5%, HR 0.78 [95% CI 0.61–0.98]) whilst maintaining similar antithrombotic efficacy (MACE 2.7 versus 3.3%, HR 0.83 [95% CI 0.53–1.31). Thus, after ascertaining the pharmacogenomic effectiveness of

clopidogrel administration, this may be a feasible option in ACS patients as well, with less bleeding complications as compared to unguided prescription of potent P2Y12 inhibitors.

As stated above, all of the above options may be considered for selected patients for whom (maintained) potent P2Y12 inhibition is undesirable.

Residual risk at 1 year after acute coronary syndrome

While patients with a higher bleeding risk benefit from a reduced duration of DAPT, patients with a higher thrombotic risk may benefit from an extended (>1 year) duration of DAPT (Figure 50.4). When balancing the risks and benefits of extended DAPT, we have to consider that the overall thrombotic risk – including mortality – after ACS has decreased due to evidence-based treatments and the use of newer generation DES leading to decreased rates of especially late ST. Therefore, DAPT late after ACS to reduce ST is not needed in the majority of patients. On the other hand, DAPT also reduces spontaneous MI, stroke, and in the highest-risk patients, mortality but at the cost of more bleeding. Further, it is important to acknowledge the different grades of severity in both bleeding and ischaemic events, as not all events have the same impact on mortality. Therefore, a careful assessment should be made to select those patients who may benefit from extended antithrombotic therapy.

The DAPT study showed superiority of continued 30 months DAPT compared to standard 12 months of DAPT in the occurrence of MI and ST, while moderate or severe bleeding was increased to a similar degree. Importantly, non-cardiovascular death was numerically higher, suggesting that not all patients should be treated with DAPT beyond 12 months. This topic was further studied in the PEGASUS-TIMI 54 trial, including only patients who had had a previous MI and had additional thrombotic risk factors. At 3 years, DAPT (aspirin plus ticagrelor 90 and 60 mg BID) reduced the composite of cardiovascular death, MI or stroke. As expected, major bleeding was higher with ticagrelor again roughly in a similar degree as the reduction of thrombotic events. Therefore, these data suggest that only patients who have had a spontaneous ACS are candidates for extended DAPT, which is in line with the latest ESC guidelines recommendations: extended DAPT should be considered in ACS patients at high ischaemic risk without increased risk for major or life-threatening bleeding (class IIa, level of evidence A).

Another option to reduce the long-term thrombotic risk in ACS patients may be dual pathway inhibition (rivaroxaban

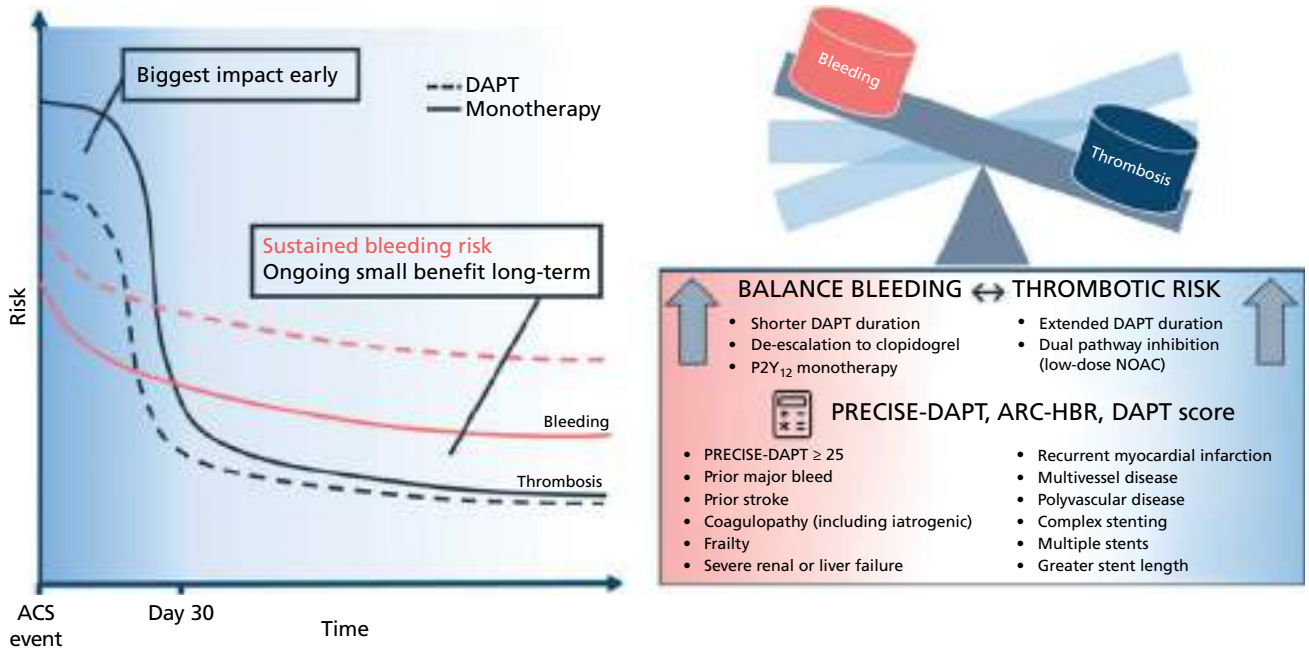

Figure 50.4 Optimal duration of dual antiplatelet therapy (DAPT) DAPT decreases thrombotic risk after acute coronary syndromes (ACS) whereas it increases bleeding risk. Its benefit is greatest in the early phase and diminishes but is sustained on the long term. Personalised decisions should be made regarding earlier de-escalation for those at high bleeding risk, and prolonged or intensified treatment for those at high thrombotic risk in absence of bleeding complications. Risk scores and clinical risk factors for bleeding or thrombotic events can guide treatment decisions.

[2.5 mg BID] on top of aspirin), which reduces the incidence of cardiovascular death, MI and stroke in the ATLAS ACS 2-TIMI 51 trial. The COMPASS trial also tested dual pathway inhibition and included CCS patients of which >50% had a previous MI. The composite of cardiovascular death, stroke or MI was lower with rivaroxaban (2.5 mg BID) plus aspirin than with aspirin alone. Major bleeding, but not fatal bleeding, was higher with rivaroxaban plus aspirin than with aspirin alone. Importantly, death occurred in 3.4% with rivaroxaban plus aspirin as compared with 4.1% with aspirin alone (HR 0.82, 95% CI 0.71–0.96). Risk reductions with rivaroxaban plus aspirin were larger in patients at high ischaemic risk (e.g. both coronary artery disease and peripheral artery disease or concomitant diabetes). Also, the 2020 ESC guidelines for the management of ACS patients without persistent ST-segment elevation state that rivaroxaban 2.5 mg BID plus aspirin should be considered in patients at high thrombotic risk and without an increased risk for major or life-threatening bleeding.

So, although there is evidence for extended antithrombotic therapy in ACS patients, there is no consensus on which patients this can be applied. This is due to the fact that 'higher thrombotic risk' is not well defined and that many patients with a higher thrombotic risk also have a higher bleeding risk. In addition, there is also no consensus in whom to continue DAPT and in whom to use dual pathway inhibition. In deciding on optimal antithrombotic therapy, risk stratification is essential and according to the ESC guidelines. The PRECISE-DAPT or ARC-HBR score could be used at discharge to reduce the duration of DAPT in those patients with a higher bleeding risk. Further, residual thrombotic risk at 1 year should be assessed in all patients that tolerated DAPT and had no thrombotic or bleeding event. To select patients that may benefit from extended DAPT, the ESC guidelines advise the use of the DAPT score, the criteria used in the PEGASUS-TIMI 54 study, or the criteria for high ischaemic risk mentioned in the ESC guidelines, which consist of clinical and angiographical/procedural risk factors (i.e. diabetes mellitus requiring medication, polyvascular disease, bifurcation stenting, etc.). It is noteworthy that the ESC criteria have not yet been extensively validated, and that none of these risk scores has been tested in a randomised fashion against no use of a score. Finally, extended DAPT and dual pathway inhibition with aspirin plus low-dose rivaroxaban have not been compared head-to-head to extended DAPT and therefore make the choice for the best antithrombotic therapy difficult. An option may be to keep the patient on DAPT who has well-tolerated DAPT and start low-dose rivaroxaban in a patient with a high thrombotic risk treated with aspirin alone especially when this patient has both coronary artery and peripheral arterial disease. When DAPT is continued, ticagrelor 60 mg BID is preferred, but there is also data for both clopidogrel and prasugrel from the DAPT trial. The data supports the use of extended antithrombotic therapy up to 4 years post-ACS, but some patients at a continuous high ischaemic risk may have a lifelong indication as long as the bleeding risk is not increased. A yearly evaluation of both the thrombotic and the bleeding risk is therefore mandated.

Secondary prevention in transient ischaemic attack and ischaemic stroke (non-embolic)

TIA and minor ischaemic stroke account for 30–50% of all cerebral ischaemic events. Aspirin with or without dipyridamole has been the mainstay of antithrombotic management for decades. In the large PRoFESS, trial aspirin with dipyridamole was compared with clopidogrel showing no difference in efficacy, but with fewer gastrointestinal bleedings in the clopidogrel arm, leading to a further increment in use of clopidogrel only for secondary stroke prevention.

In patients with acute ischaemic stroke or TIA, the combined treatment of aspirin and clopidogrel is recommended for 21 days; longer use of DAPT has no benefit due to increased bleeding risk. A major disadvantage of clopidogrel, as discussed before, is its variable and genetically determined metabolism, resulting in variable concentrations of active metabolite, hence a variable degree of inhibition of the platelet P2Y12 inhibitor. Current studies suggest that the presence of poor metabolism status (genotyped) associated with HTPR (platelet phenotyping) for clopidogrel, is a risk factor for recurrent stroke, as well as for worse stroke outcome. Platelet reactivity while on clopidogrel does not seem to be associated with bleeding risk. Such data suggest that at least genotyping patients with stroke for sensitivity to clopidogrel would be helpful in selecting this agent for long-term secondary prevention, or not.

Given the variable degree of platelet inhibition of clopidogrel, different strategies have been tested in the management of acute ischaemic stroke or TIA, including aspirin plus clopidogrel versus aspirin alone (CHANCE trial) showing superiority for DAPT over the initial 3 weeks. Assuming that a more potent P2Y12 inhibitor would have advantage over aspirin and clopidogrel, the SOCRATES study tested ticagrelor versus aspirin in acute TIA/minor stroke; ticagrelor was not superior over aspirin except for a pre specified subgroup of patients with >50% stenosis of the ipsilateral carotid artery. The subsequent THALES trial tested the combination of ticagrelor plus aspirin versus aspirin alone in high risk for recurrent stroke patients, showing superiority with regard to reducing recurrent stroke or death, but not death alone by 30 days. The price was a fourfold increase in major, but not fatal bleeding at 5 days already.

Studies comparing aspirin plus clopidogrel versus aspirin plus ticagrelor may be needed to assess the relative efficacy and safety of each DAPT combination for the initial management of acute stroke or TIA, for 3 weeks. Whether DAPT is also an option for those with clopidogrel resistance is subject of ongoing study. Whether other combined antithrombotic strategies

including aspirin or clopidogrel in combination with cilostazol will be of benefit in high risk for recurrent stroke patients, remains to be studied. Prasugrel, another potent P2Y12 inhibitor is contra-indicated in stroke patients, for increased risk of intracranial bleeding. Dual pathway inhibition with rivaroxaban and aspirin cannot be applied in these patients due to lack of evidence (these patients were not recruited in the Compass trial).

Arterial thrombosis in the heart; antithrombotic management in patients with AF

Thrombus formation in the heart can have different origins, depending on underlying disease and localisation. In case of AF, thrombus formation occurs in the left atrium and in particular the left atrial appendix (Figure 50.5). In AF, all elements of Virchov's triad are affected; flow conditions are obviously altered and contribute to abnormal patterns of blood circulation, increasing interaction of blood cells with the atrial endothelium. Within the left atrium and appendix orifice, the endothelial phenotype is altered to stimulate blood coagulation, while fibrinolysis is impaired due to an imbalance between local tPA and PAI-1 concentrations. In conjunction with advanced age and comorbidity (e.g. hypertension) inflammatory mechanisms will further perturb the endothelium towards a prothrombotic surface. Systemically, elevated markers of platelet activation suggest platelet hyperreactivity and systemic hypercoagulability is a key element of AF too, already detectable at an early stage in otherwise apparently healthy subjects (lone AF). At advanced age, thrombo-inflammatory effects will further increase, which explains the increased risk of thromboembolic stroke. The interplay of elements is apparently such, that this process is poorly inhibited with antiplatelet agents as shown in clinical trials. Hence, different from atherosclerosis, the endothelial cell properties in concert with flow and hypercoagulability conditions, favour a clotting process that is best inhibited with anticoagulants.

AF is a common disorder, occurring in an age-dependent manner with marked increase in prevalence over the age of 70 years, both in men and women. The risk of thromboembolism in AF is mostly estimated by the CHA_2DS_2-VASc (Congestive heart failure, Hypertension, Age ≥75 years, Diabetes mellitus, Stroke, Vascular disease, Age 65–74 years, Sex category [female]) score (Table 50.1). This score is central in risk classification according to current ESC guidelines, taking into account its limitations mainly involving fairly gross risk estimations. Further refinement may be possible by also including certain biomarkers as in the ABC (Age, Biomarker, Clinical history) risk score. A Patient-Centred Outcomes Research Institute (PCORI)-commissioned systematic review of 61 studies comparing diagnostic accuracy and impact on clinical decision making concluded CHA_2DS_2-VASc and ABC risk scores to have the best evidence for predicting thrombo-embolic risk. In all scores, the total number of points guides the decision to start with oral anticoagulant therapy (Table 50.1).

The decision to actually prescribe anticoagulation is also influenced by considering bleeding risk-enhancing factors, most

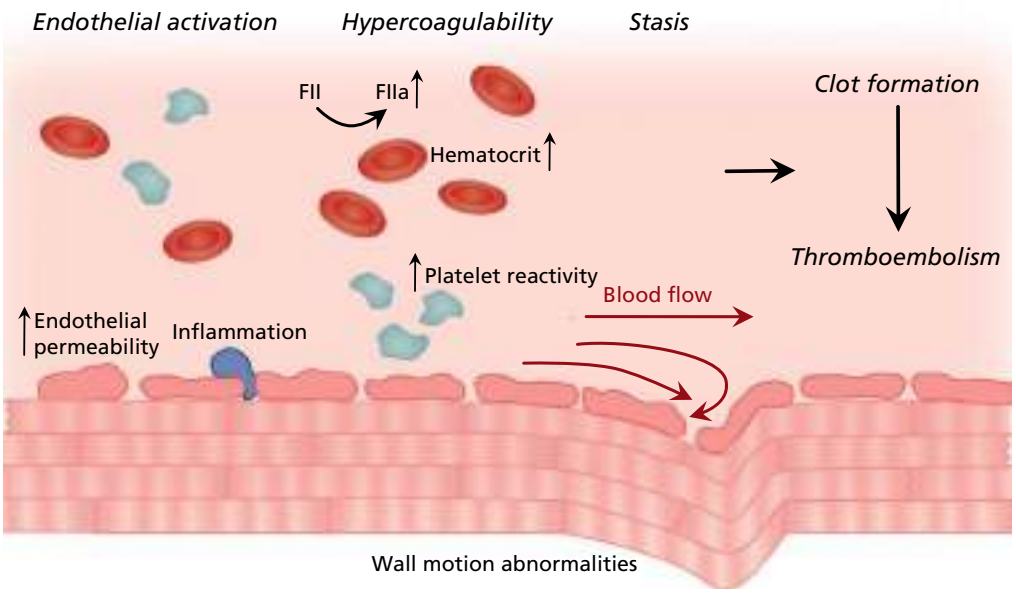

Figure 50.5 captures the main mechanisms involved in thrombogenesis during atrial fibrillation, where the left atrial appendix (indicated at the bottom) is the primary site of thrombus formation. The interaction of the typical Virchov factors (flow, activated endothelium and activated coagulation) precipitate thrombus formation and embolisation that comprises a risk for thromboembolic stroke.

Table 50.1 Risk scores to estimate risk of ischaemic stroke and bleeding respectively, in patients with atrial fibrillation (AF). While based on the CHA2DS2-VASc score an indication for the use of oral anticoagulants is made, the purpose of the bleeding risk assessment is to determine the presence of any modifiable risk factors in order to reduce the bleeding safety hazards related to anticoagulation.

	CHA2DS2-VASc score	score
C	Congestive heart failure or LVEF ≤40%	1
H	Hypertension	1
A	Age ≥75 yr	2
D	Diabetes	1
S	prior Stroke, TIA or thromboembolism	2
V	Vascular disease	1
A	Age 65–74 yr	1
Sc	Sex category (female)	1
	Average to high risk, indication for anticoagulation	≥2
	HAS-BLED score	**score**
H	Hypertension	1
A	Abnormal renal and/or liver function (1 point each)	1–2
S	Stroke	1
B	Bleeding	1
L	Labile INR	1
E	Elderly (≥65 yr)	1
D	Drugs or alcohol (1 point each)	1–2
	High bleeding risk	≥3

commonly assessed with the HAS-BLED score (Table 50.1), which in the PCORI-commissioned systematic review comparing 38 studies with bleeding risk assessment provided the best evidence for predicting bleeding risk (moderate strength of evidence) (Table 50.1). In particular, potentially modifiable risk factors for bleeding like anaemia, renal or liver failure, hypertension and interacting medication, require attention. In the era of VKA, labile INR also was a relevant element and in those with current VKA this is a factor to be addressed; practically, this would mean discussing causes of INR instability (intake, illness, drug interactions, food, adherence) and the need for switching to a DOAC or, in some countries towards a longer acting VKA preparation.

When the joint decision is to prescribe an anticoagulant the choice of a DOAC is preferred over VKA, according to current guidelines. Current DOAC's comprise four different preparations in most countries, including the direct thrombin inhibitor dabigatran and the factor Xa inhibitors rivaroxaban, apixaban and edoxaban. The choice of DOAC depends on several considerations, including preference for once or twice daily dosing, capsule or tablet, expected side effects (e.g. dyspepsia which may occur with dabigatran), drug interactions and renal and liver function. All 4 DOAC's were compared against VKA in large, randomised controlled trials that unequivocally demonstrated non-inferiority with regard to efficacy, i.e. prevention of ischaemic stroke. None of the DOACs have been compared to each other so it remains difficult to assess relative efficacy and in particular safety for bleeding risk for one against the other. Network meta-analyses suggest a favourable bleeding risk profile for apixaban, as compared to others. However for reasons of adherence, once-daily DOACs may also be preferred. The risk of bleeding is highest for gastrointestinal bleeding (±2% annual risk), which is obviously influenced by comorbidity, drug interactions and other factors as estimated in the HAS-BLED score. Recent studies suggest that DOAC pharmacokinetics may be a factor to consider in estimating bleeding risk. DOAC peak anti-Xa levels vary considerably between individuals, due to pharmacodynamic and -kinetic factors and peak levels have been associated with bleeding risk. One reason for variation in bleeding risk amongst DOACs may be that such peak variation is less evident for twice daily dosed DOACs like apixaban, as compared to once daily dosed rivaroxaban. Although DOACs should not be routinely monitored with assays that reflect their plasma level, such testing may be helpful in establishing an individual patient profile, in order to guide the selection of the optimal drug in patients that are vulnerable for any reason (very old age, under or overweight, comorbidity etc.). At least annual surveillance of DOAC use is warranted in all patients focusing on complications, drug adherence, interactions and side effects, laboratory assessment of liver and kidney function. The frequency of such monitoring should be dependent on critical factors that influence decisions on dose adjustment such as kidney function (estimated clearance).

The presence of active gastrointestinal or urogenital cancer is a specific reason to be careful with any form of systemic anticoagulant and the use of DOAC for AF prevention should be frequently monitored in such patients (temporary replacement with LMWH may be needed in case of actively bleeding tumours). The same precautions may play a role in patients with malignancies treated with chemotherapy and anticipating temporary reductions in platelet count; for the management in such conditions, the reader is referred to guidelines from relevant haemato-oncological societies.

Although not the preferred anticoagulants anymore, VKA can still be used for patients with AF, in particular, if the shared decision-making suggests a potential advantage of VKA over DOAC. Such considerations can include cost of medication, expected or experienced side effects, concerns over medication adherence (favouring INR-nurse monitored and supervised anticoagulant treatment), severe renal or liver failure. Thanks to the huge worldwide experience with VKA of more than 70 years, there are few unexpected issues related to VKA that may be encountered and INR control is worldwide established, although not always in anticoagulation clinics.

The effects of antithrombotic therapy on the vessel wall and atherogenesis: clinical relevance?

Antiplatelet agents

Given the multiple roles of platelets beyond thrombosis and haemostasis, beneficial effects of antiplatelet therapy beyond the inhibition of the thrombotic response have been reported. Platelets are actively involved in the inflammatory response. Upon platelet activation, platelets release many pro-inflammatory mediators from their granules, thereby enhancing an inflammatory response. Overall, data from *in vitro,* as well as *in vivo* mouse studies and patient studies point to an overall reduction in the amplification of the inflammatory response by platelets when antiplatelet therapy is administered. The reduction seen in the number of platelet–leucocyte aggregates and the levels of sCD40L, hsCRP and IL-6 upon clopidogrel, prasugrel or ticagrelor treatment in combination with aspirin argue for an anti-inflammatory effect of antiplatelet therapy. In case of P2Y12 inhibition, the anti-inflammatory effect appears to be dependent on the level of P2Y12 inhibition, although P2Y12- independent effects cannot be excluded.

Further, the targets of antiplatelet therapy, COX1 and P2Y12 are not solely expressed by platelets, but can be found in other cells present in the vasculature as well. As such, beneficial effects of antiplatelet drugs on other cells than platelets have been postulated. *In vitro*, there have been indeed reports on the (off-target) effects of aspirin and P2Y12 inhibitors on the function of endothelial cells and smooth muscle cells. Whether these effects are clinically relevant is unclear. Also, data from *in vivo* mouse experiments advocate protection of the vasculature and attenuation of atherosclerosis by aspirin or P2Y12 inhibitors, although here contrasting results have been published as well. In patient studies vascular protective effects of antiplatelet therapy have been demonstrated in ACS patients undergoing PCI, where especially administration of prasugrel pre-PCI improved endothelial function. In a cross-over study design, no evidence was found for adenosine-mediated off-target effects of ticagrelor on endothelial function.

Anticoagulants

Many decades of use of VKA have revealed a few long-term side effects, of which increased vascular calcification may be the most relevant one. These vascular effects are attributable to the inhibition of carboxylation of specific vitamin K-dependent proteins like matrix Gla protein, a protein involved in the inhibition of both medial and intimal calcification. There is strong preclinical evidence for this mechanism and also studies in humans demonstrate increased calcification in the media of large arteries. While calcification in absence of VKA is a prognostic marker for CVD and mortality, there is no evidence yet that VKA-related calcification is harmful to the patient. However, as with any off-target effects, it is unintended and therefore ideally avoided.

In contrast, DOACs do not interfere with vitamin K metabolism and biological effects should be different. There is ample evidence from preclinical studies that administration of a DOAC (whether a direct thrombin or factor Xa inhibitor) delays the onset and progression of atherosclerosis in mice and factor Xa inhibition may even cause reversal of atherosclerotic lesions. While several lines of study are ongoing to establish the molecular biological mechanisms underlying these effects, it seems clear that DOAC by inhibiting specific coagulation proteases inhibits PAR-mediated cell signalling. Clinically, limited evidence from observational studies with DOACs shows diminished calcification and less plaque instability features in patients on DOAC versus VKA. It is too early to conclude that DOACs have protective effects on the human vasculature and further studies are clearly warranted.

PART VI

Consultative haematology, supportive care and miscellaneous disorders

CHAPTER 51

Haematological aspects of conditions that occur primarily in tropical countries

51

Imelda Bates[1] and Ivy Ekem[2]

[1] Liverpool School of Tropical Medicine, Liverpool, UK

Introduction

The chapter has been divided into two sections; the first section covers parasitic infections in which the organisms can be visualised in the blood or bone marrow and the second section covers secondary haematological abnormalities associated with infections. Knowing about the haematological aspects of tropical diseases is important because haematologists are increasingly involved in managing patients who have travelled to, or are from, tropical regions.

In 2019, 3.5% of the world's population lived outside their country of origin. The majority were economic migrants, often moving from tropical countries to temperate ones. Data from the UK Office for National Statistics indicate that in the UK long-term net migration (i.e. immigration and emigration) has remained stable since the end of 2016. In the year ending June 2019, 609,000 people moved to the UK with an intention to stay for 12 months (i.e. prior to COVID-related travel restrictions). Worldwide travel means that haematologists need not only to know about the tropical diseases that can cause haematological abnormalities, but also be able to take relevant travel histories from patients and appropriately interpret haematological results obtained from investigations. They also need to be aware of ethnic variations in reference ranges to avoid wasting resources on unnecessary investigations and to avoid causing undue anxiety for the patient.

Ethnic variations in reference ranges

The white blood cell count and relative and absolute neutrophil counts are lower in people of African and Middle Eastern descent than in Caucasians. After the age of 1 year, Africans have lower counts than West Indians or African Americans (Table 51.1). The difference is due to a greater number of neutrophils in the storage pool of the non-Caucasian populations. Stimulation of a neutrophil response in these ethnic groups leads to rises in the neutrophil count to the same level as white populations, irrespective of the baseline level. Indian, Chinese and Southeast Asian populations have the same white blood cell and neutrophil counts as northern Europeans. The platelet counts in healthy West Indians and Africans may be 10–20% lower than in Europeans living in the same environment. It is not clear whether there are true ethnic variations in eosinophil counts, but counts of up to 2×10^9/L have been described in healthy blood donors in Africa. Interpretation of variations in blood counts should therefore take account of the individual's ethnic background. It must be borne in mind that 'normal' values derived from populations

Table 51.1 Automated white cell (WBC) and neutrophil counts in adults of different ethnic origins (95% ranges).

	Male		Female	
	WBC ($\times 10^9$/L)	Neutrophil count ($\times 10^9$/L)	WBC ($\times 10^9$/L)	Neutrophil count ($\times 10^9$/L)
Caucasian	3.7–9.5	1.7–6.1	3.9–11.1	1.7–7.5
Afro-Caribbean	3.1–9.4	1.2–5.6	3.2–10.6	1.3–7.1
African	2.8–7.2	0.9–4.2	3.0–7.4	1.3–3.7

with high background prevalence of ill health may include individuals with asymptomatic conditions.

Parasitic diseases with organisms in peripheral blood or bone marrow

Malaria

Epidemiology and biology

Until 2004, only four species of plasmodia were known to cause malaria in humans: *Plasmodium (P) falciparum*, *P. vivax*, *P. ovale* and *P. malariae*; since then there have been increasing numbers of cases of infection by a fifth plasmodium, i.e. *P. knowlesi* predominantly reported from Malaysia, Malaysian Borneo and Thailand. *P. falciparum* remains by far the most dangerous and causes the greatest mortality and morbidity (see Figure 51.1).

The total number of cases of malaria imported into the UK has remained stable at around 1500/year since 2000. Approximately 80% of *P. falciparum* infections in the UK are acquired in sub-Saharan Africa and 80% of *P. vivax* infections are acquired in South Asia, especially India and Pakistan. In 2018, 1683 cases of malaria were reported in the UK, of which 1375 (82%) were due to *P. falciparum,* 143 (8.5%) due to *P. vivax* and 117 (7%) due to *P. ovale*. The rest were due to *P. malariae (36) P. knowlesi* (2) or mixed/unspecified (10). There were six deaths. Around a third to a half of all malaria cases in the UK are due to a visit to families in countries of origin and many of these travellers have not taken malaria prevention tablets. Malaria has also been reported in travellers who have transited through airports in malarious areas.

Malaria is transmitted by the bite of an infected female *Anopheles* mosquito. The infecting agent is the spindle-shaped sporozoite and thousands of these may be injected by a single bite. Infrequently, transmission may also occur through blood transfusion, bone marrow transplantation and transplacentally (0.5% of all UK cases). There have also been reports of malaria transmission in aircraft or near airports in temperate zones due to infected mosquitoes being brought to non-malarious areas.

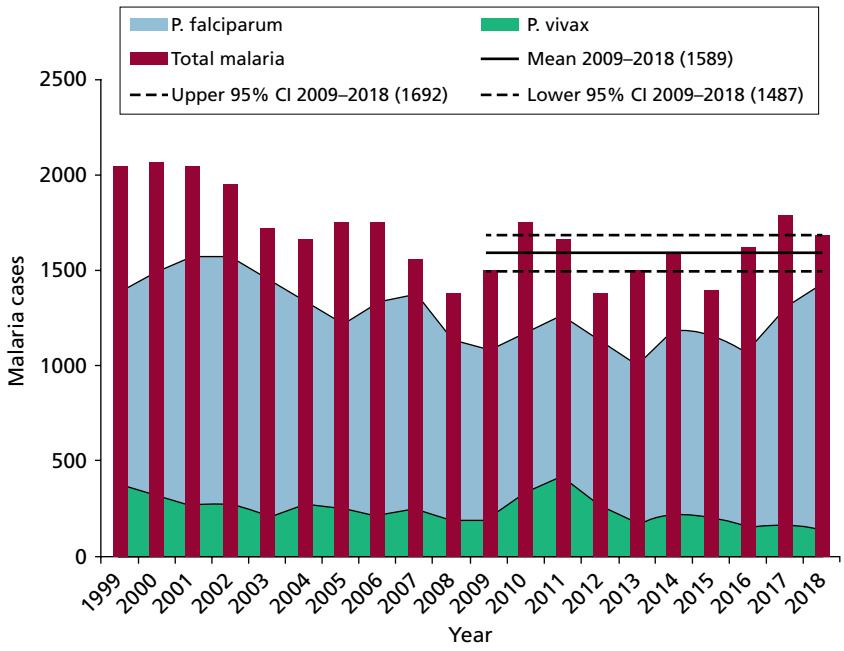

Figure 51.1 Cases of malaria in the United Kingdom: 1999–2018 (Source: Data from the PHE Malaria Reference Laboratory.)

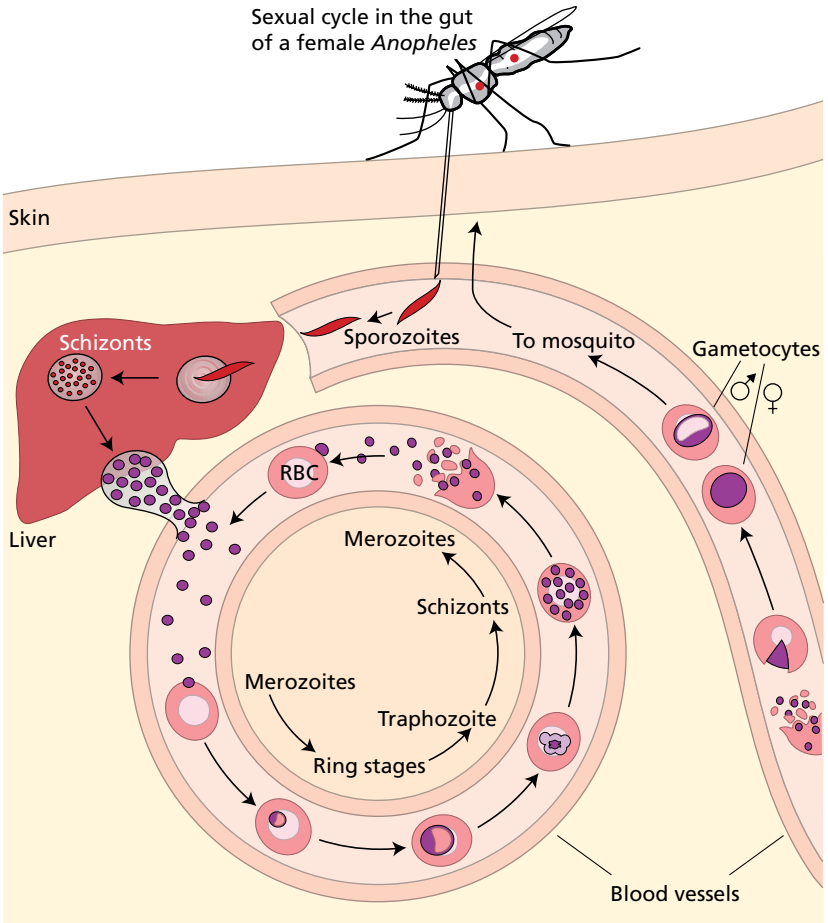

Figure 51.2 Life cycle of the malaria parasite.

P. knowlesi is transmitted by *Anopheles latens*. It does not occur in Africa because its reservoir hosts, long-tailed and pig-tailed macaques, are not found in Africa.

Within a few hours of an infected bite, the sporozoites enter the hepatocytes, where they divide (Figure 51.2). Rupture of the hepatocyte releases the parasites into the blood, where they attach to red cell membranes using specific receptors. In the red cells, asexual replication of the trophozoites (ring forms) occurs, giving rise to erythrocyte schizonts. The schizonts mature into merozoites and are released into the circulation to re-infect other red cells. The periodicity of this release varies with the species and is responsible for the classical cyclical nature of malaria fevers. Relapses, which can occur months or years after the primary illness, are characteristic of infection with *P. vivax* and *P. ovale*, and are due to maturation of persistent hypnozoites in the liver.

A few of the trophozoites develop into male and female banana-shaped gametocytes and are taken up by the mosquito at a blood meal. Inside the midgut of the mosquito, they undergo sexual reproduction and sporozoites migrate to the salivary glands, ready to infect another host when the mosquito bites. Unlike the schizonts of *P. vivax*, *P. ovale P. malariae* and *P. knowlesi*, those of *P. falciparum* are not commonly seen in the peripheral blood of the human host. This is because *P. falciparum*-infected cells have surface cytoadherence molecules that enable them to be sequestered in the deep tissues. Therefore *P. falciparum* schizonts only appear in the blood in very severe infections or in splenectomised patients. Sequestration is responsible for some of the severe clinical consequences of *P. falciparum* malaria, such as cerebral malaria.

Clinical features

The time between the infected bite and the appearance of clinical symptoms and parasites in the peripheral blood varies between species. It is 7–30 days (mean 10 days) in *P. falciparum,* but can be months, or even years, with other species, particularly *P. vivax* and *P. ovale*, because of their hypnozoite stage.

All five *Plasmodium* species produce factors that cause release of tissue cytokines, which produce fever and contribute to anaemia through marrow suppression. Splenomegaly is a common feature of acute malaria and mild jaundice may also occur secondary to haemolysis. Other clinical features vary with different

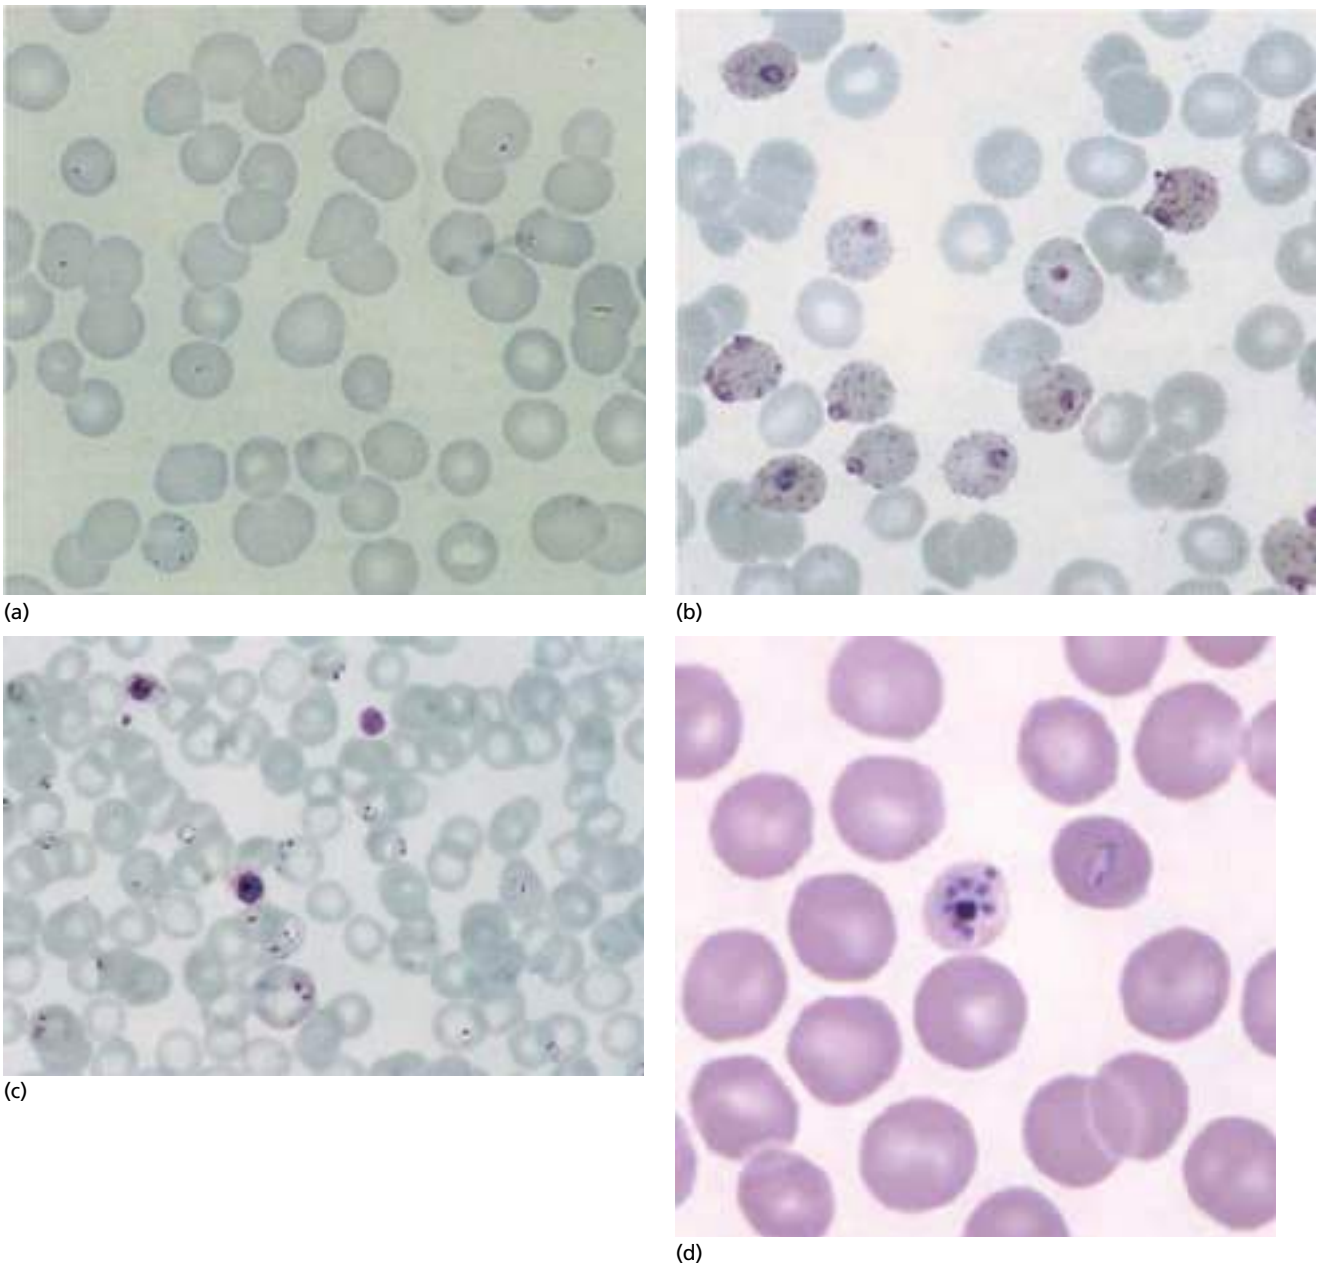

Figure 51.3 Stages in the life cycle of *Plasmodium falciparum* in Giemsa-stained thin films; the cells are not enlarged or decolourised: (a) delicate early ring forms, (b) ring forms with prominent Maurer's clefts and (c) ring forms and early and late schizonts (schizonts are not commonly seen in the peripheral blood). (d) Ring form and schizont of *Plasmodium knowlesi* (Part (d) Source: GEFOR (2012). Reproduced with permission of Galería de imágenes y recursos.)

species. Maximal immunity to malaria takes around 10 years to develop and is lost over the course of 1–5 years if the individual leaves a malarious area and is no longer exposed to infections.

Plasmodium falciparum

Plasmodium falciparum is the most common species associated with complicated and severe disease (Figure 51.3) though *Plasmodium vivax* has also been associated with severe and fatal disease. In *P. falciparum* infections, death may occur after a single exposure to malaria, particularly in those with no immunity, such as non-immune travellers or young children in endemic countries. Recurrent attacks with different strains lead to the development of clinical immunity, but not necessarily to complete clearance of parasites. Parasites

Table 51.2 Clinical features of *P. falciparum* malaria infection.

Target organ	Clinical features	Potential common misdiagnosis
Gastrointestinal	Diarrhoea, vomiting	Traveller's diarrhoea
Respiratory	Cough, pulmonary oedema	Pneumonia, cardiac failure
Neurological	Delirium, coma, convulsions, focal neurological signs	Encephalitis, meningoencephalitis
Renal	Oliguria, haemoglobinuria	Nephritis
Hepatic	Jaundice, hypoglycaemia	Hepatitis
Haematological	Anaemia, splenomegaly	Viral infection, lymphoma

may therefore be detected in a high proportion of clinically asymptomatic adults in endemic areas. In addition to fever with rigours, nausea and hot and cold phases, *P. falciparum* infection can also present with diarrhoea and cough (Table 51.2). Serious complications include severe anaemia, cerebral involvement, and kidney and liver failure.

During pregnancy, immunity to malaria is reduced and parasite density increases. Even when parasites cannot be visualised in the peripheral blood, they may be sequestered in the placenta and compromise fetal development. Malaria is an important cause of low birth weight in neonates and anaemia in pregnant women, both of which have a detrimental effect on the later development of the infant.

Plasmodium malariae

The incubation period of *P. malariae* may be several weeks. It is associated with recurrent fever, anaemia and enlargement of the liver and spleen. Without treatment or following incomplete treatment of the primary infection, re-crudescences may occur with decreasing severity over many years. Clinical symptoms of malaria have been reported up to 30 years after the initial infection.

Plasmodium vivax and *Plasmodium ovale*

These species cause a similar clinical picture with bouts of fever occurring periodically up to 5 years after the initial infection. These are relapses due to reinvasion of red cells by hypnozoites. The trigger for hypnozoites to reactivate after dormancy is unknown.

Plasmodium knowlesi

The incubation period of *P. knowlesi* infection is about 11 days. It causes severe, and occasionally fatal, malaria. This is because the parasite invades red cells of all ages and has a short life cycle of 24 hours.

Haematological abnormalities

Normochromic normocytic anaemia is common in malaria, particularly in children, but the degree and rapidity of onset are variable. The haemoglobin may fall by up to 20 g/L each day. In malaria-endemic regions, chronic anaemia due to nutritional deficiencies, intestinal helminths, HIV infection and haemoglobinopathies may be compounded by anaemia due to malaria. In chronically anaemic patients, the oxygen dissociation curve is shifted to the right so they are better able to tolerate further falls in haemoglobin. The clinical effects of anaemia in malaria are therefore due to a combination of the degree and rate of fall of haemoglobin.

Anaemia due to malaria has multiple aetiologies: red cells containing parasites are removed from the circulation by the reticuloendothelial system; there is accelerated destruction of non-parasitised cells and dyserythropoiesis in the bone marrow. Both parasitised and non-parasitised red cells lose deformability and the high shear rates in the spleen enhance their removal. In acute malaria, reticulocyte response is suppressed and erythropoietin levels are elevated, although this may be less than expected for the degree of anaemia.

Uncommon complications of malaria that can exacerbate the anaemia are hyper-reactive malarial splenomegaly (HMS) and 'blackwater fever'. HMS is characterised by massive splenomegaly with hypersplenism (see later) and occurs as a result of a disordered immune response to malaria. Blackwater fever is characterised by severe intravascular haemolysis with haemoglobinuria and can lead to acute renal failure. It has most commonly been associated with malaria, antimalarial drugs (particularly quinine) and glucose-6-phosphate dehydrogenase (G6PD) deficiency.

The high prevalence of severe anaemia in areas with intense malaria transmission has generally been ascribed to malaria. However, studies in Malawian children have shown that the anaemia is multifactorial. In these children, bacteraemia, malaria, hookworm, HIV and deficiencies of G6PD, vitamin A and vitamin B12, but not iron and folate, deficiency, were associated with anaemia.

Case fatality rates of children with severe anaemia in Africa are 9–18% and mortality rise steeply at haemoglobin concentrations of less than 40 g/L. Severe decompensated malarial anaemia can be accompanied by hypovolaemia and acidosis and therefore requires careful rehydration (avoiding rapid fluid boluses which may be harmful), and blood transfusion. Since there are risks associated with transfusions, it is important to prevent and adequately treat mild and moderate anaemia to

minimise transfusions. Antimalarial prophylaxis, prompt treatment of malaria and avoidance of mosquito bites (for example by using insecticide-impregnated bed nets and topical repellants) are valuable in reducing malaria infections and anaemia, especially in vulnerable groups, such as pregnant women and young children.

The white cell count in malaria is usually normal but may be raised in severe disease. Other white cell changes that have been described in malaria include a leucoerythroblastic response, monocytosis, eosinopenia and a reactive eosinophilia during the recovery phase. Neutrophil activation may be apparent in severe malaria. Thrombocytopenia due to increased splenic clearance, and thus increased platelet turnover and raised thrombopoietin levels is usually mild with counts around 100×10^9/L, but can be marked in *P. knowlesi* infection. Pancytopenia without massive splenomegaly has also been described.

The bone marrow of patients with acute malaria due to any of the species shows prominent dyserythropoiesis. This may persist for weeks after the acute infection and is caused by intramedullary cytokines produced by the infection. Erythrophagocytosis and macrophages containing malaria pigment are frequently seen in marrow samples.

Although malaria is associated with thrombocytopenia and activation of the coagulation cascade and fibrinolytic system, bleeding and haemorrhage are uncommon even though the prothrombin and partial thromboplastin times may be prolonged. Clinically apparent bleeding or disseminated intravascular coagulation is associated with very severe disease and a high mortality. Severe *P. falciparum* infection is associated with endothelial cell activation, abnormal circulating ultra large vWF multimers and reduced plasma ADAMTS13 function. These changes may result in intravascular platelet aggregation, thrombocytopenia and microvascular disease. Fibrinogen levels are often increased and there is rapid fibrinogen turnover with consumption of antithrombin and factor XIII resulting in increased fibrin degradation products. Microparticle formation from platelets, red cells and macrophages also causes widespread activation of blood coagulation. Haematological indicators of a poor prognosis in severe malaria include:

- leucocytosis $>12 \times 10^9$/L;
- severe anaemia (packed cell volume <15%);
- thrombocytopenia $<50 \times 10^9$/L;
- prolonged prothrombin time (>16 s);
- prolonged partial thromboplastin time (>40 s);
- reduced fibrinogen (<2 g/L);
- hyperparasitaemia >100,000/μL (high mortality >500,000/μL);
- >20% of parasites are pigment-containing trophozoites and schizonts;
- >5% of neutrophils contain visible malaria pigment.

Effective anti-malarial agents are important in the treatment of coagulopathy in malaria. Antiplatelet agents should be avoided since they interfere with the protective effect of platelets against malaria.

Genetic haematological mechanisms that protect against severe malaria

Plasmodium vivax and *P. knowlesi* need Duffy blood group antigen as a receptor to enter red cells. This antigen is absent in at least two-thirds of all Africans who consequently have a natural resistance to infection with *P. vivax and P. knowlesi*. Hb AS has a substantial (up to 10 times) protective effect against severe malaria and a similar, but less marked protection is associated with other genetic red cell abnormalities such as G6PD deficiency, thalassaemia trait and Hb C trait.

Diagnosis

Microscopy and rapid diagnostic tests (RDTs) are the primary choices for diagnosing malaria in the field, but they cannot detect low-density malaria infections.

Microscopy

Direct visualisation of parasites by light microscopy using a combination of thick and thin blood films is the gold-standard diagnostic technique for malaria (Table 51.3 and Figure 51.3). A Romanowsky stain (e.g. Field, Giemsa and Leishman) pH 7.2 is used so that the parasite cytoplasm stains blue and the nuclear chromatin stains red. A thick blood film examined by two observers, each viewing a minimum of 200 high-power fields, should be used as the first screening tool as it allows larger volumes of blood to be examined than the thin film. However, the parasites appear distorted in thick films due to the process of lysing the red cells so this method cannot be used for parasite morphology and speciation. A thin blood film should be performed on any sample that yields a positive or uncertain thick film result. This allows visualisation of undistorted parasites and an assessment of the size and shape of the red cells, so speciation and quantification (parasites/μL) can be carried out. However, the thin film has low sensitivity because of the small amount of blood that can be examined.

The disadvantages of basing a diagnosis of malaria on blood film examination include:

- An initial negative film does not exclude malaria: at least three films taken during episodes of fever should be examined in the absence of antimalarial drugs to confirm a negative blood film.
- A positive film does not prove that symptoms are due to malaria: asymptomatic parasitaemia is common in adults from endemic areas.
- *P. malariae* and *P. knowlesi* cannot be distinguished morphologically.
- Parasites, particularly *P. falciparum* gametocytes, may be washed off the slide during staining and bulk staining may result in transfer of parasites between slides.
- Parasite density does not necessarily correlate with disease severity, although heavy parasitaemia (>5% of red cells infected) indicates a poor prognosis.

Table 51.3 Differentiating epidemiological and stained thin blood film features of the five *Plasmodium* species affecting humans compared to *Babesia* species.

	P. falciparum	*P. knowlesi*	*P. vivax*	*P. ovale*	*P. malariae*	*Babesia* sp.
Main site of distribution, proportion in the endemic area (%)	Global, most common in Africa, 80–90 (Africa)	South-east Asia,1–60	Mostly in Asia, 50–80	Africa, 5–8	Global, 0.5–3	
Life-threatening	Yes	Yes	Yes	No	No	
Parasitemia	Can be high	Can be high	<2%	<2%	<2%	
Treatment	Combinations with arthemisinine derivatives: atovaquone plus proguanil; mefloquine; quinine +/– doxycycline	Probably all the medications listed for the other plasmodia	Chloroquine followed by primaquine	Chloroquine followed by primaquine	Chloroquine	
Appearance of infected red blood cells (size and shape)	Normal size and shape	Normal size and shape although some have irregular edges	1.5–2 times larger than normal; shape normal or oval	As for *P. vivax*, but some have irregular edges	Normal shape; size normal or smaller	Both normal
Red cells with multiple parasites/cell	Common	Common	Occasional	As for *P. vivax*	Rare	Common
Stages present in peripheral blood	Rings and gametocytes; occasionally schizonts	All stages: late stages similar to *P. malariae*	All stages	As for *P. vivax*	All stages	Only rings and rare pear-shaped forms ('Maltese cross'); no gametocytes
Ring form (young trophozoite)	Delicate small ring; scant cytoplasm; sometimes at the edge of red cell ('accolé form')	Similar to *P. falciparum*	Ring one-third to half of the diameter of cell; heavy chromatin dot	As for *P. vivax*	Ring one-third of the diameter of cell; heavy chromatin dot; vacuole sometimes 'filled in'	Resembles ring of *P. falciparum*; look for pear-shaped structure
Gametocyte	'Crescent' or 'sausage' shape is characteristic	Similar to *P. malariae*; comprise 1–3% of infected erythrocytes	Round or oval	Round or oval (smaller than *P. vivax*)	Round or oval; dark coarse pigment	No gametocyte

Malaria pigment may persist in phagocytic cells for several weeks after an acute attack and may be helpful in retrospective diagnosis of malaria. Automated haematology analysers may produce an abnormal pattern on the white cell differential count histogram. Debris below the white cell threshold may be due to malaria parasites and manual examination of blood films is indicated if this pattern is flagged up by the analyser.

Malaria rapid diagnostic tests (antigen detection)
Malaria RDTs detect specific antigens produced by malaria parasites (e.g. histidine-rich protein 2 or parasite lactate dehydrogenase) in the blood of infected individuals. Since 2018 evaluations of RDTs have been managed by the WHO. There are >200 RDTs available: some detect a single Plasmodium species, some detect multiple species and others can distinguish between *P. falciparum* and non-*P. falciparum* infection, or other species. Blood for the test is obtained from a finger-prick and results are available within 15–30 minutes. The drawbacks of RDTs are false positives because HRP2 persists in the blood for several days after infection clearance and false negatives due to gene deletions. RDTs have a sensitivity of ~100 parasites/μL though new 'ultra-sensitive' RDTs may be helpful in distinguishing between active versus recently cleared malaria infections.

Antibody detection
Malarial antibodies can remain in the blood after the eradication of parasites, so their detection is not useful for diagnosis in the acute attack. The main uses of malarial antibody detection are for excluding malaria as a cause of recurrent fever, for population surveys and as a screening test for blood donors in non-endemic areas.

Nucleic acid amplification tests
Nucleic acid amplification tests (NAATs) can detect low-density malaria infections (<1 parasite/μL). They can quantify parasite load and detect sexual- and asexual-stage parasites. Currently, WHO recommends that NAATs should only be used for research until more evidence is available on the public health impact of detecting and treating low-density infections.

Haematological implications of treatment for malaria

Currently, the recommended first-line treatment for uncomplicated falciparum malaria, for mixed infections and for chloroquine-resistant vivax malaria is artemisinin-based combination therapy. The following drugs used for treating malaria may have haematological side effects.

Pyrimethamine is used in combination with a long-acting sulfonamide, such as sulfadoxine (as in Fansidar), a dihydrofolate reductase inhibitor, which may therefore induce megaloblastic anaemia and other cytopenias. The sulfur component of these combinations may also cause methaemoglobinaemia.

Dapsone acts by inhibiting the synthesis of dihydrofolic acid and is used as part of a fixed combination with proguanil or chlorproguanil. It may be associated with haemolytic anaemia, methaemoglobinaemia and eosinophilia.

Primaquine, an inhibitor of protein synthesis, is active against the hypnozoites of *P. vivax* and the gametocytes of *P. falciparum*. It causes oxidant haemolysis in patients with G6PD deficiency and, rarely, methaemoglobinaemia.

Quinine is usually reserved for life-threatening infections, especially in endemic countries. It acts by disrupting the food vacuole of the parasite. Rarely, it is associated with immune thrombocytopenia and severe intravascular haemolysis.

Mefloquine, halofantrine and artemisinin-related compounds do not commonly cause significant haematological side effects. A combination of artemether and lumefantrine (Coartem or Riamet) is commonly used as first-line treatment in endemic areas.

Some antibacterial drugs, such as doxycycline, clindamycin, trimethoprim and sulfonamides, have also been used for their antimalarial effect and may be associated with haematological side effects.

For malaria due to *P. vivax*, *P. ovale, P. malariae and P. knowlesi*, chloroquine is still widely used for treatment, as resistance is generally low; primaquine is added to prevent relapses in vivax, ovale and knowlesi malaria.

Anti-coagulation and malaria chemoprophylaxis

Travellers on warfarin should begin malaria chemoprophylaxis one week (2–3 weeks for mefloquine) before travelling and the INR should be stabilised before travel. There is limited experience of chemoprophylaxis in people taking direct-acting oral anticoagulants.

Babesiosis in the differential diagnosis of malaria

Babesiosis can be confused clinically and haematologically with malaria, presenting with fever and haemolysis. It occurs worldwide as an infection of livestock occasionally infecting humans, and clinical babesiosis has been reported in both immunocompromised and immunocompetent patients. There are more than 100 species. It is endemic and increasing in the north-eastern and upper midwestern regions of the USA particularly affecting middle-aged and elderly white males. It is found sporadically in other parts of the USA, Europe, Asia, Africa and South America. It is due to a protozoan parasite transmitted by the bite of the ixodid tick. Following the bite,

the organisms penetrate red cells, where they take on an oval, round or pear shape and multiply by budding. The erythrocytic ring forms of *Babesia microti* and *B. divergens* may be confused with malaria *P. falciparum* rings, but they do not produce pigment or cause alterations in red cell morphology. A minority of organisms take on a folded shape and are thought to be gametocytes.

Babesia bovis, *B. microti* and *B. divergens* are responsible for the majority of human infections. The consequences of babesiosis can range from asymptomatic infection to severe and occasionally fatal outcomes. Most of the cases reported from Europe have been due to *B. divergens* and occurred in patients without a functioning spleen. In North America, almost all the cases have been due to *B. microti*, which usually produces a subclinical infection but can be life-threatening and occasionally fatal. Transfusion-transmitted cases have been reported in the US. Specific laboratory diagnosis of babesial infection is made by morphological examination of Giemsa-stained blood smears, serology and amplification of babesial DNA using polymerase chain reaction.

Filariasis

Epidemiology and biology

There are two groups of human filariasis: those that occur in the blood (lymphatic filariasis) and those that occur in the skin (onchocerciasis). Only lymphatic filariasis is considered in this chapter, as it is associated with detectable organisms in the peripheral blood.

Three species of filarial worms cause lymphatic filariasis in humans, *Wuchereria bancrofti, Brugia timori* and *Brugia malayi*. They have different geographical distributions, with *W. bancrofti* being the most widespread. More than 90% of infections due to *W. bancrofti* are found in Asia. It also occurs in Africa, America and the Pacific islands. Filariasis due to *B. malayi* occurs in China, Indo-China, Thailand, Malaysia, Indonesia, the Philippines and southwest India, *Brugia timori* has predominantly been reported in Indonesia (Figure 51.4).

The worms are 4 mm (male) to 10 mm (female) in length and can live for over 10 years in the lymphatics. Microfilariae, which are 250–300 µm long, are produced by the female worm

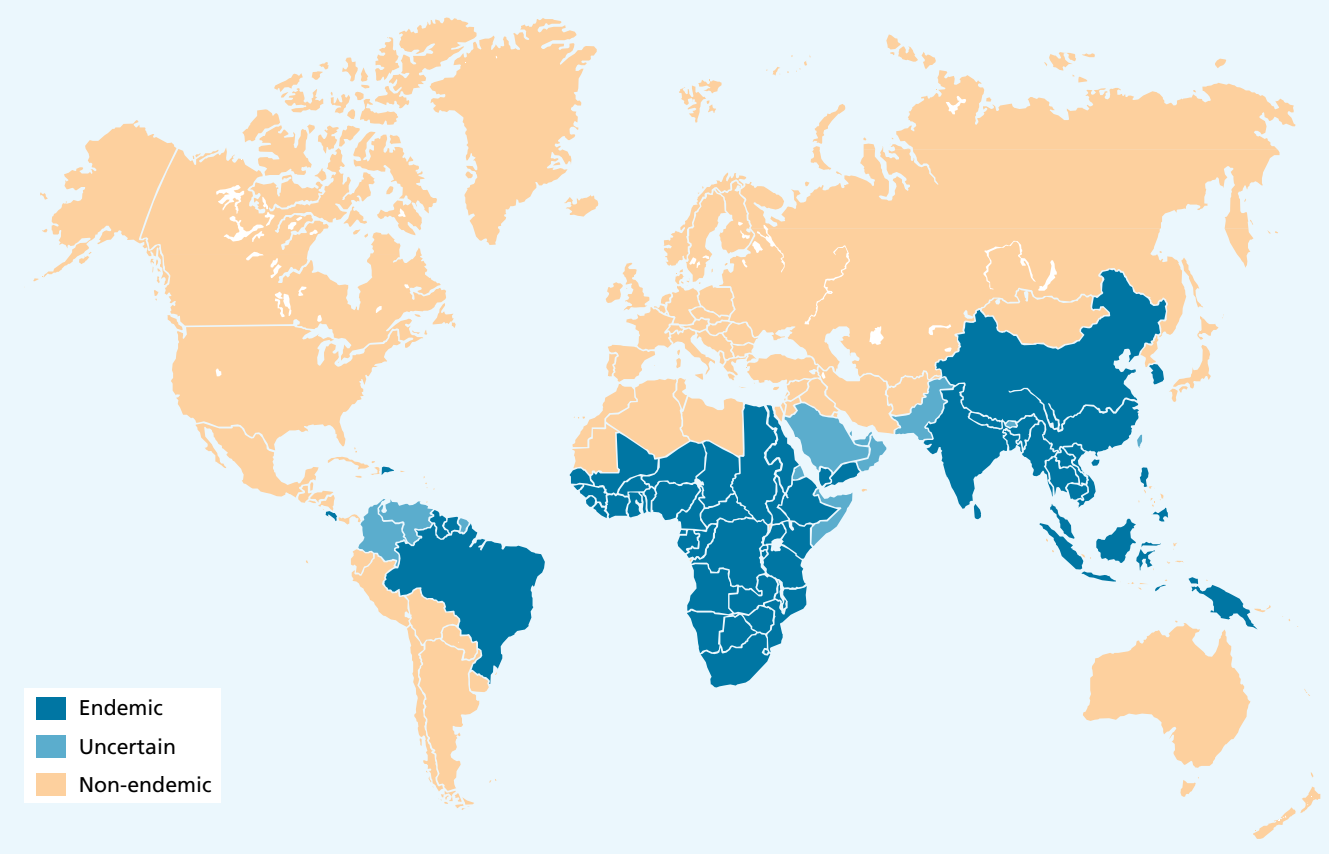

Figure 51.4 Global distribution of lymphatic filariasis.

and released into the blood after 3–8 months, where they may live for up to 1 year. Microfilariae densities can reach 10,000/mL but are usually much lower. They exhibit daily periodicity in the blood and this timing is designed to match the biting habits of their mosquito vectors, culicine and anopheline mosquitoes. The microfilariae develop into infective larvae in the mosquito and pass into the proboscis, ready to be transmitted into a new host.

Clinical presentation

There is wide variation in the presenting features of lymphatic filariasis, which may occur 6 months or more after the infective bite. The symptoms and signs are due to lymphangitis. There are recurrent bouts of fever with heat, redness and pain over lymphatic vessels. In fair-skinned people, the lymphangitis can be seen to spread distally (i.e. the opposite direction to septic lymphangitis). In *W. bancrofti* infection, these repeated episodes of inflammation eventually result in the typical chronic picture of filariasis, including hydrocele, lymphoedema and elephantiasis, chyluria and tropical pulmonary eosinophilia. The clinical picture in *B. malayi* infection is similar, but it does not cause hydrocele or chylous urine. *B. timori* causes lymphoedema characteristically limited to the leg below the knee.

Other filariae with blood-inhabiting larvae

Loa loa

This occurs in the rainforest belt of Africa, especially West Africa. The adult worms migrate through the subcutaneous tissues, including the conjunctiva, and occasionally can be seen passing across the eye.

Mansonella perstans

This is a common infection in Africa. It can cause angioedema, pruritus, abdominal pain and eosinophilia. These organisms often coexist in the blood with *W. bancrofti*, but can be distinguished by their smaller size and absence of a sheath.

Mansonella ozzardi

This is probably non-pathogenic and occurs in the West Indies and South America. The adult worm lives in the body cavities and mesentery, rarely causing any symptoms.

Haematological abnormalities in filariasis

Eosinophilia is the major and most frequent haematological abnormality found in lymphatic filariasis. Tropical pulmonary eosinophilia is a complication of filariasis and is due to an immunological hyper-responsiveness to microfilariae in the lungs. It is more common in men than women. Although microfilariae are absent from the blood in this syndrome, they may be seen in lung biopsies and adult worms can be visualised in lymphatics on ultrasound. There is an extreme eosinophilia, with eosinophil counts of greater than 10×10^9/L; the level of eosinophilia is not related to the severity of symptoms. A study of filariasis in India in 2013 found that, in addition to eosinophilia, there was leucocytosis, neutrophilia, thrombocytosis, raised erythrocyte sedimentation rate and raised mean corpuscular volume. Haemoglobin, total red cell count, lymphocytes, basophils, monocytes, mean corpuscular haemoglobin and mean corpuscular haemoglobin concentration was reduced. In tropical pulmonary eosinophilia, diethylcarbamazine treatment reduces the eosinophil count and produces resolution of symptoms. This rapid response to treatment distinguishes filariasis from other causes of marked eosinophilia associated with helminths such as *Ascaris*, *Strongyloides*, *Schistosoma* subsp. *trichinosis* and *Toxocara*.

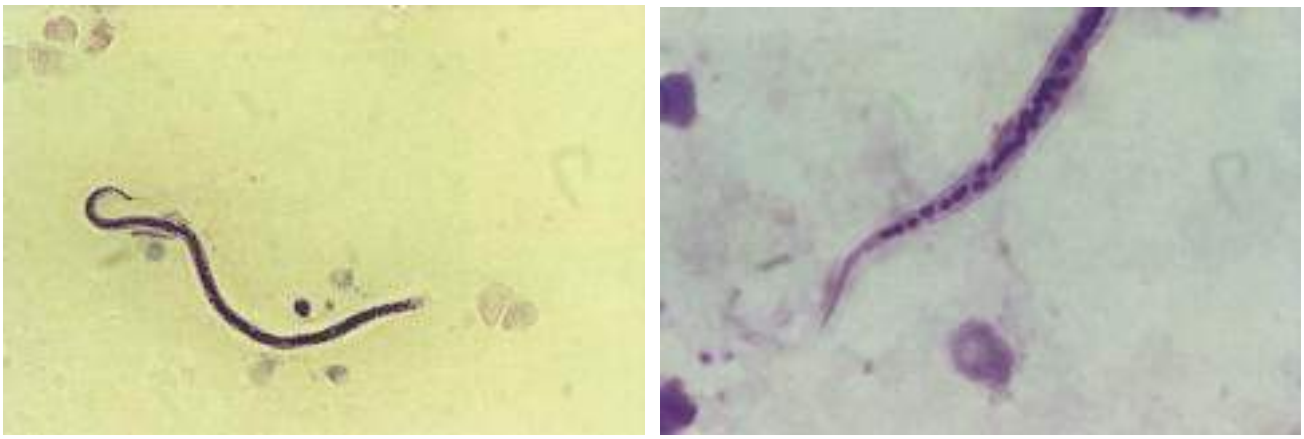
Diagnosis of filariasis

Diagnosis is based on finding microfilariae in the peripheral blood. The level of filaraemia is inversely related to the clinical signs because much of the damage is due to immunological responses to the microfilariae rather than to the organisms themselves. Furthermore, the presence of microfilariae does not necessarily mean that they are causing clinical problems and, conversely, a lack of microfilariae in the blood does not exclude a diagnosis of filariasis. The peripheral blood findings must therefore be assessed in the context of the clinical picture.

To optimise the chances of finding scant microfilariae in the blood, the sample should be taken at the appropriate time for the expected peak concentration of microfilariae (i.e. around midnight or midday for nocturnally and diurnally periodic forms, respectively). There are many techniques for demonstrating microfilariae in the laboratory. The simplest method is a wet preparation of fresh blood. Microfilariae will survive in venous blood collected into EDTA for 2 days at room temperature. Motile microfilariae can be seen on a slide under low power and can be counted in a counting chamber. Numbers of microfilariae may be low, requiring concentration techniques such as blood filtering.

For species identification, thick and thin blood films should be stained with Giemsa or haematoxylin and the microfilariae differentiated according to the pattern of their sheaths, nuclei distribution and size (Figure 51.5). The edges of the film should be examined carefully as microfilariae tend to be concentrated at the periphery and are easily missed unless the whole film is scanned at low magnification.

Detection of circulating antigen by enzyme-linked immunosorbent assay (ELISA) or immunochromatography (ICT) has replaced microscopy for the diagnosis of bancroftian, but not brugian, filariasis. An antigen ICT card test is available for the



(a) (b)

Figure 51.5 Microfilariae of *W. bancrofti* in thick film: (a) microfiliaria showing the negative impression of the sheath (× 365); (b) tail of the microfilaria showing that the nuclei do not extend into the tail (× 912).

detection of *W. bancrofti*, which does not react with other filariae and is highly sensitive (100%) and specific (92%). Filarial DNA can be detected by PCR, and ultrasound scans can help identify adult worms within the lymphatic system. Serological tests are not very helpful as most individuals from endemic areas have antibodies to crude filarial antigens and there is cross-reactivity with other filariae and nematodes.

Haematological implications of treatment for filariasis

Oral diethylcarbamazine is the drug of choice in all forms of lymphatic filariasis, including subclinical infection. Alternative treatments include combinations of albendazole and ivermectin. None of these drugs has common, serious haematological side effects. Depletion of *Wolbachia* endobacteria, a symbiont of *Onchocerca*, by tetracycline antibiotics leads to long-lasting sterility of adult female worms.

African trypanosomiasis (sleeping sickness)

Epidemiology and biology

African sleeping sickness is caused by the haemoflagellate protozoa *Trypanosoma brucei gambiense* in West and Central Africa, and *T. brucei rhodesiense* in eastern Africa (Figure 51.6). These parasites are fusiform in shape, 12–35 µm long and morphologically indistinguishable from each other. The disease is transmitted by the bite of the tsetse fly, which is only found in Africa. The trypanosomes multiply by fission in the vicinity of the infected bite and are then disseminated by the bloodstream. Congenital transmission has also been described.

The distribution of African sleeping sickness is determined by the ecological limits of the tsetse fly vector and lies in the region between Senegal and Somalia (Latitude 14° north) and the Kalahari and Namibian deserts (Latitude 20° south). Sleeping sickness is an important public health problem in Central African Republic, Chad, Democratic Republic of Congo, Côte d'Ivoire, Guinea, Malawi, Uganda and United Republic of Tanzania. During recent epidemic periods, the prevalence reached 50% in several villages in the Democratic Republic of Congo, Angola and southern Sudan. Improved surveillance has consistently reduced the number of new cases over the last two decades. For the first time in 50 years, the number of reported cases dropped below 10,000 (9878) in 2009 and the decline has continued; 3796 cases were recorded in 2015, the lowest since data collection started 76 years ago.

Clinical features

The bite of a tsetse fly is very painful and causes a small indurated lesion that may persist for some days. The local multiplication of the trypanosomes may cause a marked inflammatory reaction (a chancre) that regresses after 2–3 weeks. Entry of the trypanosomes into the bloodstream is associated with fever, which tends to be less marked in West African trypanosomiasis than in the East African variety. East African trypanosomiasis is primarily a disease of cattle and only enters human hosts by accident. It has a more aggressive course and severe symptoms than West African sleeping sickness.

The early stages of sleeping sickness can be associated with prominent lymphadenopathy, particularly of the posterior cervical nodes, and mild splenomegaly. These features may be suggestive of infectious mononucleosis, tuberculous lymphadenitis or a lymphoproliferative disorder. Severe anaemia, haemorrhages and petechiae may occur at this stage.

Both types of African sleeping sickness cause a protracted febrile illness which, despite the name, is not always associated with drowsiness. Death is inevitable if the disease is left

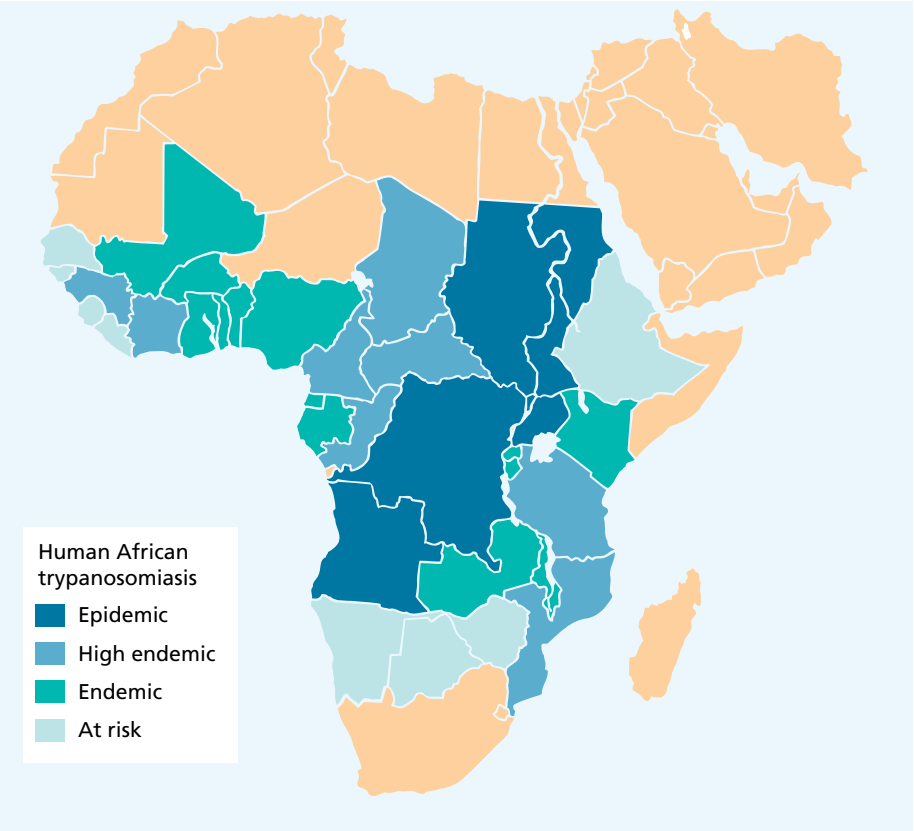


Figure 51.6 Global distribution of African trypanosomiasis.

untreated. As the disease progresses, parasitaemia decreases, trypanosomes invade the central nervous system (CNS) and neurological disturbances due to inflammatory chronic meningoencephalitis supervene. In West African trypanosomiasis, the disease runs its course over several years, but in East African trypanosomiasis infection CNS involvement may occur within weeks.

Haematological abnormalities

The aetiology of the anaemia in sleeping sickness is multifactorial, but primarily due to phagocytic removal of immune complex-coated red cells from the circulation. Trypanosomes liberate haemolytic factors that contribute to this process, and increases in plasma volume cause a dilutional anaemia. There is a failure to incorporate iron into red cell precursors and the resulting dyserythropoiesis means that the bone marrow is unable to compensate for the fall in haemoglobin. There may be a moderate leucocytosis with increased monocytes, lymphocytes and plasma cells. Mott morular cells have also been described as sleeping sickness. The bone marrow is hypercellular, focal loss of haematopoietic cells and deposition of extracellular gelatinous substances, which histochemically are mucopolysaccharides, rich in hyaluronic acid.

As the disease advances, a bleeding tendency may develop due to thrombocytopenia, vascular injury and coagulopathy. Platelet dysfunction has also been described and is manifest as clumping and abnormal aggregation responses. DIC with raised FDPs may occur in the later stages. Although some of these haematological changes can be linked to the non-specific polyclonal activation of B cells, overall the underlying mechanisms are not well understood.

Diagnosis

Trypanosomes can be seen on stained thin blood films, but the number of trypanosomes in the circulation can vary considerably and is often low, so concentration techniques are usually required. Quantitative buffy coat method is the technique of choice for diagnosis of African sleeping sickness. This involves concentrating the trypanosomes at the plasma–platelet interface in a special microhaematocrit tube using differential centrifugation. Parasites are identified by labelling with the fluorescent marker acridine orange.

Wet preparations of fluid aspirated from the lymph nodes, bone marrow or cerebrospinal fluid (CSF) may also reveal live motile organisms. This technique is more likely to be productive in the case of infection with *T. brucei rhodesiense* than

T. brucei gambiense. The organisms are fragile, so care must be taken not to damage them when making the smears. The highly specific and sensitive serological card agglutination test for trypanosomiasis (CATT) may be used in conjunction with a direct visualisation method. If these tests are positive, then CSF examination is mandatory to determine the stage of the illness.

Haematological implications of treatment

Pentamidine and suramin are the drugs of choice for the early stages of West and East African trypanosomiasis, respectively. They have a cure rate of around 90% but are only able to achieve modest CSF concentrations so they cannot be used for later stages of the disease. The most common haematological side effects of pentamidine are leucopenia, thrombocytopenia and anaemia. Suramin has serious side effects, including haemolytic anaemia and bone marrow toxicity.

Melarsoprol, an arsenic-based compound, has been the drug of choice for late-stage sleeping sickness, but is highly toxic, with a mortality of 4–12%. Its main adverse effect is a fatal encephalopathic syndrome; haematological toxicity is not a problem. Eflornithine is expensive, but is of benefit in late-stage, particularly West African, disease; 25–50% of patients treated with this drug exhibit bone marrow toxicity with pancytopenia.

American trypanosomiasis (Chagas disease)

Epidemiology and biology

Chagas disease is caused by *T. cruzi*, which is transmitted by triatomine bugs that infest poor-quality housing. It can also be transmitted through blood transfusions and congenitally. It was restricted to a region in the Americas between Argentina and the southern states of the USA; however, because of increasing population mobility between Latin America and the rest of the world it is now detected in other parts of the United States of America, Canada, many European and some Western Pacific countries.

Clinical features

The incubation period is usually 7–14 days but may exceed 40 days if transmission is through blood transfusion. In the acute phase, swelling at the site of entry of the organism (chagoma) may be accompanied by fever, hepatosplenomegaly and lymphadenopathy. The trypanosomes multiply intracellularly in muscle, particularly the heart, colon and oesophagus. Once infection has occurred, the organisms will be present for life unless treatment is given. The chronic phase is associated with heart disease in 30% of cases, manifesting as arrhythmias and cardiomegaly. A small proportion of patients have involvement of the gastrointestinal tract and other hollow organs, resulting in loss of peristalsis, organomegaly and organ failure. Asymptomatic infection is common and poses a problem for blood transfusion services, so some countries routinely screen blood for American trypanosomiasis. Many cases do not become symptomatic until the chronic stage, which can occur 5–40 years after infection.

Diagnosis

Microscopy of blood smears can be helpful, but only in the acute phase of infection when parasites are circulating in blood. Sensitive serological tests based on enzyme immunoassay or immunofluorescence are therefore more commonly used as the primary diagnostic tool. Diagnosis is made based on at least two positive but different serologic tests. PCR may also be useful.

Haematological implications of treatment

Treatment of *T. cruzi* infection is with nifurtimox or benznidazole and if started early, the disease is curable. Major haematological side effects are uncommon with either drug, although agranulocytosis has been reported with benznidazole.

Leishmaniasis

Epidemiology and biology

Visceral and cutaneous leishmaniases are caused by protozoan flagellates that are transmitted through the infective bite of a phlebotomine sandfly. Leishmaniasis is second only to malaria as the most common parasitic cause of mortality. Following an infected bite, parasites spread from the inoculation site to the mononuclear phagocytic system. Only the visceral form (kala-azar) is associated with organisms in haemopoietic tissues and thus is considered here. Visceral leishmaniasis is due to the species *Leishmania donovani* and *L. infantum*. In 2013, it was endemic in 75 countries throughout the world, with extension limits from 45° N to 32° S. Over 90% of cases occur in Bangladesh, Brazil, Ethiopia, India, South Sudan and Sudan (Figure 51.7). A concomitant HIV infection increases the risk of developing active visceral leishmaniasis by between 100 and 2320 times. In southern Europe, up to 70% of cases of visceral leishmaniasis in adults are associated with HIV infection.

Clinical features

This depends on both the genotypic potential of the parasite and the immunological response of the patient. Incubation period varies from days to years but is generally 2–6 months. Onset can be sudden with high fever, or gradual with intermittent fever. Diarrhoea, joint pain, weight loss and bleeding gums occur in the acute phase. This is followed by progressive muscle wasting, fever, weight loss, anaemia and hepatosplenomegaly. The splenomegaly which appears early and worsens with the duration of the disease may reach into the left hypochondrium. In immunocompromised patients, such as transplant recipients and those with advanced HIV disease, kala-azar behaves like an opportunistic infection.

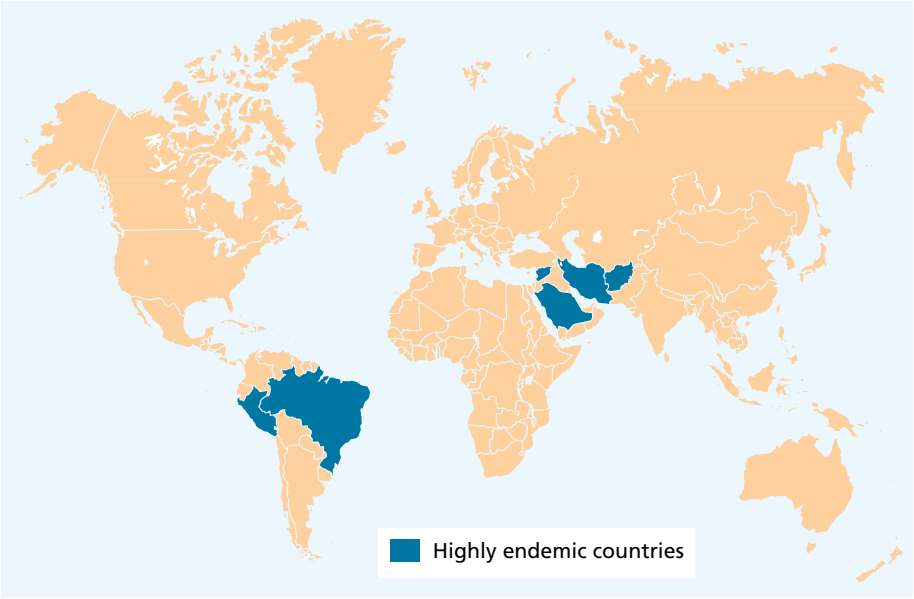

Figure 51.7 Global distribution of visceral leishmaniasis.

Haematological abnormalities

Normochromic normocytic anaemia is a frequent feature, and haemoglobin levels of 70–100 g/L are common. The massive splenomegaly results in hypersplenism with consequent pancytopenia. Liver dysfunction with jaundice, ascites and deranged coagulation may occur in the late stages and has a poor prognosis. The bleeding tendency may be exacerbated by thrombocytopenia. In all patients with unexplained splenomegaly, pancytopenia and fever, a high index of suspicion of leishmaniasis needs to be maintained to prevent fatalities.

Diagnosis

Definitive diagnosis is based on detection of the parasites, or their DNA, in smears of bone marrow, splenic aspirate or fluid aspirated from enlarged lymph nodes.

On microscopy, *Leishmania* are usually seen as intracellular amastigotes in mononuclear cells, but can also be seen extracellularly (Figure 51.8). They are 2–6 µm in diameter and contain a nucleus lying close to the rod-shaped kinetoplast, and an internal flagellum. Using a Romanowsky stain, the nucleus and kinetoplast stain purple and can be clearly distinguished. Amastigotes can be seen in both bone marrow aspirates and in trephine-impression smears. They are rarely seen in peripheral blood and then only in buffy coat preparations.

Microscopy is less sensitive than molecular diagnosis, particularly when there is coinfection with HIV. PCR can be performed on lesion aspirate, marrow, blood and biopsy material. The indirect fluorescent antibody tests ELISA and DAT are useful for detecting antibodies to visceral leishmaniasis, but results may be inconclusive in immunosuppressed patients.

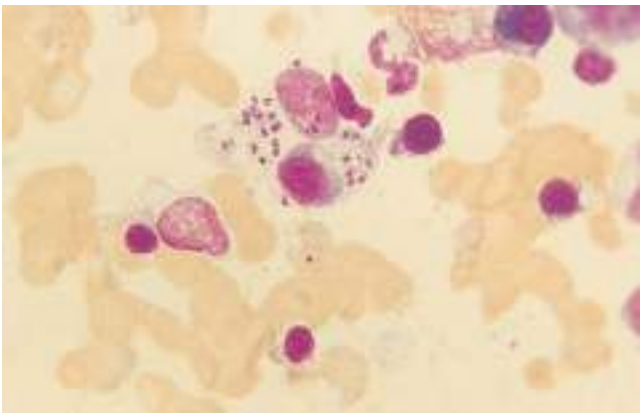

Figure 51.8 Bone marrow aspirate of leishmaniasis infection showing a macrophage containing numerous organisms. The presence of both a nucleus and a small paranuclear kinetoplast gives the organisms their characteristic 'double-dot' appearance (MCG × 940).

Haematological implications of treatment

For decades, the treatment of leishmaniasis has been based on pentavalent antimonials, although their mode of action is still unclear. Sodium stibogluconate is the most commonly used. It can be associated with worsening anaemia and thrombocytopenia, although its most detrimental effects are on cardiac function. Resistance levels to antimonials are high in countries such as India, Bangladesh, Brazil and Sudan, so other options including amphotericin, paromomycin and miltefosine need to be considered. HIV-coinfected patients do not respond well to antimonials, so for these individuals, amphotericin is the drug of choice. Amphotericin

commonly causes normocytic normochromic anaemia, but its most serious toxicity is related to renal, cardiac, neurological and hepatic dysfunction. Side effects can be reduced by using the liposomal preparation. Immunocompromised patients may require prophylaxis to prevent relapses.

Tropical diseases associated with changes in FBC and/or coagulation

Hookworm infection

Hookworms (*Ancylostoma duodenale*) and (*Necator americanus*) are common in the tropics and subtropics and affect 600 million people worldwide. They cause significant iron deficiency anaemia in all age groups, including 30–50% of anaemia in pregnancy. The hookworm eggs are generally transmitted between humans through contact with faeces. Most infections are asymptomatic, but chronic blood loss through the gut eventually leads to severe iron deficiency anaemia, and even cardiac failure. Other symptoms include itch, rash and abdominal discomfort. Eosinophilia is common and characteristic eggs can be seen on faecal microscopy. Albendazole or mebendazole are the usual treatments and iron deficiency should also be treated. Transfusion is rarely necessary and if it is required blood needs to be given very cautiously to avoid cardiac overload.

Schistosomiases (Bilharzia)

Schistosomiasis is a common intravascular infection caused by trematode worms acquired through contact with contaminated water. It occurs across Africa, Asia and South America. *Schistosoma. mansoni, intercalatum, japonica* and *mekongi* all cause intestinal schistosomiasis, whilst *S. haematobium* causes urinary schistosomiasis. There are three stages; acute (Katayama syndrome), chronic and advanced. Schistosomiasis is the second most common cause of iron deficiency worldwide after hookworm infection. It is due to blood loss from the urinary and gastrointestinal tracts. Eosinophilia occurs in 80% of cases. Anaemia of chronic disease, massive splenomegaly with hypersplenism, hepatomegaly and generalised lymphadenopathy can all occur. Iron deficiency should be treated and schistosomiasis treatment is with praziquantel, which has no significant haematological complications.

Viral haemorrhagic fevers

These are caused by arenaviruses, filoviruses, bunyaviruses and flaviviruses and are classified according to their reservoir hosts and their primary means of transmission. They are divided into:

- rodent-associated viruses (e.g. Lassa fever, hantaviruses);
- arthropod-borne viruses (e.g. dengue, yellow fever and Chikungunya viruses);
- unknown vectors or hosts (e.g. Marburg, Ebola).

They often occur in epidemics, have human-to-human transmission and, in non-tropical settings, may only be suspected if a relevant travel history is elicited from the patient. Dengue and yellow fever are becoming increasingly important imported infections.

Dengue

The four types of dengue virus belong to a group of flaviviruses and are transmitted by *Aedes* mosquitoes. Dengue is endemic in tropical areas of Asia, Africa, South America and the Caribbean and is particularly virulent in Southeast Asia, including Thailand and Vietnam. There has been a resurgence of the disease as a result of urbanisation, poverty and increasing travel. A recent study has shown that the introduction of the bacteria *Wolbachia pipientis* into *Anopheles aegypti* mosquitoes was effective in reducing the incidence of symptomatic dengue and hospitalisations.

Primary infection in young children is usually asymptomatic. Older children and adults develop acute fever, headache and myalgia ('breakbone fever'). Leucopenia may accompany this stage of the illness. Severe complications may arise in those who have had previous infection. These include hypotensive shock, bone marrow hypoplasia with neutropenia and abnormal megakaryopoiesis, leading to severe thrombocytopenia and spontaneous bleeding.

Yellow fever

Yellow fever virus is transmitted by *Aedes* mosquitoes and exists throughout equatorial Africa, northern and central southern America. Ninety percent of cases and deaths each year occur in Africa. Eliminate Yellow fever Epidemics (EYE) is a strategy that was launched in 2017 to support 40 at-risk countries in Africa and the Americas to prevent, detect and respond to suspected yellow fever cases and outbreaks. The partnership aims at protecting at-risk populations, preventing international spread and containing outbreaks rapidly.

The virus invades hepatocytes, causing hepatocellular dysfunction. After an incubation period of 3–4 days, fever, myalgia and back pain may be followed by jaundice, bleeding and, in severe cases, renal failure. Haematological changes include leucopenia with relative neutropenia, thrombocytopenia as part of a consumptive coagulopathy, initial haemoconcentration, and subsequent haemorrhage and haemodilution. Coagulation abnormalities include reduced fibrinogen and clotting factors II, V, VII, VIII, IX and X, with increased PT and APTT, as well as the presence of fibrin degradation products. In 85% of cases, there is spontaneous improvement, with the disappearance of symptoms in 3–4 days. The remaining 15% enter a toxic phase which has a 50% mortality.

Diagnosis can be difficult, as yellow fever (preventable by vaccination) can be confused with several febrile and haemorrhagic illnesses. Antibodies can be detected in the serum and treatment is symptomatic.

Lassa fever, Ebola virus and Marburg virus

These are endemic in equatorial Africa and are important because they cause potentially fatal infections and have the ability to spread from person to person. Only about 10% of infected individuals become ill. Of these 1–2% develop fatal disease. The clinical features of these three haemorrhagic fevers are similar and are characterised by headache, fever and oesophagitis. Spontaneous bleeding occurs in 25% of hospitalised patients and is thought to be due to increased vessel permeability and abnormal platelet function. Death is due to multi-organ failure and shock. Case reports suggest that treatment with ribavirin may be helpful and a promising vaccine against Ebola virus has recently been tested in clinical trials in west Africa. To date, there is no licenced vaccine against Ebola but one has been approved for compassionate use.

Non-specific haematological abnormalities associated with tropical diseases

Anaemia

Anaemia of chronic disease is a common and non-specific finding in many types of tropical infections and may be exacerbated by nutritional deficiencies. Some infections are responsible for specific types of anaemia. For example, hookworm (which is common in farmers who work barefoot on infected soil), and schistosoma infections are two of the most common causes of iron deficiency anaemia worldwide. For both conditions, a good clinical history and a thorough examination of a stool (for hookworms and schistosoma) or urine sample (for schistosoma) is important for diagnosis. Secondary megaloblastic anaemia can result from consumption of the human host's vitamin B12 when they are infected by the tapeworm *Diphyllobothrium latum*. Intraerythrocytic parasites, such as those that cause malaria and babesiosis, may be associated with significant intravascular haemolysis.

White cell abnormalities

Severe infections, particularly those due to bacteria, may cause a neutrophilia and a leukaemoid reaction with circulating myeloid precursors and neutrophils with toxic granulation, vacuolation and Döhle body formation. Lymphocytosis with neutropenia, splenomegaly, nose bleeds, rash and neurological complications can occur in rickettsial infections (e.g. typhus, Q fever and trench fever). Some of these, such as trench fever, may persist for many years and are transmissible in blood transfusions. The absence of neutrophilia in association with marked fever is a particular feature of typhoid. Lymphocytosis or monocytosis may also be present in typhoid; other clinical features include hepatosplenomegaly and, in severe disease, haemorrhage from ileal ulcers exacerbated by disseminated intravascular coagulation. Helminths and other predominantly tropical organisms that invade tissues may be associated with a significant eosinophilia ($>0.5\times10^9$/L). Such diseases include loaiasis, lymphatic filariasis, schistosomiasis, trichinosis, toxocariasis, strongyloidiasis, hydatid disease, oriental liver flukes and guinea worm.

Platelet abnormalities

Thrombocytosis may occur as a non-specific change associated with inflammatory conditions, including severe infections. Thrombocytopenia is usually secondary to hypersplenism (e.g. due to schistosomiasis, hyper-reactive malarial splenomegaly or disseminated intravascular coagulation). Thrombocytopenia can also occur in malaria, typically due to *P. falciparum*, either as a consequence of direct invasion of platelets by the parasite or by secondary mechanisms.

Hypersplenism

Hypersplenism is a clinical syndrome characterised by splenomegaly, with a reduction in the number of one or more types of blood cells. There is reduced survival of platelets and red cells and a normocellular or hypercellular bone marrow. Hypersplenism can result from any cause of splenomegaly, but it is most commonly associated with splenomegaly secondary to portal hypertension and haematological disorders. Tropical infections associated with massive splenomegaly (Figure 51.9) include hyper-reactive malarial splenomegaly, visceral leishmaniasis, schistosomiasis and trypanosomiasis. In the tropics, portal hypertension associated with schistosomiasis is one of the commonest cause of hypersplenism.

The cytopenias in hypersplenism are due to a combination of sequestration and haemodilution and the degree of plasma volume expansion is roughly proportional to the size of the spleen. The thrombocytopenia and neutropenia are rarely severe enough to cause clinical problems. The thrombocytopenia is primarily due to pooling of platelets in the spleen which, when massively

Figure 51.9 Patient with massive splenomegaly due to hyper-reactive malarial splenomegaly.

enlarged, can hold up to 90% of the platelet mass. Neutropenia is the result of increased marginalisation of granulocytes. Treatment of the underlying disorder generally leads to regression of the splenomegaly, with resolution of the haematological abnormalities. Occasionally, splenectomy is necessary, but this should only be undertaken after a careful assessment of the risks and benefits, and adherence to recommendations (e.g. vaccinations, antibiotic prophylaxis) regarding infection prevention.

CHAPTER 52

Lysosomal storage disorders

52

Derralynn A Hughes

Lysosomal Storage Disorders, Royal Free London NHS Foundation Trust and University College London, London, UK

Lysosomal storage disorders

Lysosomes are membrane-bound intracellular organelles which function as the major degradative compartment of mammalian cells. They are morphologically heterogeneous and are distinguished from other organelles by the presence of catalytic enzymes and lysosome-associated membrane proteins (LAMPs). More than 50 lysosomal hydrolases, active at acidic pH, catalyse the degradation of macromolecules (lipids, proteins, nucleic acids, glycosaminoglycans and oligosaccharides). These include breakdown products of blood cell membranes, gangliosides from neurons and glycosaminoglycans derived from connective tissue and extracellular matrix as well as substrate of intracellular origin. Substrate is delivered to the lysosome by endocytosis, pinocytosis, phagocytosis or autophagocytosis, or imported from the cytoplasm using biological chaperones. Apart from its role in the disposal and recycling of cellular waste, the lysosome is currently viewed as a dynamic regulatory hub for several cellular functions, such as cholesterol handling and adaptation to nutrient status and environmental stimuli.

In most lysosomal storage disorders (LSD), an inherited deficiency of a specific lysosomal enzyme results in the accumulation of undegraded substrates within the lysosome. In others, deficiency or malfunction of activator or transport proteins results in substrate accumulation. Individual mutations of relevant genes give rise to variable levels of residual enzyme activity, one of the determinants of phenotypic severity. The resulting diseases are categorised according to the major accumulated substrate, for example the mucopolysaccharidoses, sphingolipidoses and glycoproteinoses. Whilst different lysosomal storage diseases have the characteristic organ distribution patterns of the stored metabolites, clinical manifestations often extend beyond this and there can be considerable interindividual heterogeneity. Genotype–phenotype relationships are often unclear, and siblings can have disparate clinical manifestations, suggesting the modifying effect of genetic and environmental factors on presentation and severity.

The pathophysiology of lysosomal disorders results both from the disruptive effect of storage on cellular organisation and membrane functions including signal transduction and ion transport and also on direct stimulatory effects of the substrate molecule. This may result in immune stimulation, cytokine secretion, cellular proliferation, disturbed calcium homeostasis, exaggerated inflammation and perturbed control of apoptosis.

Prevalence

The prevalence of LSDs ranges from 1 in 57,000 for Gaucher disease to as low as 1 in 4.2 million for sialidosis. Recent screening studies suggest that the genetic prevalence may be higher; for example approximately 1:2500 for Fabry disease with under detection due to minimally symptomatic forms and lack of awareness or misdiagnosis of multisystem conditions. Although the diseases are individually rare, their combined overall birth prevalence is 1 in 5000–8000.

Diagnosis

The diagnosis of LSDs requires a high degree of clinical suspicion. Storage material may be discovered incidentally within biopsy specimens taken to investigate unexplained symptoms; e.g. a bone

Hoffbrand's Postgraduate Haematology, Eighth Edition. Edited by Adam J Mead, Michael A Laffan, Graham P Collins, Deborah Hay, and A Victor Hoffbrand (Consulting Editor).

Companion website: www.wiley.com/go/mead/HPH8e

marrow for the investigation of cytopenias in Gaucher disease or kidney biopsy for unexplained renal dysfunction in Fabry disease. A number of LSDs may present with hepatosplenomegaly or other haematological manifestations (Table 52.1).

The identification of substrate deposits in tissue biopsy is subject to a differential including other LSDs and pseudo forms due to high cellular turnover in unrelated conditions or lysosomal effects of some drugs (Table 52.2); and thus, requires the measurement of lysosomal enzymes or identification of a mutation to confirm the specific diagnosis. Substrate levels may also be measured in plasma or urine and may be used as biomarkers of severity or response to therapy but are rarely used in isolation as diagnostic tests.

Activity of lysosomal enzymes may be measured in plasma or leucocytes using commercially available synthetic or naturally occurring labelled substrates. Subsequent identification of a specific mutation in the corresponding gene may facilitate prognostication and rapid screening of other family members.

Early or pre-symptomatic diagnosis through cascade screening has been advocated to optimise the possibility of monitoring and early intervention with specific therapies. Analysis of blood (blood spot on filter paper) or urine for enzymes or substrate-derived metabolites has facilitated high throughput screening for LSDs, and newborn screening for specific conditions is now available routinely in some areas.

Therapy

Specific treatment of lysosomal storage disorders involves reduction of the stored compound and prevention of its re-accumulation. This has been achieved by elevation of enzyme activity through stem cell transplantation, infusion of the missing enzyme (enzyme replacement therapy or ERT) and gene therapy or stabilisation of protein folding variants by pharmacological chaperones. Conversely, reduction of the substrate can also be achieved by limiting its synthesis through inhibition of anabolic enzymes, so-called substrate reduction therapy (SRT).

Stem cell transplantation

Patients with Gaucher disease, metachromatic leucodystrophy, Krabbe disease and MPS type I have undergone stem cell transplantation. Donation of stem cells has largely been from HLA-identical siblings, but as the highest level of enzyme activity will be supplied by donor cells from non-carriers, cord blood from unrelated donors has recently been used with good results. In LSDs without a neurological component, other forms of treatment have largely superseded stem cell transplantation.

Table 52.1 Haematological presentations of Lysosomal storage disorders.

	Blood cells	Plasma	Bone Marrow	Liver and spleen	Abnormalities of coagulation
Gaucher disease	Cytopenias	Mono clonal gammopathy Elevated markers of macrophage activation	Gaucher macrophages	Hepatosplenomegaly	Platelet dysfunction Coagulation factor deficiencies possibly due to consumption
Pompe Disease	PAS-positive glycogen granules in lymphocytes			Hepatomegaly in infantile Pompe disease	
CESD/ Wolmans	Cytopenias related to hypersplenism		Features of secondary HLH	Hepatomegaly and in some cases splenomegaly	
MPS	Cytopenias related to hypersplenism			Hepatosplenomegaly	
Fabry	Renal anaemia		Lipid laden macrophages		
Niemann Pick	Cytopenias related to hypersplenism		Sea Blue histiocytes (NPB) Lipid-laden macrophages NPC	Hepatosplenomegaly	

Table 52.2 Examples of differential diagnosis of lipid-laden macrophages, pseudo-Gaucher cells and drug-related lysosomal storage.

Differential diagnosis of Foam Cells	Causes of pseudo Gaucher cells	Drugs
Niemann–Pick Disease	Chronic myeloid leukaemia	Amiodarone
Sea Blue histiocytosis	Multiple myeloma	Chloroquine
Obesity	Thalassaemia	Prolonged liposomal amphotericin
Multiple sclerosis	Haematological proliferative disorders	Parenteral nutrition with fat emulsion
Batten disease	Mycobacterial infections affecting the bone marrow	
Takayasu's arteritis		

Enzyme replacement therapy

Intravenous ERT is now standard therapy for a number of LSDs. Recombinant human enzyme can be produced in transduced eukaryotic cell lines, using Chinese hamster ovary (CHO) cells or plant (e.g. carrot or tobacco) cells. Gene activation technologies have been applied to cultured human fibroblasts for the manufacture of lysosomal enzymes. The effectiveness of ERT depends on the accessibility of the site of the pathology to exogenous enzyme and the ability of affected cells to internalise the enzyme. ERT is effective in reducing the non-neuronopathic manifestations of a number of disorders, including Gaucher disease type I, Fabry disease, Pompe disease and MPS types I, II, IVA, VI and VII and Lysosomal acid lipase deficiency (Wolman disease/Cholesterol Ester Storage Disorder). Infused enzymes do not cross the blood–brain barrier and ERT does not prevent the onset and progression of neurological symptoms. Intrathecal administration is under investigation in neurological forms of MPS I and II. Intraventricular infusion of cerliponase alfa in patients with ceroid lipofuscinosis type 2 (CLN2) has been shown to modify disease course; although early trials were hampered by adverse events including failure of the intraventricular device and device-related infections. Anti-Drug Antibodies may develop, especially in the absence of endogenous enzyme (Cross-reactive immunological material or CRIM negativity) and this may result in infusion reactions and attenuate the effectiveness of the enzyme.

Substrate reduction therapy

Analogues of small molecules are used to inhibit the activity of synthetic enzymes, thereby decreasing the rate of substrate accumulation. For example, ceramide analogues can be used to reduce the activity of the anabolic enzyme glucosylceramide synthetase. SRT is available for Gaucher disease and under clinical investigation in Fabry disease The small molecules used in SRT can be given orally, are easily absorbed and have a wide tissue distribution. SRT may also potentially have therapeutic utility in crossing the blood– brain barrier and studies are currently underway in the investigation of SRT for the neurological manifestations of type III Gaucher disease and a late-onset form of Tay–Sachs disease.

Pharmacological chaperone therapy

Some mutations lead to reduced activity of a lysosomal enzyme by causing misfolding or abnormal intracellular transport. The oral administration of a small molecule (pharmacologic chaperone) may improve enzyme activity by binding specifically to mutant peptides, aiding their passage through the endoplasmic reticulum and rescuing them from proteasomal degradation; ultimately guiding the synthesised enzyme to the lysosome. The agent dissociates from the enzyme within the acidic environment of the lysosome. Of note, pharmacological chaperones are only effective where the individual mutation results in a protein which is 'amenable' to binding of the chaperone and enhancement of residual enzyme activity; therefore, it can be viewed as an example of a personalised approach to therapy. Pharmacological chaperone therapy is available for Fabry disease where approximately 40–50% mutations are 'amenable' to the agent.

Genetic therapies

Agents that bind to ribosomes (e.g. derivatives of gentamicin) and which modify the processing of RNA transcripts to allow 'read-through' of premature stop codon mutations are another class of mutation-specific therapy currently being evaluated in lysosomal storage disorders. Independently, gene therapy is under investigation for Fabry and Gaucher, Pompe and the MPS disorders. In the case of ex vivo gene therapy, autologous stem cells are transduced with a virus (e.g. lentivirus) containing the gene of interest and after conditioning chemotherapy the modified cells are given back to the patient. Stem cells populate various organs, and synthesise and secrete enzyme into the local environment. In vivo, gene therapy requires a viral vector to insert copies of the gene of interest into target cells. For example, in the case of adenoviral vectors hepatocytes express the therapeutic transgene and the enzyme is secreted from liver into the circulation from where it is taken into relevant cells and organs. Additional investigational approaches include mRNA therapy (wherein the enzyme transcript is encapsulated within a lipid nanoparticle and directed to the liver) and gene editing involving the CRISPR system.

Prognosis

The clinical course of infants diagnosed with an LSD associated with central neurological involvement usually follows a predictable path of loss of learned skills and neurological deterioration until premature death results from infection and progressive organ damage. When onset is later, in adolescence or adulthood, the clinical course is more varied, and the prognosis depends on the major organ systems affected.

Gaucher disease

Gaucher disease is an autosomal recessive condition resulting from mutation within the *GBA* gene and deficiency of the enzyme β glucocerebrosidase, a lysosomal enzyme that hydrolyses glucosylceramide to glucose and ceramide (Figure 52.1). The substrate, glucosylceramide, accumulates in lysosomes of both reticuloendothelial cells and cells outside of the reticuloendothelial system such as immune cells and osteoblasts. It is one of the commonest LSDs, with an estimated incidence of 1 in 60,000 to 1 in 80,000 individuals.

Clinical features

Three main clinical phenotypes are observed (Table 52.3), determined in large part by the residual activity of the mutant enzyme. All three types are progressive disorders. Enzyme activity in type II is so low that abnormal cells accumulate in the central nervous system (CNS). This is the acute neuronopathic form of the disease, which presents with neurological complications in early

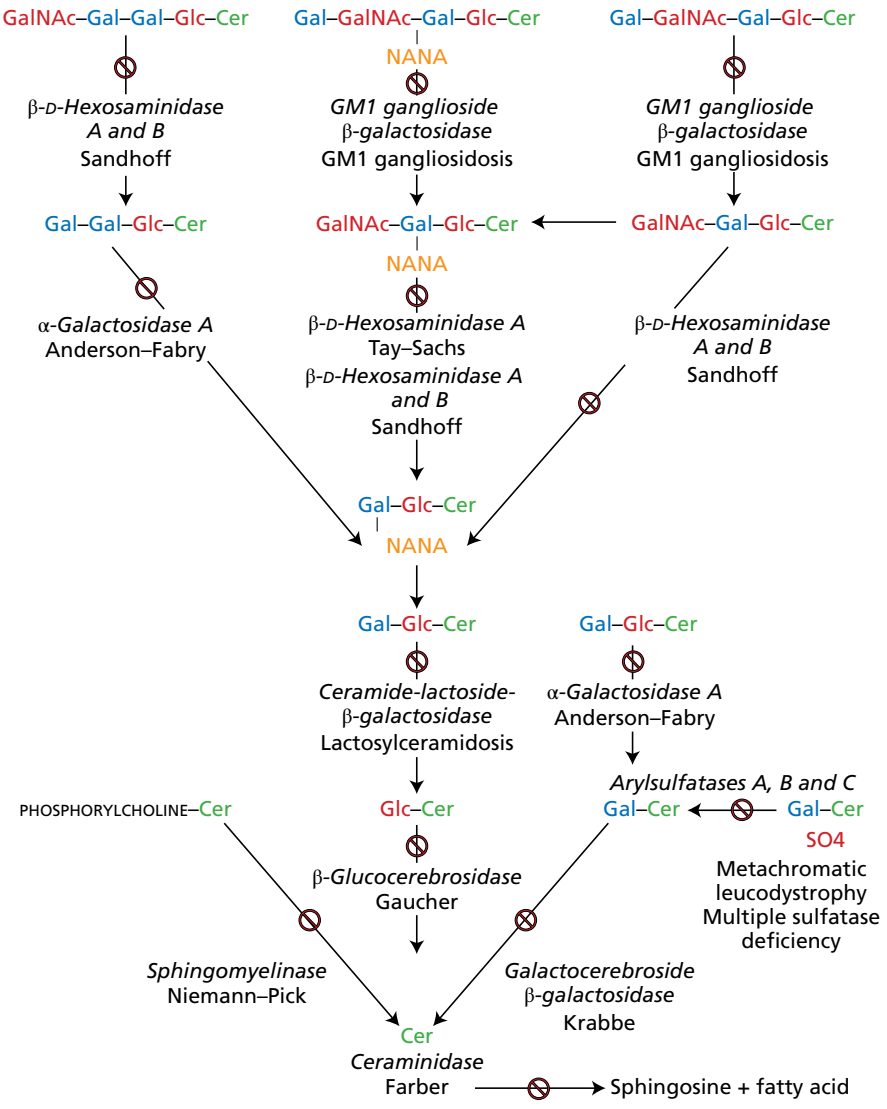

Figure 52.1 Biochemistry of lysosomal storage disorders.

Table 52.3 Clinical manifestations of Gaucher disease.

Manifestation	Type I	Type II	Type III
Onset	1 year	<1 year	2–20 years
Hepatosplenomegaly	++	+/−	+
Bone disease	++	−	+/−
Cardiac valve disease	−	−	+
CNS disease	−	+++	+/−
Oculomotor apraxia	−	+	+/−
Corneal opacities	−	+/−	+/−
Age at death	60–90 years	<5 years	<60 years

infancy and usually leads to death before the age of 2 years. Type III disease is the subacute neuronopathic form that leads to a slowly progressive neurodegenerative disorder.

Type I is the commonest form of Gaucher disease and typically does not cause neurological disease. It is particularly prevalent amongst subjects of Ashkenazi Jewish origin; where as many as 1 in 15–20 subjects are carriers, and approximately 1 in 800–1000 subjects are affected (i.e., homozygous or compound heterozygotes). Type I Gaucher disease is a heterogeneous disorder that may present in childhood through to late adult life. It is likely that many undiagnosed subjects are asymptomatic. Tissue damage due to accumulation of sphingolipid-laden macrophages in reticuloendothelial organs causes hepatosplenomegaly, skeletal disease and bone marrow infiltration, leading to cytopenias. Bone disease includes osteonecrosis, osteosclerosis, reduced bone density and in some cases pathological fractures. Rarer manifestations of type I Gaucher disease include lymphadenopathy, pulmonary disease, skin involvement and peripheral neuropathy. Patients with type I Gaucher disease have an increased incidence of malignancy generally and an increased incidence of haematological malignancies, especially B-lymphocyte disorders (myeloma, monoclonal gammopathy of undetermined significance) and myelodysplasia. Attribution of bone pathology to myeloma may be difficult in the context of Gaucher-related bone disease and care should be taken in monitoring the progression to myeloma amongst patients with a monoclonal gammopathy. Also, there is an increased incidence of Parkinson disease amongst affected individuals and carriers. The underlying mechanism is unknown, but experimental and animal model studies suggest that either diminished activity or misfolding of glucocerebrosidase may lead to excess deposition of α-synuclein in the basal ganglia, which is a pathological hallmark of Parkinson disease.

Laboratory features

More than 300 different mutations have been described in *GBA1*. The commonest mutation causing type I disease is a single base-pair substitution in codon p.Asn409Ser (formerly known as p.N370S), which accounts for approximately 70% of mutant alleles in affected Ashkenazi Jewish subjects. A base-pair substitution in codon p.Leu483Pro (formerly known as p.L444P) is the most frequent mutation underlying neuronopathic Gaucher disease. Diagnosis is confirmed by enzymatic assay of β-glucocerebrosidase activity in leucocytes or fibroblasts. Enzyme activity does not always identify heterozygote subjects and measured enzyme activity correlates poorly with clinical severity.

Splenic enlargement and marrow infiltration frequently lead to anaemia, thrombocytopenia and leucopenia. Polyclonal gammaglobulinaemia is found in more than one-third of patients, and monoclonal gammopathy of undetermined significance (MGUS) is seen in up to 20%. Liver function tests are often abnormal, reflecting infiltration of the liver by Gaucher cells leading to necrosis, fibrosis and, occasionally, cirrhosis. There is an increased incidence of gallstones. The serum cholesterol level is typically lowered. Gaucher disease is associated with a bleeding diathesis, attributable to abnormal platelet function and thrombocytopenia. Factor XI deficiency is commonly observed and is largely due to co-inheritance of other genetic abnormalities that are also common amongst Ashkenazi Jews.

The abnormal lipid-laden macrophages are readily detected on tissue biopsy (e.g. bone marrow aspirate; Figure 52.2), although biopsy is no longer considered necessary to make the diagnosis. The enzyme chitotriosidase is derived from macrophages and is typically grossly elevated in untreated Gaucher disease; it declines progressively with treatment.

However, up to 6% of the population are chitotriosidase deficient because of a 24-bp duplication in the encoding gene and in this case Pulmonary activation-regulated cytokine (PARC, CCL18), which is also elevated in plasma of patients with Gaucher disease may be useful for monitoring. PARC is a member of the CC chemokine family and its over-expression may be relevant to some of the pathophysiological features of Gaucher disease, such as abnormalities in neutrophil chemotaxis. Biomarkers of macrophage activation are complemented by measurement of

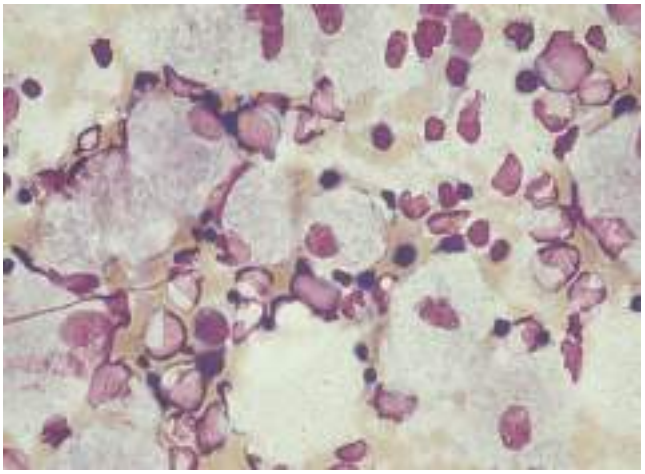

Figure 52.2 Gaucher cells in the bone marrow.

substrate-related metabolites in plasma. In particular, the level of the deacetylated derivative of glucosylceramide, glucosyl sphingosine (Lyso-GL1) has been demonstrated to correspond well to overall disease burden, mutation and response to therapy.

The serum levels of ferritin, angiotensin-converting enzyme (ACE), tartrate-resistant acid phosphatase (TRAP) and transcobalamin 2 are also typically elevated in Gaucher disease, and a wide variety of enzymes, cytokines and coagulation factors are perturbed. Interleukin (IL)-1, IL-6, IL-10 and tumour necrosis factor (TNF) have been implicated in the pathogenesis of Gaucher disease. Elevated serum levels of IL-6, which is produced by macrophages, endothelial cells, fibroblasts and T cells, have been found to correlate with an index of severity in patients with Gaucher disease and may be instrumental in the pathogenesis of B-cell dysregulation and bone disease. IL10, which in general inhibits the synthesis of other inflammatory cytokines, is also elevated; and may represent an abnormal state of immune activation. Whilst providing insights into the pathogenesis of Gaucher disease, these molecules are not routinely measured in the management of patients with Gaucher disease.

Treatment

Patients with Gaucher disease should be evaluated by an experienced physician. Gaucher disease is the first lysosomal storage disorder to be treated with ERT, and a number of different ERT preparations are now available for the treatment of type I Gaucher disease (Cerezyme Sanofi Genzyme; VPRIV Takeda; Taliglucerase Pfizer Protalix). Biosimilar ERT preparations are available commercially in some areas. Indications for ERT include significant cytopenias (e.g. Hb < 100 g/L, platelets < 100×10^9/L), skeletal disease and significant hepatosplenomegaly. ERT has no discernible impact on CNS disease; type II Gaucher disease is therefore unresponsive to ERT and ERT is indicated for the systemic, but not the CNS, manifestations of type III.

ERT is administered by intravenous infusion (often in the patient's home) at a dose of up to 60 units per kg every 2 weeks. The dose of therapy is titrated against the severity of clinical and laboratory changes and may be gradually lowered as the disease burden declines. Patients with less advanced disease may require lower doses, and some patients may eventually only require monthly infusions. A small proportion of patients (<10%) develop antibodies, but these are not usually neutralising and do not affect treatment efficacy. Infusion reactions are rare and easily managed. Patients are monitored regularly in specialist units with blood tests and evaluation of bone response by MRI of the skeletal system and bone densitometry.

Two forms of oral SRT are approved for Gaucher disease. Miglustat (Actelion/Johnson and Johnson) is licenced for mild to moderate type I disease where ERT is not possible; reported side effects include gastrointestinal disturbance and peripheral neuropathy. Eliglustat (Sanofi Genzyme) is a ceramide analogue that has more recently been developed as SRT. It is approved for use in naive or ERT-experienced patients. It is metabolised through CYP2D6 and determination of metaboliser status of patients is required for correct dosing and prediction of potential drug-drug interactions. Allogeneic stem cell transplantation is curative, although not without risk. Gene therapy is currently under investigation.

Supportive therapy is frequently required. The skeletal disease (Figure 52.3) is painful and patients may require analgesia. Regular orthopaedic assessments are advised. Prior to the use of ERT, patients frequently developed acute 'bone crisis' – episodic severe pain, typically in the limbs and often precipitated by fever and dehydration. Blood component therapy may be required for cytopenic patients, particularly at the time of orthopaedic or other surgical intervention. Splenectomy should be avoided if possible as splenectomised subjects are more likely to develop tissue infiltration in other organs (e.g. liver, lungs and skeleton).

Figure 52.3 MRI scan showing skeletal changes in Gaucher disease.

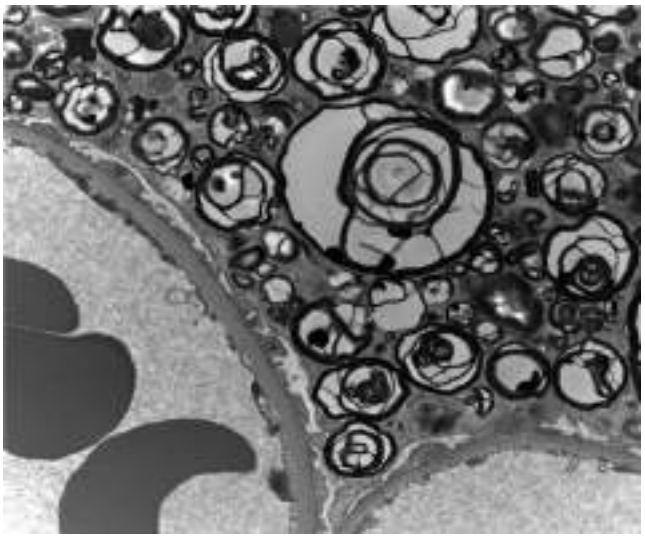

Figure 52.4 Renal biopsy in Fabry disease showing accumulation of inclusions on electron microscopy.

Fabry disease

Fabry disease is an X-linked lysosomal storage disorder due to mutation within the gene for α-galactosidase A (*GLA*) (see Figure 52.1). The resulting inability to catabolise glycosphingolipids leads to progressive accumulation of the substrate globotriasylceramide and its analogues including globotriaosylsphingosine (Lyso GL3) in tissues. In contrast to Gaucher disease, the lipid accumulation in Fabry disease affects a range of cells (e.g. endothelial cells, epithelial cells, myocytes) within a broad distribution of tissues and organs, particularly the kidneys (leading to renal failure), heart (causing ventricular hypertrophy and conduction disturbances) and vasculature of the CNS (increasing the risk for stroke). It is panethnic and whilst the incidence has been reported to be 1:100,000 it is likely to be underdiagnosed and milder variants may be much commoner and may present as left ventricular hypertrophy, stroke/transient ischaemic attack and renal failure. Although it is X-linked, Fabry disease typically causes manifestations in females, though these occur later and are usually less severe than in males. Diagnosis is by assay of α-galactosidase A activity in leucocytes and detection of molecular abnormalities within the *GLA* gene. Diagnosis may be suggested by skin, cardiac or renal (Figure 52.4) biopsy but should be confirmed by enzyme and DNA analysis.

Clinical features and treatment

A skin rash (angiokeratoma) and burning pain in limbs (acroparaesthesia) are early symptoms (under 10 years old). In late childhood, reduced sweating, abdominal symptoms and lymphoedema are characteristic. Renal failure, cardiac failure, stroke and CNS organ involvement are later features. When untreated, life expectancy in the classical form of the condition is 40–50 years for men and 50–65 years for most women.

ERT for Fabry disease has been available since 2001. Three formulations are available: a recombinant galactosidase that is generated in CHO cells (agalsidase β, Sanofi Genzyme Corporation, MA, USA); and an enzyme produced in a human fibroblast cell line (agalsidase α, Takeda), and a pegylated enzyme produced in tobacco cells (pegunigalsidase alfa Chiesi, Parma, Italy). Beneficial clinical effects have been observed in renal and cardiac function, pain, hearing loss and gastrointestinal symptoms. More recently, an oral pharmacological chaperone (migalastat, Amicus Therapeutics New Jersey USA) has been approved for patients with Fabry disease and amenable mutations. The drug is taken every other day and has been demonstrated to have beneficial effects on disease substrate, left ventricular mass and Fabry-related clinical events. Patients in phase III clinical studies exhibited stability of renal function. Substrate reduction therapies and gene therapy are currently in development.

Pompe disease

Pompe disease (glycogen storage disease type II) is caused by deficiency of acid α-glucosidase. It is characterised clinically by an early infantile subtype associated with cardiomyopathy, hypotonia and reduced survival and a later-onset form with features consistent with a limb-girdle muscle disease phenotype and survival into adulthood. On blood film examination, lymphocytes show glycogen vacuolation, which is positive on PAS staining. The prevalence of Pompe disease has been estimated to be 1 in 146,000. In untreated patients with the late-onset form of Pompe disease, muscle strength and pulmonary function deteriorate over time.

Alglucosidase-α (Myozyme) is a recombinant formulation of human acid α-glucosidase generated from the transduction of CHO cells. In infantile-onset patients, enzyme therapy has been shown to extend overall and ventilator-free survival and improve lung function and mobility in adults with later onset form of Pompe. Two novel intravenous enzyme replacement therapies, one in combination with an oral pharmacological chaperone have recently become available, and gene therapy is in clinical phase development.

Niemann–Pick disease

Niemann–Pick disease is divided into subtypes A and B resulting from sphingomyelinase deficiency and subtype C resulting from defects in cellular cholesterol trafficking. NPC can arise

from mutations in one of two non-catalytic proteins: NPC1 a lysosomal transmembrane protein, and NPC2 which is an intralysosomal soluble protein. Patients with type A exhibit neurodegenerative disease resulting in death in infancy, those with type B have lung, but not neurological involvement, and those with type C show slowly progressive neurological disturbance. Hepatosplenomegaly may be found in all three types. Over 100 sphingomyelinase mutations causing Niemann–Pick disease type A or B have been described, and DNA-based carrier screening has been implemented in the Ashkenazi Jewish community. A clinical trial of ERT (olipudase alfa) has demonstrated safety and efficacy in treating adult patients with non-neurological sphingomyelinase-deficient Niemann–Pick disease. The use of inhibitors of glycolipid synthesis, including miglustat, appears promising in the therapy of Niemann–Pick disease type C. Two other options: 2-hydroxypropyl-β-cyclodextrin A (a solubilising agent of lipophilic compounds) and arimoclomol (which amplifies the heat shock response to target NPC protein misfolding), are currently also under investigation for their effectiveness in treating NPC.

MPS disorders

In individuals with MPS disorders, deficiency or malfunction of specific lysosomal enzymes leads to accumulation of mucopolysaccharides (glycosaminoglycans) in the bone, cartilage, tendons, corneas, skin and connective tissue; affecting the respiratory system, liver, spleen, central nervous system and bone marrow. There are several different types of mucopolysaccharidosis and with the exception of MPS II which is X-linked, are mainly autosomal recessive traits. Affected individuals may have normal intellect, or in the case of more severely affected profound intellectual disability, developmental delay or severe behavioural problems including hyperactivity. Coarse facial features, thickened skin, corneal clouding, short stature skeletal irregularities and hepatosplenomegaly are amongst the shared clinical features. People with MPS also have a significantly shortened life span. ERT is available for MPS I, MPS II, MPS IVA, MPS VI and MPS VII, and in development for other disorders along with gene therapy. Bone marrow transplantation has been used with variable effect.

Cholesteryl ester storage disease and Wolman's disease

Cholesteryl ester storage disease (CESD) results from deficiency of the lysosomal acid lipase (LAL) enzyme. Mutations in the encoding *LIPA* gene that are associated with residual enzyme activity cause CESD, whereas mutations that abrogate enzyme activity cause Wolman disease. In CESD, patients present with hypercholesterolemia, hypertriglyceridemia, HDL deficiency, abnormal lipid deposition in many organs, hepatomegaly and in some cases splenomegaly. Liver involvement may progress to cirrhosis. Wolman disease manifests in childhood with adrenal calcifications, abdominal distention, vomiting and significant hepatosplenomegaly. Therapeutic tools include a hypolipidaemic diet and statins, and where indicated hepatic transplantation. ERT with sebalipase alfa (Kanuma, Alexion Pharmaceuticals Inc) is available.

CHAPTER 53

Obstetric haematology

53

Gillian Swallow and Sue Pavord

Consultant Haematologist, Oxford University Hospitals NHSFT, UK

Introduction

Obstetric haematology concerns the care of women before, during and after pregnancy with primary or secondary haematological disease. This is a high-stakes area of medicine where careful planning involving the multidisciplinary team and attention to detail can make the difference between life and death of a young woman and/or her baby. Normal pregnancy is associated with substantial physiological changes to meet the needs of the developing fetus but these changes, particularly if unbalanced, can themselves lead to complications. For example, the massive increase in uterine blood flow and vascular compliance necessary to maintain blood supply to the fetus can lead to significant haemorrhage at the time of placental separation. Changes in coagulation factors help to mitigate this risk but increase the potential for systemic thromboembolic events. The increased demand for iron and other nutrients by the growing fetus frequently results in maternal deficiencies and close proximity of the fetal and maternal circulations enables an effective transfer of nutrients and oxygen but exposes the mother to fetal antigenic material with potential alloimmune sensitisation. Although most pregnancies progress without problem, knowledge and awareness in this field of medicine are critical to prevent avoidable complications.

Cellular changes during pregnancy

Physiological changes in haematological parameters occur during normal pregnancy and in the puerperium. It is important to understand these changes to permit accurate interpretation of investigation results and avoid over-diagnosing abnormality.

Red cells

Plasma volume increases by up to 50% during pregnancy to accommodate the requirements of the developing fetus. This increase exceeds the 20–30% corresponding increase in red cell mass and results in a decrease in haemoglobin concentration. This physiological or 'dilutional' anaemia begins towards the end of the first trimester and is maximal at 28–30 weeks gestation. Red cell count and haematocrit are correspondingly lower in pregnancy. Mean cell volume (MCV) increases by around 6fl but mean cell haemoglobin (MCH) and mean cell haemoglobin concentration (MCHC) remain unchanged.

The World Health Organisation and British Society for Haematology define anaemia in pregnancy as;

- Hb <110 g/L in first trimester
- Hb <105 g/L in second and third trimester
- Hb <100 g/L postpartum

White cells

Total white cell count is increased during pregnancy due to over 50% rise in neutrophils, which begins in the first trimester. An increased number of band neutrophils are seen with occasional more immature forms such as metamyelocytes or myelocytes. Toxic granulation is common. Lymphocytes are reduced by around one third. There is a monocytosis which is thought to help modulate the maternal immune response and prevent fetal rejection. Basophils and eosinophils do not change. The white cell count further increases during labour, delivery and the

Companion website: www.wiley.com/go/mead/HPH8e

postpartum period, returning to pre-delivery levels by 7 days postpartum and to pre-pregnancy levels by around 3 weeks.

Platelets

The platelet count falls during normal pregnancy with levels in the third trimester being approximately 10% lower than pre-pregnancy levels. The exact mechanism is unknown but thought to be a combination of haemodilution, increased consumption and pooling of platelets in the placenta. Thrombocytopenia outside of pregnancy is defined as a platelet count $<150 \times 10^9$/L; however, the lower limit of the normal range during pregnancy has been suggested to be 115×10^9/L. Thrombocytopenia is the second most common haematological abnormality seen during pregnancy after anaemia, with prevalence at the end of pregnancy between 6.6 and 11.6%. Severe thrombocytopenia is far less common with only 1% of healthy women having a platelet count $<100 \times 10^9$/L.

Anaemia

Iron deficiency

Iron deficiency is by far the most common cause of maternal anaemia and has substantial health implications for mother and baby as iron is needed for every cell in the body. Complications include fatigue, cardiovascular strain, cognitive and immune dysfunction, increased likelihood of blood transfusion, low birth weight, preterm birth, postpartum haemorrhage, postnatal depression and increased maternal and perinatal mortality.

UK guidelines are in place to aid prompt diagnosis and appropriate treatment. Haemoglobin is routinely checked in early pregnancy and at 28 weeks' gestation. If anaemia is diagnosed a trial of oral iron should be initiated without delay and used as a diagnostic tool, with assessment for Hb response 2 weeks later. Further investigation is only necessary if the Hb fails to show improvement after 2 weeks, in which case serum ferritin and folate should be checked in the first instance. Serum ferritin is also required in women with known haemoglobinopathy to exclude an iron-loading state before treatment is given.

Non-anaemic iron depletion is also important to treat to avoid the complications of iron deficiency as well as the development of anaemia. Risk factors for iron deficiency should be considered, such as previous anaemia, history of bleeding or blood donation, an interpregnancy interval less than 1 year, multiple pregnancy and multiparity. These women should either be offered oral iron empirically or have their serum ferritin checked to confirm iron depletion.

Whilst all women should receive dietary advice, to optimise iron intake, this is inadequate as sole treatment for established iron deficiency and iron supplementation is necessary. Tablets containing 60 mg elemental iron are ideal and tolerance is significantly improved by correct administration. This includes taking tablets with water or orange juice on an empty stomach an hour before food, drink, multivitamins and other medications, all of which interfere with iron absorption. Tablets should be preferably taken early in the morning when hepcidin levels are lowest. Optimal value from each tablet is gained by daily, or alternate day, administration, to allow time for the increase in hepcidin levels to return to baseline.

Intravenous iron should be offered to anaemic women in the second trimester onwards who are intolerant of or unresponsive to oral iron and women presenting after 34 weeks' gestation with confirmed iron deficiency anaemia and Hb <100 g/L where there is insufficient remaining time before delivery for correction of anaemia with oral iron.

Women at risk of postpartum anaemia for example due to blood loss of more than 500 mL or uncorrected antenatal anaemia should have their Hb checked within 48 hours of delivery. If anaemia is confirmed, iron replacement with oral or intravenous iron should be initiated. Blood transfusion may be required if Hb is less than 70 g/L and there is cardiovascular compromise or significant risk of re-bleeding.

Folate deficiency

Women are advised to take 400 mcg/day of folic acid before conception until 12 weeks of pregnancy for the prevention of neural tube defects. Beyond 12 weeks, women remain at risk of folate deficiency and consequent anaemia as there is a significant increase in folate requirements, due to the increased cell replication that takes place in the fetus, uterus and bone marrow. Plasma folate concentrations decrease throughout pregnancy, reaching to half the non-pregnant levels by term.

Maternal anaemia due to folate deficiency may be difficult to diagnose. Coexisting iron deficiency can mask a macrocytosis and red cell indices are not necessarily helpful. Clinical suspicion is important; a diet containing low amounts of legumes and leafy green vegetables, malabsorption (most commonly coeliac disease), hyperemesis gravidarum and multiparity should prompt a test for serum folate. If anaemia is not responding to compliant iron replacement, folate deficiency should be considered. If found to be low, treatment is with oral folic acid 5 mg/day.

Folate requirements are increased in conditions associated with peripheral red cell destruction, such as sickle cell disease and other haemolytic anaemias, as well as with certain medications including antiepileptics. Prophylactic folic acid at 5 mg/day should be prescribed for women with these conditions.

Vitamin B12 deficiency

Vitamin B12 deficiency is uncommon during the reproductive years and as it can be associated with infertility, it is a rare finding in pregnancy. Serum vitamin B12 levels variably drop during pregnancy due to a fall in the inactive component of B12,

holohaptocorrin, and low levels rarely indicate true deficiency. Clinical assessment is therefore important, taking into account relevant symptoms such as paraesthesia and glossitis, along with consideration of risk factors such as a vegan diet, anorexia, gastrointestinal disease or surgery, and a personal or family history of autoimmune disease such as vitiligo, hypothyroidism and pernicious anaemia. The active B12 component, holotranscobalamin, can be assayed in some laboratories. Management of true B12 deficiency is with oral cyanocobalamin or intramuscular hydroxycobalamin depending on the likely cause.

Congenital anaemias

Inherited defects in red cell structure, and abnormal haematopoiesis, lead to chronic red cell destruction and anaemia. Conditions include red cell membrane disorders (such as hereditary spherocytosis), enzymopathies (for example G6PD deficiency), haemoglobinopathies and congenital dyserythropoietic anaemia. Disease severity in the mother varies from mild chronic anaemia to transfusion dependency, and in the fetus from being unaffected to hydrops fetalis. Diamond Blackfan syndrome may be also associated with physical anomalies in approximately 40%, and fetal loss has been reported to occur in up to 60% of cases.

Haemoglobinopathies

Haemoglobinopathy is defined as a group of inherited conditions in which there is abnormal production or structure of the haemoglobin molecule. Quantitative deficiency in globin chain synthesis causes impaired production and imbalance resulting in thalassaemia. Structural disorders cause qualitative abnormalities and result in variant haemoglobins, most commonly HbS. Comprehensive guidelines are available for the management of sickle cell disease and thalassamia in the UK, which include the management of pregnancy.

UK haemoglobinopathy screening service

The UK NHS Sickle and Thalassaemia Screening Program is a linked antenatal and neonatal program, launched in 2006. Antenatal screening aims to detect couples at risk of having a child with a major haemoglobinopathy before 12 weeks' gestation in order to offer prenatal diagnosis. Postnatally, all births in England are screened for haemoglobinopathy via the newborn heel prick sample with the primary aim of early detection of sickle cell disease (SCD).

Sickle cell disease

Sickle cell disease is an inherited autosomal recessive condition most commonly due to homozygous HbSS. Other compound heterozygous states such as HbSC, HbSβ-thalassamia or $HbSD_{punjab}$ also cause a sickling disorder with varying clinical severity. The clinical features of SCD are a result of chronic haemolytic anaemia and vasocclusion leading to painful crises, tissue ischaemia and infarction causing multiorgan damage.

Pregnancy associated with maternal SCD has an increased risk of maternal and fetal complications and should only be managed in specialist centres. Maternal sickle-related complications include worsening anaemia, increased painful crises, acute chest syndrome and infection. Maternal mortality is significantly increased and pregnancy-related complications occur more frequently, including hypertension, pre-eclampsia, thromboembolism and postpartum haemorrhage. Complications are generally fewer in women with HbSC disease, as compared to HbSS, except those effects of splenomegaly, such as thrombocytopenia, may occur and risk of venous thrombosis is higher. Risks to the fetus include increased miscarriage, intrauterine growth restriction, preterm delivery and stillbirth. The caesarean section rate is increased and perinatal mortality is reported at 4–6%.

Ideal management begins pre-conceptually with an assessment of pre-existing complications and optimisation of disease. Counselling about the risks of pregnancy should be undertaken and partner screening if appropriate. Pre-implantation genetic diagnosis can be offered to couples at risk of an affected child. Any teratogenic medication should be withheld, such as iron chelators, hydroxycarbamide and ACE inhibitors.

Antenatally, women should be reviewed at a minimum every 4 weeks until 24 weeks, every 2 weeks until 34 weeks and weekly thereafter. Blood pressure and urinalysis are required at each visit and an FBC monthly. In addition to routine standard scanning at 12 and 20 weeks, serial growth scans are offered every 4 weeks from 24 weeks.

Aspirin should be given between 12 and 36 weeks' gestation to reduce the risk of pre-eclampsia, and oral folic acid and penicillin prophylaxis should be continued. Hydroxycarbamide should be avoided if possible but risks vs benefits considered on an individualised basis. It is important that a plan is made for acute painful crisis occurring in pregnancy and fetal wellbeing is monitored during any admission with sickle crisis. VTE risk assessment is required and LMWH thromboprophylaxis offered from 28 weeks gestation, or earlier if there are additional risk factors for venous thrombosis, until 6 weeks postpartum. Screening for diabetes is recommended and a referral to the obstetric anaesthetic team should be planned for the third trimester. Prophylactic red cell transfusion is not routinely recommended but should be considered on an individualised basis, particularly in women with significant previous pregnancy complications and those previously on hydroxycarbamide.

Timing and mode of delivery are guided by obstetric indication, there is no evidence to support elective caesarean section for SCD alone. In view of the increased risk of complications in

the third trimester, with higher rates of stillbirth, placental insufficiency and abruption, many obstetricians would offer induction of labour at term. Hydration and oxygenation are advised during labour and continuous fetal heart monitoring recommended. Close monitoring in the postnatal period is recommended as the increased risk of painful crises continues.

Thalassaemia

Thalassaemia describes a group of disorders whereby there is an inherited quantitative defect in the production of otherwise normal globin chains. Although this most commonly affects the alpha (α) and beta (β) globin chains, thalassaemia of other chains such as gamma (ϒ) or delta (δ) are also described.

Classification is based on the type of globin chain production which is deficient. In complete absence of globin chain synthesis, the nomenclature α^0 or β^0 is used. When there is a reduced rate of synthesis, α^+ or β^+. The reduced rate of production of one of the globin chains results in an excess of the remaining normal chains; these precipitate in red cell precursors causing ineffective erythropoiesis, damaged red blood cells and chronic extravascular haemolysis. Further complexity occurs when a thalassaemic mutation is co-inherited with other thalassaemias or structural disorders.

Clinical classification is based on the severity of resulting anaemia and requirement for transfusion and a simplified version is shown in Table 53.1.

Thalassaemia carriage/trait

The mainstay of management for women with thalassaemia trait is determination of risk to the baby depending on paternal haemoglobin variants, and consideration of antenatal diagnosis. Maternal anaemia requires assessment and management of concomitant iron deficiency.

Table 53.1 Classification and haematological parameters of thalassaemia.

Syndrome	Genotypes	Phenotype
α Thalassaemia		
Normal	αα/αα	Normal

Non-transfusion-dependent (previously β thalassaemia intermedia)	β^+/β^+	Moderate microcytic anaemia
	β^0/β^+	HbA2 >3.5%***
	Coinheritance of other variants†	Increased HbF
Transfusion-dependent (previously β thalassaemia major)	β^0/β^0	Severe transfusion dependent microcytic anaemia
	β^0/β^+	Increased HbF
	HbE/β^0	

* MCH is used in the antenatal screening programme to identify women at risk of α^0 carriage and request partner screening.
** HbE is a β+ mutation.
*** Used in the antenatal screening programme to identify β thalassaemia and request partner screening.
† Other variants include Hb E (in combination with heterozygosity for a beta thalassaemia variant), hereditary persistence of fetal haemoglobin (HPFH; in combination with homozygous beta thalassaemia), alpha thalassaemia (in combination with homozygous β^+ thalassaemia), or triplicated or quadruplicated alpha genes (αα/ααα or αα/αααα; in combination with heterozygous beta thalassaemia). Dominantly acting beta thalassaemia variants can also occur.

All women known to the haematology service should be offered prenatal counselling about the management of pregnancy, including the offer of partner screening where appropriate. Specific treatment varies depending on the type of thalassamia.

Non transfusion dependent thalassamia

Pregnancy may exacerbate haemolysis in non transfusion dependent thalassamia (NTDT) such that some will require transfusion support. Hb should be monitored and transfusion considered for worsening maternal anaemia. In these cases, a pre-delivery Hb target of 100 g/L is advised. Maternal anaemia is a risk factor for fetal growth restriction (FGR) and regular growth scans are indicated from 24 weeks. Development of FGR is an indication of maternal transfusion support. In view of increased red cell turnover, folate supplementation (5 mg daily) is recommended.

Both NTDT and thalassaemia major (TM) (see below) are prothrombotic, especially if women have previously undergone splenectomy. Aspirin 75–100 mg daily should be offered to women who have undergone splenectomy or who have a platelet count $>600 \times 10^9$/L. If women have both, or if indicated by an individualised VTE risk assessment, low-molecular-weight heparin thromboprophylaxis should also be offered. All women should receive LMWH for 6 weeks postnatally.

Transfusion-dependent thalassaemia major

Individuals with TM require lifelong red cell transfusion support. This results in iron overload with subsequent cardiac, hepatic and metabolic bone disease. Endocrine dysfunction causes hypogonadotropic hypogonadism and subfertility, diabetes and hypothyroidism as well as small stature, which has implications for delivery. A full assessment of iron status and end-organ function is advised in advance of pregnancy.

Patients are routinely treated with iron chelation therapy from childhood. Preconceptually, chelation should be optimised as this can reduce overall iron burden and thus end-organ damage. Iron chelators are potentially teratogenic and deferasirox and deferiprone should be discontinued 3 months before conception. Desferrioxamine should be avoided in the first trimester due to lack of safety data but there is growing evidence that low-dose desferroxamine can be used safely in the second and third trimester. This should be considered in women with high risk of cardiac decompensation. Women with TM should receive chelation with intravenous desferrioxamine for the duration of labour to reduce the risk of free radical damage and cardiac dysrhythmia.

Women with TM require management in specialist centres with access to a multidisciplinary team including obstetricians, haematologists, cardiologist and diabetes specialist. Transfusion requirements tend to increase in pregnancy, and haemoglobin should be carefully monitored to maintain a baseline Hb of 100 g/L. Folic acid 5 mg daily is recommended and regular growth scans from 24 weeks to assess for FGR. The risk of haemolytic disease in the newborn needs to be considered in women with atypical red cell antibodies. Screening for diabetes is advised and thyroid function monitored.

Thrombocytopenia in pregnancy

Thrombocytopenia is common during pregnancy. Most cases are clinically mild with no intervention required and no adverse outcomes for mother or baby. Occasionally thrombocytopenia is more severe and cases can be associated with systemic disorders with implications for both mother and baby. Causes of thrombocytopenia in pregnancy are shown in Figure 53.1.

Gestational thrombocytopenia

Approximately 75% of cases are due to gestational thrombocytopenia, a benign condition most commonly occurring from the mid-second to third trimester. It typically resolves by 6 weeks postpartum but may recur in subsequent pregnancies. Thrombocytopenia is usually mild to moderate and the platelet count rarely falls $<70 \times 10^9$/L. There is no association with neonatal thrombocytopenia or bleeding.

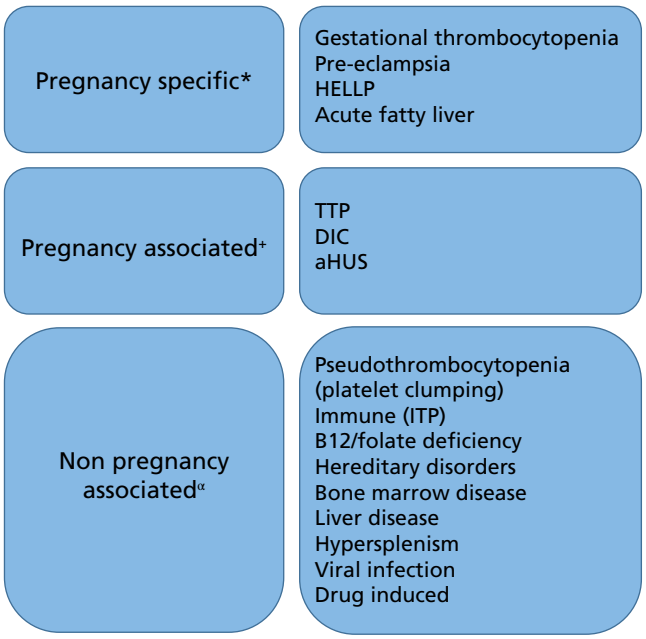

Figure 53.1 Causes of thrombocytopenia in pregnancy. *Occur only during pregnancy, +Occur in both pregnant and non-pregnant states but may be triggered by pregnancy or the postpartum period, αOccur in both pregnant and non-pregnant states. aHUS, atypical haemolytic uraemic syndrome; DIC, disseminated intravascular coagulation; HELLP, haemolysis elevated liver enzymes and low platelet syndrome; TTP, thrombotic thrombocytopenic purpura.

There is no diagnostic test for this condition; it remains a diagnosis of exclusion. Gestational thrombocytopenia (GT) is clinically most likely if the woman is well, with no previous personal or family history of thrombocytopenia or bleeding, a normal blood film and no other cause for thrombocytopenia evident. A normal platelet count outside of pregnancy is reassuring.

Woman can be counselled regarding the benign nature of the condition and the importance of presenting if they develop symptoms of bleeding. The platelet count should be monitored, particularly in the weeks leading up to delivery and the diagnosis reviewed if the platelet count falls below 70×10^9/L. A repeat FBC should be taken 6–8 weeks postnatally to ensure the platelet count has normalised.

Preeclampsia is the second most common cause of thrombocytopenia in pregnancy and, as with gestational thrombocytopenia, only occurs after 20 weeks gestation. Haemolysis, elevated liver enzymes and low platelets (HELLP) syndrome is considered a variant of preeclampsia although in 20% hypertension is not a feature. Risk factors include multiple pregnancy and caucasian ethnicity. Epigastric pain is common, the haemolysis is microangiopathic with fragmented red cells, lactate dehydrogenase (LDH), aspartate transaminase and/or alanine transaminase are elevated and there is thrombocytopenia. The clinical and laboratory features are similar to thrombotic thrombocytopenia purpura (TTP) but the LDH:transaminase ratio is higher in TTP where hepatic impairment is unusual. Unlike TTP, HELLP improves with delivery of the baby, although in a minority of cases, symptoms progress in the early postpartum period before recovery occurs, and in 20% the is onset postpartum.

Immune thrombocytopenia

Immune thrombocytopenia (ITP) occurs in 2–3% of women who are thrombocytopenic in the third trimester and can be difficult to distinguish from GT. However, it is the commonest cause of thrombocytopenia if presenting in the first trimester. Approximately 2/3 of women have a pre-existing diagnosis whereas 1/3 are diagnosed during pregnancy.

Maternal considerations

There are few randomised trials to aid management of ITP in pregnancy with guidance based on consensus approach and expert opinion. Decisions regarding treatment are based on gestation, platelet count and urgency of platelet increment balanced against potential side effects of treatment. Approximately 1/3 of women require treatment during pregnancy.

Antenatally in the absence of bleeding, a platelet count of $20–30 \times 10^9$/L is thought to be safe. Consensus recommends a platelet count $>50 \times 10^9$/L for vaginal or caesarean birth and $>70 \times 10^9$/L for neuraxial anaesthesia. Consideration particularly should be given to the balance of risk between spinal anaesthesia in the context of thrombocytopenia vs the risks of general anaesthetic to facilitate operative delivery. A referral to the obstetric anaesthetic team should be made in advance of delivery.

First-line treatment is usually oral prednisolone, starting with 20 mg and titrated to the lowest dose possible to maintain a safe platelet count. Intravenous immunoglobulin (IVIG) can be used if there is a more urgent need to increase the platelet count but response is usually transient. A combination of steroids and IVIG can be used in refractory cases. Azathioprine and cyclosporin are safe in pregnancy but may take several weeks to achieve platelet response. There is growing experience with the use of Rituximab and this can be considered in severe refractory cases; however, a potential complication is neonatal immunosuppression and subsequent infection with monitoring required in the infant.

Data regarding the use of thrombopoetin receptor agonists (TPO-RA) in pregnancy are limited to small case series. Both romiplostim and eltrombopag are able to cross the placenta raising concern about potential harm to the fetus. However, there is positive experience with their use in the latter half of pregnancy for refractory cases. Splenectomy is rarely done and should ideally be performed laparoscopically in the second trimester.

Considerations in the fetus/neonate

Maternal autoantibodies are IgG and can cross the placenta with the potential to cause thrombocytopenia in the neonate. Approximately 10% of neonates born to mothers with ITP have platelets $<50 \times 10^9$/L and 5% have platelets $<20 \times 10^9$/L. There is no correlation between the neonatal and maternal platelet count; however, a previous history of neonatal thrombocytopenia is a strong predictor of recurrence. Severe maternal disease and a history of splenectomy are also considered risk factors for a low neonatal platelet count. As severe thrombocytopenia is unusual, very low platelets counts warrant exclusion of neonatal alloimmune thrombocytopenia (NAIT). In contrast to NAIT, the risk of intracranial haemorrhage in severe neonatal ITP is very low at <1%.

Mode of delivery is by obstetric indication. Interventions associated with an increased risk of neonatal haemorrhage such as fetal scalp blood sampling or electrodes, ventouse delivery and rotational forceps should be avoided. An umbilical cord platelet count should be taken at delivery and repeated at 3–5 days of age if low. Cranial USS should be performed if the platelet count is $<50 \times 10^9$/L. Symptomatic bleeding or a platelet count $<30 \times 10^9$/L are indications for treatment with IVIG.

Other autoimmune disorders

Autoimmune haemolytic anaemia

Haemolytic anaemia describes a shortened red cell lifespan. Increased erythropoiesis in the bone marrow is able to compensate when haemolysis is mild but as the rate of haemolysis exceeds capacity for compensation, anaemia occurs.

Autoimmune haemolytic anaemia (AIHA) is caused by the production of autoantibodies which bind to a red cell surface antigen resulting in premature removal; predominantly in the spleen, but also in the liver and occasionally intravascularly. AIHA can be classified as warm (predominantly IgG antibodies) or cold (mainly IgM or complement-fixing antibodies). It may be primary, or secondary to drugs, infection, autoimmune disease (typically systemic lupus erythematosus), neoplasia or other haematologic disorders.

Typical laboratory findings include anaemia, increased LDH and bilirubin, reticulocytosis and reduced haptoglobin; these are common to all causes of haemolytic anaemia. The distinguishing diagnostic test is the direct antiglobulin test (DAT or direct Coombs test) which is positive in immune-mediated haemolysis and negative in non-immune causes. The blood film shows polychromasia and spherocytosis with red cell agglutination seen in cold AIHA. Thrombocytopenia should prompt investigation for an alternative cause and red cell fragmentation requires urgent consideration of microangiopathic haemolytic anaemia (MAHA).

AIHA is seen only rarely during pregnancy, estimated to complicated 1:140,000 maternities. Conversely, anaemia is very common and therefore an index of suspicion is required in the case of a rapidly falling haemoglobin in the absence of another cause.

First-line treatment is with oral prednisolone, tapered to the minimum effective dose. Use of other immunosuppressive agents such as azathioprine, IVIG and rituximab has been described but the rarity of the condition means that there is little evidence upon which to base treatment decisions in steroid-refractory cases.

Supportive red cell transfusion may be required, however cross-matching red cells can be problematic. Autoantibodies coating the red cell surface have the potential to 'mask' underlying red cell alloantibodies causing difficulty in selecting suitable units for transfusion. Specialised laboratory testing may be required, which can delay the provision of red cells. Women with cold AIHA require transfusion through a blood warmer to avoid worsening red cell agglutination.

Haemolysis is a risk factor for thrombosis and consideration should be given to antenatal thromboprophylxaxis. All women require thromboprophylaxis during the highest risk time for thrombosis which is the first 6 weeks postpartum unless a contraindication exists. Oral folic acid 5 mg daily is prescribed to meet the increased folate requirements of red cell production.

IgG antibodies are able to cross the placenta and can cause antenatal or postpartum haemolysis in the fetus/neonate. Antenatally, women may require serial USS for growth and doppler USS of the fetal middle cerebral artery to screen for neonatal anaemia. Umbilical cord FBC, bilirubin and DAT should be taken at delivery and the neonate monitored for the development of anaemia and hyperbilirubinaemia. Although the DAT is often positive, severe fetal/neonatal haemolysis is rare. Management of neonatal AIHA is similar to that in haemolytic disease of the newborn (HDN).

Neutropenia

Neutropenia is defined as an absolute neutrophil count of $<1.5\times10^9$/L. It has many causes and most cases are mild. Neutropenia is described as severe if the neutrophil count is $<0.5\times10^9$/L and very severe if the count is $<0.2\times10^9$/L. There is ethnic variation in the normal neutrophil count with individuals of African and Caribbean descent typically having a lower count than their Caucasian counterparts.

Autoimmune neutropenia is a rare disorder caused by granulocyte-specific autoantibodies. Cases can be primary or secondary to other autoimmune conditions. Although testing for anti-neutrophil antibodies is possible, it is generally not helpful and does not guide management. Diagnosis is predominantly by exclusion of other causes.

Pregnant woman with neutropenia should be investigated in the same way as the non-pregnant patient including a careful history, review of medication and clinical examination. A peripheral blood film should be examined. Bone marrow examination can be performed safely in pregnancy if this is clinically indicated; however, this is rarely required unless a sinister cause is suspected.

The main maternal risk with severe neutropenia is sepsis which may be life-threatening, promote miscarriage or precipitate early labour. Close monitoring of maternal and fetal wellbeing is required. Infection should be treated promptly and consideration given to prophylactic antibiotics to cover invasive procedures, labour and delivery.

Outside of pregnancy, recombinant granulocyte colony-stimulating factor (GCSF) is used to treat patients with severe chronic neutropenia. Although there is limited data on the use of GCSF in pregnancy, adverse events have not been reported and the benefits are likely to outweigh the risks in a patient with repeated infections.

There is a risk of neonatal neutropenia and an umbilical cord sample should be taken for assessment of the full blood count. Neonatal infections are usually mild and serious morbidity from sepsis is rare; however, infants should be closely monitored for signs of infection.

Alloimmune disorders

Transplacental transfer of immunoglobulin G (IgG) begins early in the second trimester and fetal-maternal alloimmune disorders may arise from maternal sensitisation to fetal antigens, causing immune-mediated destruction of fetal cells. The most common alloimmune conditions are red cell alloimmunisation and NAIT with risk of fetal anaemia and thrombocytopenia, respectively.

Haemolytic disease of the fetus and newborn

Haemolytic disease of the fetus and newborn (HDFN) is most commonly due to RhD sensitisation, but anti-c and anti-Kell antibodies may be implicated as well as others at high titre (>1:32 dilution) such as anti E.

One in six RhD-negative women will sensitise after delivery of a term RhD-positive baby. Immune-mediated red cell destruction of a subsequent RhD-positive fetus gives rise to hyperbilirubinaemia. While the fetus is largely protected by placental passage, the newborn's immature liver is unable to conjugate bilirubin causing risk of kernicterus and long-term neurological sequelae. Furthermore, worsening fetal anaemia in utero leads to a compensatory increase in fetal erythropoiesis, initially in the bone marrow but subsequently dependant on extramedullary red cell production causing enlarged liver and spleen. As anaemia becomes more severe, cardiac output increases and without intervention, cardiac failure develops, leading to hydrops fetalis with widespread accumulation of extravascular fluid. In pregnancies at risk, detection of fetal anaemia by ultrasound scan of the fetus' middle cerebral artery guides management, with timely delivery or intrauterine red cell transfusion, to prevent this fatality.

Newborns need close observation. A cord sample should be taken for blood group, DAT, Hb and bilirubin. As bilirubin levels rise sharply after birth, repeat estimations may be required to determine the need for phototherapy. IVIG acts by blocking Fc clearance of red cells as well as inactivating circulating maternal immunoglobulin and, if anaemia is present, a single dose of IVIG 0.5–1.0 g/kg given shortly after birth reduces the need for exchange transfusion and ongoing top-up transfusions.

All women are screened for the development of atypical red cell antibodies in early pregnancy and at 28 week's gestation. For RhD-negative women, the fetal RhD type can be identified from a maternal blood sample, enabling counselling, a plan of management and if maternal antibody is not yet present, prevention of sensitisation with an injection of exogenous antiD, derived from pooled human plasma. This is offered at 28 weeks and after delivery to all RhD-negative women with a RhD-positive baby to prevent sensitisation and reduce risk to subsequent pregnancies.

Fetal neonatal alloimmune thrombocytopenia

Fetal neonatal alloimmune thrombocytopenia (FNAIT) occurs in approximately 1 in 1000 pregnancies and differs from red cell alloimmunisation in that the first pregnancy is often affected. Human platelet antigens (HPAs) are expressed on fetal platelets from 11 week's gestation and may cross the placenta and cause sensitisation in the mother whose immune system does not recognise the paternally-derived antigens. The anti-HPA antibodies may cause destruction of fetal platelets with ensuing thrombocytopenia and risk of bleeding. As there is direct targeting of fetal platelet antigens, thrombocytopenia can be severe, more so than caused by random binding of maternal autoantibody in ITP. Anti HPA 1a accounts for 80% of cases, anti HPA 5b 15% of cases, other anti-HPA antibodies are occasionally implicated.

Presentation is most commonly thrombocytopenia and bruising in the neonate but fetal intracranial haemorrhage (ICH) occurs in around 20% and may cause hydrocephalus, fetal demise or long-term neurological sequelae.

Diagnosis is made by serological testing for maternal anti-HPA antibody, paternal or neonatal genotype, and if necessary cross-match between mother's serum and father's platelets. The human leucocyte antigen (HLA)-DRB3*0101 in women is associated with clinically significant FNAIT and absence of this HLA has a negative predictive value of 99%.

The success of weekly IVIG therapy, usually from 16 week's gestation, has meant that invasive fetal blood sampling and platelet transfusion are no longer undertaken except before planned delivery when it may be beneficial to raise the platelet count to reduce risk of bleeding. Women at high risk, defined as a previous baby with an ICH or platelets under 20×10^9/L should receive IVIG 1 g/kg from 12 week's gestation with escalation of treatment at 20 weeks by doubling IVIG or adding steroids. Those at very high risk defined as ICH occurring before 28 weeks, should receive IVIG 2 g/kg weekly from 12 weeks with addition of steroids at 20 weeks.

Unlike for red cell antibodies, routine screening for anti-HPA antigens is not considered beneficial as it may lead to overdiagnosis by revealing transient antibodies. In addition, there is no way to prevent sensitisation, although research is underway on an anti-HPA-1a immunoglobulin to prevent women forming immune anti-HPA-1a. Anti-HPA 1a monoclonal antibodies are also in development which compete with maternal antibodies for binding to fetal HPA but unable to activate Fcg receptors and cause platelet destruction.

Physiological changes in coagulation status during pregnancy

To meet the needs of the developing fetus and placenta, uterine blood flow increases from 50 mL/min before pregnancy to over 1 L/min by term. The placenta has around 200 spiral arteries

which straighten and lose their vascular resistance so that almost 90% of the flow is directed to the placental intervillous spaces for transplacental exchange with the fetus. Not surprisingly, therefore, there is a high risk of obstetric haemorrhage during delivery when the placenta separates, particularly if contraction of the uterus is impaired.

To mitigate the risk of obstetric haemorrhage, there are physiological changes to the haemostatic system. Factors II, VII, VIII and X increase markedly with gestation and remain elevated in the early postpartum period. Factors V, IX and XI are unchanged. Factor XIII levels are lower in early pregnancy with a gradual increase in the second and third trimester. Fibrinogen concentration increases with a normal range of 4–6 g/L by the end of pregnancy. Von Willebrand factor (VWF) increases two to fourfold in the antenatal period which is thought to be due to oestrogen stimulation of endothelial cells to increase production of VWF. Levels peak during labour and delivery and begin to fall within the first few days after delivery, decreasing back to baseline in most women within 2–3 weeks.

The natural anticoagulant protein S decreases, protein C and antithrombin levels remain steady and there is increased resistance to activated protein C. Despite an increase in profibrinolytic proteins plasminogen and tissue-type plasminogen activator (tPA), overall fibrinolytic activity is reduced. This is due to an increase in inhibitors of fibrinolysis including thrombin activatable fibrinolytic inhibitor (TAFI) and plasminogen activator inhibitor 1 (PAI-1). During pregnancy, the antifibrinolytic protein PAI-2 is produced by placental villous cells, further adding to the anti-fibrinolytic effect. Fibrin degradation products, including the d-dimer, are increased, making this an unsuitable test to reliably exclude a diagnosis of VTE in the pregnant patient.

These physiological adaptations result in a shift in the balance of normal haemostasis to a prothrombotic, hypofibrinolytic state during pregnancy. Whilst this is necessary in order to maintain placental function and prevent haemorrhage at the time of delivery, these changes contribute to the increased thrombotic risk, which is well described in pregnant women.

Inherited bleeding disorders

Pregnant women with von Willebrand disease (VWD), carriers of haemophilia, or rare factor deficiencies are at increased risk of bleeding. VWF and Factor VIII levels increase from 6 to 8 weeks' gestation, reaching concentrations of three to fivefold baseline by term. Although this provides protection for delivery for women with haemophilia A carrier status and most women with VWD, they remain vulnerable in early pregnancy before levels peak, and in the puerperium when concentrations can fall abruptly. Desmopressin (DDAVP) increases release of stored FVIII and VWF, raising plasma levels threefold, and can be used to cover first-trimester procedures and the postpartum period. Tranexamic acid is useful to prevent excessive postpartum bleeding and is best given intravenously in established labour or by tablet after delivery.

Factor IX concentration does not change in pregnancy, and women with low factor IX (carriers of haemophilia B) may require recombinant factor concentrate for invasive procedures and delivery. Factor concentrations of 50% are generally considered safe for vaginal delivery and regional anaesthesia, although concentrations of 80% are preferred for caesarean section.

Inheritance risk to the baby needs to be considered and decisions made in early pregnancy and preferably pre-conceptually regarding prenatal diagnosis. Women who are carriers of severe haemophilia can be offered *in vitro* fertilisation with prenatal genetic diagnosis and embryo selection, or determination of fetal genotype in the early stages of pregnancy. Free fetal DNA can be extracted from a maternal blood sample from as early as 9 week's gestation for determination of fetal sex. If male, chorionic villous sampling for DNA analysis to determine haemophilia status can be undertaken between 10- and 12-weeks' gestation if results would influence the mother's decision whether to proceed with the pregnancy. Otherwise, amniocentesis at 34–36 weeks' gestation for genetic determination of haemophilia status allows informed decisions when planning delivery. Ventouse, rotational forceps, scalp electrodes and scalp sampling should be avoided if the male baby is affected with severe haemophilia.

UK guidelines on the management of inherited bleeding disorders in pregnancy have stratified risk for both mothers and babies according to disease type and severity. A summary is shown in Tables 53.2 and 53.3.

Obstetric haemorrhage

Maternal haemorrhage is a leading cause of maternal death. Haemorrhage commonly results from uterine atony as spiral arteries are then left open. Rarer causes include placental abruption, placenta praevia or accreta, and uterine rupture. Once blood loss exceeds 2000 mLs, dilutional coagulation deficits are common, exacerbating bleeding and ultimately leading to disseminated intravascular coagulation (DIC) and hypovolaemic shock when bleeding exceeds around 5000 mL. DIC can also be triggered by eclampsia, sepsis, retained products or amniotic fluid embolus and it is vital to consider the underlying cause of haemorrhage to determine the likelihood of early coagulopathy. All units should have a transfusion protocol for the management of massive obstetric haemorrhage such as that shown in Figure 53.2

Lessons learned from the UK and Ireland confidential enquiries into maternal deaths from haemorrhage include

- Optimisation of haemoglobin before delivery.
- Stimulating or augmenting uterine contractions in accordance with current guidance, paying particular attention to avoiding uterine tachysystole or hyperstimulation.

Table 53.2 Stratification of maternal bleeding risk in inherited bleeding disorders.

Risk level	Stratification of maternal bleeding risk	Suggested management of delivery (and note for postpartum care)
High risk	• Type 3 VWD • Severe (homozygous) rare coagulopathies • Severe platelet function disorders • Haemophilia carriers with a significant bleeding history	Adequate replacement therapy to be given after the onset of established labour. Avoid central neuraxial anaesthesia unless adequate replacement therapy has been confirmed. Maintain normal levels for at least 3 days postpartum or 5 days for caesarean section
Medium risk	• Type 2 VWD • Mildly reduced third-trimester maternal levels of factor VIII, IX or WWF activity • Factor XI deficiency with clinical bleeding phenotype	Adequate replacement therapy to be given after the onset of established labour. Avoid central neuraxial anaesthesia unless adequate replacement therapy has been confirmed. Maintain normal levels for at least 3 days postpartum or 5 days for caesarean section
Mild risk	• Mild platelet dysfunction disorders • Carriers for haemophilia with third-trimester factor VIII/IX levels ≥ 0.5 iu/mL • Type 1 VWD with corrected VWF activity >0.5 iu/mL	Consider tranexamic acid for delivery and postpartum.
Unlikely to be at risk	• Rare coagulopathies without bleeding phenotype (e.g. heterozygous factor V, VII, X, XI deficiency) • Factor XII deficiency (any severity)	No replacement therapy needed. Able to have central neuraxial anaesthesia.

Dysfibrinogenaemia tends to be associated with thrombosis but may cause bleeding.
VWD, von Willebrand disease; VWF, von Willebrand factor.

Table 53.3 Stratification of Neonatal bleeding risk in Inherited Bleeding disorders.

Risk stratification of bleeding, according to possible or confirmed diagnosis of fetus		Suggested management of delivery
High Risk	Males with severe and moderate haemophilia A or B Type 3 vWD Severe (homozygous) rare coagulopathies or severe platelet disorders	Consider third-trimester amniocentesis. Discuss mode of delivery taking maternal and fetal factors into consideration, but avoid mid cavity forceps, ventouse, FBS, FSE, Cord sample for factor assay. Oral vitamin K, unless the result is known to be normal.
Medium Risk	• Males with mild haemophilia A or B • Type 2 vWD	• Consider third-trimester amniocentesis. • Avoid mid cavity forceps, ventouse, • Judicious use of FBS and FSE to facilitate vaginal delivery. • Cord sample for factor assay. • Oral vitamin K, unless the result is known to be normal.
Mild Risk	• Clinically moderate or severe type 1 vWD in family • Female fetuses who are obligate/possible carriers of severe haemophilia B • Mild platelet function disorders	• Consider avoiding ventouse and external cephalic version. • Judicious use of rotational forceps, FBS and FSE.
Unlikely Risk	• Clinically mild type 1 vWD in family • All other obligate/possible haemophilia carrier female fetuses • Heterozygous rare coagulopathies	No special precautions.

Figure 53.2 Example protocol for the management of obstetric haemorrhage (Source: Pavord and Maybury 2015/With permission of Elsevier.)

- Avoidance of delays to fluid resuscitation and blood transfusion,
- Being alert to warning signs and understanding that the normal physiological responses to haemorrhage may not be present early on, as young women compensate remarkably well. Although tachycardia commonly develops, there can be a paradoxical bradycardia and hypotension is always a very late sign, so continuing bleeding should be acted on without delay.
- Pre-empting coagulopathy, considering risk factors and providing blood components before coagulation indices deteriorate. This should include assessment and replacement of fibrinogen which when below 2 g/L or falling, is a predictor of severity of haemorrhage.
- Early recourse to hysterectomy if medical and surgical interventions are proving ineffective.

Patient blood management in obstetrics

Patient blood management (PBM) refers to the care of patients who may require a blood transfusion. Prevention of inappropriate or avoidable transfusions is particularly important in obstetrics due to the impact of any alloimmunisation on obtaining compatible blood in an emergency and to the fetus or newborn of haemolytic disease. Furthermore, pregnant women are significantly younger than the general population of transfused patients and potential unknown blood pathogens with long incubation times could impact their future health.

The three pillars of PBM; optimising erythropoiesis, minimising blood loss and managing anaemia, are addressed at different stages of pregnancy. The first requires adequate management of iron deficiency in the antenatal period to ensure normal Hb levels by term and adequate reserves in the event of haemorrhage at delivery. Iron deficiency also increases risk of postpartum haemorrhage, likely due to impaired uterine contractility.

Minimising blood loss in the intrapartum period involves prevention and prompt management of haemorrhage. Patients at risk should be identified and a delivery plan developed. Where unanticipated haemorrhage occurs, prompt multidisciplinary management is vital, considering the underlying cause of bleeding and likelihood of coagulopathy. Point of care viscoelastic testing (Thromboelastography [TEG] and rotational elastometry [ROTEM] can be helpful in the context of obstetric haemorrhage and whilst they do not replace laboratory tests, they can be performed within 10–15 min enabling rapid assessment of haemostasis facilitating prompt management. Local normal ranges and thresholds for intervention should be established, as shown in Figure 53.2.

Postpartum anaemia should be managed with iron supplements, and transfusion only given to a non-bleeding patient if Hb is under 70 g/L and there is cardiac compromise or risk of re-bleeding. If blood transfusion is necessary, information should be provided and consent obtained and only one unit should be given followed by reassessment.

Venous thromboembolism (VTE) in pregnancy

Pregnancy and the postnatal period are well-established risk factors for VTE, which remains the leading direct cause of maternal death in the UK. The combination of hypercoagulability, stasis of blood flow due to the gravid uterus and endothelial damage during delivery contribute to this risk. VTE can occur at any stage of pregnancy with the highest risk in the postnatal period where it is 25 times more common than in the non-pregnant population. VTE can present as an isolated deep vein thrombosis (DVT), or embolisation resulting in pulmonary embolism (PE). All women in the UK undergo individualised VTE risk assessment in early pregnancy which is repeated as clinical status changes, in accordance with guidelines from the Royal College of Obstetricians and Gynaecologists. Thromboprophylaxis with low molecular weight heparin (LMWH) is offered to those at the highest risk.

Diagnosis

Other than an increased propensity for the left leg (90% of DVT during pregnancy), the presentation of DVT and PE is the same as the non-pregnant population. Clinical assessment in both cases is unreliable. The higher index of suspicion for VTE during pregnancy and the overlap of symptoms with other pregnancy morbidity reduces the accuracy of clinical diagnosis to approximately 8% for DVT and less than 5% for PE. To add to the diagnostic difficulty, the Wells score is not validated in pregnancy and the d-dimer physiologically increases throughout normal pregnancy making this an unreliable marker for exclusion of VTE. Objective testing is therefore required in women with suspected thrombosis.

Compression duplex ultrasound scan (USS) is the primary diagnostic test for DVT. If the USS is negative and a high level of clinical suspicion exists, anticoagulant treatment should be discontinued but the USS is repeated on days 3 and 7. For the diagnosis of iliac vein thrombosis, USS of the iliac vein, MRI venography or conventional contrast venography may be considered.

Women with suspected PE who have symptoms and signs of DVT should have initial USS performed; if DVT is confirmed, no further investigation for PE is required. All other women require an initial CXR followed by ventilation/perfusion (VQ) scan or computerised tomography pulmonary angiogram (CTPA). Choice of imaging will depend on local availability and patient preference. CTPA is the imaging technique of choice if the CXR is abnormal. Expert consensus recommends VQ scanning where possible due to the high negative predictive value, the lower radiation dose to the maternal breast and the reduced likelihood of co-existing lung pathology in the young pregnant

population. Women should be advised that there is a slightly increased risk of childhood cancer with VQ scanning but the absolute risk is very small.

Management

Baseline FBC, renal and liver function are required prior to treatment. Therapeutic anticoagulation with LMWH is recommended at suspicion of VTE; unlike vitamin K antagonists such as warfarin, LMWH does not cross the placenta and has a good safety record for use in pregnancy. During pregnancy, changes in volume of distribution and renal glomerular filtration rate result in alterations in the pharmacokinetics of LMWH and historically, guidelines have recommended a twice-daily dosing regimen for enoxaparin and dalteparin. More recent evidence supports safety of a once-daily dosing regimen; however, there remains uncertainty regarding the optimum dosing for pregnant women.

LMWH should be continued throughout pregnancy. It is not established whether it is safe to recommend a dose reduction after the initial period of anticoagulation although this practice is employed successfully in some centres. Monitoring of anti-Xa levels is not routinely required unless there are concerns of renal impairment, extremes of body weight or a known diagnosis of antithrombin deficiency. Monitoring of platelet count is not required as heparin-induced thrombocytopenia (HIT) is extremely rare in pregnancy.

Massive life-threatening PE

Massive life-threatening PE is an emergency. Women present with haemodynamic compromise, hypoxaemia and evidence of right ventricular dysfunction. Cardiorespiratory arrest may ensue. Immediate assessment by a multidisciplinary team of experienced physicians, obstetricians, haematologists and interventional radiologists is required with assessment on an individual basis whether a woman receives intravenous unfractionated heparin (IV UFH), thrombolytic therapy or thoracotomy and surgical embolectomy

IV UFH is the preferred, initial treatment in massive PE due to its rapid effect and extensive experience of use. It can also be adjusted easily if thrombolytic therapy is required. Urgent portable ECHO or CTPA is advised within an hour of presentation however in extreme circumstances immediate thrombolysis may be indicated.

Delivery

Consideration should be given to planned delivery to avoid the risk of labour with full-dose anticoagulation. Therapeutic LMWH should be discontinued 24 hours prior to planned operative delivery, or 12 hours for prophylactic LMWH. In the event of spontaneous labour, women should be advised to omit LMWH and attend for review. For VTE occurring very close to term, IV UFH is an option due to the short duration of activity. Protamine sulphate to reverse heparin should be available for use if required. Unlike UFH, protamine only achieves partial reversal of LMWH and tranexamic acid may be a helpful adjunct for women in labour on therapeutic LMWH.

Regional anaesthetic techniques are not recommended until at least 24 hours after the last dose of therapeutic LMWH. LMWH should not be given for 4 hours after the use of spinal anaesthesia or removal of epidural catheter, and the epidural catheter should not be removed within 12 hours of the most recent injection. Referral to the obstetric anaesthetic team is advised.

Postnatal management

A prophylactic dose of LMWH can be given 4 hours after delivery. Although some guidance recommends that therapeutic LMWH can be recommenced as early as 8–12 hours after delivery, many centres build up more gradually over 48 hours, particularly in the event of caesarean section, to avoid the risk of wound haematoma. Therapeutic anticoagulation should be given for a minimum of 6 weeks postnatally and no less than 3 months of total treatment. LMWH and warfarin can both be used safely in breastfeeding women. Although there is emerging evidence for the use of direct oral anticoagulants (DOACs) in breast-feeding women, these are currently not recommended for routine use pending more data.

Bone marrow disorders

Myeloproliferative neoplasms

Pregnancy in women with myeloproliferative neoplasms (MPN) may be complicated by thrombosis or haemorrhage and around 30% risk of first-trimester fetal loss, higher with polycythaemia vera. Management should start before conception with counselling about risks, optimisation of the condition and general health, and withdrawal of potentially teratogenic medications such as hydroxycarbamide and anagrelide. Haematocrit <45% and blood counts should be controlled, with venesection, interferon and platelet- or leukapheresis as necessary. Aspirin helps prevent fetal loss, and heparin thromboprophylaxis may be necessary if additional risk factors for venous thrombosis are present. An algorithm for management of MPN in pregnancy is shown in Figure 53.3.

Haematological malignancy

Leukaemia or lymphoma diagnosed during pregnancy poses difficult dilemmas for the woman, her family and the multidisciplinary team. Timing of chemotherapy depends on the health

of the mother, the natural course of the condition, teratogenicity of its treatment and the gestation and progress of the pregnancy. In general, chemotherapy and radiotherapy in the first trimester are associated with significant risks of congenital malformations and miscarriage which lessens with advancing pregnancy.

For women with previous haematological malignancy, late effects of chemotherapy such as anthracycline-induced cardiomyopathy and bleomycin-induced pulmonary fibrosis should be considered and appropriate screening tests performed.

Aplastic anaemia and paroxysmal nocturnal haemoglobinuria

Pregnancy outcomes in women with aplastic anaemia are generally good, depending on the degree of bone marrow suppression. Regular monitoring is required to guide appropriate support with red cell and platelet transfusions, and prompt antibiotics for infections. Most cases of acquired aplastic anaemia are autoimmune and if cytopenia becomes severe, anti-thymocyte globulin (ATG), methylprednisolone and/or Cyclosporin can be given.

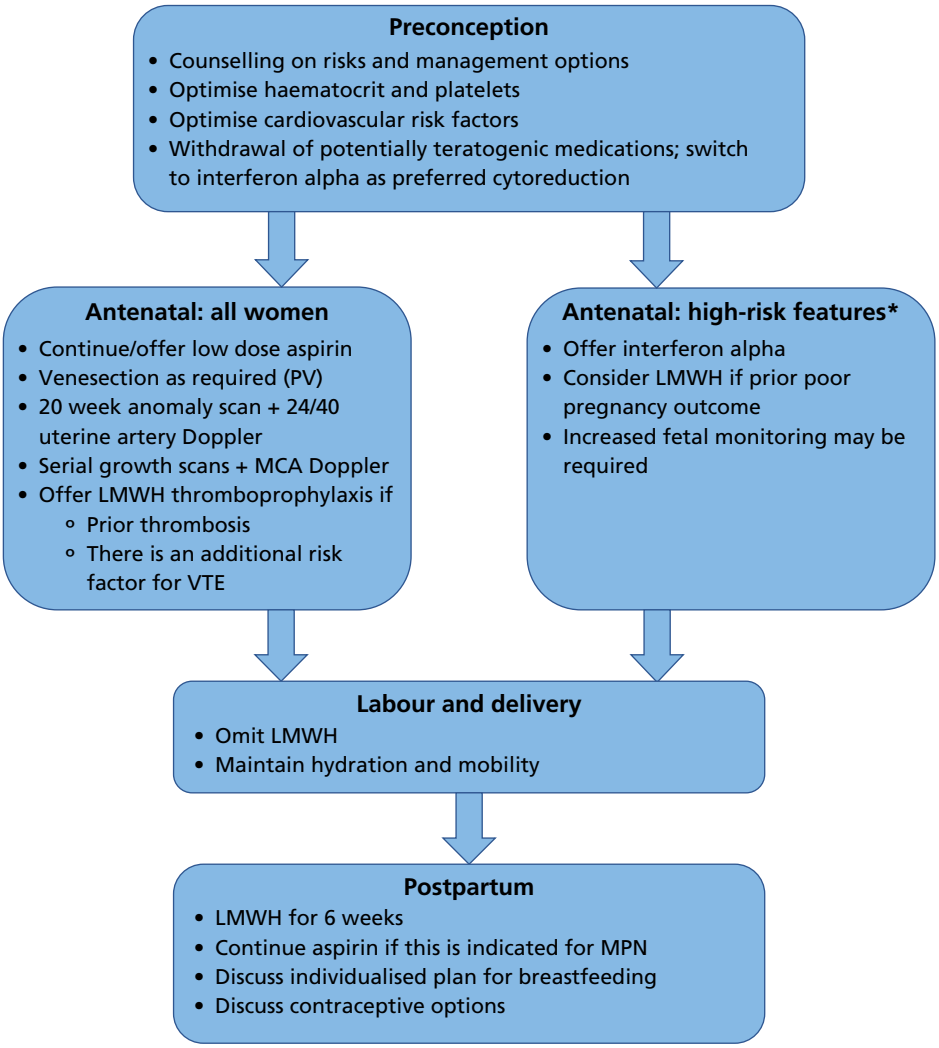

Figure 53.3 Management of MPN in pregnancy. *High-risk pregnancy criteria may suggest an increased risk of fetal or maternal complications. Previous venous or arterial thrombosis, previous haemorrhage attributed to MPN. Previous pregnancy complication towards which MPN may have contributed: Three pregnancy losses <12 weeks or one or more pregnancy loss >12 weeks. Intrauterine growth restriction, preeclampsia or other evidence of placental dysfunction. Intrauterine death or stillbirth with no other cause identified. Antepartum or major postpartum haemorrhage requiring red cell transfusion. Platelet count rising to >1500 × 10^{-9}/L before or during pregnancy$^{\Delta}$. Diabetes or hypertension requiring treatment$^{\Delta}$. $^{\Delta}$ These criteria would be an indication for cytoreductive treatment but not LMWH.

Associated paroxysmal nocturnal haemoglobinuria (PNH) increases risk of maternal and fetal morbidity and mortality and requires consideration of thromboprophylaxis and transfusion support for intravascular haemolysis. Risks and benefits of complement inhibitor treatment should be discussed but it is likely necessary to continue pre-pregnancy management to maintain stability for the pregnancy.

Developmental haemopoiesis

In humans, haemopoiesis begins in the yolk sac in the third week of gestation and moves sequentially to the aorto–gonado–mesonephros (AGM) by 5 weeks gestation, the liver by 6–8 weeks and the bone marrow around the 11th week of gestation. The AGM involutes early in the first trimester and the liver is the principal site of haemopoiesis until the end of the third trimester. Fetal haemopoietic stem cells (HSCs) have different molecular and functional characteristics compared to adult HSCs. These differences ensure that fetal HSCs meet the specific needs of the fetus for different types of mature blood cells. The predominant lineage during fetal life is erythropoiesis, but platelets and all types of leucocyte found in adult blood are also seen from as early as 4–5 weeks gestation.

There are a number of differences between erythropoiesis in neonates and adults: red cell morphology is distinctive with large numbers of crenated red cells, particularly in preterm neonates (Figure 54.1); red cell lifespan is reduced (35–50 days in preterm infants, 60–70 days in term infants); susceptibility to oxidant-induced injury is increased because of differences in the glycolytic and pentose phosphate pathways; the erythropoietin response to anaemia is blunted and specific embryonic and fetal globin chains are synthesised (Table 54.1). The first globin chain produced is ε-globin, followed by α- and γ-globin chains. Haemoglobin F (HbF, $\alpha_2\gamma_2$) is produced from 4–5 weeks' gestation and is the predominant haemoglobin until after birth. Adult haemoglobin (HbA, $\alpha_2\beta_2$) is produced from 6–8 weeks' gestation, but remains at low levels until after birth. In term babies, the average HbF at birth is 70–80%, the HbA is 25–30%, there are small amounts of HbA_2 and sometimes a trace of Hb Barts (γ_4).

Immediately after birth, rates of haemoglobin synthesis and red cell production fall in response to the sudden increase in tissue oxygenation at birth. In term babies, the haemoglobin reaches a mean of 130–140 g/L at the age of 4 weeks and 95–110 g/L at 7–9 weeks of age. Studies of well-preterm infants show a steeper fall in haemoglobin, reaching a mean of 65–90 g/L at 4–8 weeks of age. The reticulocyte count falls soon after birth as erythropoiesis is suppressed and increases back to normal values at 6–8 weeks of age. The blood volume at birth varies with gestational age and the timing of clamping of the cord. In term infants, the average blood volume is 80 mL/kg and in preterm infants 106 mL/kg (range 85–143 mL/kg). Term and preterm babies have adequate stores of iron, folic acid and vitamin B_{12} at birth. However, stores of both iron and folic acid are lower in preterm infants and are depleted more quickly, leading to deficiency after 2–4 months if the recommended daily intakes are not maintained.

Neonatal anaemia

Definition and pathophysiology

Any neonate with a haemoglobin of less than 130 g/L at birth should be considered anaemic and may require investigation (Figure 54.2). However, it is important to be aware that the haemoglobin concentration is affected by the site of sampling (it is up to 40 g/L lower in venous samples than in heel-prick samples in the first few days of life) and the timing of the clamping of the

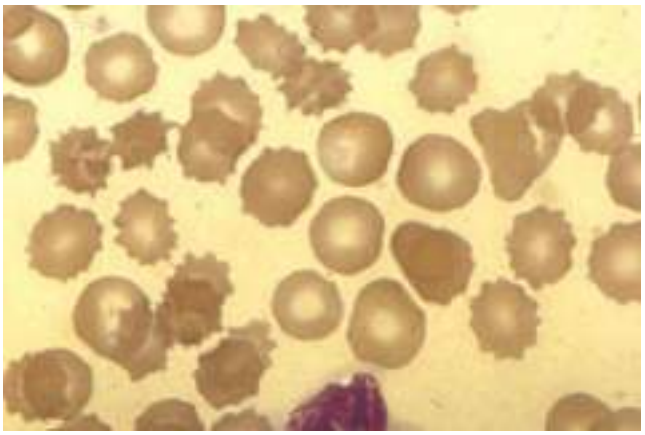

Figure 54.1 Typical erythrocyte morphology in a preterm neonate. Crenated red cells are a normal feature of the blood film of preterm neonates during the first few weeks of life. This film is from a neonate born at 26 weeks' gestation and shows the number of crenated cells present in neonates under 28 weeks' gestation. The number of these cells is inversely proportional to gestational age at birth.

cord (around 30 g/L higher after late clamping). The clinical significance of neonatal anaemia depends on whether the baby is able to maintain adequate tissue oxygenation. This in turn depends on the position of the haemoglobin–oxygen dissociation curve, which is principally determined by the concentrations of HbF and 2,3-diphosphoglycerate (2,3-DPG); a high HbF and low 2,3-DPG both shift the curve to the left, i.e. the affinity of haemoglobin for oxygen is increased and less oxygen is released to the tissues. This is the situation just after birth and may be more of a problem for very preterm babies as their HbF levels are greater than 90%. Over the first few months of life, 2,3-DPG levels rise and HbF levels fall so that the haemoglobin–oxygen dissociation curve gradually shifts to the right, the oxygen affinity of haemoglobin falls and oxygen delivery to the tissues increases, ameliorating the effects of the falling haemoglobin.

Table 54.1 Composition of haemoglobins in the human embryo, fetus and neonate.

	Globin chains		
Haemoglobin	**α-Globin gene cluster***	**β-Globin gene cluster***	**Gestation**
Embryonic			
Hb Gower 1	ξ_2	ε_2	From 3–4 weeks
Hb Gower 2	α_2	ε_2	
Hb Portland	ξ_2	γ_2	From 4 weeks
Fetal			
HbF	α_2	γ_2	From 4 weeks
Adult			
HbA	α_2	β_2	From 6–8 weeks
HbA_2	α_2	δ_2	From 30 weeks

* The α-globin gene cluster is situated on chromosome 16 and the β-globin gene cluster on chromosome 11. Note that fetuses and neonates with α-thalassaemia major, who are unable to synthesise α-globin chains, will have Hb Portland as well as Hb Barts (β_4), detectable by haemoglobin electrophoresis or HPLC.

Causes of neonatal anaemia

Anaemia may be caused by reduced red cell production, increased red cell destruction (haemolysis) or blood loss (Table 54.2).

Neonatal anaemia due to reduced red cell production

The main diagnostic clues to reduced red cell production are the combination of a low reticulocyte count ($<20\times10^9$/L) with a negative direct antiglobulin test (Coombs test). The most common causes are congenital parvovirus B19 infection and genetic red cell aplasias, particularly Diamond–Blackfan anaemia (DBA).

Parvovirus B19 and fetal/neonatal anaemia

Maternal infection with parvovirus B19 can cause severe fetal anaemia and in 9% of cases leads to intrauterine death. The baby has marked reticulocytopenia (often $<10\times10^9$/L) and thrombocytopenia may also occur. The diagnosis is made by maternal serology and demonstration of B19 DNA in the fetus or neonate by dot-blot hybridisation or polymerase chain reaction (PCR) of peripheral blood (bone marrow aspiration for morphology and parvovirus B19 PCR may be necessary in difficult cases). Severe cases require intrauterine transfusion, but have a good long-term outcome if they survive to delivery.

Genetic red cell aplasia

Apart from DBA, the genetic causes of congenital red cell aplasia are extremely rare. They include congenital dyserythropoietic anaemia (CDA) and Pearson syndrome; haematological evidence of the other inherited bone marrow failure syndromes, such as Fanconi anaemia, are almost never present at birth. These genetic causes of congenital red cell aplasia can normally be distinguished from each other through a combination of their distinctive bone marrow morphology, family history and the presence, or not, of additional congenital anomalies.

DBA

The incidence of DBA is estimated at five to seven cases per million live births. DBA has a clear family history in 20% of cases (autosomal dominant or recessive) and appears to be sporadic

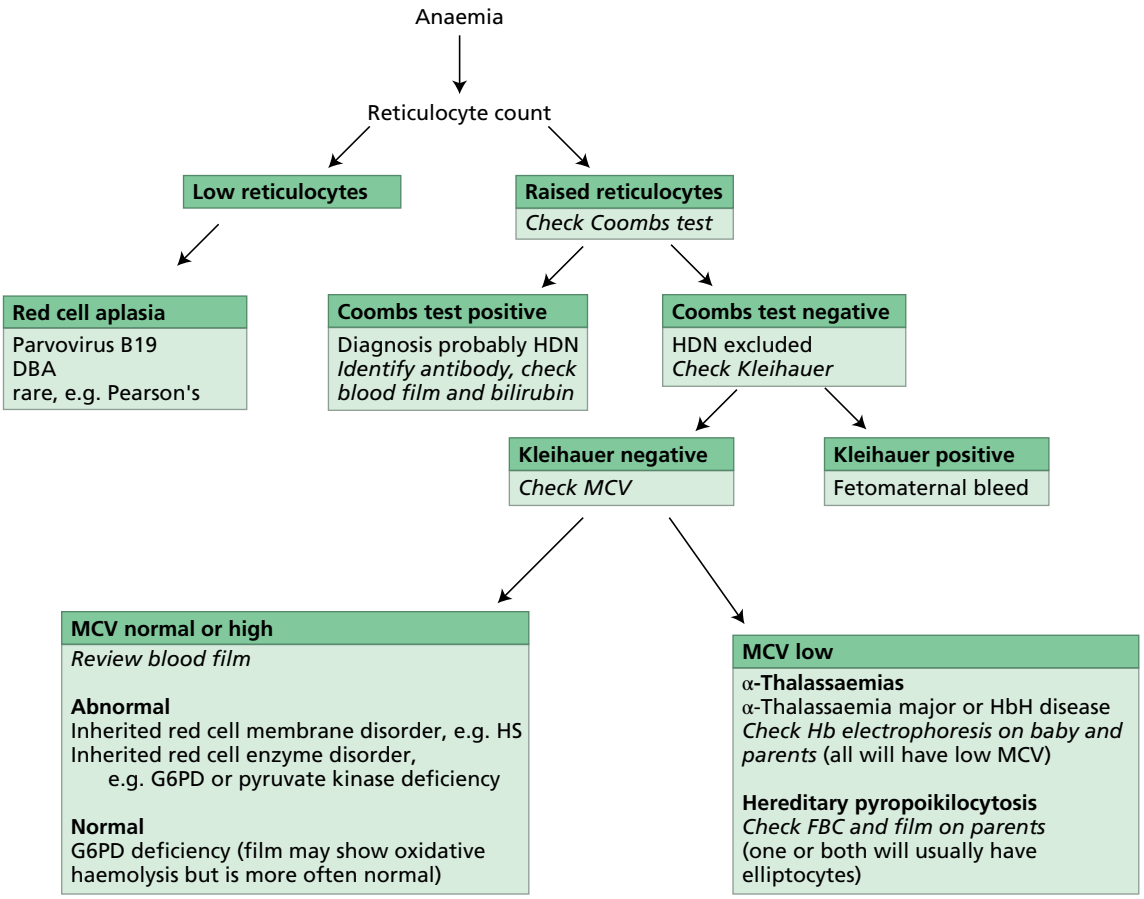

Figure 54.2 A diagnostic algorithm for neonatal anaemia. The most useful screening tests for investigating unexplained neonatal anaemia are the reticulocyte count, the Coombs' test and the mean corpuscular volume (MCV) of the red cells. DBA, Diamond–Blackfan anaemia; G6PD, glucose-6-phosphate dehydrogenase; HDN, haemolytic disease of the newborn; HS, hereditary spherocytosis.

in the remaining 80%. Presentation in the neonatal period or first few months of life with increasing anaemia from birth is typical, but more severe cases manifest as second-trimester anaemia or hydrops fetalis. Around 40% of infants have associated congenital anomalies, particularly craniofacial dysmorphism, neck anomalies and thumb malformations similar to those seen in Fanconi anaemia. In neonates, the blood film shows normochromic red cells with an absence of polychromasia and nucleated red cells despite severe anaemia (Figure 54.3). Reticulocytopenia is usually severe, but automated reticulocyte counts of $20–30 \times 10^9$/L are sometimes seen. Erythroid precursors are very low or absent in the bone marrow aspirate. These features are diagnostic of DBA if parvovirus infection is excluded. Raised red cell levels of adenosine deaminase (ADA) in the patient and/or parents may be useful for confirming the diagnosis, although normal red cell ADA levels do not exclude DBA. Recent studies indicate that most cases of DBA are due to defects in the synthesis and function of structural ribosomal proteins (RP). At present mutations in 20 *RP* genes have been identified and account for about 80% of DBA cases, *RPS19* mutations being the commonest (25% of all DBA). Additionally, DBA- like phenotype has been identified in patients with recessive inheritance with mutations in the *EPO* gene, and X-linked inheritance with mutations in *GATA1* and *TSR2* genes. In approximately 20% of patients, the molecular basis for the disease has proved elusive, even after extensive sequencing using targeted next generation sequencing and screening for large deletions. It is expected that further work with whole genome sequencing will help find some of these.

In the neonatal period, the only treatment of DBA is red cell transfusion, although steroids are used in older infants and children.

Pearson syndrome

This rare condition nearly always presents within a few days or weeks of birth. Pearson syndrome is caused by mutations or deletions in mitochondrial DNA and presents with normochromic anaemia, neutropenia, thrombocytopenia and failure to thrive. Most affected neonates have low birth weight, and metabolic acidosis, exocrine pancreatic deficiency and

Table 54.2 Common of neonatal anaemia.

Reduced red cell production
- Diamond–Blackfan anaemia
- Congenital viral infections, e.g. parvovirus, cytomegalovirus
- Congenital dyserythropoietic anaemia
- Pearson syndrome

Increased red cell destruction (haemolysis)
- Alloimmune: haemolytic disease of the newborn (Rh, ABO, Kell, other)
- Red cell membrane disorders, e.g. hereditary spherocytosis
- Red cell enzyme deficiencies, e.g. pyruvate kinase deficiency
- Some haemoglobinopathies, e.g. α-thalassaemia major, HbH disease

Blood loss
- Occult haemorrhage before or around birth, e.g. twin–twin, fetomaternal
- Internal haemorrhage, e.g. intracranial, cephalhaematoma
- Iatrogenic, due to frequent blood sampling

Anaemia of prematurity
- Impaired red cell production plus reduced red cell lifespan

abnormal liver and renal function are common. The most useful haematological clue to the diagnosis is the highly characteristic vacuolation of early erythroid cells on the marrow aspirate (Figure 54.4). Interestingly, large mitochondrial gene deletions have also been reported in a small subgroup of DBA patients. When these cases were re-evaluated, they were found to be

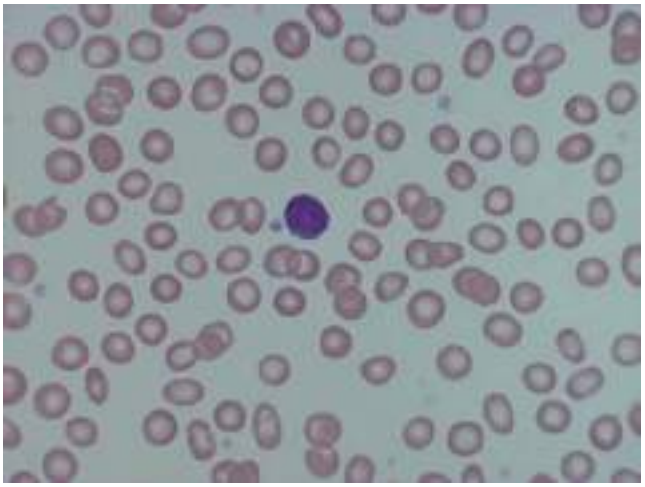

Figure 54.3 Blood film from a neonate with Diamond–Blackfan anaemia. This baby presented with fetal anaemia at 20 weeks' gestation and received intrauterine transfusion. At birth, the baby had normochromic anaemia and the blood film showed a complete absence of polychromasia and nucleated red cells, despite a haemoglobin of 70 g/L.

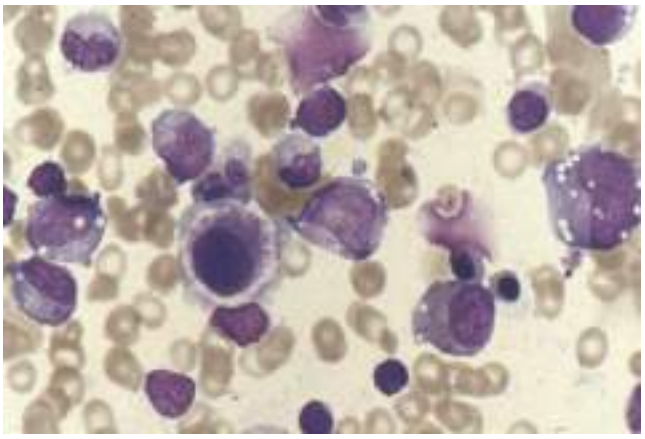

Figure 54.4 Pearson syndrome. Bone marrow aspirate from a neonate with Pearson syndrome showing typical vacuolation of erythroblasts and a dysplastic megakaryocyte.

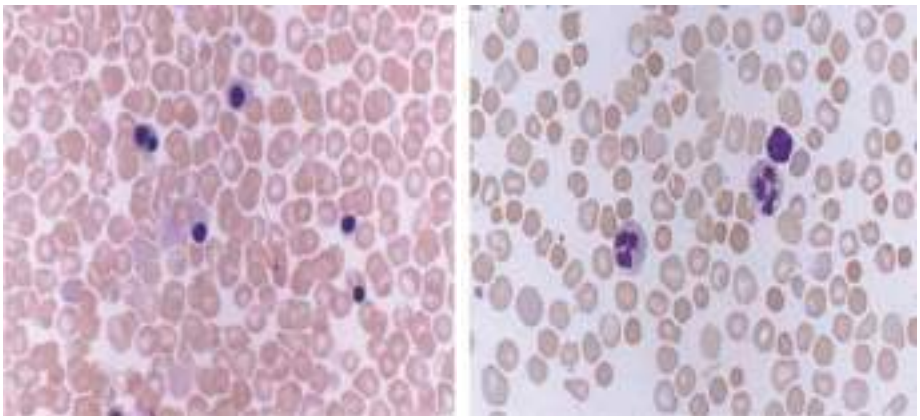
cases of Pearson syndrome which had been misdiagnosed as DBA. Unfortunately, the prognosis for children with Pearson syndrome is very poor, with few surviving beyond the second year of life.

CDA

The clinical presentation of CDA is extremely variable. While the most severe forms may present as hydrops fetalis in association with fetal anaemia, milder forms of the disease may not present until adulthood. CDA is conventionally classified into three main types (I, II and III) with additional variant types of CDA. Most case reports of CDA presenting in the neonatal period are Type I or CDA variants. CDA type I is caused by mutations in the *CDAN-1* gene or, occasionally, in the *C15ORF41* gene. Type II CDA is due to mutations in the *SEC23B* gene and CDA type III, which is very rare, is due to mutations in the *KIF23* gene, while some variant forms of CDA are due to mutations in *LPIN2* or in the transcription factor genes *GATA1* or *KLF1*. Due to the widespread availability of newer DNA sequencing technologies, several other genes such as *PARP4, VPS4A* and *PRDX2* have recently been identified in a few pedigrees with CDA-like anaemias but the pathogenicity of these variants is yet to be conclusively validated.

Neonatal anaemia due to increased red cell destruction (haemolysis)

The main diagnostic clues suggesting a haemolytic anaemia are increased numbers of reticulocytes and/or circulating nucleated red cells (Figure 54.5), unconjugated hyperbilirubinaemia, a positive Coombs' test (if immune) and characteristic changes in the morphology of the red cells on a blood film (e.g. hereditary spherocytosis; Figure 54.5). The main cause of immune haemolytic anaemia is haemolytic disease of the newborn. The main



(a) (b)

Figure 54.5 Haemolytic disease of the newborn. (a) Blood film from a baby with rhesus haemolytic disease of the newborn due to anti-D showing polychromasia and large numbers of nucleated red cells, but relatively few spherocytes. (b) Blood film from a neonate with ABO haemolytic disease of the newborn due to anti-A, showing very large numbers of spherocytes, polychromasia and no nucleated red cells.

causes of non-immune neonatal haemolysis are red cell membrane disorders, red cell enzymopathies and, occasionally, haemoglobinopathies (Table 54.2).

Immune haemolysis, including haemolytic disease of the newborn

The principal alloantibodies causing haemolytic disease of the newborn are those against Rh antigens (anti-D, anti-c and anti-E), anti-Kell, anti-Kidd (J^k), anti-Duffy (F^y) and antibodies of the MNS blood group system, including anti-U. Anti-D is the most frequent alloantibody causing significant haemolytic anaemia, affecting 1 in 1200 pregnancies. Anti-Kell antibodies are less common but can cause severe fetal and neonatal anaemia as they inhibit erythropoiesis as well as causing haemolysis. Most babies with haemolytic disease of the newborn present with jaundice and/or anaemia; in severe cases, there is hepatosplenomegaly and/or skin deposits due to extramedullary haemopoiesis. ABO haemolytic disease occurs only in offspring of women of blood group O and is confined to the 1% of such women who have high-titre IgG antibodies. Haemolysis due to anti-A is more common (1 in 150 births) than that due to anti-B. In contrast with anti-Rh antibodies, both anti-A and anti-B usually cause hyperbilirubinaemia without significant anaemia; however, hydrops has occasionally been described. The blood film in ABO haemolytic disease characteristically shows very large numbers of spherocytes with little or no increase in nucleated red cells (see Figure 54.5a); this contrasts with rhesus haemolytic disease of the newborn, in which there are few spherocytes and large numbers of circulating nucleated red cells (see Figure 54.5b). Non-invasive prenatal testing of maternal blood samples for cell-free fetal DNA for relevant fetal antigens is currently in routine use in some countries to assess fetal genotype in women with alloantibodies in order to help with management of pregnancy.

Management of haemolytic disease of the newborn: All neonates at risk should have cord blood taken for measurement of haemoglobin, bilirubin and a Coombs' test and should remain in hospital, or under close outpatient supervision, until hyperbilirubinaemia and/or anaemia have been properly managed. Rhesus-alloimmunised infants with haemolysis should receive phototherapy from birth, as the bilirubin can rise steeply; this prevents the need for exchange transfusion in some infants. In haemolytic disease due to anti-Kell, anaemia is usually more prominent than jaundice and minimal phototherapy may be necessary despite severe anaemia. ABO haemolytic disease of the newborn usually just requires phototherapy, as anaemia is uncommon.

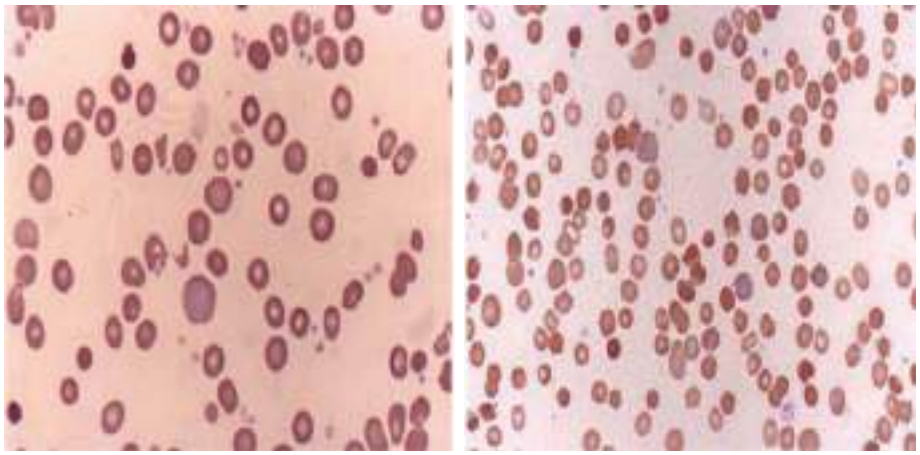
The indications for exchange transfusion in haemolytic disease of the newborn are:

- severe anaemia (haemoglobin <100 g/L at birth) and/or
- severe or rapidly increasing hyperbilirubinaemia.

The British Society for Haematology (BSH) has published useful guidelines for neonatal exchange transfusion. Intravenous immunoglobulin can be used to reduce the need for exchange transfusion, but the value of this approach remains to be proven in clinical trials. Neonates with haemolytic disease due to anti-Rh antibodies may develop 'late' anaemia at a few weeks of age, requiring 'top-up' transfusion; irradiated blood must be used for infants previously receiving intrauterine transfusion to prevent the risk of transfusion-associated graft-versus-host disease. Recombinant erythropoietin sometimes prevents the need for top-up transfusion for late anaemia but is not effective when haemolysis is brisk and there are currently no data from randomised trials to support its routine use in this setting. Folic acid (500 µg/kg daily) should be given to all babies with ongoing haemolysis until they reach 3 months of age.

Neonatal haemolytic anaemia due to red cell membrane disorders

In neonates, these disorders usually present with jaundice, with or without anaemia, and abnormal red cell morphology on the blood film. Many cases of hereditary elliptocytosis present as an incidental finding in a neonate being investigated for a



(a) (b)

Figure 54.6 Red cell membrane disorders. (a) Blood film from a baby with hereditary pyropoikilocytosis showing microspherocytes, red cell fragments and polychromasia. (b) Blood film from a neonate with hereditary spherocytosis showing large numbers of spherocytes and polychromasia.

non-haematological disorder; anaemia is rare in heterozygotes and jaundice is often minimal. Most cases of hereditary spherocytosis do have jaundice in the neonatal period and moderate anaemia is fairly common. On the other hand, severe transfusion-dependent neonatal haemolytic anaemia due to an inherited red cell membrane disorder is very uncommon and typically due to hereditary pyropoikilocytosis which can be readily identified because of the characteristic low mean corpuscular volume (MCV) of 50–60 fL and bizarre red cell morphology. The main clues are a family history and an abnormal blood film, as red cell membrane disorders can nearly always be recognised by the characteristic shape of the red cells (Figure 54.6a). Identification of the exact type of membrane abnormality may require specialised investigations. The osmotic fragility test is of limited value in neonates and recent data indicate that the dye binding test is more useful. If the clinical phenotype is severe and family history or family studies are unhelpful, further investigation is useful to clarify the diagnosis and pattern of inheritance. This is mostly achieved by molecular methods, using next-generation sequencing panels targeting a number of genes known to be associated with red cell membranopathy. Ektacytometry, an automated method of demonstrating red cell osmotic fragility, is also used where available and can often be useful as a phenotypic readout of rare or new variants identified in the sequencing analyses.

Hereditary spherocytosis

This is the most common of the red cell membrane disorders to cause symptomatic anaemia, affecting 1 in 5000 live births to parents of northern European extraction. Hereditary spherocytosis is caused by mutations in the genes for *spectrin*, *ankyrin*, *protein 4.1* or *protein 3* and is usually inherited in an autosomal dominant fashion. About 10 to 15% cases of hereditary spherocytosis are inherited as a recessive disease due to bi-allelic mutations in genes encoding *protein 4.2*, *alpha-spectrin* or *ankyrin*. The blood film shows spherocytes and typically has an identical appearance to that of ABO haemolytic disease (Figure 54.6b). Neonatal anaemia due to hereditary spherocytosis is usually moderate (haemoglobin 70–100 g/L); it is not uncommon for affected neonates to require one or two transfusions during the neonatal period before a transfusion-free plateau haemoglobin of 80–100 g/L is achieved after a few months.

Hereditary elliptocytosis

This disorder is also caused by mutations in the *spectrin*, *ankyrin* or *protein 4.1* genes, but which have a different functional consequence to the mutations associated with hereditary spherocytosis. In neonates, hereditary elliptocytosis usually has no clinical manifestations apart from elliptocytes on the blood film. However, neonates who are homozygous or compound heterozygous for hereditary elliptocytosis mutations have severe haemolytic anaemia. The most common form is *hereditary pyropoikilocytosis*, which causes severe, persistent, transfusion-dependent haemolytic anaemia presenting in the neonatal period. The diagnosis is usually easily made from the low MCV and blood films of the baby (which show bizarre fragmented red cells and microspherocytes; see Figure 54.6a). Examination of the parental blood films is very helpful since one or both parents typically has common hereditary elliptocytosis, although silent *spectrin* mutations and de novo mutations may also occur and produce a severe phenotype in the baby despite apparently normal parental blood films. The treatment of neonates with hereditary pyropoikilocytosis is red cell transfusion. Transfusions should continue on a regular basis until the child is old enough to undergo splenectomy, to which there is an excellent response, with all patients rendered transfusion-independent.

Neonatal haemolysis due to red cell enzymopathies

The commonest inherited red cell enzymopathies presenting in the neonatal period are glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency (see also Chapter 16).

G6PD deficiency

The prevalence of G6PD deficiency is particularly high in individuals from Central Africa (20%) and the Mediterranean (10%) but is also seen in the Indian subcontinent, the Far East and the Middle East. In neonates, G6PD deficiency nearly always presents with jaundice within the first few days of life; the vast majority of affected neonates are boys, as the *G6PD* gene is on the X chromosome. Neonatal jaundice due to G6PD deficiency is often severe, whereas anaemia is uncommon. The blood film is usually completely normal, but in the small number of neonates with anaemia due to G6PD deficiency, the blood film shows typical changes of oxidative haemolysis. The diagnosis is made by assaying G6PD on a peripheral blood sample. The pathogenesis of the jaundice is unclear, as most babies with G6PD deficiency have no evidence of haemolysis. Management of neonatal G6PD deficiency requires close monitoring of the bilirubin to prevent kernicterus, particularly when interactions with other risk factors for neonatal hyperbilirubinaemia are present, such as Gilbert syndrome, haemolytic disease of the newborn or hereditary spherocytosis, and also the counselling of the babies' parents regarding which medicines, chemicals and foods may precipitate haemolysis. G6PD deficiency does not cause chronic haemolysis (except in a few extremely rare G6PD variants) and therefore folic acid supplements are not indicated.

Pyruvate kinase deficiency

Although pyruvate kinase deficiency is the second most common inherited red cell enzymopathy in neonates, the estimated prevalence is only 50 cases/million, and therefore even large neonatal centres will only identify 1 case every 5 years. Pyruvate kinase deficiency is inherited in an autosomal recessive fashion. It is clinically heterogeneous, varying from anaemia severe enough to cause hydrops fetalis to a mild unconjugated hyperbilirubinaemia. In severe cases, the jaundice has a rapid onset within 24 hours of birth and exchange transfusion may be required. The diagnosis is made by measuring pretransfusion red cell pyruvate kinase activity where available. Mutation analysis of the *PKLR* gene that encodes this enzyme is increasingly used to confirm the diagnosis and provide genetic counselling if appropriate. In mild cases, enzyme activity may be relatively modestly reduced making the diagnosis difficult and it is often useful to assay levels in the parents for confirmation. The blood film is sometimes distinctive but more often shows non-specific changes of non-spherocytic haemolysis. Management in the neonatal period depends on the severity of the jaundice and anaemia. Some, but not all, children with pyruvate kinase deficiency are transfusion dependent and folic acid supplements should be given to prevent deficiency due to chronic haemolysis.

Other red cell enzymopathies

The other red cell enzymopathies are rare. The most important in the neonatal period is *triosephosphate isomerase deficiency*, as one-third of patients present with neonatal haemolytic anaemia, often many months before the devastating neurological features of this disorder become apparent. Another cause of acute haemolysis confined to the neonatal period is *infantile pyknocytosis*. This poorly understood condition, which is probably due to transient glutathione peroxidase deficiency, usually presents at 1–6 weeks of age. Infantile pyknocytosis is more common in preterm neonates and when it occurs in twins, both are usually affected. The anaemia associated with infantile pyknocytosis is often moderately severe, requiring one to two red cell transfusions before gradually resolving by the age of 2–3 months. The blood film typically shows changes of oxidative haemolysis during the neonatal period, but returns to normal as the haemolysis resolves (Figure 54.7) Measurement of glutathione peroxidase levels in affected neonates may be useful (parental levels are normal) but the diagnosis is usually easily made from the blood film. There are no reports of recurrence of haemolysis out-with the neonatal period in babies with infantile pyknocytosis and care should be taken to exclude other causes of haemolytic anaemia in any cases where the haemolysis does not resolve, or recurs, after the age of 3 months.

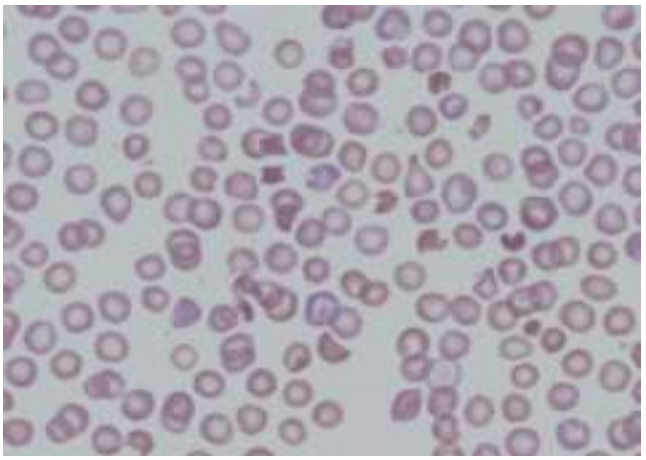


Figure 54.7 Infantile pyknocytosis. Blood film from a neonate with infantile pyknocytosis and a low level of erythrocyte glutathione peroxidase showing pyknocytes, fragmented red cells, polychromasia and occasional spherocytes.

Neonatal haemolysis due to haemoglobinopathies

The only haemoglobinopathy that typically presents in the neonatal period is α-thalassaemia major, as all four *α-globin* genes are deleted. Severe cases of HbH disease may also present with severe fetal or neonatal anaemia, although this is uncommon. Occasional non-thalassaemic structural *α- and γ-globin* gene mutations, which are clinically completely silent in adults and children, cause transient neonatal haemolytic anaemia in the neonate because they are unstable (e.g. Hb Hasharon, Hb Poole), whereas the major β-globin haemoglobinopathies (sickle cell disease and β-thalassaemia major) rarely manifest clinically in neonates.

α-Thalassaemia major

This predominantly affects families of Southeast Asian, Mediterranean or Middle Eastern origin, and presents with second-trimester fetal anaemia or hydrops fetalis, which is almost always fatal within hours of delivery. The only long-term survivors of α-thalassaemia major are those who have received intrauterine transfusions followed by regular postnatal transfusions and/or a bone marrow transplant. There is also a high incidence of hypospadias and limb defects in survivors, and others have severe neurological problems. If intrauterine transfusions are delayed until anaemia is severe, neonatal pulmonary hypoplasia is a cause of early mortality. The diagnosis of α-thalassaemia major should be suspected in any case of severe fetal anaemia that presents in the second trimester, and any case of hydrops fetalis with severe anaemia in which the parents come from high-prevalence areas, particularly Southeast Asia. Checking the blood counts of the parents will immediately identify whether they are at risk of having a child with α-thalassaemia major: both parents will have hypochromic microcytic red cell indices, with MCV usually below 74 fL and mean corpuscular haemoglobin (MCH) usually less than 24 pg. Prenatal diagnosis and genetic counselling are offered to all pregnant women at risk of having a baby with α-thalassaemia major. In countries with high prevalence of α-thalassaemia major but limited access to prenatal genetic diagnosis, screening is also done by early trimester ultrasound scan to detect fetal anaemia. The diagnosis of α-thalassaemia major is confirmed by DNA analysis that demonstrates deletions in all four genes encoding α-globin. Haemoglobin electrophoresis or HPLC from the affected fetus or infant shows Hb Barts, Hb Portland and sometimes HbH; HbF and HbA are absent); the blood film shows hypochromic microcytic red cells with vast numbers of circulating nucleated red cells (Figure 54.8).

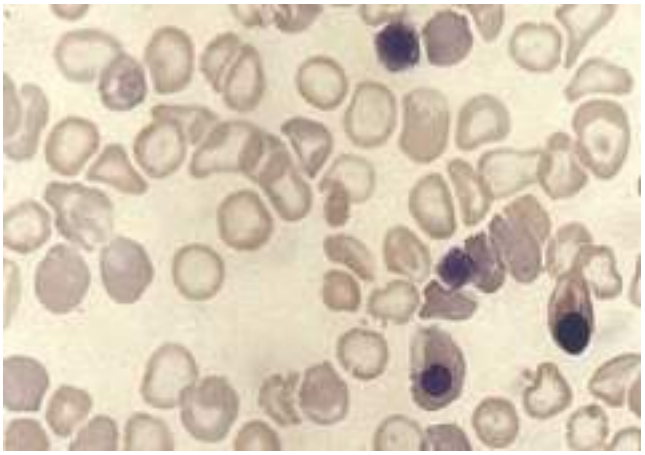

Figure 54.8 α-Thalassaemia major. Blood film from a neonate with α-thalassaemia major, born at 28 weeks' gestation, showing severe hypochromia, microcytosis, target cells, polychromasia and nucleated red cells.

Neonatal anaemia due to blood loss

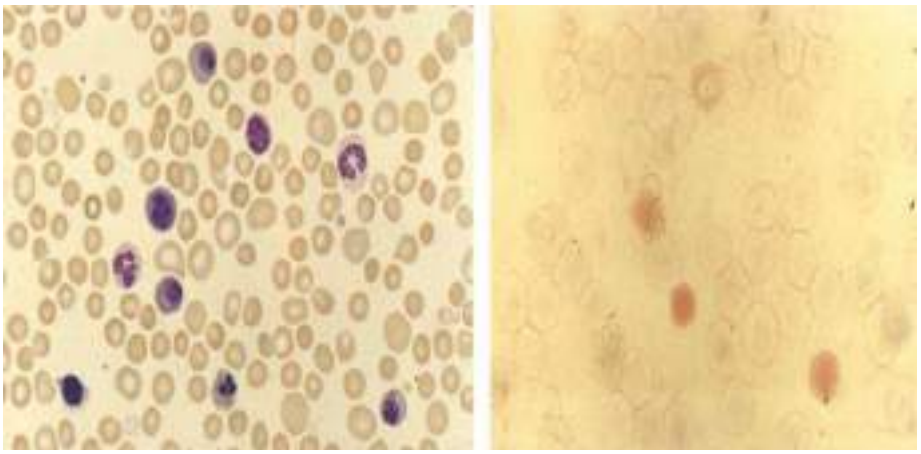
Blood loss as a cause of neonatal anaemia may be very obvious (e.g. a cephalhaematoma or rupture of the cord) or the blood loss may be concealed and easy to miss unless specifically sought (e.g. fetomaternal bleeds). Usually, the most serious blood loss occurs prior to delivery and important causes of this are twin-to-twin transfusion and fetomaternal blood loss.

Twin-to-twin transfusion

This occurs in monochorionic twins with monochorial placentas where there are two amniotic sacs (diamniotic). Twin-to-twin transfusion syndrome carries a mortality of up to 80% without treatment and 15–40% with treatment. In most cases, bleeding is chronic, which usually results in a marked difference in birth weight between the twins. The donor twin is smaller, pale and lethargic and may have overt cardiac failure. By contrast, the recipient twin is often plethoric, with hyperviscosity, hyperbilirubinaemia, polycythaemia and, in the most severe cases, disseminated intravascular coagulation (DIC). Where twins survive to delivery, the difference in Hb between donor and recipient twin where there has been chronic blood loss is usually <50 g/L. Bleeding may also occur acutely during labour, with signs similar to those of fetomaternal haemorrhage. Early detection can improve outcomes in twin-to-ttwin transfusions. This is undertaken by ultrasound screening and fetoscopic laser surgery to stop aberrant placental blood flow.

Fetomaternal haemorrhage

Most significant fetomaternal bleeds occur during the third trimester, either spontaneously or secondary to trauma and involve very small quantities of blood (0.5 mL or less). Much more of a clinical problem are acute fetomaternal bleeds where there is loss of more than 20% of the blood volume. This may cause intrauterine death or the baby may be born with hydrops or circulatory shock. In some cases, the baby appears well, but pale, at birth and collapses a few hours later. Diagnostic clues are anaemia at birth in an otherwise well baby with no or minimal jaundice. The most useful diagnostic tests are a Coombs test to exclude immune haemolysis, a reticulocyte count to exclude red cell aplasia, a Kleihauer test on maternal blood to quantify the number of HbF-containing fetal red cells in the maternal circulation and a blood film (Figure 54.9). In RhD-negative women, accurate quantification of fetal blood in maternal circulation is undertaken by flow cytometry so that the appropriate dose of anti-D can be administered to prevent alloimmunisation. Quantification of fetal blood loss in this manner is not routinely available to RhD-positive women, although a case may be made in its support as it will assist the neonatal team in managing the baby. Blood loss around the time of delivery is usually due to obstetric complications (e.g. placenta praevia, placental abruption); in these circumstances, the babies are often extremely ill, with circulatory shock, anaemia worsening rapidly after birth, large numbers of circulating nucleated red cells and DIC.



(a) (b)

Figure 54.9 Fetomaternal haemorrhage. (a) Blood film from a neonate with a haemoglobin of 50 g/L at birth due to a large fetomaternal haemorrhage; the main features are the marked polychromasia, large numbers of nucleated red cells and normal red cell morphology. (b) Kleihauer test showing HbA-containing maternal 'ghost' cells and pink-staining HbF-containing fetal cells.

Anaemia of prematurity

The normal fall in haemoglobin in preterm neonates has been termed 'physiological anaemia of prematurity', as it does not appear to be associated with any abnormalities in the baby. The pathogenesis is not fully elucidated, but contributory factors include the reduced lifespan of fetal erythrocytes, the relatively low erythropoietin concentration, the rapid growth rate and iatrogenic blood loss. Routine supplementation of preterm neonates with folic acid and iron means that nutritional deficiency rarely plays a role. The diagnosis is usually straightforward: a well-preterm baby with a slowly falling haemoglobin, unremarkable blood film showing normochromic/normocytic red cells, slightly low reticulocytes (20×10^9/L) and no nucleated red cells.

Management of anaemia of prematurity and the role of erythropoietin

The severity of anaemia of prematurity and thereby the need for red cell transfusion can be reduced by: (i) limiting iatrogenic blood loss by appropriate use of blood tests, (ii) administering iron and folate supplements to all preterm infants (iron 3 mg/kg daily from 4–6 weeks of age or iron-fortified formula with 0.5–0.9 mg/dL of iron and folic acid 50 µg daily or 500 µg once weekly) and (iii) judicious use of erythropoietin. The many controlled trials of recombinant erythropoietin for prevention of neonatal anaemia have been reviewed extensively. Erythropoietin reduces the number of transfusions in relatively well infants with low transfusion requirements, but not in sick preterm infants who have a need for frequent phlebotomy and multiple transfusions. The main roles for recombinant erythropoietin in neonates are in ameliorating the anaemia in infants who have received intrauterine transfusions for alloantibody-mediated anaemia and in preterm babies of Jehovah's Witnesses. The usual dose is 300 µg/kg of epoetin-β by subcutaneous injection three times per week, starting in the first week of life, together with oral iron supplements.

Indications for red cell transfusion in neonatal anaemia

The BSH guidelines for transfusion of fetuses, neonates and older children contain recommendations about the products and indications for red cell transfusion in neonates. These are consensus guidelines and need to be adapted for use in each individual neonatal intensive care unit, depending on the case mix of babies, as adherence to strict neonatal transfusion guidelines reduces both the number of transfusions and donor exposure.

A simple diagnostic approach to neonatal anaemia

Red cell disorders associated with neonatal or fetal anaemia present in three main ways: with a low haemoglobin, with jaundice due to haemolysis or with hydrops. A diagnostic algorithm to help identify which of these causes is most likely, which can be excluded and what further investigations are most appropriate is shown in Figure 54.2.

Neonatal polycythaemia

For both term and preterm infants, polycythaemia can be defined as a central venous haematocrit of greater than 0.65, as there is an exponential rise in blood viscosity above this level. However, even at haematocrits greater than 0.70, only a minority of neonates have clinical signs of hyperviscosity, such as lethargy, hypotonia, hyperbilirubinaemia and hypoglycaemia. Causes of polycythaemia are shown in Table 54.3. Treatment is controversial and is not necessary for infants with very minor

Table 54.3 Causes of neonatal polycythaemia.

- Intrauterine growth restriction
- Maternal hypertension
- Maternal diabetes
- Chromosomal disorders: trisomy 21, 18 or 13
- Twin–twin transfusion
- Delayed clamping of the cord
- Endocrine disorders: thyrotoxicosis, congenital adrenal hyperplasia

symptoms (e.g. borderline hypoglycaemia or poor peripheral perfusion). Infants with neurological signs and a haematocrit greater than 0.65 should have a partial exchange transfusion (using a crystalloid solution such as normal saline) to reduce the haematocrit to 0.55.

White cell disorders

Normal values

In the neonate, normal values for leucocytes, particularly neutrophils, are affected by a number of factors including gestational age, postnatal age, antenatal history, perinatal history and ethnic origin. Neutrophil counts in healthy babies increase for the first 12 hours and then fall to a nadir at 4 days of age. The neutrophil count is higher in capillary samples and after vigorous crying; it is lower in neonates of African origin. Healthy preterm babies often have circulating myeloblasts and lymphoblasts, although these usually form less than 5% of the white cell differential count.

Neutropenia

A pragmatic approach is to consider a neutrophil count at birth of less than 2×10^9/L as abnormal and worth monitoring, and a neutrophil count during the first month of life of less than 0.7×10^9/L as significant enough to merit further investigation.

Causes of neutropenia

The commonest cause of neutropenia at birth in preterm neonates is reduced neutrophil production, secondary to intrauterine growth restriction or maternal hypertension. Most affected neonates also have thrombocytopenia and increased erythropoiesis (polycythaemia and/or increased circulating nucleated red cells). The underlying mechanism for these haematological abnormalities is chronic fetal hypoxia. The neutropenia resolves spontaneously usually within a few days of birth and does not persist beyond the first 2 weeks of life. The commonest cause of neutropenia in term infants is bacterial or viral infection. Infection-associated neutropenia is also self-limiting and therefore persistent neutropenia in a term or preterm baby should always be investigated. Other important causes of neutropenia are alloimmune neutropenia and severe congenital neutropenia (SCN) due to failure of neutrophil production (e.g. Kostmann syndrome), both of which predispose to severe neonatal infection.

Alloimmune neutropenia

This is the neutrophil equivalent of haemolytic disease of the newborn and alloimmune thrombocytopenia. Alloimmune neutropenia occurs when fetal neutrophils express paternally derived neutrophil-specific antigens absent on maternal neutrophils and against which the mother produces IgG neutrophil alloantibodies. The causative antibodies are usually anti-HNA1 or -HNA2. Severe cases present in the first few days of life with fever and infections of the respiratory tract, urinary tract and skin, particularly due to *Staphylococcus aureus*, and the mainstay of treatment is antibiotics. The diagnosis is made by demonstrating antineutrophil antibodies in the mother and baby, which react against paternal, but not maternal, neutrophil antigens. The neutropenia is self-limiting, usually resolving within 1–2 months. Since alloimmune neonatal neutropenia in everyday clinical practice is very uncommon, and yet case series show that it affects 3% of all deliveries, it is likely that most milder cases are missed as they do not present with clinical problems and routine full blood counts are not performed on well babies.

Congenital and inherited neonatal neutropenias

Although rare, it is important to identify SCN in the neonatal period, since such babies are at risk of life-threatening infection from birth. Investigations are indicated where neutropeneutropenia persists beyond the first 2 weeks of life, despite resolution of infection, if there is a relevant family history or consanguinity, if the neutropenia is severe ($< 0.5 \times 10^9$/L) or if the baby has typical dysmorphic features (e.g. thumb/radial abnormalities in Fanconi anaemia). SCN is the most likely cause in the neonatal period. Infants usually present with severe infections and a marked neutropenia ($<0.2 \times 10^9$/L), often with a compensatory monocytosis. The diagnosis is made by the severity of the neutropenia, the bone marrow appearance (arrest of differentiation at the myelocyte/promyelocyte stage) and the absence of antineutrophil antibodies. The inheritance of SCN can be autosomal recessive or dominant or X-linked. The molecular basis of most cases is increasingly being identified both through classical linkage studies and gene discovery approaches. The causative genes are important for normal myeloid homeostasis, including neutrophil differentiation, survival and function. Mutations in *ELA2* (neutrophil elastase) are the most common cause of SCN, but other causes include mutations in *GFI1* (growth factor-independent protein 1), *WAS* (Wiskott–Aldrich syndrome protein, WASp), *JAGN1* and several genes affecting the endosomal–lysosomal system, such as *AP3B1, LAMTOR2, VPS13B* and *VPS45*. In 2007 biallelic mutations in the *HAX1* gene were found to explain the SCN in

the original Kostmann family first described in 1956, but this appears to be a rare cause of the disease.

Congenital leukaemias

Congenital leukaemia is rare, affecting ~5 neonates/per million live births. The most common form of congenital leukaemia is the transient leukaemia seen in neonates with Down syndrome, up to 10% of which will be affected. In children without Down syndrome, the majority of congenital leukaemias are associated with rearrangement of the *MLL* gene and manifest as acute lymphoblastic leukaemia (ALL) in 60% of cases and acute myeloid leukaemia (AML, typically monoblastic) in the remaining 40%.

Leukaemia in neonates with Down syndrome

Around 5–10% of neonates with Down syndrome have a transient megakaryoblastic leukaemia, also known as transient abnormal myelopoiesis (TAM) or transient myeloproliferative disorder (TMD), characterised by leucocytosis and circulating blast cells (Figure 54.10). TAM develops in fetal life and nearly always presents in the first week of life. Most cases spontaneously resolve within 2–3 months and no treatment is indicated. In severe cases, (10–20%) neonates develop progressive disease within days or weeks of birth due to blast cell infiltration of the liver in association with liver fibrosis. In such cases pleural/pericardial effusions, ascites, hepatomegaly, liver dysfunction and coagulopathy are common and treatment with low-dose cytosine arabinoside is often successful. TAM is unique to neonates with Down syndrome and is now known to be caused by the effects of acquired mutations in the haemopoietic transcription factor gene *GATA1* in fetal liver haemopoietic cells. Acquired *GATA1* mutations are now known to affect almost 30% of all neonates with Down syndrome, but only half of these will manifest with clinical or haematological signs; the remaining cases are clinically silent because the mutant *GATA1* clones are very small. In most cases, the mutant *GATA1* clones disappear over the first few months of life, as all signs of TAM disappear. In up to 10% of neonates with Down syndrome who have TAM or silent *GATA1* mutations, an acute megakaryoblastic leukaemia (DS-AMKL) develops before the age of 5 years, usually between 12 and 18 months of age. In these cases, the TAM usually appears to resolve, but this is followed several months later by myelodysplasia, which subsequently evolves to acute leukaemia. DS-AMKL, unlike TAM, is not transient and must be treated with chemotherapy when the outcome is usually very good, with 80–90% long-term survival. Since the same *GATA1* mutations are present both in TAM and DS-AMKL, this indicates that the leukaemia arises from a mutant *GATA1* clone present at birth. Mutations in the cohesin complex genes have been shown in several studies to be the most common mechanism responsible for transformation of TAM to DS-AMKL.

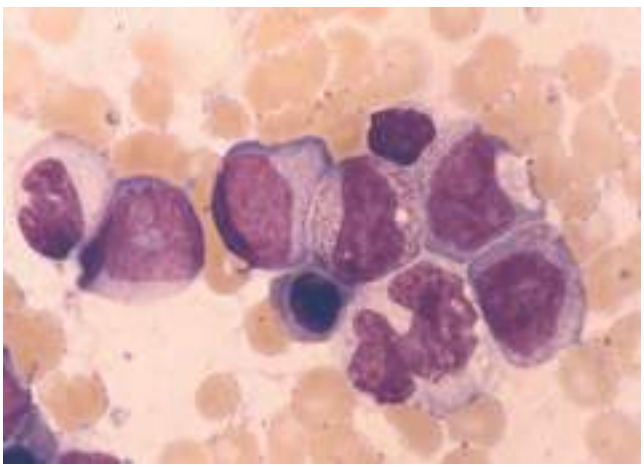


Figure 54.10 Transient leukaemia in a neonate with Down syndrome. Leucoerythoblastic blood film showing increased numbers of blast cells, which spontaneously returned to normal by 2 months of age.

Leukaemia in children without Down syndrome

Affected babies present, often within hours of birth, with signs of anaemia, thrombocytopenia and/or skin lesions caused by leukaemic infiltration. Congenital leukaemia with nodular skin deposits of leukaemic cells is one cause of the classical 'blueberry muffin' rash in a newborn baby. Some cases present *in utero* with intrauterine death or hydrops. CNS leukaemia in a neonate may present as a bulging fontanelle. The blood film and bone marrow aspirate show large numbers of primitive blast cells. The most common cytogenetic abnormalities are translocations involving 11q23 resulting in rearrangement of the *MLL* gene and t(1;22), which is associated with the *OTT::MAL* fusion gene and an aggressive form of acute megakaryoblastic leukaemia. The prognosis is extremely poor (~20% long-term survival); few are cured by chemotherapy and bone marrow transplantation may be the best option.

Haemostasis and thrombosis in the newborn

Bleeding and thrombotic problems are relatively common in neonates, particularly in those who are preterm and/or sick. The vast majority of bleeding problems are acquired and secondary to perinatal complications, including perinatal asphyxia and severe infection. Inherited bleeding disorders, with the exception of haemophilia A and B, are rare in the newborn. By contrast, there has been a marked increase in the identification of inherited thrombophilias in neonates and the most challenging aspect of this has been understanding their significance, both for management of the neonate and for genetic counselling.

Developmental haemostasis

Coagulation proteins are present at measurable levels from the 10th week of gestation and gradually rise during fetal life. They do not cross the placenta, or do so in very small amounts, and therefore need to be independently synthesised by the fetus. 'Normal values' in the neonate vary not only with gestational age, but also with postnatal age. Data for babies at less than 30 weeks' gestation derive from fetoscopy samples: levels of the vitamin-K-dependent factors (FII, FVII, FIX and FX) and of FXI and FXII are all low (<40% of adult values) and remain so during the first month of life. In contrast, even in preterm babies (>30 weeks gestation at birth), levels of FV, FXIII and fibrinogen are normal at birth and levels of FVIII and von Willebrand factor (VWF) are normal or increased.

Platelet counts at birth in term and preterm neonates are within the normal adult range. However, increasing evidence points to significant differences in platelet production during fetal life. Fetal megakaryocytes are smaller and of lower ploidy despite being more proliferative in *ex-vivo* cultures than adult megakaryocytes and are more sensitive to thrombopoietin. Interestingly, in response to consumptive thrombocytopenia, neonates increase the number of megakaryocytes rather than megakaryocyte size consistent with fundamental differences in regulation of platelet production in the fetus and newborn compared to later in life. These differences may help to explain why many studies have found impaired *in vitro* function of neonatal platelets. The most consistent abnormalities are reduced aggregation in response to adrenaline, ADP and thrombin. Their significance in clinical practice is still not clear, as the bleeding time is normal in term and preterm infants (≤135 s).

Screening tests for bleeding disorders

Nearly all significant bleeding disorders in neonates can be identified using simple screening tests; exceptions are FXIII deficiency and platelet function disorders. It is often helpful to test both parents for coagulation abnormalities to help identify inherited disorders as there is considerable overlap between coagulation factor levels in inherited or acquired deficiency states and neonatal normal ranges, particularly in preterm neonates. In addition, it is advisable to repeat investigations for the levels of coagulation factors at the age of 6–12 months to confirm (or exclude) inherited deficiencies. The most useful screening tests in neonates are the prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT), fibrinogen and platelet count. Bleeding times are generally unhelpful in neonates and investigation of platelet function abnormalities is often deferred until a few months of age when platelet aggregometry becomes practical.

Inherited coagulation disorders

The commonest inherited disorders presenting in the neonatal period are FVIII deficiency (haemophilia A), which has a frequency of 1 in 5000 male births, and FIX deficiency (haemophilia B), which occurs in 1 in 30,000 male births.

Factor VIII deficiency

Almost 40% of patients with inherited FVIII deficiency present in the neonatal period. The clinical signs include intracranial haemorrhage, cephalohaematomas and bleeding after circumcision or from venous or arterial puncture sites. As in adults, the diagnosis is made by finding an isolated prolonged APTT and reduced FVIII clotting activity. Acute management of the bleeding neonate with haemophilia requires intravenous administration of recombinant FVIII (50–100 units/kg twice daily) to achieve FVIII levels of 1.0 unit/mL. As the half-life of FVIII is shorter than in adults, more frequent dosing or a continuous FVIII infusion may be required. For neonates with intracranial bleeding, treatment with FVIII should continue for at least 2 weeks. Fibrin glue may be useful in circumcision-associated bleeds. The optimal mode of delivery for carriers known to be carrying an affected child or at risk of carrying an affected child remains controversial. However, there is general agreement that instrumental delivery, fetal blood sampling and use of fetal scalp electrodes should be avoided. Where available, non-invasive prenatal testing of cell-free fetal DNA in maternal serum is sometimes used for sex determination while late amniocentesis can be used to identify unaffected fetuses where delivery can safely proceed without intervention. The role of prophylactic FVIII administration to affected newborns following difficult delivery to reduce the risk of intracranial bleeding (1–4%) is controversial but is increasingly used. Prophylactic FVIII should also be used for an affected newborn when a previous sibling has had a major intracranial bleed.

Factor IX deficiency

Deficiency of FIX is clinically indistinguishable from FVIII deficiency. As FIX levels are also low in liver disease and vitamin K deficiency, it is important to recheck FIX levels at 6 weeks and 6 months of age if the diagnosis is in doubt. Neonates with bleeding are treated with recombinant FIX concentrate (100 units/kg IV once daily, monitored to achieve a FIX level of 1.0 IU/mL).

von Willebrand disease in neonates

The two forms of von Willebrand disease (VWD) that can present in neonates are type 2B vWD and type 3 VWD. Type 2B disease presents with thrombocytopenia and bleeding and is very uncommon. Type 3 vWD has a clinical phenotype similar

to haemophilia, as levels of both VWF and FVIII are low. The inheritance in type 3 vWD is autosomal recessive. The diagnosis is made by measuring VWF, FVIII and the pattern of VWF multimers. At present, type 3 vWD is treated with a high-purity VWF:FVIII concentrate (such as Wilate®).

Factor XIII deficiency

This rare autosomal recessive disorder usually presents with delayed bleeding from the umbilical cord during the first 3 weeks of life. The diagnosis is made by measuring clot solubility in 5 mol/L urea solution as a screening test, followed by a specific FXIII assay. Molecular tests for the common FXIII mutations are also available. The routine diagnostic coagulation screen is normal in Factor XIII deficiency. Bleeding is treated with FXIII concentrate.

Acquired disorders of coagulation

Causes of acquired coagulopathy in neonates include vitamin K deficiency, DIC, liver disease, metabolic disorders, extracorporeal membrane oxygenation (ECMO) and giant haemangioendotheliomas (Kasabach–Merritt syndrome).

Vitamin K deficiency

Levels of vitamin-K-dependent procoagulant factors (FII, FVII, FIX and FX), protein C and protein S are low at birth because of poor placental transfer of vitamin K, low vitamin K stores at birth, low vitamin K in breast milk and the lack of bacterial vitamin K synthesis in the sterile neonatal gut. Vitamin K deficiency can lead to haemorrhagic disease of the newborn, also known as vitamin K deficiency bleeding (VKDB). Early VKDB presents in the first 24 hours of life with severe gastrointestinal and intracranial haemorrhage. It is usually due to maternal medication that interferes with vitamin K, for example, anticonvulsants (phenobarbital, phenytoin), antituberculous therapy or oral anticoagulants. Classical VKDB presents at 2–7 days in 0.25–1.7% of babies who have not received prophylactic vitamin K at birth, especially if breastfed or with poor oral intake. Late VKDB occurs between 2 and 8 weeks after birth and presents with sudden intracranial haemorrhage in an otherwise well, breastfed term baby or in babies with liver disease.

The diagnosis of VKDB is usually made by an isolated prolonged PT, which corrects following vitamin K administration. If doubt remains, assays of the inactive form of FII (decarboxyprothrombin; PIVKA II) can be used to confirm the diagnosis. Treatment of VKDB is vitamin K 1 mg intravenously or subcutaneously with fresh-frozen plasma only in severe haemorrhage. Classic and late VKDB can be prevented by a single intramuscular dose of vitamin K or, slightly less effectively, by weekly 1-mg oral doses of vitamin K over the first 12 weeks of life (in exclusively breast-fed infants neither single oral dose of vitamin K nor daily very low-dose vitamin K 25 μg are effective in preventing classic VKDB). Some studies, but not others, suggest a link between intramuscular vitamin K at birth and later childhood malignancies. In healthy babies, the choice of which route of administration is increasingly being left to parents. However, infants of mothers taking drugs that inhibit vitamin K (e.g. warfarin) are at risk of early VKDB and these babies should receive intramuscular vitamin K 1 mg as soon as possible after birth.

Disseminated intravascular coagulation

The main triggers of DIC in neonates are severe hypoxia and/or acidosis and sepsis. The main causes are DIC secondary to acute perinatal hypoxia (for example in association with placental abruption or a large, acute fetomaternal haemorrhage), severe sepsis and necrotising enterocolitis. DIC may also be seen secondary to perinatal Coxsackie virus infection. Neonates with DIC are nearly always very sick and the clinical signs include generalised bleeding, pulmonary haemorrhage and oozing from venepuncture sites. The usual pattern of coagulation abnormalities in neonatal DIC is prolongation of the PT, APTT and TT, together with low platelets and fibrinogen. D-dimers are increased, but are not specific and can be found in healthy neonates with no evidence of coagulopathy. The most important aspect of management of DIC is treatment of the underlying cause. Blood product replacement is indicated for clinical bleeding, aiming to maintain the platelet count above 30×10^9/L, normalisation of PT and APTT and fibrinogen greater than 1 g/L.

Neonatal thrombocytopenia

Thrombocytopenia occurs in 1–5% of all neonates and in up to 50% of neonates who are preterm and sick. It usually presents in one of two clinical patterns: early onset thrombocytopenia (within 72 hours of birth) and late-onset thrombocytopenia (after 72 hours of life) (Table 54.4). The most frequent causes of early thrombocytopenia in preterm infants are intrauterine growth restriction and maternal hypertension or diabetes; the most frequent causes in term infants are neonatal alloimmune thrombocytopenia (NAIT) and thrombocytopenia secondary to maternal immune thrombocytopenic purpura (ITP). The most common causes of late thrombocytopenia are sepsis and necrotising enterocolitis.

Neonatal alloimmune thrombocytopenia

NAIT is the platelet equivalent of haemolytic disease of the newborn and affects around 1 in 1000 pregnancies. It is frequently severe (platelet count $<30 \times 10^9$/L) and occurs in the first pregnancy in almost 50% of cases. Thrombocytopenia results from transplacental passage of maternal platelet-specific antibodies to human platelet antigens (HPA), which the mother lacks, but

Table 54.4 Causes of neonatal thrombocytopenia.

Early onset (<72 hours)
- Placental insufficiency (PET, IUGR, diabetes)
- Neonatal alloimmune thrombocytopenia
- Birth asphyxia
- Perinatal infection (group B *Streptococcus*, *Escherichia coli*, *Listeria*)
- Congenital infection (CMV, toxoplasmosis, rubella, Coxsackie)
- Maternal autoimmune (ITP, SLE)
- Severe Rh- antigen associated HDN
- Thrombosis (renal vein, aortic)
- Aneuploidy (trisomy 21, 18, 13)
- Congenital/inherited (TAR, Wiskott–Aldrich)

Late onset (>72 hours)
- Late-onset sepsis and necrotising enterocolitis
- Congenital infection (CMV, toxoplasmosis, rubella)
- Maternal autoimmune (ITP, SLE)
- Congenital/inherited (TAR, Wiskott–Aldrich)

CMV, cytomegalovirus; HDN, haemolytic disease of the newborn; ITP, idiopathic thrombocytopenic purpura; IUGR, intrauterine growth restriction; PET, pre-eclampsia; SLE, systemic lupus erythematosus; TAR, thrombocytopenia with absent radii.

which the fetus inherits from the father. In 80% of cases amongst Caucasian women in whom antibodies are detectable, these are anti-HPA-1a antibodies and in 10–15% anti-HPA-5b; occasional cases are due to anti-HPA-3a. HLA-DRB3* 0101-positive women are 140 times more likely to make anti-HPA-1a than HLA-DRB3* 0101-negative women. Intracranial haemorrhage occurs in 10% of cases, with long-term neurodevelopmental sequelae in 20% of survivors. The diagnosis is made by demonstrating platelet antigen incompatibility between mother and baby and anti-HPA antibodies in the mother. Where possible the neonate and both parents should have platelet genotyping performed to determine their HPA alloantigen status: HPA-1a, -2, -3, -5b and -15 are the most common genotypes in Caucasian women and account for 95% cases while NAIT due to HPA-4b, 6b and 21b is more common in Asian families. Where a clinical diagnosis of NAIT is made and no antibodies or maternal–neonatal platelet incompatibility to the most common HPA antigens has been excluded, it is not usually possible to identify the causal platelet antigen. Very few of these unexplained cases are due to antibodies against minor HPA (such as HPA-6w and HPA-9w) and, therefore, most groups currently do not routinely screen for these very low-frequency HPA antigens, except in selected severe cases.

Management of NAIT

Management depends on the gestation and postnatal age of the baby, the history of previously affected siblings, the platelet count and the extent of any bleeding. All neonates suspected to have NAIT should have a cranial ultrasound scan to exclude the presence of an ICH. Since the platelet count usually falls over the first 4–7 days of life, all thrombocytopenic neonates with NAIT should be monitored until there is a sustained rise in their platelet count into the normal range. Platelet transfusion is not indicated in a term neonate with platelet counts $>30 \times 10^9$/L who has no evidence of bleeding. Transfusion with HPA-compatible (usually HPA1a, 5b-negative) platelets is recommended for:
- platelet counts below 30×10^9/L in term neonates who have no evidence of bleeding;
- platelet counts below 50×10^9/L and an ICH and/or a previously affected sibling with an ICH and/or birthweight < 1000 g.

Neonates who have received intrauterine platelet transfusions should be given irradiated platelets to prevent transfusion-associated graft-versus-host disease. In some cases, thrombocytopenia may persist for up to 8–12 weeks. In such cases, intravenous IgG (total dose 2 g/kg, over 2–5 days) may be useful to reduce the need for repeated platelet transfusions. Antenatal management of NAIT depends on the severity of previously affected neonates, the HPA genotype of the father and on the HPA antibody specificity. Most centres have abandoned the invasive approaches based on fetal blood sampling plus fetal transfusion with HPA-compatible platelets as this carries a risk of preterm delivery and fetal death. Instead, most centres now use a non-invasive approach relying on maternal intravenous IgG therapy during the second half of the pregnancy.

Neonatal autoimmune thrombocytopenia

The majority of cases are secondary to transplacental passage of maternal platelet autoantibodies in maternal ITP, which affects 1–2 in 1000 pregnancies. Most of the remaining cases are secondary to maternal systemic lupus erythematosus (SLE) although neonatal Kawasaki disease has also been reported. Around 10% of infants develop thrombocytopenia, of which around half will develop platelets $<20 \times 10^9$/L. The risk of major haemorrhage, including ICH, is estimated at ~1%. In babies with severe thrombocytopenia, intravenous IgG (400 mg/kg/day given over 2–4 hours for 5 days or 1 g/kg/day for 2 days, total dose 2 g/kg) is usually effective. In some cases, neonatal thrombocytopenia is prolonged and may last up to 12 weeks before spontaneously resolving.

Indications for platelet transfusion

A number of countries have published consensus guidelines to help decide the indications for platelet transfusion in term and preterm neonates. In general, platelet transfusion is not considered necessary in well babies if the platelet count is above $20–30 \times 10^9$/L. Most groups agree that the threshold for transfusing sick babies, particularly preterm babies in the first few weeks of life, should be higher ($30–50 \times 10^9$/L).

Neonatal thrombosis: physiology and developmental aspects

Neonates have an increased risk of thrombosis (2.4 per 1000 hospital admissions) compared with older infants and children. This is largely due to the physiologically low levels of many of the inhibitors of coagulation and the frequent use of indwelling vascular catheters. Concentrations of antithrombin, heparin cofactor II and protein C at birth are 30–50% of adult values; protein S levels are also low, but overall protein S activity is normal as it exists mainly in its free active form due to the virtual absence of its binding protein (C4b-BP) in neonates. Levels of plasminogen at birth are only 50% of adult values so neonates have a reduced ability to generate plasmin in response to fibrinolytic agents.

Screening tests for thrombophilia in neonates

The only inherited deficiencies for which there is a proven role in neonatal thrombosis are deficiencies in proteins C and S, which cause purpura fulminans, and deficiency of antithrombin, although presentation in the neonatal period is extremely rare. FV Leiden and the prothrombin 20210A promoter mutation (prothrombin^{20210A}) have not yet been reported to cause neonatal thrombotic problems in isolation. The role of thrombophilia screening in neonates is controversial, since the significance of any findings remains very difficult to assess, particularly since the risk of recurrence of thrombosis after an episode in the neonatal period is very low (~3%). Guidelines from the Haemostasis and Thrombosis Task Force of the British Society for Haematology state that congenital thrombophilia should be considered and screened for in any child with:

- clinically significant thrombosis, including spontaneous thrombotic events, unanticipated or extensive venous thrombosis, ischaemic skin lesions or purpura fulminans and
- a positive family history of neonatal purpura fulminans

The screening tests that should be performed in all suspected cases of thrombophilia include protein C activity, protein S, antithrombin, FV Leiden and prothrombin ^{20210A}. In addition, babies with thrombosis born to mothers with SLE and/or antiphospholipid syndrome should be tested for lupus anticoagulant, as antiphospholipid antibodies may cross the placenta and are a rare cause of neonatal thrombosis in such babies. The relevance of serum liporotein a and the MTHFR genotype to neonatal management is unclear at present.

Inherited thrombotic disorders in neonates

Proteins C and S deficiency

Protein C deficiency occurs in 1 in 160,000–360,000 births. Affected babies usually present within hours or days of birth with purpura fulminans, in which there is DIC and rapidly progressive life-threatening haemorrhagic necrosis due to dermal vessel thrombosis or cerebral, renal vein or ophthalmic thrombosis. The diagnosis of protein C deficiency is made by the clinical picture and undetectable levels of protein C (<0.01 U/mL) in the patient, together with heterozygote levels in the parents. Protein-C-deficient heterozygotes rarely present as neonates and have low protein C levels, which may overlap with the lower limit of normal in the first few months of life, delaying diagnosis until 6 months or later. Treatment is with protein C concentrate (40 U/kg, aiming to maintain a plasma level >0.25 U/mL). Protein S deficiency presents with identical features; levels of protein S are undetectable (<0.01 U/mL) and treatment is with fresh-frozen plasma (10–20 mL/kg) to maintain a plasma protein S in excess of 0.25 U/mL. The rarity of thrombosis in neonates with protein S deficiency may in part reflect the relatively high level of active protein S because of the undetectable levels of C4b-binding protein. Patients are usually managed in specialised haemophilia centres and confirmatory genetic diagnosis by next-generation sequencing is increasingly being performed in these rare conditions.

Antithrombin deficiency

Homozygous antithrombin deficiency usually presents later in childhood, but neonatal deep venous thrombosis and inferior vena cava thrombosis have been reported. Heterozygous antithrombin deficiency is more common (1 in 2000–5000 births); it usually presents in the second decade of life, but neonatal presentation with aortic thrombosis, myocardial infarction and cerebral dural sinus thrombosis may occur.

Acquired thrombotic problems in neonates

The most common risk factors for neonatal thrombosis are the presence of an intravascular catheter and shock, secondary to sepsis, hypoxaemia or hypovolaemia. Maternal factors, such as maternal thrombophilia, alcohol and cocaine use and preeclampsia, may also increase the risk of neonatal thrombosis. Thrombosis particularly affects the renal veins, the aorta, aortic arch or cerebral vessels. Catheter-related thrombosis causes more than 80% of venous thromboses and more than 90% of arterial thromboses. The diagnosis is made by Doppler ultrasound or contrast angiography. Treatment of catheter-related thrombosis depends on the severity and extent of thrombosis. The first step is prompt removal, where possible. If signs progress despite catheter removal, unfractionated heparin or low-molecular-weight heparin should be started using a dosing regimen adapted for neonates. Thrombolytic therapy with urokinase or tissue plasminogen activator has been used successfully for catheter-related thrombosis in neonates, but experience in preterm neonates is very limited. It is important to maintain fibrinogen at levels greater than 1 g/L and the platelet count greater than 50×10^9/L in neonates receiving thrombolytic therapy, and heparin (starting dose 28 U/kg per hour) is often given to maintain vessel patency after thrombolytic therapy, although

there is no evidence that this is beneficial. Excellent guidelines for antithrombotic therapy in neonates are regularly updated by the American College of Chest Physicians.

CHAPTER 55

Supportive care in the management of leukaemia

55

Renuka Palanicawandar and Jiří Pavlů

Centre for Haematology, Imperial College London at Hammersmith Hospital, London, UK

Introduction

Supportive care significantly contributes to the success of therapy for leukaemia and other haematological malignancies. It is defined as a broad range of interventions that ameliorate the symptoms of a disease, the side effects of treatment, whilst also addressing psychological, cultural, social and spiritual factors. Traditionally, the main focus was reactive on restoring health (rehabilitation) but increasing the focus is on prevention and preparation for therapy (prehabilitation) to subsequently allow swifter post-treatment recovery.

For purpose of this chapter, we divide supportive care into:

- Psychological, social and financial aspects
- Reproductive aspects
- Blood count abnormalities
- Skin, nail, dental, auditory and visual complications
- Infections
- Metabolic complications
- Nutrition and physiotherapy
- Chemotherapy-induced nausea and vomiting (CINV)
- Pain control and palliation.

Psychological, social and financial aspects

Optimal healthcare for leukaemia involves active consideration of the psychological factors that can affect clinical outcomes, patient experience of care and quality of life.

It is important to evaluate and target psychological factors that can affect safe and optimal treatment. Psychological factors such as self-efficacy, health beliefs, health-related trust and trauma, are systematically related to the self-management behaviour that is required of patients – e.g. medication adherence, timely reporting of symptoms, engagement in rehabilitation, etc. Current advances in outpatient treatment pathways (e.g. ambulatory haematopoietic stem cell transplants) require psychological expertise in evaluating individual capabilities and risks, and stratifying care and pathways accordingly.

In relation to patient experience and quality of life, the aims of comprehensive healthcare are to prevent distress, provide personalised support and promote psychological adjustment.

The term 'psychological adjustment' refers to the continuous, iterative process of adaptation that is taking place psychologically as people move through the 'journey' of cancer diagnosis and treatment. The pre-existing 'mental models' that the person enters into this process with (for instance, assumptions about independence, control, physical integrity and an open future) will be challenged by a multitude of intense and unpredictable physical and psychosocial experiences. Coping with and processing these adversities and re-constituting one's 'mental models' to fit new realities, will involve periods of distress as well as new personal growth, starting at diagnosis and extending for a lifetime.

As part of the process, it is common and normal for patients to experience periods of heightened distress. While these are often described loosely as 'anxiety' or 'low mood', it is important

Hoffbrand's Postgraduate Haematology, Eighth Edition. Edited by Adam J Mead, Michael A Laffan, Graham P Collins, Deborah Hay, and A Victor Hoffbrand (Consulting Editor).

Companion website: www.wiley.com/go/mead/HPH8e

not to unduly medicalise emotional reactions. Equally, it does mean that a 'universal' base level of psychosocial support is required for all patients. Within this, medical professionals hold a very important role in providing:

- compassionate and well-paced communication, that takes into account the person's state of mind and existing health beliefs when providing information.
- a reliable doctor–patient relationship, that respects the universal human need for 'safe attachment' to care and protection when vulnerable.
- active attention to the person's emotional responses and psychosocial context, and encouragement to engage with the necessary support resources.

As with any other clinical skill, these require explicit and active development, ideally through feedback and regular updates. Systematic screening for patient distress at key points, by using validated patient-reported measures (e.g. the Distress Thermometer and Concerns Checklist) is typically recommended. This can inform a 'supportive care plan' created collaboratively with the patient, which can encourage use of self-management resources (e.g. using a mobile app for guided stress-relief relaxation exercises, managing fatigue or improving sleep hygiene) and peer support resources (e.g. an online community or a creative group activity).

Where there is evidence of heightened distress and difficulties coping, an 'enhanced' level of support will be required to sustain the person through treatment and recovery. This involves active keyworking (e.g. by a nurse specialist or social worker) with more detailed exploration of psychosocial factors and needs (e.g. social support, work and financial stability, personal strengths and vulnerabilities) and provision of first-line psychological support (e.g. guidance to apply worry management coping skills).

Indications of pre-existing or newly symptomatic mental health difficulties (e.g. adjustment, mood or anxiety disorders, post-traumatic stress) or neurodevelopmental differences (e.g. autism, learning difficulties) require clinical assessment at a specialist level (e.g. clinical psychologists or liaison psychiatrists in psycho-oncology). The focus of intervention will be on the interactions between these difficulties and leukaemia treatment and recovery, and thus on-site participation in the haematology MDT is a requisite.

The compassionate and thoughtful care of people with leukaemia needs to be underpinned by equal attention to the wellbeing of healthcare staff. Combined with high workload demands, the long-term emotional labour, exposure to suffering and loss, and risk of moral injury, can and do take their toll. The impact is not only on the individual (burnout and mental health disorders) but on teamwork and the organisational levels of culture, safety and efficiency. Processes to protect and promote the resilience of staff, such as described in the ABC framework (West and Coia 2019) need to be a central concern for medical leadership and intrinsic to modern healthcare environments.

Social support is a critical, yet under-utilised resource when undergoing cancer care. Under-utilisation occurs in two conditions: (i) when patients fail to seek out information, material assistance and emotional support from family and friends or (ii) when family and friends fail to meet the individualised needs and preferences of patients. Patient's supportive groups run by departments, hospitals, organisations or charities might provide major social support to patients and relatives.

Most cancer patients experience financial problems. This might be more relevant to patients with acute leukaemia, as profound immunosuppression and delayed immune reconstitution may result in prolonged absence from work with devastating financial losses. Therefore, governmental bodies, health boards, organisations and charities must do more to ensure people living with cancer are signposted to good-quality specialist and timely welfare benefits support to help them cope and manage the financial impact of their diagnosis.

Reproductive aspects

Fertility preservation is an emerging discipline. As survivorship increases, quality of life issues such as the ability to have a child become increasingly important. Assisted reproductive technologies are now available that are effective and rapidly available to patients facing potentially sterilising treatment.

Options for males

Cryopreservation of sperm is a technique that has been available for decades for men and post-pubertal boys. Semen is produced by masturbation, and now with the use of intra-cytoplasmic sperm injection, treatment is effective even when only very small concentrations of sperm are available. In prepubertal males, there have been attempts to surgically recover spermatogonial cells directly from the testes for subsequent autotransplantation. Although promising, this remains experimental (Gul *et al.* 2020).

Options for females

The mainstay of fertility preservation for post-pubertal females is egg cryopreservation (or embryo-cryopreservation for women with male partners). Rapid treatments starting at any time of the menstrual cycle using gonadotrophin-releasing hormone (GnRH) antagonists to control the pituitary gland and follicle-stimulating hormone stimulation to produce multiple eggs followed by egg collection and freezing allow treatments to

occur within 12 days. In certain situations, this short delay prior to chemotherapy or radiotherapy may be acceptable to clinicians and patients. Pregnancy results using frozen eggs and embryos are now nearly equivalent to those with fresh embryos (Human Fertilization and Embryology Authority 2016). These results remain constant and do not reduce as the patient ages. Although not ideal, there is some limited experience with patients having ovarian stimulation and egg collection post-chemotherapy. In many cases despite these advances, there remain concerns around any delay prior to oncology intervention. In these patients, laparoscopic ovarian cortex collection can be performed as an urgent day-case procedure. The ovarian cortical biopsies contain many hundreds of immature eggs. This tissue can then be cryopreserved with a view to either future auto-transplantation, or *in vitro* maturation to create embryos for transfer. There have now been several hundred pregnancies following auto-transplantation (both spontaneously and following *in vitro* fertilisation), but access to this approach remains limited (Centerport *et al.* 2019). It has also been used successfully in prepubertal girls. Careful analysis of transplanted tissue is critical to avoid transferring cancerous cells back into a cured patient.

The use of GnRH agonist treatment as an ovarian protectant during cryopreservation is widespread but the evidence to support this remains somewhat equivocal. For those patients who have no time to undergo fertility preservation of their own gametes, treatments utilising egg and sperm donation remain effective. In women who have had pelvic radiotherapy or hysterectomy, surrogacy can be considered. For many patients, the risk of sterility following cancer treatment can be difficult to quantify. Dealing with this uncertainty remains an important part of the fertility preservation consultation. Guiding principles of fertility preservation include counselling, rapid access to fertility clinics and if appropriate treatment, individualised advice and honest and realistic management of expectation.

Blood count abnormalities

Anaemia

Chemotherapeutic agents induce anaemia through directly impairing haemopoiesis, including synthesis of red blood cell (RBC) precursors, in the bone marrow. Nephrotoxic effects of particular cytotoxic agents (e.g. platinum-containing agents) may lead to anaemia through decreased renal production of erythropoietin. The malignancy itself can lead to or exacerbate anaemia through bone marrow infiltration or production of cytokines that lead to iron sequestration, which decreases RBC production and may even shorten their survival. Additional potential contributors include nutritional deficiencies and changes in coagulation capability.

There is no good evidence to support a particular red cell transfusion policy in leukaemia. Therefore, the decision to conduct RBC transfusion should not be made strictly based on whether the haemoglobin level has reached a certain threshold or 'trigger'. As a general rule, transfusion is rarely indicated when the Hb level is greater than 90 g/L. However, different transfusion thresholds should be adopted, having taken into consideration three general categories of patients: (i) asymptomatic without significant comorbidities, for which observation and periodic reevaluation are appropriate, (ii) asymptomatic with comorbidities or high risk, for which transfusion should be considered and (iii) symptomatic, for which patients should receive transfusion. Older age and the presence of pre-existing cardiovascular, pulmonary or cerebral vascular disease may compromise a patient's ability to tolerate anaemia.

Use of erythroid-stimulating agents (ESA)

RBC production is normally controlled by erythropoietin, a cytokine produced in the kidneys. First introduced in 1989, ESAs are a synthetic, recombinant human erythropoietin that can stimulate erythropoiesis in patients with low RBC levels. The use of ESA remains very common in patients treated by chemotherapy for solid tumours and lymphoid malignancies. The American Society of Haematology (ASH) and the American Society of Clinical Oncology (ASCO) recommend a strict benefit/risk evaluation by clinicians for its use compared with RBC transfusions.

Concerns about ESA use come from some evidence of worsened outcomes in patients with solid malignancies observed firstly in randomised trials and later in three meta-analyses of randomised controlled trials. However, this association has been refuted by two other meta-analyses reporting no significant effect of ESAs on mortality or progression. In addition, several recent pharmacovigilance trials reported no decrease in survival with ESA use in patients with chemotherapy-related anaemia.

In patients receiving chemotherapy for acute myeloid leukaemia or undergoing allogeneic haemopoietic cell transplantation, the use of ESAs has not been clearly assessed.

Special considerations

All patients in whom allogeneic transplantation may be considered should receive cytomegalovirus (CMV)-negative or leucodepleted products until their CMV status is known. Patients treated who received purine analogue-based chemotherapeutic regimens (i.e. FLAG) should be supported with irradiated blood products. There is no good evidence to support a particular transfusion policy in leukaemia (Table 55.1).

Table 55.1 Summary of blood product transfusion in patients with acute leukaemia.

Packed red cell transfusion
- Transfuse if haemoglobin <70 g/L. However, consider underlying cardiovascular compromise and raise the threshold of transfusion as appropriate.
- Delay transfusion if features of hyperviscosity.
- Assess risk factors for transfusion associate circulatory overload (TACO): age, cardiac failure, renal impairment, fluid overload, hypoalbuminaemia, low body weight. Diuresis may be required if deemed at risk of TACO.
- Patients on purine analogue (e.g. fludarabine, cladribine) should receive irradiated blood components lifelong.
- Patients receiving allogeneic haematopoietic cell transplantation should continue to receive irradiated blood component until all four criteria are met:
  1 >6 months have elapsed since the transplant date
  2 the lymphocyte count is $>1.0 \times 10^9$/L
  3 the patient is free of active chronic graft versus host disease
  4 the patient is off all immunosuppression.

  If chronic GvHD is present or continued immunosuppressive treatment is required, irradiated blood components should be given indefinitely.
- All patients undergoing autologous haematopoietic cell transplantation should receive irradiated cellular blood components from initiation of conditioning chemo/radiotherapy until 3 months post-transplant (6 months if total body irradiation was used in conditioning).
- Patients with a history of Hodgkin Lymphoma are currently recommended in the UK to receive irradiated blood products lifelong.

Platelet transfusion
- Give prophylactic platelet transfusions to patients receiving intensive chemotherapy or undergoing allogenic haematopoietic cell transplantation to maintain a platelet count at or above 10 x 10^9/L.
- Increase threshold to 20×10^9/L in patients who are febrile and /or receiving antimicrobial therapy for suspected bacterial or fungal infection.
- Do not give platelet transfusions routinely for bone marrow aspirate and trephine biopsy, peripherally inserted central catheters, or traction removal of tunnelled central venous catheters.
- Patients requiring lumbar puncture, central-line insertion, percutaneous organ biopsy and for most invasive surgeries aim platelet count $>50 \times 10^9$/L.
- ABO-matched platelets should be used when available to maximise increments.
- Patients with HLA antibodies should receive HLA-selected platelet transfusion.

Plasma transfusion
- ABO identical plasma-derived product should be used as the first choice.

Thrombocytopenia

Prophylactic platelet transfusion should be administered to patients with thrombocytopenia resulting from impaired bone marrow function to reduce the risk of bleeding when the platelet count falls below a predefined threshold level (Table 55.1). This threshold level for transfusion varies according to the patient's diagnosis, clinical condition and treatment modality. The optimal platelet dose has not been identified.

Several recent clinical trials have addressed the question of which peripheral blood platelet count should trigger prophylactic transfusions, i.e. transfusions given to patients with severe thrombocytopenia without clinical haemorrhage. The prophylactic strategy seems beneficial, and available clinical guidelines generally recommend prophylactic transfusions when the peripheral blood platelet count falls to 10×10^9/L. This recommendation is supported by four randomised clinical trials that showed no statistically significant difference between the compared groups with regard to mortality, remission rates of the malignant disease, frequency of severe haemorrhages or erythrocyte transfusion requirements when comparing 10×10^9/L with a higher threshold. The use of 10×10^9/L as the threshold is in addition supported by a retrospective study comparing 224 patients transfused at a threshold of 20 and 256 patients transfused at a threshold of 10; these two groups showed similar bleeding incidence and erythrocyte transfusion requirements.

Another trial suggested that a policy of giving platelet transfusions only as treatment for bleeding might become a new standard of care in selected patients. However, higher rates of grade 3 or 4 bleeding events were reported amongst patients with acute myeloid leukaemia who received no prophylaxis, as compared with those who did receive prophylaxis. On the basis of these findings, and the results of a study by Stanworth *et al.*, the use of prophylactic platelet transfusions appears to be important as the proportion of patients

who had bleeding events of WHO grade 2, 3, or 4 was reduced by 7% overall in the group that received prophylactic platelet transfusions.

Platelet preparations

Platelets for transfusion can be prepared either by separation of units of platelet concentrates from whole blood, which are pooled before administration, or by apheresis from single donors. Comparative studies have shown that the post-transfusion increments, haemostatic benefit and side-effects are similar with either product. Thus, in routine circumstances, they can be used interchangeably. In most centres, pooled platelet concentrates are less costly. Single-donor platelets from selected donors are preferred when histocompatible platelet transfusions are needed. Both preparations can be stored for up to 5 days after collection at 20–24 °C with good maintenance of platelet viability.

Thrombopoietin receptor agonists

Thrombopoietin mimetics, such as romiplostim and eltrombopag, have been developed to treat patients with refractory immune thrombocytopenia. Thrombopoietin is a potent endogenous cytokine that binds to its receptor (c-Mpl) on megakaryocyte progenitors and stimulates a number of signal transduction events promoting megakaryocyte proliferation and maturation, and platelet release. Recent studies have suggested that use of thrombopoietin mimetics can be of clinical value in the treatment of refractory severe aplastic anaemia. Multiple studies have been undertaken to explore the potential utility of eltrombopag in the treatment of thrombocytopenia in patients with AML or MDS. Given the platelet-increasing effects, the *in vitro* and *in vivo* antileukaemia effects and the potential to chelate excess iron in multiply transfused patients, the utility of eltrombopag in patients with AML and MDS is actively being explored as a dual thrombopoietic and antineoplastic agent in different types of cancer.

Neutropenia

Granulocyte transfusions

Small randomised controlled studies over the past 20 years have shown some efficacy in the use of granulocytes; however, most of the studies lack power and provide inconclusive evidence. The largest study so far (RING study) showed no benefit of granulocyte infusions in patients post chemotherapy and post haemopoietic cell transplantation however, the analysis suggested that patients receiving a high dose (more than 0.6×10^9/L) might benefit. As HLA alloimmunisation has been reported in 17% of patients, patients who are transplantation candidates should be re-tested after granulocyte transfusions to ensure the absence of HLA antibodies directed against the potential donor. This might be more relevant in recipients of haploidentical transplants.

Granulocyte colony-stimulating factor

Myelosuppression due to cytotoxic drugs is a major limiting factor in the treatment of leukaemia. Neutropenia places patients at a high risk of infections, septicaemia and ultimately death. Three prophylactic strategies that have garnered much attention are: prophylactic antibiotics with antibacterial and antifungal agents, prophylactic Granulocyte colony-stimulating factor (G-CSF) and hospitalisation during severe neutropenia.

Recombinant human G-CSF (filgrastim) was licensed in 1991 by the United States Food and Drug Administration (FDA) for use in patients undergoing cytotoxic treatment for decreasing the incidence of febrile neutropenia and reducing the duration of neutropenia and fever following myeloablative chemotherapy. Products with similar activity (filgrastim biosimilars) are now available. The efficacy of G-CSF administered during and/or after induction chemotherapy in patients with acute leukaemia has been examined in randomised, multicentre trials producing conflicting results. Results of a meta-analysis suggest that use of colony-stimulating factors in febrile neutropenia accelerates neutrophil recovery and reduces the duration of hospitalisation. Practical use of G-CSF was limited by relatively short duration of its effects (half-life 3–4 hours, often requiring daily administration. Attachment of polyethylene glycol (PEG) molecule to filgrastim extended its half-life allowing administration every 2 weeks. As G-CSF overstimulates myeloid precursors, it changes appearance of diagnostic bone marrow specimens which may sometimes complicate their interpretation.

Hyperleukocytosis and leukostasis

Hyperleukocytosis is usually defined as a white blood cell count over 100×10^9/L. Whereas in chronic lymphocytic leukaemia (CML), this is rarely symptomatic, in chronic myeloid malignancies, and particularly in acute leukaemia (both myeloid and lymphoblastic) hyperleukocytosis is associated with a number of clinical problems. These include organ failure and early death secondary to leukostasis, bleeding, sometimes due to disseminated intravascular coagulation, and tumour lysis syndrome (TLS). Many laboratory tests and some clinical tests became unreliable in presence of hyperleukocytosis.

Although hyperleukocytosis leads to significant increase in leukocrit (fractional volume of leucocytes), it does not normally lead to increased blood viscosity due to simultaneous decrease of haematocrit associated with bone marrow infiltration. However, blood passage through microcirculation is impaired, and this may be related to the cell size or more likely to the interactions between leukaemic cells and the endothelium, mediated by adhesion molecules. Clinical symptoms and some laboratory phenomena associated with hyperleukocytosis may therefore arise in patient with white blood cell counts as low as 50×10^9/L.

In CML, patients usually remain asymptomatic unless the white blood cell count exceeds 200×10^9/L and even then, symptoms are rare or subtle. Headaches and retinal haemorrhage are

relatively common, sometimes causing impaired vision. Priapism may occur in male patient. Pulmonary leukostasis is extremely rare in CML, even with very high white blood cell counts (above 500×10^9/L). On the other hand, in patients with acute leukaemia, particularly in acute monoblastic leukaemia, pulmonary manifestation (tachypnoea, dyspnoea and cough) may appear early and be the first presentation of leukaemia. Chest radiographs may show diffuse alveolar consolidation compatible with alveolar oedema, diffuse reticulonodular infiltrates compatible with the diagnosis of pneumonia or they can show normal chest findings. Renal leukostatis may lead to renal failure. Central nervous system manifestations reported in hyperleukocytic patients include visual blurring, dizziness, tinnitus, slurred speech, ataxia, confusion, somnolence and coma. Administration of diuretics for incorrect presumption of heart failure may worsen the symptoms. Patients with hyperleukocytosis are in a risk of brain haemorrhage. Respiratory failure and cerebral haemorrhage are the most common causes of death in these patients. In some patients, the hyperleukocytosis syndrome, particularly its pulmonary manifestations, does not develop until intensive chemotherapy is administered.

Management of patients is further complicated by a number of spurious or potentially spurious laboratory results. Measurement of arterial partial oxygen pressure is very unreliable as there is very rapid consumption of oxygen *in vitro* and even cooling of the blood sample on ice does not prevent a spuriously low result. Metabolic activity and fragility of blasts also cause spurious hyperkalemia and hypophosphataemia. Measured lactate levels are likely to be higher than *in vivo* and glucose levels lower. There is likely to be an overestimation of the haemoglobin concentration and of haematocrit. Platelet counts may be inaccurate.

Decisions about modality, intensity and urgency of treatment depend mainly on clinical symptoms and signs and the cytological type of leukaemia. There is no threshold absolute white blood cell count for the initiation of therapy. Supportive care with adequate hydration, oxygenation, correction of coagulation and administration of platelets is paramount. Increasing platelet transfusion threshold to 20 or 50×10^9/L seems appropriate. Leukapheresis should be considered if available as an initial treatment modality as it rapidly reduces signs and symptoms of hyperleukocytosis and reduces tumour mass, thus reducing the risk of TLS. As the mechanical removal of leucocytes have only a temporary effect, it should be followed by or coincide administration of chemotherapy. High doses of oral hydroxycarbamide may be preferred to urgent intensive intravenous chemotherapy as the latter is more likely to exacerbate symptoms of leukostasis and trigger TLS. In a retrospective study of 779 patients with AML (Stahl *et al.* 2020) who presented with a white blood cell count above 50×10^9/L clinical leukostasis was reported in 27%, and leukapheresis was used in 15%. Use of leukapheresis did not significantly impact 30-day mortality, achievement of remission or survival in multivariate analysis. Thirty-day mortality was 17%, median survival was 12.6 months amongst all patients, and 4.5 months amongst those ≥65 years. This very poor prognosis in older patients poses an ethical dilemma regarding appropriateness of intensive treatment in this clinical situation, especially as this often cannot be fully discussed with rapidly deteriorating patients.

Skin, nail, dental, auditory and visual complications

Skin

Skin reactions to drug therapy are extremely common. Chemotherapy drugs can cause dry skin, hyperpigmentation, discolouration, serpentine hyperpigmentation, photoallergic reactions and acne (mainly treatment with steroids). Radiation treatment can cause dry or red skin in the area being treated. Certain areas are more sensitive than others. Patients should be encouraged to use moisturising creams on a regular basis. They should protect their skin from the sun by wearing a hat and clothing that covers the arms and legs, and apply sunscreen with a sun protection factor of 30 or higher before going outside.

Nail changes include:

- Beau's lines (horizontal depressions of the nail plate). These skin reactions can occur a few weeks after a course of chemotherapy.
- Mee's lines (white horizontal discolouration of the nail plate involving the entire nail width).
- Leukonychia (white horizontal discolouration involving partial nail width).
- Onycholysis (separation or loosening of a fingernail or toenail from its nail bed).
- Onychodystrophy (malformation of the nail).

Nails should be trimmed and kept clean and gloves should be worn for house-cleaning. Occasionally antibiotics and antifungal agents might be necessary to treat underlying infections.

Radiation recall is a skin reaction that can occur when certain chemotherapy drugs are given after radiation therapy. It usually appears in the area of skin where the radiation was given. The skin becomes red and tender. It may peel or blister, resembling sunburn. Radiation recall may be treated with corticosteroids to lessen inflammation or chemotherapy may be delayed until the skin heals.

Dental problems

Dental care is very important. Leukaemia and chemotherapy can make the mouth sensitive, easily infected and likely to bleed. Patients should receive a complete dental examination and, if possible, undergo necessary dental care before chemotherapy begins, since any existing lesions that might normally lie dormant can flare up and become life-threatening once the patient is immunosuppressed. Dental extractions should preferably be

performed at least 10–14 days before the commencement of chemotherapy so that epithelisation of the extraction site has been completed prior to the initiation of treatment. Dental procedures that could trigger a bleeding episode or/and bacteraemia during the aplastic phase should be avoided. The use of saline or alcohol-free chlorhexidine mouthwash is very important, primarily during the phase of aplasia. Aesthetic restorations of the enamel defects are often necessary, especially after completion of treatment.

Auditory toxicity

The auditory system is vulnerable to many chemical exposures. Antibiotics, such as the aminoglycosides, and chemotherapeutic agents, such as cisplatin, can cause considerable ototoxicity in as many as 40% of patients. Dosage reduction and regular assessment with auditory studies during the course of therapy might reduce toxicity and prevent further damage.

Visual toxicity

Ophthalmic complications induced by cytotoxic chemotherapy are often underestimated and underreported due to priority given to other life-threatening conditions; however, most of the ophthalmic complications are reversible if detected early enough. Amongst the functional complaints are blurred vision, decreased colour vision, diminished visual acuity, diplopia, night blindness and photophobia.

Amongst the drugs used on a regular basis to treat leukaemia, cytarabine can cause conjunctivitis and methotrexate can cause oedema, ocular pain, blurred vision, photophobia, conjunctivitis and blepharitis. Chlorambucil has been reported to cause keratitis and daunorubicin excessive lacrimation and conjunctivitis. Alemtuzumab can cause optic neuropathy and endophthalmitis. Finally, imatinib can cause periorbital oedema in up to 47% of patients.

The possible reversal of some of these side-effects, if discovered in time, emphasises the need for clinicians to be aware of these ocular reactions and suggest immediate consultation by an ophthalmologist.

Infections

Infection in leukaemic patients may be life-threatening and significantly contributes to mortality and morbidity in both community and hospital settings. Patients with leukaemia are at risk for infections both due to severe and prolonged neutropenia and as a consequence of chemotherapy with impaired innate immunity and destruction to physical barriers. Despite advances in antimicrobial prophylaxis and treatment, as well as diagnostic methods such as fungal serology, leukaemia patients remain at risk for life-threatening infection which leads to increased mortality, morbidity, prolonged hospitalisation and higher treatment cost.

Patients with leukaemia are predisposed to infections with many organisms including normal commensals from the gastrointestinal tract, oropharynx or skin, but also numerous opportunistic pathogens, including those in the environment and nosocomial infections. Table 55.2 lists important pathogens in this patient cohort, and Table 55.3 lists the locations of access for endogenous bacteria frequently causing invasive infection.

Following the introduction of chemotherapy for the treatment of leukaemia, Gram-negative organisms were the leading cause of blood stream infections in neutropenic patients. There has been a shift in the aetiology of infections in the setting of leukaemia over more recent years with an increase in Gram-positive bacteraemias and the emergence of resistant Gram-negative organisms. This in part may be related to use of central venous catheters as well as the increasing use of quinolone antibiotic prophylaxis in this patient group. Patients with leukaemia are frequently exposed to antibiotics and the hospital environment, predisposing them to the risk of colonisation and infection with antibiotic-resistant strains.

Over the past decade, there has been a rise in infections with resistant-strains such as extended-spectrum beta-lactamase (ESBL)-production in Enterobacteriaceae (including carbapenemase-producing organisms), multidrug-resistant *Pseudomonas* spp. and *Acinetobacter* spp., vancomycin-resistant enterococcus (VRE) and methicillin-resistant *Staphylococcus aureus* (MRSA). Table 55.3 lists those host factors responsible for increasing the risk and severity of infection. Most patients will have more than one such risk factor.

The risk of infection increases with the duration and severity of neutropenia. Bacterial infections can occur at any stage during neutropenia; however, fungal infections typically occur later with invasive *Candida* spp. infections after 7 days of neutropenia and invasive moulds such as *Aspergillus* spp. after around 14 days.

Invasive fungal infection (IFI) carries significant morbidity and mortality. An increased risk of IFI is associated with induction/re-induction chemotherapy for AML and MDS, the use of purine analogues (such as fludarabine, clofarabine), and in allogeneic stem cell transplant recipients with graft-versus-host disease requiring corticosteroids and prolonged immunosuppression including the use of tumour necrosis factor-α blockade (TNF-α). Patients classified as being 'high risk' should receive antifungal prophylaxis with agents active against both yeasts and moulds.

Neutropenic fever

Patients with neutropenic fever must undergo a thorough clinical assessment and receive prompt empiric antibiotic therapy according to institutional neutropenic sepsis guidelines. A comprehensive clinical examination should include the skin, cardiorespiratory system, abdomen, oropharynx, central venous catheter and perianal region.

Table 55.2 Important pathogens in leukaemia patients.

	Bacteria	Endogenous/exogenous source of infection, notable characteristics
Gram-positive bacteria	*Coagulase-negative staphylococci*	Endogenous
	Staphylococcus aureus	Endogenous
	Enterococcus spp.	Endogenous
	Viridans group streptococci	Endogenous
	Streptococcus pneumoniae	Endogenous
	Streptococcus pyogenes	Endogenous
Gram-negative bacteria	*Escherichia coli*	Endogenous
	Klebsiella spp.	Endogenous
	Enterobacter cloacae	Endogenous
	Pseudomonas aeruginosa	Endogenous or exogenous; associated with water; colonises medical devices
	Acinetobacter spp.	Exogenous Typically acquired in the intensive care unit environment. Forms resistant biofilms on devices, often multi-resistant, and survives in the environment
	Stenotrophomonas maltophilia	Exogenous Low-virulence organism typically unable to overcome host barriers. Infection associated with carbapenem use, to which it is constitutively resistant
Yeasts and moulds	*Candida* spp.	Responsible for both superficial skin and mucosal infections and fungemia
	Aspergillus spp.	Causes rapidly progressive pneumonia Responsible for ca. 90% of invasive fungal infection in this cohort, of which >90% are pulmonary
	Pneumocystis jirovecii	Rare in this group; but not negligible
	Cryptococcus spp.	Rare cause of pneumonia and meningitis
	C. immitis, H. capsulatum, B. dermatitidis, P. brasiliensis, sporotrichosis, P. marneffei	Endemic, geographically limited highly virulent pathogens
	Zygomycetes, Fusarium, Scedosporium spp.	Low pathogenicity; tendency to produce skin lesions, disseminated disease and high mortality; difficult to treat

Blood cultures must be taken at the onset of fever and prior to antibiotic administration. A minimum of two sets of blood culture is recommended, taken peripherally and from central venous catheters (from each lumen). Approximately 10–15 mL of blood should be inoculated in each bottle (aerobic and anaerobic) as volumes lesser or greater will reduce the diagnostic yield. Blood cultures are typically incubated for 5 days; most cultures from bacteraemic patients are positive within 24 hours. A full identification is usually obtained within 24–48 hours. Recent advances in molecular diagnostics now allow for the rapid identification of organisms.

Empiric antibiotic therapy

The majority of infections in febrile neutropenia are treated empirically as only 30% or less of cases have positive microbiological identification. Febrile neutropenia is a medical emergency with life-threatening complications. Mortality rates vary and can be as high as 40%. Gram-negative sepsis carries a mortality of over 95% if not recognised early and treated adequately. Therefore, febrile neutropenic patients must be immediately treated with broad-spectrum antibiotics with antipseudomonal activity, typically a β-lactam/β-lactamase inhibitor combination

Table 55.3 Locations of access for endogenous bacteria frequently causing invasive infection.

		Typical context of pathogenicity	Important considerations
Skin	*Coagulase-negative staphylococci*	Line-associated infections	Biofilm formers often highly antibiotic-resistant
	Corynebacterium spp.	Bacteraemia associated with indwelling devices	*C. jeikeium* has a predilection for bacteremia via iv devices in this group
	Propionibacterium acnes	Rare cause of endocarditis and septic arthritis	Invasive infection often associated with indwelling prostheses
Oropharynx	Anaerobes	Dental abscesses	Often associated with polymicrobial infections
	Viridans streptococci	Dental plaque and caries Opportunistic cause of infective endocarditis	Pre-existing gum and tooth disease may relapse during chemotherapy
Nasopharynx and upper respiratory tract	*Streptococcus pneumoniae*	Pneumonia, otitis media, bacteraemia, meningitis	Risk markedly increased in asplenia or decreased serum (IgG). Polyvalent vaccine available but not necessarily effective in leukaemia
GI tract	*Enterobacter cloacae*	Urinary tract infections, bacteraemia	Resistant to beta-lactam antibiotics except carbapenems in some countries
	Enterococcus faecalis	Bacteraemia, endocarditis, urinary tract infections	Typically replaced by *Enterococcus faecium* (which is more resistant) following antibiotic treatment
	Escherichia coli	Urinary tract infections, bacteraemia	Often spontaneously translocates from the gut in neutropenia
	Klebsiella pneumoniae	Urinary tract infections, bacteraemia	Often highly antibiotic-resistant. Forms resilient biofilms on plastic.

(e.g. piperacillin/tazobactam) or with a carbapenem (e.g. meropenem). The latter can also be used in most cases of penicillin allergy, although some cross-reaction does exist. The use of more than one empiric antibiotic of a different class may be employed to minimise the chance of treatment failure in view of the rising trend in antimicrobial resistance.

Haematology units must review their local and national bacterial epidemiology and resistance patterns at intervals and tailor the empirical therapy accordingly. Subsequent isolation of a pathogen and its sensitivities will then allow for evidence-based, focused de-escalation of antibiotic therapy in most cases based on clinical improvement. Current patterns of resistance in most countries suggest the addition of an aminoglycoside (e.g. gentamicin or amikacin) to the initial β-lactam/β-lactamase inhibitor combination or carbapenem.

In cases with MRSA colonisation or suspected central venous catheter infection, the use of additional therapy with vancomycin or teicoplanin is essential. Previous infections with resistant organisms should guide the choice of empiric antibiotics and this is particularly important at the present time with the global increase in Gram-negative resistance, including against carbapenems. Some countries (such as the UK) recommend testing for multidrug-resistant organism colonisation, usually by means of a pre-emptive rectal swab.

In patients presenting with febrile neutropenia, antibiotic treatment with a β-lactam/β-lactamase inhibitor combination (e.g. piperacillin/tazobactam) or carbapenem (e.g. meropenem), aminoglycoside (e.g. gentamicin or amikacin) and additional vancomycin or teicoplanin in the presence of a central venous catheter is recommended. Patients who are on long-term immunosuppression, such as those with graft-versus-host disease, may not mount a febrile response to infections and present with hypothermia ('cold sepsis'). These patients should be assessed as soon as they present and started on empiric antibiotics promptly as any delays may be fatal.

The first-line use of empiric antifungal treatment is generally not recommended. Antifungal treatment should be considered in neutropenic patients with unremitting fevers not responsive to broad-spectrum antibiotic therapy or in the presence of clinical or radiological signs supporting the diagnosis of an IFI.

The choice of antifungal treatment will depend on the evidence of pre-existing fungal colonisation (such as *Candida* spp. colonisation of skin/oropharynx), previous fungal isolates and local epidemiological surveillance of prevalent fungal pathogens.

Investigating neutropenic fever

Although most episodes of neutropenic fever are not associated with localising symptoms or signs, a thorough history and clinical examination are essential as this will then guide appropriate investigations to identify and treat the source of infection promptly.

Respiratory infections

A chest radiograph must be performed on all patients with respiratory symptoms at the time of presentation. The differential diagnosis includes bacterial, fungal and viral causes.

Aspergillus spp. are responsible for the majority of invasive pulmonary fungal infections in neutropenic patients and may be associated with cough, pleuritic pain and haemoptysis. Severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2) and the subsequent disease, coronavirus infectious disease-2019 (COVID-19) should be excluded in all patients in the current pandemic. Correct technique in performing nasopharyngeal/oropharyngeal viral swabs is essential and samples should be sent for real-time reverse transcription-polymerase chain reaction (RT-PCR) determined diagnosis of SARS-CoV-2, influenza, parainfluenza subtypes, adenovirus, metapneumovirus and respiratory syncytial virus.

Patients with prolonged neutropenia and persistent fevers despite broad-spectrum antibiotics should proceed to computed tomography (CT) imaging to assess for pulmonary +/− sinus fungal infection. High-resolution CT imaging is the preferred imaging modality and the presence of lung nodules or infiltrates with a halo sign in a neutropenic patient is highly indicative of invasive aspergillosis. The air crescent sign seen on high-resolution CT is often a late and non-specific finding. Radiological findings in patients with pulmonary mucormycosis include consolidation, mass-like lesions, lung nodules and cavitation. The presence of multiple nodules (>10 nodules) as well as pleural effusions appear to be more common in pulmonary mucormycosis than in invasive aspergillosis. The reverse halo sign is often described in pulmonary mucormycosis and is more specific for mucormycosis than invasive aspergillosis; however, the differential diagnosis may include infections such as pulmonary tuberculosis. The presence of diffuse and bilateral parenchymal abnormalities often suggests a diagnosis of either viral-induced pneumonitis or *Pneumocystis jirovecii* pneumonia. Bacterial infections due to *Pneumococcus* or *Haemophilus* spp. typically appear as more confluent areas of anatomically well-defined consolidation.

High-resolution CT has an important role in the diagnosis and management of COVID-19 pneumonia. The common CT findings among patients with COVID-19 pneumonia include predominantly peripheral, bilateral ground-glass opacities with or without consolidation and interlobular septal thickening producing a 'crazy-paving' appearance. Although an important diagnostic tool with high sensitivity for COVID-19 pneumonia, CT findings of COVID-19 pneumonia can be non-specific and may resemble various infectious and non-infectious complications often seen in the neutropenic/immunosuppressed haematology patient. Therefore, awareness and knowledge of radiological findings are important in the early diagnosis and treatment of infections in the haematology patient during the current pandemic. The duration of symptomatology, degree and duration of neutropenia or immunosuppresssion, ancillary diagnostic tests, and follow-up imaging is helpful in the differential diagnosis in the haematology patient presenting with fever and respiratory symptoms.

Broncheoalveolar lavage (BAL) +/− tissue biopsy in the appropriate clinical setting are preferred over radiological findings alone. BAL is a useful tool and can be safely performed, but in patients who have been on prolonged antimicrobials the diagnostic yield is reduced to approximately 20%. Bronchoscopy and BAL are recommended in patients with lung infiltrates on imaging with no clear cause for infection. BAL results (microscopy, culture/sensitivity and PCR) can help identify microorganisms and allow de-escalation of antimicrobials.

Galactomannan, which is a polysaccharide component of the *Aspergillus* spp. cell wall (as well as other closely related filamentous fungi), can be released by fungal hyphae into the blood and other body fluids during invasive growth. The presence of this antigen can be sustained for up to 8 weeks and the level of circulating serum or plasma galactomannan is indicative of fungal burden. However, there are some limitations; its sensitivity in diagnosing invasive aspergillosis is reduced by exposure to mould-active antifungals, and therefore absent galactomannan from serum or plasma in patients receiving mould-active antifungals should be interpreted with caution in parallel with clinical and radiological findings. Exposure to certain antibiotics (piperacillin/tazobactam, amoxicillin/clavulanic acid, ampicillin and phenoxymethylpenicillin) and diet can lead to false-positive results. BAL galactomannan is, however, more sensitive for detection of invasive pulmonary aspergillosis compared to serum in at-risk patients.

(1,3)-Beta-D glucan testing is not mould-specific, and is found in a wide range of fungal pathogens, for example *Candida* spp., *Aspergillus* spp., and *Pneumocystis jirovecii*, but is useful as an alternative serological diagnostic test especially for exclusion in the appropriate clinical setting. *Aspergillus* PCR on blood and BAL fluid also provides an additional diagnostic tool for the diagnosis of *Aspergillus* infection.

Other pathogens capable of causing pulmonary disease, such as *Nocardia* spp., *Mycobacterium tuberculosis*, *Toxoplasma gondii*, *Histoplasma* and *Cryptococcus* spp., as well as rare moulds should be part of the differential diagnoses in this highly

vulnerable group. Patients with leukaemia are at risk of *Mycobacterium tuberculosis* infection. The tuberculin skin test and interferon-γ release assays are not reliable diagnostic tools in this patient group as the tests require intact cellular immunity. Detection of acid-fast bacilli under microscopy and/or culture or PCR positivity for *M. tuberculosis* should prompt combination therapy under expert advice and relevant infection control measures.

Other opportunistic respiratory pathogens such as *Pneumocystis jirovecii*, *Toxoplasma gondii*, atypical mycobacteria and *Nocardia* spp. should be considered in patients who do not respond to conventional antibiotics and antifungals. Patients with *Pneumocystis jirovecii* pneumonia typically present with dry cough, dyspnoea and hypoxia (especially on exertion). Chest radiography is usually the initial imaging modality but findings are non-specific and up to one-third of infected patients may have normal radiographic findings. The hallmark finding of *Pneumocystis jirovecii* pneumonia on high-resolution CT is bilateral ground-glass opacities and less frequently, consolidation, nodules, unilateral infiltrates, pleural effusions, cysts and spontaneous pneumothorax. The detection of *Pneumocystis jirovecii* DNA by quantitative real-time PCR on BAL fluid or sputum specimens is suggestive of active infection (or colonisation if low levels are detected). Elevated serum beta-D glucan levels can be used to support the diagnosis of probable *P. jirovecii* disease in the appropriate clinical context provided other IFIs have been excluded.

The range of possible respiratory pathogens highlights the importance of obtaining diagnostic sputum, BAL and/or tissue samples and PCR-based diagnostics whenever possible. Potential delays in diagnostic procedures may lead to clinical deterioration and missed opportunities in obtaining diagnostic yield, especially in patients on prolonged antimicrobial therapy.

Gastrointestinal infections

Patients with leukaemia commonly suffer from gastrointestinal symptoms which may be chemotherapy-induced or infective in origin. Chemotherapy toxicity leads to mucosal ulceration and defects throughout the gastrointestinal tract. Symptoms such as diarrhoea, abdominal pain and fever can be caused by either chemotherapy-induced destruction of gut mucosa (with consequences for bacterial penetration to deeper tissues and translocation to the blood), or by a primary, local process of invasion. Neutropenic enterocolitis/typhilitis is a life-threatening condition with a high mortality rate. Early recognition and prompt treatment are essential. Most patients respond to broad-spectrum parenteral antimicrobials, typically a carbapenem (with its anaerobic activity) alongside supportive management with fluids, electrolyte replacement and analgesia. Anti-diarrhoeal agents should be avoided.

Neutropenic patients with persistent fever despite antimicrobial treatment and without evidence of an infective focus should have abdominal imaging. This should be in the form of an ultrasound scan in the first instance to investigate for evidence of hepatosplenic candidiasis. Any identified lesions in the liver should be biopsied if at all possible. Whilst *Candida* spp. remains the most likely causative pathogen of multiple hepatosplenic lesions, a very broad range of alternative pathogens exists including many species of bacteria, mycobacteria and fungi.

Patients with upper gastrointestinal symptoms such as epigastric pain and intractable nausea/vomiting should undergo endoscopy with biopsies to exclude infection with *Candida* spp., *Cytomegalovirus* or *Herpes* spp.-related oesophagitis/gastritis.

Severity of *Clostridium difficile* infection ranges from benign diarrhoea to lethal pseudomembranous colitis. *Clostridium difficile* should always be excluded with relevant stool antigen and toxin tests as well as abdominal CT in cases with severe symptoms. Treatments include vancomycin, metronidazole and fidaxomicin. Intestinal microbiota transplant can be considered in patients with multiple recurrences or refractory *Clostridium difficile* infection despite antibiotic treatment. Neutropenic patients with perianal pain should undergo MRI to further investigate the cause of the pain. Abnormalities such as fistulas and haemorrhoids can lead to bacterial infection and require treatment with broad-spectrum antibiotic in order to prevent the spread of infection.

Skin infections

Skin lesions often represent metastatic spread of infection and punch biopsies should be performed for histopathology, viral PCR and culture for bacteria, fungi and mycobacteria. *Ecthyma gangrenosum* is a serious skin infection characterised by ulcerative lesions with necrotic centres. These lesions are typically seen in the perineum, axillae and submammary regions as well as limbs and trunk, and are caused by systemic *Pseudomonas aeruginosa* infection which is associated with a high mortality rate. These patients present with sepsis/shock with concurrent *Pseudomonas* bacteraemia. Fungi, particularly *Aspergillus* spp., *Candida* spp. and *Fusarium* spp., can also disseminate to the skin causing papular lesions with necrotic centres. The latter organisms also often involve the retina therefore fundoscopy is mandatory in these cases to prevent permanent blindness. Infection with atypical mycobacteria can present with skin lesions, typically nodules.

Infections due to central venous catheters

A central venous catheter is commonly used to deliver chemotherapy and is a common source of infection in the neutropenic patient. Central venous catheters are susceptible to colonisation with bacteria, fungi and mycobacteria. The presence of fever in the absence of an infective focus should always prompt the possibility that the device is responsible for the fever, and blood cultures should be taken via the line lumens (each being cultured separately) as well as peripherally. Central venous catheters should be removed promptly if there is

evidence of infection at the catheter site, or in the presence of fevers associated with line use.

Central venous catheters should be removed in the setting of bacteraemia with *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Klebsiella* spp., *Stenotrophomonas* spp. and *Candida* spp. due to their virulence and ability for haematogenous spread to heart valves and joints. These organisms tend to adhere to plastic and lead to biofilm formation, resulting in failure of antimicrobial therapy.

Intraluminal colonisation of the catheter (with no local signs of infection) can be treated with antibiotic line locks in an attempt to sterilise the line. However, infection around the catheter site will usually require catheter removal as the infection is at the avascular tissue/plastic interface and therefore not amenable to antibiotic-mediated killing.

In the context of a febrile neutropenic patient with a suspected line infection, vancomycin or teicoplanin should be added to the empirical antibiotic regimen. Lines infected with coagulase-negative Staphylococci can be salvaged with combined systemic antibiotics and antibiotic line locks. If the fevers do not resolve despite line removal, then an ultrasound scan should be performed to exclude an underlying infected thrombus.

Invasive fungal infection

IFIs are a major cause of morbidity and mortality in leukaemic patients. The risk of IFIs is highest for patients undergoing remission induction chemotherapy for acute myeloid leukaemia and myelodysplastic syndrome, those treated with purine analogues (fludarabine, clofarabine), prolonged duration of severe neutropenia, and recipients of allogeneic haematopoietic cell transplant (HCT) with graft-versus-host disease requiring steroids and multiple lines of immunosuppressive therapy. This group of high-risk patients should therefore receive primary antifungal prophylaxis with a mould-active antifungal agents. There is sufficient data to support posaconazole as the prophylactic agent of choice in this high-risk population.

Liposomal amphotericin, echinocandins and posaconazole/voriconazole form the mainstay of antifungal treatment. It may be noted, however, that the azoles may be associated with significant side-effects and have unpredictable metabolism and drug interactions, making their use challenging.

Liposomal amphotericin is active against almost all fungal pathogens, while voriconazole has a similar broad spectrum of action except for lacking activity against *Mucor* spp. Fluconazole has good activity against *C. albicans*, most non-albicans *Candida* and *Cryptococcus* spp., but is not active against moulds, for example *Aspergillus* spp., *Mucor* spp. and *Fusarium* spp. Flucytosine, the echinocandins and itraconazole have a similar spectrum of activity to fluconazole but itraconazole is active against *Aspergillus* spp., and the echinocandins lack activity against *Cryptococcus* spp.

The most virulent pathogen in this setting is *Aspergillus* spp. – most commonly fumigatus or flavus. These moulds are not susceptible to fluconazole. For this reason, the use of mould-active agents in high-risk patients for IFI is critical. The choice of prophylactic agent varies between centres and between countries, and the choice is dependent on local preference and cost-benefit analysis. Mould-active agents include the later generations of triazole antifungals, such as itraconazole, voriconazole (almost exclusively reserved for treatment rather than prophylaxis) and posaconazole. Isavuconazole, a novel triazole drug with broad-spectrum antifungal activity, has shown safety and efficacy in treating IFIs.

There is robust data showing the effectiveness of posaconazole in reducing the incidence of invasive mould infection in these high-risk patients; however, the drug is expensive and (like other azoles except fluconazole) has variable and unpredictable oral absorption profile in its syrup form. This relates to its lipophilic properties, shared with the other azoles apart from fluconazole. All rely on an acid pH for ionisation and absorption and this is often impeded by the concurrent administration of powerful antacid medication, including H2 blockers and proton pump inhibitors. A different oral tablet formulation of posaconazole with better absorption is now available.

Due to the high pharmacokinetic variability of azoles, regular therapeutic drug monitoring is essential to optimise dosage in order to maximise the therapeutic potential while limiting adverse reactions. Recent data as well as recommendations from the Infectious Diseases Society of America support therapeutic drug monitoring for the mould-active triazole antifungals such as itraconazole, voriconazole and posaconazole.

Antibiotic resistance

Antibiotic resistance is a major public health concern. The most important prevention is to ensure proper use of antibiotics as well as infection control measures to reduce transmission of these resistant strains in hospitalised patients. These include proper hand hygiene, contact precautions and regular environmental cleaning. Implementation of antibiotic stewardship should be encouraged to promote careful use of antimicrobials and local surveillance of antimicrobial resistance patterns.

Identification of the colonisation or infection in a patient with an antibiotic-resistant organism should immediately prompt review of the current treatment as well as consideration of the empiric antibiotic regimen to be used should they become febrile at a later date. Table 55.4 shows major antibiotic resistance mechanisms; of note is that several may coexist, rendering treatment choices exceedingly limited if not entirely impossible.

Investigation of persistent fever

Some patients continue to have persistent fever despite broad-spectrum antimicrobials. Frequent changes in antimicrobials

Table 55.4 Mechanisms of resistance and important considerations flowing therefrom.

Antibiotic	Bacteria	Comments
Chromosomal *AMP C* β-lactamase	*Citrobacter freundii* *Enterobacter* spp. *Morganella morganii* *Proteus* spp. *Serratia* spp.	Able to break down penicillins and cephalosporins. Treatment with third-generation cephalosporins (includes ceftazidime and ceftriaxone) induces hyperproduction of resistance enzymes. Not inhibited by clavulanic acid. Usually require treatment with a carbapenem.
Extended spectrum β-lactamases	Most commonly found in: *E. coli* *Klebsiella pneumoniae* Described in other Gram-negative bacilli	Confer resistance to penicillins and cephalosporins. Usually inhibited by a β-lactamase inhibitor, such as clavulanic acid.
Carbapenem	Enterobacteriaceae, particularly: *E. coli* *Klebsiella pneumonia* *Pseudomonas aeruginosa*	Multiple known mechanisms of acquired carbapenem resistance. Very challenging management. May remain sensitive to tigecycline, colistin, fosfomycin or aminoglycosides. These infections often require dual or triple therapy combinations.
Methicillin	*Staphylococcus aureus*	Resistant to all β-lactams due to altered penicillin-binding site. All UK isolates so far sensitive to glycopeptides (vancomycin and teicoplanin). Variable sensitivity to doxycycline, aminoglycosides, trimethoprim and rifampicin. Alternatives: daptomycin, linezolid.
Vancomycin	*Enterococcus* spp.	Vancomycin-resistant enterococci are typically acquired through exposure to glycopeptide treatment and can lead to persistent carriage in the GI tract

may not be necessary unless the patient is clinically deteriorating with rising inflammatory markers, haemodynamic instability or there is evidence of progressive infection either radiologically or clinically. Patients must be reviewed daily, and every effort should be made to diagnose the source of infection. Blood cultures should be taken regularly in the patient with persistent fever, and repeat high-resolution CT of chest, CT sinuses and abdominal imaging should be considered in the appropriate clinical setting. Consideration should also be given to removing the central venous catheter if no other infective source is identified.

Opportunistic infections such as tuberculosis, atypical mycobacterial infection, toxoplasmosis, and in patients with geographic risk factors, malaria, brucellosis and Strongyloides should be considered in patients with ongoing fevers who do not respond to conventional antibiotics and antifungals. Travel history, country of origin and pre-existing serology may be helpful to guide investigations and management in the setting of pyrexia of unknown origin.

When to stop anti-infective agents

Oral antibiotic step-down is generally not recommended once sepsis has resolved. Intravenous antibiotics can be stopped once there is clinical improvement (radiological improvement can sometimes lag) and upon resolution of fever. However, there are special situations, for example in the setting of *Staphylococcus aureus* blood stream infection, in which a prolonged course of treatment is indicated and after completion of at least 14 days of intravenous therapy an oral sequential therapy can be considered to complete the desired course of treatment. The decision regarding a prolonged course of antibiotics should be made following consultation with the Microbiology/Infectious Diseases team. The prolonged use of antibiotics without a clear indication should be discouraged as this practice promotes antibiotic resistance and predisposes to *C. difficile* infection.

Antifungal therapy, however, should continue in the setting of continued fevers with worsening radiological changes, prolonged neutropenia and ongoing steroid treatment/immunosuppression for graft-versus-host disease. IFIs should be treated for a minimum of 6 weeks; however, this is very much guided by patient factors such as the anticipated duration of neutropenia and ongoing immunosuppression, and some patients may need a very prolonged course of antifungal therapy. Antifungal stewardship and collaboration between the Haematology, Microbiology and Respiratory teams should be encouraged in order to rationalise antifungal usage, managing drug toxicity and the associated cost implications of these agents.

Special considerations in allogeneic haematopoietic cell transplant recipients

Infections are a common cause of morbidity and mortality following an allogeneic HCT and these patients are at risk of opportunistic infections for long periods of time, starting with the conditioning therapy in the peri-transplant period to potentially several years following the transplant.

Transplant conditioning regimens include the use of high-dose chemotherapy +/− radiotherapy which causes prolonged impairment of haematopoiesis rendering the recipient neutropenic with impaired phagocytic function. It also leads to destruction of mucocutaneous barriers, and consequently, the skin and gastrointestinal tract allow translocation of bacteria, fungi, and other organisms causing potentially serious infections. Herpes simplex virus (HSV) reactivation can occur during this period and it is recommended that all cell transplant recipients receive prophylactic antivirals from the start of conditioning. Following sustained neutrophil engraftment there is restoration of effective phagocytic function, which greatly reduces the risk for bacterial and fungal infections.

These patients rapidly lose all B- and T-lymphocytes following conditioning, along with immune memory from past exposure to infections and vaccination. Recipients of allogeneic HCT will continue to have impaired cell-mediated immunity, the extent of which is influenced by severity of graft-versus-host disease and degree of immunosuppression.

One of the most important infections in the allogeneic cell transplant context is CMV disease. Prior to the introduction of the first effective anti-CMV agent (ganciclovir) in the late-1980s CMV pneumonitis was one of the most common causes of post-transplant mortality, with significant morbidity arising from CMV enteritis and hepatitis. However, regular screening for CMV infection/reactivation following transplantation using whole blood or plasma RT-PCR has allowed the early detection and treatment to commence prior to the development of CMV disease, and due to this improvement in detection and the availability of effective antiviral agents CMV has become an uncommon cause of post-transplant mortality. Interestingly, CMV also potentiates infection with opportunistic pathogens, especially in patients with active graft-versus-host disease through complex interactions with the immune system. Treatment options for CMV infection include ganciclovir, valganciclovir, foscarnet and cidofovir. Letermovir is a novel antiviral agent that inhibits CMV replication and is now licensed for prophylaxis in CMV-seropositive allogeneic HCT recipients.

Allogeneic HCT recipients have immune system dysfunction for months to years following the transplant and have impaired cell-mediated and humoral immunity putting them at risk for CMV, varicella-zoster virus (VZV), EBV-related post-transplant lymphoproliferative disease, respiratory viruses, and infections with encapsulated bacteria (e.g. *Haemophilus influenzae* and *Streptococcus pneumoniae*).

Allogeneic HCT recipients should also routinely be re-vaccinated, starting at 6–12 months post-transplant (Table 55.5). However, there is no standardised vaccine schedule for HCT recipients and individual transplant centres should review available guidance in order to make recommendations.

There are now guidelines and recommendations for COVID-19 vaccination in patients with haematological malignancy and allogeneic HCT recipients. This is a new and evolving area and further recommendations will likely follow in due course. At the present time, the immunogenicity and efficacy of the SARS-CoV-2 vaccines in allogeneic HCT recipients and the impact of both graft-versus-host disease and prolonged immunosuppression on vaccine responses remains unknown.

Conclusions

The two major causes of outcome failure in the management of patients with leukaemia are disease progression/relapse and fatal infections. These patients develop infections both as a consequence of the disease itself and as a result of the therapy necessary for remission and/or cure. Febrile neutropenia and sepsis of bacterial origin represent a clinical emergency and the protocol of antibiotics used must be appropriate and sufficient. Recent global changes in Gram-negative resistance patterns make these choices increasingly difficult, and rectal screening for carriage of multidrug-resistant Gram-negative organisms ahead of the period of neutropenia is becoming more widespread and clinically important. Equally, the correct management of fungal infection relies on risk stratification and in appropriate cases, prophylaxis. The utility of fungal diagnostics is currently suboptimal making empiric antifungal treatment, usually based on CT scanning and exclusion of other causes of fever, the norm. Response rates and 'cure' in such patients often relates to the prognosis of the underlying leukaemia; persistent malignant disease very significantly impacts on the ability of these drugs to eradicate the fungal infection. Finally, viral infections remain a significant threat for those in whom cell-mediated immunity is poor, either subsequent to the disease or to chemotherapy. In addition, many such infections can rapidly spread through an inpatient haematology unit emphasising the need for strict infection control precautions.

Metabolic complications

Fluid balance

Fluid balance should be monitored carefully in patients treated with intensive chemotherapy or haematopoietic cell transplantation. Daily weight monitoring is equally important. Fluid input/output monitoring should take place several times within each 24-hour period in order to be able to observe unwanted

Table 55.5 ECIL recommendations for allo-HSCT recipients.

Vaccine	No. of doses*	Time post-HCT to initiate vaccine	Grading
Influenza (inactivated)	1 (or 2, special cases)**	>6 months As long as patient is judged to be IS Yearly, lifelong from 3 months in case of a community outbreak	AIIr BIIr BIIr
Measles–mumps–rubella			
• Measles	1 (2 in children) MMR	≥24 months	BIIu
In sero(-) patients, with no GVHD, no IS, no REL of underlying disease, and no IGIV at least 8 months		≥12 months in case of measles outbreak in patients with low grade IS	CIII
• Rubella	1 MMR	≥24 months	CIIu
In sero(-) women and of childbearing potential, with same precautions as for measles vaccine			
Virus hepatitis B***			
• Sero(-) patients before HCT and patients vaccinated pre-HCT but lost their immunity at 6 months)	3†	6–12 months 6-12 months	BIIt BIII
• Previously infected and anti-HBs <10 IU/L		Vaccine before transplant	BIII
• Sero(-) patients with a donor with positive anti-HBc			
Human papilloma virus (HPV) Follow recommendations for general population in each country	According to official label	From 6 to 12 months	BIIu
Inactivated polio	3‡	6–12 months	BIIu
Live-attenuated varicella vaccine	1	Can be considered in sero(-) patients, with ALL the following: >24 m from HST, no GVHD, no IS, no REL of the underlying disease, and no IGIV in the last 8 months	BIIr
	2	The addition of a second dose in adults may be considered in patients who were sero(-) before HST or had no history of VZ infect	
Live-attenuated zoster vaccine	Not recommended		DIII
Pneumococcal conjugate (PCV)	3	3 months	AI
Polysaccharidic vaccine in case of GVHD, use PCV instead of PPS for this 4th dose (BIIr)	1	12 months (no earlier than 8 weeks after last PCV)	BI
Meningococcal conjugate (in accordance with country recommendations and local prevalence)	2	From 6 months For men-C or tetravalent vaccine For men-B vaccine	BIIu BIII
Haemophilus influenzae conjugate	3	3 months or 6 months	BIIr
Diphtheria-tetanus (DT is preferred to Td)	3‡	From 6 months	BIu
Pertussis (acellular) (DTaP is preferred over Tdap)	3	From 6 to 12 months	CIII

Note for auto-HCT: same recommendations but grading changes for some vaccines: influenza BIIr (instead AII); PCV BIII (instead AI).
* If not specified otherwise, the interval between dose is 1 month.
** Influenza: A second dose of influenza vaccine, after 3–4 weeks from the first, may have a marginal benefit and should preferably be considered in patients with severe GVHD or low lymphocyte count (BIIr) and also for the patients vaccinated early (from 3 months after transplant) (BIIr). Children ≥6 months through 8 years, receiving influenza for the first time after transplant, should receive a second dose at least 4 weeks after the first dose.
*** HBV. After post-transplant vaccination, if anti-HBs is <10 mIU/mL, an additional three doses should be considered, but the benefit of this second series of vaccination is uncertain. IDSA guidelines (Rubin *et al.* 2014) give the same recommendations (strong, low). For adolescents and adults, a high dose of vaccine (40 µg) is recommended for these booster doses (strong, low).
† Three doses: interval 0, 1, and 6 months.
‡ At 1–2 months interval.
Source: Cordonnier *et al.* (2017)/ECIL.

changes in fluid balance and to be able to intervene, if necessary. Elderly patients are more susceptible to fluid imbalance due to underlying comorbidities, including congestive heart failure and renal insufficiency, and therefore should be monitored more closely.

Vomiting is common in patients on chemotherapy and in combination with diarrhoea and sweating due to pyrexia might rapidly lead to dehydration. Potential vasodilatation due to sepsis might exacerbate hypovolaemia and therefore strict monitoring and fluid replacement should be undertaken.

Hydration prior to cytotoxic agents

Hydration, urine alkalinisation (pH 7–8), and electrolyte monitoring can prevent hyperuricaemia, hyperphosphataemia, hypocalcaemia and hyperkalaemia. This is more relevant at diagnosis as the disease bulk is increased and the risk appears to be higher. The goal hydration is to improve renal perfusion and glomerular filtration and induce a high urine output to minimise the likelihood of uric acid or calcium phosphate precipitation in the tubules. However, intravenous hydration can lead to potentially dangerous fluid overload in patients with underlying acute kidney injury or cardiac dysfunction. Close monitoring is therefore important to prevent complications associated with TLS or fluid overload.

Tumour lysis syndrome

TLS is an oncologic emergency that is caused by massive tumour cell lysis with the release of large amounts of potassium, phosphate and nucleic acids into the systemic circulation. Catabolism of the nucleic acids to uric acid leads to hyperuricaemia, and the marked increase in uric acid excretion can result in the precipitation of uric acid in the renal tubules. It can induce renal vasoconstriction, decreasing renal blood flow and inflammation, resulting in acute kidney injury. Hyperphosphatemia with calcium phosphate deposition in the renal tubules can contribute to acute kidney injury. TLS is a frequent complication of advanced-stage Burkitt lymphoma and acute leukaemia with hyperleukocytosis. The symptoms associated with TLS reflect the associated metabolic abnormalities (hyperkalaemia, hyperphosphatemia and hypocalcaemia). These may include nausea, vomiting, anorexia, lethargy, cardiac dysrhythmias, seizures, muscle cramps, tetany, syncope and possible sudden death.

Aggressive intravenous hydration is the cornerstone of preventing TLS and is recommended prior to therapy in all patients at intermediate or high risk for TLS. Patients at risk for TLS should receive 2–3 L/m^2 per day of fluid. Urine output should be monitored closely and maintained within a range of 80–100 mL/m^2 per hour. Diuretics can be used to maintain the urine output, if necessary, but should not be required in patients with relatively normal renal and cardiac function. The best diuretic for patients with TLS is unknown; loop diuretics such as furosemide appear preferable because they not only induce diuresis, but may also increase potassium secretion.

Allopurinol is a hypoxanthine analogue that competitively inhibits xanthine oxidase, blocking the metabolism of hypoxanthine and xanthine to uric acid. Allopurinol decreases the formation of new uric acid and reduces the incidence of obstructive uropathy in patients at risk for TLS. Because it acts by decreasing uric acid formation, allopurinol cannot reduce the serum uric acid concentration already present before treatment is initiated. Thus, for patients with pre-existing hyperuricaemia (serum uric acid $\geq$7.5 mg/dL [446 µmol/L]), rasburicase is the preferred agent. Allopurinol increases serum levels of the purine precursors hypoxanthine and xanthine, which may lead to xanthinuria, deposition of xanthine crystals in the renal tubules, and acute kidney injury. Since allopurinol also reduces the degradation of other purines, dose reductions of 65–75% are needed in patients being treated with mercaptopurine or azathioprine. Allopurinol has the potential to interact with a number of other drugs, including cyclophosphamide, high-dose methotrexate, ampicillin and thiazide diuretics. Amongst patients who are unable to take oral medications, intravenous allopurinol can be administered. Treatment is normally initiated 24–48 hours before the start of induction chemotherapy and is continued for up to 3–7 days after treatment, until there is normalisation of serum uric acid and no other laboratory evidence of tumour lysis.

An alternative approach to allopurinol for lowering serum uric acid levels is to promote the degradation of uric acid by the administration of rasburicase. This is an active enzyme, urate oxidase (uricase), which catalyses oxidation of uric acid to the much more water-soluble compound allantoin. Rasburicase rapidly breaks down serum uric acid and is effective in preventing and treating hyperuricaemia and TLS. This rapid reduction in serum uric acid is in contrast to the effect of allopurinol. The enzymatic oxidation of uric acid results in an oxidative stress to the erythrocytes. Uric acid itself is a potent free-radical scavenger, so its rapid removal further exacerbates this oxidative stress. Administration of rasburicase therefore in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency therefore triggers haemolysis and methaemoglobinaemia. This may happen even in patients with mild G6PD deficiency, including females, who were previously asymptomatic. We recommend routine screening, although this may be challenging, both because of its cost-effectiveness and technical difficulties. G6PD screens can be falsely negative during acute haemolytic episodes and when the testing is done after blood transfusion, as donor red blood cells can mask G6PD deficiency. White cells contain a significant amount of G6PD, and ideally, they should be removed prior to assay, especially if the count is above the lab's reference interval upper limit which is often the case in leukaemia. Furthermore, it can be logistically difficult to delay rasburicase therapy because of the high morbidity and mortality associated with delayed treatment of TLS and variability in turnaround time of G6PD screening results.

Differentiation syndrome (DS)

Differentiation syndrome (DS), also known as retinoic acid syndrome, is the main life-threatening complication of therapy with differentiating agents, all-*trans* retinoic acid (ATRA, tretinoin) or arsenic trioxide, in patients with acute promyelocytic leukaemia. It typically occurs during induction therapy with differentiating agents, especially in patients presenting with high white blood cell count at diagnosis or relapsed disease. The median day of onset of clinical manifestations of the DS ranges between 7 and 12 days after starting therapy with differentiating agents.

This syndrome is characterised by unexplained fever, weight gain, hypotension, acute respiratory distress with interstitial pulmonary infiltrates and/or a vascular capillary leak syndrome leading to acute renal failure. The diagnosis of DS is mainly based on clinical and radiological features; however, it usually requires the exclusion of alternative causes that could explain the signs and symptoms of the syndrome. The early addition of chemotherapy to ATRA and the administration of high doses of steroids in the form of dexamethasone at the onset of the first sign or symptom has reduced the mortality associated with this syndrome from 30% down to 5% or less. It is recommended to start treatment with intravenous dexamethasone at a dose of 10 mg twice daily promptly at the very earliest suspicion of DS. Most patients will show rapid improvement and complete resolution of signs and symptoms after starting intravenous dexamethasone. Corticosteroid therapy should be continued until the complete disappearance of symptoms and then tapered. Other supportive measures are crucial in the correct management of DS. Furosemide is usually administered to treat signs or symptoms of fluid overload. Some cases with refractory acute renal failure and/or fluid overload may need renal replacement therapy. Invasive or non-invasive mechanical ventilation is indicated in some patients with severe acute respiratory failure who do not respond to high-flow oxygen therapy. Patients with prerenal failure and hypotension require careful fluid monitoring in conjunction with inotropic support.

Temporary discontinuation of ATRA or ATO is recommended in the cases of DS with very poor clinical conditions or severe organ dysfunction, such as patients developing renal failure or requiring mechanical ventilation because of respiratory distress. Otherwise, these differentiating agents could be maintained unless progression to overt syndrome or lack of response to dexamethasone is observed. If a favourable response is obtained, dexamethasone should be maintained until complete disappearance of signs and symptoms, and then ATRA or ATO should be resumed.

Nutrition and physiotherapy

High dose therapies, particularly haematopoietic cell transplantation have marked effects on metabolic demands and significantly impair nutritional intake. Treatment associated side-effects such as severe mucositis, nausea and vomiting can lead to rapid deterioration of nutritional status. Furthermore, reduced physical activity and loss of mobility due to hospitalization and prolonged isolation result in reduced muscle mass, particularly in a previously active patient. Nutrition support alongside of physiotherapy are therefore recognised as an important adjunct to high-dose therapy.

Optimal nutrition may improve tolerance to treatment and outcome in malnourished patients and well-nourished individuals may experience less treatment delays, myelosuppression and infections. Studies in transplantation showed association between poor nutritional status and low body mass index (BMI) with longer time to engraftment and lower survival. Conversely, high BMI prior to HCT is linked with acute GvHD, infections and poorer 5-year survival rates. Although association is clear, causality is difficult to establish in clinical studies.

Damage to the gut mucosal barrier by high-dose therapy, bacterial overgrowth and opioid-related impairment of peristalsis has raised concerns regarding the risk of bacterial translocation, leading to recommendations to follow a 'neutropenic diet'. Small studies have not confirmed the benefit of excluding uncooked fruit and vegetables or following a low-bacterial diet. More recently, a large retrospective study suggested less infections when neutropenic dietary restrictions were removed (Trifilio *et al*. 2012). Overall, there is lack of evidence for a relationship between dietary intake and infections during high-dose therapy. Any advice given with the intention of minimising foodborne infection should focus on hygienic practices and prioritise nutritional status over theoretical risks.

Artificial nutrition is indicated where a patient undergoing therapy cannot meet their needs with oral intake. The metabolic, physiologic and economic advantages of enteral over parenteral nutrition are well established. In the allogeneic transplantation setting, enteral nutrition has demonstrated an association with lower incidence of overall and gut acute GvHD than parenteral nutrition (Beckerson *et al*. 2019), perhaps because of its ability to maintain mucosal integrity, modulate the immune response to intensive chemo/radiotherapy and support the gastrointestinal tract environment, including intestinal microbiota.

Mineral and electrolyte losses are common during chemotherapy and are often exacerbated by antimicrobial and immuno-suppressive drugs (amphotericin, ciclosporin). Losses of fluid, electrolytes and other nutrients frequently occur. Intravenous input from medications, blood products and electrolyte replacement can predispose to fluid overload. Micronutrient requirements may be raised during high-dose therapy due to increased oxidation and tissue damage however there is no evidence to support routine antioxidant or trace element supplementation. Multiple blood transfusions may elevate ferritin levels indicating iron overload. Vitamin D has a role in normal haematopoiesis and modulation of the immune system. Some evidence points to potential benefits in the treatment of

myeloid disorders and suggests the vitamin D receptor has an impact on immune reconstitution after haematopoietic cell transplantation and hence subsequent risks of infection, graft versus host disease and graft versus disease (Hall and Juckett 2013).

Repeated hospital stays for treatment can result in suboptimal vitamin D status and low calcium levels which are of particular relevance for those receiving corticosteroid therapy. In the longer term, continued hospital appointments, fatigue and susceptibility to infection significantly impact nutrition and rehabilitation after high-dose therapy. Full return to normal functioning and nutritional status can take more than 1 year after treatment is completed.

Chemotherapy-induced nausea and vomiting (CINV)

Nausea and vomiting are common in patients undergoing treatment for leukaemia. Both symptoms are distressing, cause significant morbidity and reduce quality of life. Nausea and vomiting contribute significantly to nutritional deterioration and increased pain intensity. The emetogenicity of the chemotherapeutic agents, repeated chemotherapy cycles and patient risk factors significantly influence CINV. The use of a combination of a serotonin 5-HT3 receptor antagonist, dexamethasone and a neurokinin 1 (NK1) receptor antagonist has significantly improved the control of acute and delayed emesis in single-day chemotherapy. Palonosetron, a second-generation 5-HT3 receptor antagonist with a different half-life, a different binding capacity and a different mechanism of action from the first-generation 5-HT3 receptor antagonists appears to be the most effective agent in its class. Aprepitant, the first and only agent clinically available in the NK1 receptor antagonist drug class has been used effectively as an additive agent to the 5-HT3 receptor antagonists and dexamethasone to control CINV. Rolapitant and netupitant are other NK1 receptor antagonists that are currently in Phase III clinical trials. Olanzapine, a US-FDA-approved antipsychotic, has emerged in recent trials as an effective preventative agent for CINV, as well as a very effective agent for the treatment of breakthrough emesis and nausea.

Clinical trials using gabapentin, cannabinoids and ginger have not been definitive regarding their efficacy in the prevention of CINV. Additional studies are necessary for the control of nausea and for the control of CINV in the clinical settings of multiple-day chemotherapy and bone marrow transplantation.

Non-pharmacological strategies are very important in the overall management of the patient. Examples include avoiding food with strong tastes and smells; small but frequent meals, behavioural approaches (e.g. relaxation) and acupuncture/reflexology.

Pain control and palliative care

Many leukaemia patients experience bone or joint pain that results from the bone marrow being heavily infiltrated by leukaemia cells. Oral and gut mucositis are probably the most common site of pain, especially in recipients of high-dose chemotherapy or total body irradiation. Infections can cause pain, especially in areas such as the skin, mouth, eyes and perianally. Avascular necrosis of bone is another cause of pain in patients with acute lymphoblastic leukaemia and is often severe enough to need relief with opiates. Peripheral neuropathy and associated neuropathic pain are a widespread side-effect of treatment with certain chemotherapeutic agents. The pain associated with these neurotoxic effects can be prolonged, severe and relatively resistant to intervention. The overall incidence is not clearly delineated, although it is documented frequently with vincristine and platinum-based agents.

A variety of modalities to treat and control pain include:

- Pain control drugs with non-opioid and opioid analgesics
- Neuropathic pain control drugs such as carbamazepine, gabapentin, and antidepressants (amitriptyline, nortriptyline and imipramine)
- Continuous pump infusions
- Nerve block therapies
- Psychosocial interventions – stress management, counselling and coping mechanisms
- Acupuncture
- Massage therapy
- Relaxation techniques.

Palliative care

Relapse post-chemotherapy or following a bone marrow transplant is a common theme in acute leukaemia. Intensive salvage chemotherapy or other modalities can often achieve prolonged remission; however, refractory unresponsive-to-chemotherapy disease is not uncommon in this setting. Several experimental treatments can be offered; however, it is important to weigh the possible limited benefits of a new treatment against the possible downsides as quite often further treatment might not improve the health or change the outcome or survival. Under these circumstances, palliation can be offered to the patient. Palliative care is a proactive approach involving a multi-professional team. As well as controlling pain and other distressing symptoms, it applies a holistic approach to meeting the physical, practical, functional, social, emotional and spiritual needs of patients and carers facing progressive illness and bereavement. It is not uncommon for patients to ask to remain under the care of the same haematology team; however, the palliative care team should be involved as the choice of dying at home versus dying in a hospice requires expertise and external support is better managed by palliative care services.

CHAPTER 56

General consultative haematology

56

John Willan

Frimley Health NHS Foundation Trust, UK
Oxford University Hospitals NHS Foundation Trust, UK

Cancer

Anaemia

Anaemia is the most common haematological disturbance in patients with cancer. This may arise due to a number of mechanisms and, in common with other anaemias, it can be broadly categorised as being due to either reduced production of red cells (Table 56.1), increased destruction (Table 56.2), or increased blood loss. In many patients with malignancy, the anaemia arises due to a combination of several factors, and identifying and addressing each of these may lead to a rise in the haemoglobin level potentially ameliorating the patient's symptoms of fatigue.

Anaemia due to reduced red cell production

Haematinic deficiencies can arise in patients with malignancy, especially those undergoing chemotherapy or radiotherapy, due to reduced oral intake or reduced absorption of nutrients. Systemic anti-neoplastic treatments themselves can be directly myelosuppressive, inhibiting erythropoiesis and contributing to anaemia.

Tumours, or treatments that lead to a deterioration in renal function, can directly lead to reduced levels of erythropoietin, though more often in patients with cancer this hormone is supressed in association with an anaemia of inflammation/chronic disease (see Chapter 11), with raised inflammatory markers. Exogenous erythropoietin supplementation may be beneficial in this circumstance to help correct the anaemia, and reduce fatigue.

Infiltration of the bone marrow by malignancy may directly cause anaemia and is most common with haematological malignancies, such as myeloid disorders, and myeloma. It can also occur with metastatic spread of other primary malignancies, especially from the prostate, breast or the gastrointestinal tract where it is more likely to lead to a leucoerythroblastic peripheral blood smear, characterised by the presence of myeloid precursors, nucleated red blood cells, and teardrop cells. More rarely the bone marrow can be directly infiltrated by amyloidomas which can displace normal haematopoietic activity.

Pure red cell aplasia refers to the failure of erythropoiesis only and is characterised by a normocytic anaemia with reticulocytopenia in the absence of other causes. This can occur in association with certain malignancies, most commonly haematological, such as chronic lymphocytic leukaemia (CLL), large granular lymphocytic (LGL) leukaemia, and non-Hodgkin lymphomas, but it can also occur in association with thymomas. In immunosuppressed individuals, chronic infection with parvovirus (erythrovirus) B19 will lead to pure red cell aplasia, and serology and PCR testing can be performed to investigate this possibility.

Anaemia due to increased red cell destruction

Premature red cell destruction (defined as a red cell life span of less than 100 days) can occur through either immune, or non-immune mediated haemolysis (see also Chapter 17) in patients with malignancy (Table 56.2).

Immune haemolysis

The production of antibodies leading to auto-immune haemolytic anaemia (AIHA) may occur in association with malignancy,

Table 56.1 Causes of reduced red cell production in patients with cancer.

Cause of reduced red cell production	Notes
Anaemia of chronic disease	Low transferrin and transferrin saturations, with raised inflammatory markers
Haematinic deficiency – iron	Microcytosis. Ferritin may be normal or high in patients with cancer. Characterised by low transferrin saturations.
Haematinic deficiency – B12	Typically takes years to develop, but may occur in patient with previous surgical resection of the stomach (the source of intrinsic factor production), or terminal ileum (site of absorption)
Haematinic deficiency – folate	Folate is the haematinic store first to be depleted due to poor oral intake
Cytotoxic chemotherapy agents	Can cause direct marrow suppression
Renal anaemia	Renal impairment with reduced erythropoietin levels
Direct marrow infiltration	Most commonly by haematological malignancy or amyloid deposition
Pure red cell aplasia – direct cancer effect	Especially in conjunction with chronic lymphocytic leukaemia, T-cell large granular lymphocytic leukaemia, non-Hodgkin lymphoma. Also seen in association with thymomas
Pure red cell aplasia – viral induced	Parvovirus (erythrovirus) B19

Table 56.2 Causes of increased red cell destruction in patients with cancer.

Cause of increased red cell destruction	Notes
Autoimmune haemolytic anaemia	Most often associated with chronic lymphocytic leukaemia and other haematological malignancies
Microangiopathic Haemolytic Anaemia – cancer-associated	Typically associated with mucinous adenocarcinomas
Microangiopathic Haemolytic Anaemia – therapy-associated	Ciclosporin, tacrolimus, mitomycin and platinum-based chemotherapy
Haemophagocytic Lymphohistiocytosis	Most often associated with haematological malignancies (lymphomas and leukaemias), but occasionally with solid organ cancers.

especially haematological. This is characterised by a positive direct Coombs' test, raised bilirubin and LDH, and reduced haptoglobin. The haematological cancer most frequently associated with AIHA is chronic lymphocytic leukaemia, but it can complicate other B-cell non-Hodgkin lymphomas, T-cell lymphomas, myeloid malignancies, and less commonly can occur in association with non-haematological malignancies. Most often AIHA arising in association with malignancy is warm-type, however cold agglutination haemolytic anaemia may arise, most often in association with lymphoplasmacytic lymphoma, CLL or other lymphomas.

Non-immune haemolysis

Premature red cell destruction can occur through a number of non-immune mediated mechanisms in patients with malignancy. A microangiopathic haemolytic anaemia (MAHA) can arise in association with certain cancers, most often mucinous adenocarcinomas of the stomach, breast and lung. This will be characterised by a negative direct Coombs' test, a fall in platelets, the presence of red cell fragments on a peripheral blood smear, and an elevation in LDH. Certain medications may precipitate MAHA, including ciclosporin, tacrolimus, mitomycin and platinum-based chemotherapy.

Haemophagocytic Lymphohistiocytosis (HLH) (see also Chapter 36) is a condition in which there is phagocytosis of red cells, either by macrophages, or sometimes by tumour cells themselves. It is typified by profound elevations in the ferritin level, cytopenias, splenomegaly and persistent fevers which are not responsive to anti-microbial agents. This condition can occur as a secondary complication of certain malignancies, most often lymphoma or leukaemia, and there is often an infectious trigger, most typically EBV infection.

Increased blood loss

The anatomical abnormalities that arise within a tumour can predispose to bleeding, most commonly intra-luminal in patients with gastrointestinal, or genitourinary tumours. Less commonly bleeding can occur within a tumour, for example hepatocellular carcinoma, or into body cavities such as peritoneal or retroperitoneal bleeding.

Malignancies and their treatment can cause the development of thrombocytopenia, or abnormalities of haemostasis such as disseminated intravascular coagulopathy which in turn will increase the tendency to more generalised bleeding problems.

Polycythaemia

Polycythaemia occurs in certain myeloproliferative neoplasms as a direct consequence of genetic dysregulation of the bone marrow, and in most cases, an underlying genetic mutation can be identified from analysis of the peripheral blood (see Chapter 35).

Non-haematological malignancy associated polycythaemia is rare and is generally caused by secretion from the tumour of erythropoietin, or erythropoietin-like peptides, causing an increased red cell production. This is most often associated with renal cell carcinoma or hepatoma, but can also occur in patients with uterine myoma, androgen-secreting ovarian tumours, pheochromocytoma and cerebellar haemangioblastoma.

Leucocytes

The white cell count is frequently perturbed in patients with haematological and non-haematological cancers. Malignancy will often cause a neutrophilia to develop, driven by the inflammatory state and by increased production of cytokines. Cytotoxic chemotherapy or widespread radiotherapy will typically suppress neutrophil and other white cell levels. Lymphopenia is a common finding after chemotherapy and may be chronic.

Whilst most changes in white cell levels in association with malignancy are non-specific, there are a few common associations that should be noted (Table 56.3).

Platelets

Thrombocytosis

It is common for platelet levels to be elevated in association with malignancy. In myeloproliferative neoplasms, this is due to a primary bone marrow pathology (Chapter 35). In other malignancies, it is a reactive phenomenon, driven by chronic inflammatory changes, or in association with iron deficiency, or both.

Thrombocytopenia

There are many causes of thrombocytopenia in association with malignancy (Table 56.4). Direct infiltration of the bone marrow, typically by haematological malignancies will often be associated

Table 56.3 Leucocyte changes associated with malignancy.

White cell change	Association
Neutrophilia	Myeloproliferative conditions Most malignancies Infections that may occur in the context of malignancy and its treatment
Neutropenia	Myeloid malignancies, T-cell large granular lymphocytic leukaemia, bone marrow infiltration by malignancy or as a consequence of chemo/radiotherapy
Monocytosis	Chronic myelomonocytic leukaemia, Hodgkin lymphoma
Monocytopenia	Hairy cell leukaemia, or as a consequence of chemo/radiotherapy
Lymphocytosis	Chronic Lymphocytic leukaemia, non-Hodgkin lymphoma or other lymphoproliferative disorders. Also seen post-splenectomy
Lymphopenia	Most common following systemic chemotherapy, with steroids, or in association with opportunistic infection
Basophilia	Myeloproliferative disorders
Eosinophilia	Hodgkin lymphoma, T-cell lymphomas, myeloproliferative disorders. Also as part of an allergic reaction to medication, or in association with opportunistic infection

Table 56.4 Causes of thrombocytopenia in patients with malignancy.

Cause of low platelets in association with malignancy	Association
Primary bone marrow pathology	Myeloid disorder, such as myelodysplasia or acute myeloid leukaemia
Bone marrow infiltration	Myeloma, infiltration of marrow by non-haematological malignancy
Suppression of bone marrow function	By chemo/radiotherapy
Increased platelet destruction	Microangiopathic haemolytic anaemia, Disseminated intravascular coagulation, Thrombotic thrombocytopenic purpura
Increased platelet destruction – immune	May occur in association with CLL, other lymphomas or myelodysplasia, and rarely with non-haematological malignancies
Splenic pooling	Occurs in any cause of splenic enlargement, either directly due to malignancies such as myelofibrosis, or due to liver pathologies that cause raised portal vein pressures

with a reduced peripheral blood platelet count. Progression of myeloma may also correlate with a falling platelet count.

The cytotoxic effects of many chemotherapy agents will cause a drop in platelets over several days, due to the combination of reduced marrow production with the short half-life of platelets. Widespread radiotherapy will have a similar effect.

Increased platelet destruction occurs in a number of systemic conditions associated with malignancy, including MAHA, disseminated intravascular coagulation and thrombotic thrombocytopenic purpura. Platelet destruction may also occur through immune mechanisms, most commonly in association with chronic lymphocytic leukaemia, though less frequently this can be seen in patients with lymphoma. Immune platelet destruction is occasionally associated with non-haematological malignancies.

Certain cancers will cause an increase in the size of the spleen, and this will result in increased sequestration of platelets in the spleen, and lower numbers circulating in the peripheral blood. Primary haematological malignancies causing splenomegaly include the myeloproliferative neoplasms (especially myelofibrosis or chronic myeloid leukaemia), and splenic marginal zone lymphomas. Non-haematological cancers that increase the pressures in the portal vein resulting in splenomegaly will also cause a reduction in the circulating platelet count.

Other systemic diseases

Renal disease

Anaemia

Anaemia is the most common haematological manifestation of renal disease (Table 56.5), with different mechanisms underlying its development in either acute or chronic renal impairment.

When anaemia occurs in conjunction with acute renal impairment, it is typically caused directly by the same pathology that is affecting the kidneys, and management of the underlying cause is required to ameliorate the anaemia.

In chronic renal impairment, regardless of aetiology, anaemia most often develops secondary to inappropriately low levels of erythropoietin secretion by the damaged kidneys, but other causes can also contribute (Table 56.6). Typically red cells are normocytic and normochromic, with an inappropriately low reticulocyte count. Bone marrow investigation would show normoblastic erythropoiesis, without adaptive hyperplasia of the erythroid lineage. In a population-based sample of over 15,000 patients, anaemia was seen in 1% of individuals with an estimated glomerular filtration rate (eGFR) of 60 mL/min, 9% of individuals with an eGFR of 30 mL/min, and 33% (men) to 67% (women) of those with an eGFR of 15 mL/min. Replacement of erythropoietin, typically sub-cutaneously, is usually effective in improving red cell levels, and quality of life. The dose should be titrated, aiming for a haemoglobin level of 100–120 g/L, as higher levels are associated with an increased risk of thrombosis. Blood pressure should be monitored as hypertension is common. Long-acting erythropoietin replacement allows administration weekly, or bi-weekly, rather than 3 times a week with the standard formulation. Patients under consideration for exogenous erythropoietin will often benefit from intravenous iron replacement, as deficiency of iron, often functional and due to disturbances in the mobilisation of iron, is common, and will impair the response to erythropoietin. Low transferrin saturations may be a better guide to the need for iron replacement than ferritin, which is often elevated by the inflammation associated with chronic disease.

Polycythaemia

Renal disease can be associated with polycythaemia, usually through inappropriately high levels of erythropoietin production. This phenomenon is found in up to 5% of renal cell carcinomas and up to 15% of patients following renal transplantation, where haematopoietic factors such as insulin-like growth factor 1 may also increase sensitivity to erythropoietin. Localised renal hypoxia, for example in renal artery stenosis, may also drive inappropriate erythropoietin release.

Table 56.5 Causes of anaemia in acute renal impairment.

Causes of anaemia in acute renal impairment	Notes
Microangiopathic haemolytic anaemia, Haemolytic-Uraemic syndrome Thrombotic thrombocytopenic purpura	Red cell fragments will be seen on the blood film, and there will be a reduction in platelet number. LDH is elevated. Typically in association with bacterial gastroenteritis, most often E-Coli O157 May be associated with fever, neurological and cardiac abnormalities. ADAMTS13 levels will be low
Disseminated intravascular coagulation	Most often caused by infection, but can occur in association with malignancy
Systemic infection	Renal impairment may be driven by dehydration, drugs and radiological investigation. Anaemia develops via increased red cell destruction and raised hepcidin levels

Table 56.6 Causes of anaemia in chronic renal impairment.

Causes of anaemia in chronic renal impairment	Notes
Inappropriately low erythropoietin	Normocytic, normochromic anaemia with inappropriately low erythropoietin and reticulocyte count.
Haematinic deficiency – Iron	Ferritin may be normal or high in the presence of underlying inflammation even with iron deficiency. Ferritin <200 ng/mL in a dialysis patient would suggest iron deficiency. Transferrin saturations will be low. Intravenous replacement of iron may be more efficacious than oral.
Haematinic deficiency – Folate	Folate can become depleted by dialysis and should be replaced pre-emptively
Medication-induced	Medications used in the treatment of renal disease, or in the prevention of organ rejection post-transplant may cause anaemia, for example immunosuppressants such as mycophenolate or tacrolimus
Myeloma	Myeloma can cause anaemia directly through marrow involvement. Renal impairment can occur through multiple modalities, including direct light chain toxicity, hypercalcaemia, and through medications.
Anaemia of chronic disease	Hepcidin levels are usually elevated in patients with chronic kidney disease, due to chronic inflammation and reduced renal excretion
Increased blood loss	As uraemia increases, so too does the tendency to bleeding, further exacerbating anaemia.
Aluminium toxicity	Aluminium is not efficiently removed by dialysis and may suppress erythropoiesis if levels rise, but aluminium-free dialysis fluids and phosphate binders in common use today make this a rare cause of anaemia.

Liver disease

Liver disease causes a greater range of haematological change than does disease in any organ, other than the bone marrow. The liver is an important source of erythropoietin in the fetus, and serves as a haemopoietic organ *in utero*; extramedullary haemopoiesis occurs within the adult liver only in pathological states (e.g. primary myelofibrosis, severe haemolysis or megaloblastic anaemia). The liver is the major source of thrombopoietin in adults.

Platelets

Patients with liver disease may have abnormalities of their platelet count (Table 56.7). Thrombocytopenia is the most common haematological abnormality in chronic liver disease, and a slowly progressive fall in platelets is often the first sign of such a disease emerging. Patients, even with severe cirrhosis rarely have a platelet count less than $30–50 \times 10^9$/L.

Historically, the low platelet count was attributed to congestive splenomegaly, leading to sequestration in the spleen, and whilst this is undoubtably an important contributor to thrombocytopenia, there are multiple additional mechanisms involved. Lower levels of thrombopoietin are seen in patients with chronic liver disease, and bone marrow function may be supressed, for example by alcohol or viruses, leading to reduced platelet production. There may also be reduced lifespan of these cells, due to increased activation, or by auto-immune destruction.

Table 56.7 Platelets and liver disease.

Changes in platelets in liver disease
Thrombocytopenia
Splenic pooling
Reduced levels of thrombopoietin
Bone marrow suppression, for example by viruses or alcohol
Increased platelet destruction, for example by increased shear forces, or auto-immune processes
Thrombocytosis
Rebound thrombocytosis following alcohol cessation, in combination with improved nutrition
Hepatocellular carcinoma – can secrete thrombopoietin as paraneoplastic phenomenon

Thrombocytosis is less common in liver disease, but can occur following cessation of chronic alcohol, especially when combined with improved nutritional intake. This phenomenon usually lasts up to 2 weeks before self-correcting, and is a normal physiological response that does not require treatment.

Anaemia

Anaemia in liver disease is common (Table 56.8), and generally multifactorial, with reduced production, increased destruction, blood loss and sequestration all contributing.

Table 56.8 Causes of anaemia in liver disease.

Bleeding
Haematinic deficiency – iron
Haematinic deficiency – folic acid
Haemolysis
Zieve syndrome
Anaemia of chronic disease
Alcohol-induced sideroblastic anaemia
Splenic sequestration
Alcohol-induced bone marrow toxicity
Wilson disease – may cause a Coombs' test negative haemolytic anaemia due to direct toxicity of copper ions on red cells
Viral liver disease – see section on infective diseases

Reduced production of red cells may occur due to the anaemia of chronic disease, haematinic deficiency, or via the toxic effects of medications used to treat the underlying liver disease. Acute or chronic alcohol toxicity, which may accompany liver disease, can directly cause impairment of erythropoiesis within the bone marrow.

Liver disease of any aetiology, especially alcohol-related, may lead to the development of a macrocytosis. Increased cholesterol and phospholipid content in the membrane bilayer leads to overproduction of red cell membrane and the subsequent appearance of target cells on the peripheral blood film. In more advanced liver disease, the cholesterol content of the membrane increases further, and acanthocytes (cells with 2–10 thorn-like asymmetric protrusions) may be seen, which can be associated with non-immune haemolysis ('Spur cell anaemia') especially in alcoholic cirrhosis. Stomatocytes (red cells with a slit of central clearing) may be seen in severe liver disease, especially alcohol-related. Acanthocytes should not be confused with the more commonly seen echinocytes (red cells with multiple, smaller, and more regularly distributed membrane projections). These cells are less specific for liver disease, also being seen in severe renal impairment, and are not thought to have a shortened survival. Echinocytes are thought to occur due to the deposition of abnormal high-density lipoproteins from the plasma onto the red cell membrane.

Mild haemolysis is common due to the acquired membrane defects of chronic liver disease. Zieve syndrome is a rare disorder typically occurring after an acute episode of increased alcohol intake in patients with alcoholic liver disease. It is characterised by a triad of non-immune haemolytic anaemia, cholestatic jaundice and hypertriglyceridaemia.

Increased blood loss is a common cause of anaemia in liver disease, due to a number of mechanisms. Portal hypertension may lead to the development of varices, promoting both episodic, as well as chronic blood loss. Splenomegaly leads to thrombocytopenia by sequestration of platelets and, combined with defective haemostasis due to reduced liver synthetic function, potentially accentuates bleeding. Cirrhosis of the liver may cause hypersplenism, leading to the sequestration of red cells, as well as increased clearance and haemolysis.

Polycythaemia

Hepatocellular carcinoma is associated with raised erythropoietin levels in up to 25% of cases, however, only rarely does this result in polycythaemia as its effect is usually modulated by anaemia of chronic disease or abnormal bleeding.

White cells

Neutrophilia may be seen in association with liver disease complicated by malignancy, haemorrhage, haemolysis, infection or when corticosteroids are being administered. Neutropenia may be seen in patients with hypersplenism.

Orthotopic liver transplantation

Thrombocytopenia is frequently present prior to transplantation. The count tends to fall postoperatively, despite platelet transfusions and this may be due to platelet sequestration in the transplanted liver. Immune thrombocytopenia has also been reported after orthotopic liver transplantation (OLT). Antibody-mediated haemolysis occurs in recipients of ABO-incompatible grafts, but the engrafted liver can also produce mild haemolysis due to anti-recipient ABO antibody. This is a form of humoral graft-versus-host disease (GVHD), but T cell-mediated GVHD has also been reported after OLT. Although aplastic anaemia is a rare complication of viral hepatitis, it may occur in as many as 30% of patients transplanted for fulminant non-A, non-B viral hepatitis.

Connective tissue disorders

Haematological manifestations of connective tissue disorders are very common, typically arising as a result of inflammation, auto-immune processes or drug toxicities. In most cases, therapy should be directed at better control of the underlying rheumatological disorder.

Anaemia

Anaemia frequently complicates connective tissue disorders (Table 56.9). In rheumatoid arthritis (RA), and systemic lupus erythematosus (SLE) this is usually due to the anaemia of chronic disease but can be compounded by additional mechanisms.

Long-term use of non-steroidal anti-inflammatory medications, for example by a patient with RA to control joint pain, often causes intestinal inflammation, and frequently iron deficiency due to blood loss which may not be noted by the patient.

Auto-immune haematological complications are common. Warm or cold AIHA, with a direct Coombs' test positive for IgG

Table 56.9 Anaemia in connective tissue disorders.

Anaemia of chronic disease
• With raised hepcidin levels
Blood loss +/− iron deficiency, for example through NSAID-induced intestinal inflammation
Haematinic deficiency – folic acid
Auto-immune haemolysis
• Direct antigen test positive for IgG (Warm), complement (Cold) or both (mixed)
Pure red cell aplasia
• Which may be accompanied by reticulocytopenia
Direct marrow toxicity of medications
Micro-angiopathic haemolytic anaemia – increased risk of thrombotic thrombocytopenic purpura, catastrophic anti-phospholipid syndrome or disseminated intravascular coagulopathy
• Red cell fragmentation, reduced platelet count and elevated LDH are seen.
Haemophagocytic lymphohistiocytosis/macrophage activation syndrome (see Chapter 36)
• Marked elevation of ferritin, often to greater than 10,000 µg/L is seen.

and/or complement, is a frequent occurrence in the connective tissue disorders, especially SLE where it occurs in 10% of patients, and RA. Evans syndrome, the combination of AIHA with ITP, occasionally also with auto-immune neutropenia, can be seen in patients with SLE. Pure red cell aplasia and reticulocytopenia may occur if antibodies are directed against early red cell precursors within the marrow.

Medications used in the treatment of these diseases, such as hydroxychloroquine, mycophenolate and cyclophosphamide may all suppress bone marrow function, whereas methotrexate and azathioprine can cause a megaloblastic anaemia.

White cells

Change in white cells, either reduced, or increased are common in patients with connective tissue disorders.

Neutropenia

Neutropenia and lymphopenia are both common and are usually mild in patients with connective tissue disorders.

Felty syndrome is the triad of neutropenia and splenomegaly in a patient with rheumatoid arthritis, and occurs in approximately 1% of patients with RA, typically those with severe chronic disease. Splenomegaly is not always seen, and treatment is typically with methotrexate, rituximab or steroids.

T-cell large granular lymphocytic leukaemia (T-LGL) is associated with RA in a third of cases, but can also occur in patients with Sjögren syndrome, or SLE. It presents with neutropenia in the majority of patients, as well as with an increased proportion of circulating large granular lymphocytes on the blood film. Since splenomegaly may also be seen, it may mimic Felty syndrome, and is distinguished by the identification of clonal T-cells, and on bone marrow examination, where heavy lymphocytic infiltration is seen. Unlike Felty syndrome, it may present in patients with any degree of connective tissue disorder, whereas Felty syndrome more typically occurs in those with severe disease. Treatment is with low-dose immunosuppression, typically ciclosporin or methotrexate.

Drug-induced neutropenia may be seen, and occasionally agranulocytosis, which is rarely associated with non-steroidal anti-inflammatory medications and gold salts.

Macrophage activation syndrome may occur, especially in patients with SLE, and should be considered in patients with cytopenia, unexplained fever, and very high ferritin levels (see Chapter 36).

Neutrophilia

A raised neutrophil count is common when connective tissue disorders are active, or if corticosteroids are being used in their treatment. Evidence of bacterial infection should be sought, especially in the unwell patient, or those on immunosuppressive medications.

Eosinophilia

This may complicate RA, SLE as well as the vasculitides, most commonly eosinophilic granulomatosis with polyangiitis (formally known as Churg-Strauss syndrome). This latter condition, which may affect any organ, is most often characterised by asthma which is difficult to control, chronic rhinitis, recurrent sinusitis, and eosinophilia of greater than 1.5×10^9/L. An eosinophilic infiltrate is generally seen on biopsies, along with vasculitis and necrosis.

Platelets

Immune-mediated thrombocytopenia (ITP) is the most common cause of a severe reduction in platelets in patients with connective tissue disorders and is seen in up to half of patients with SLE, where it is usually mild, and its onset may precede the diagnosis of SLE. ITP is also associated with RA and other connective tissue disorders, although less commonly.

Thrombocytosis, as a reactive phenomenon, is also seen frequently in the connective tissue disorders, and the extent of the platelet elevation often correlates with disease activity.

Congestive cardiac failure (CCF)

Anaemia is very commonly seen in patients with congestive cardiac failure (CCF), where its cause is usually multifactorial. Anaemia of chronic disease, haemodilution, medications and co-existent renal impairment may all contribute, and haematinic

deficiency should be excluded. Venous congestion may lead to the development of hypersplenism, with associated sequestration and destruction of platelets, although this is usually mild.

Endocrine disorders

A variety of changes to red cells and white cells can be seen in patients with endocrine disorders (Table 56.10). Anaemia may be seen in either hypothyroidism (typically normocytic or macrocytic), or hyperthyroidism (usually normocytic, and may be associated with a mild neutrophilia). In both disorders, there tends to be an increase in fluid retention, such that the anaemia is partially dilutional. Thyroid hormones stimulate erythropoiesis, so patients with hypothyroidism typically develop an anaemia which may be worsened by associated increases in menorrhagia and reduced iron absorption and utilisation (in part due to increased achlorhydria). Other causes of anaemia in patients with hypothyroidism include pernicious anaemia, which is also more common in patients with hypoadrenalism or hypoparathyroidism. Medications used in the treatment of hyperthyroidism (for example carbimazole and propylthiouracil) can cause aplastic anaemia or agranulocytosis.

Anaemia may be seen in patients with diabetes mellitus, often due to co-existent renal disease, anaemia of chronic disease, or as a side-effect of medications.

Table 56.10 Haematological consequences of endocrine disease.

Red cells
Thyrotoxicosis → anaemia (normochromic and usually normocytic)
Hypothyroidism → anaemia (normochromic, normocytic, occasionally macrocytic)
Diabetes mellitus → anaemia (usually when complicated by renal failure, infection, cardiac disease or enteropathy)
Hyperparathyroidism → anaemia (normochromic, normocytic)
Hypoadrenalism → anaemia (normochromic, normocytic)
Hypogonadism → anaemia (normochromic, normocytic)
Hypopituitarism → anaemia (normochromic, normocytic)
Phaeochromocytoma → Anaemia (normochromic, normocytic) or more rarely polycythaemia
Cushing syndrome → Polycythaemia by the stimulation of erythropoiesis by corticosteroids

White cells
Cushing syndrome → Neutrophilia
Phaeochromocytoma → Neutrophilia
Antithyroid drugs → Neutropenia
Diabetes mellitus → Impaired neutrophil function
Hyperthyroidism → lymphocytosis

Effect of body mass index on full blood count

A chronic, mild, leucocytosis and thrombocytosis may be seen in patients with an elevated body mass index (typically greater than 30 kg/m^2), although investigation and exclusion of other causes may be necessary depending on findings from the patient's history, examination and other blood results.

A hypoxia-driven secondary polycythaemia may develop in patients with raised body mass index, due to obstructive sleep apnoea. Patients should be screened for this condition with an Epworth Sleepiness Scale questionnaire and may require sleep studies to confirm the diagnosis.

Patients with low body weight due to anorexia, or starvation, may develop cytopenias, which generally worsen with the severity of their disease. Anaemia (normochromic, normocytic) and leukopenia, typically mixed lymphopenia and neutropenia both occur commonly (33% of outpatients, and up to 83% of in-patients). Thrombocytopenia is less common (10% of outpatients, and up to 25% of in-patients) and severe thrombocytopenia is rare. Bone marrow biopsy is hypocellular, with gelatinous deposits (serous atrophy) commonly observed. Evidence of haematinic deficiency should be sought, but recovery of bone marrow function is generally achieved only with restoration of adequate nutrition and weight.

Environmental, nutritional and age-related changes to full blood count

Other systemic causes of leukocytosis

Smoking may cause mild neutrophilia, with the degree of elevation linked to the number of cigarettes smoked per day. Polycythaemia may also be seen, driven either by hypoxia related to smoking-related pulmonary disorders or due to a reduced plasma volume caused by increased capillary permeability.

Asplenism (either surgical or via auto-infarction for example in sickling disorders) typically causes a moderate neutrophilia, often accompanied by a mild thrombocytosis. Howell-Jolly bodies and occasional nucleated red blood cells can be seen on the blood smear. Such patients often demonstrate an exaggerated white cell response (a leukaemoid reaction) to infection or inflammation.

Copper deficiency

Copper deficiency may occur due to malabsorption in patients who have had gastric bypass surgery or a previous gastrectomy, or those with coeliac disease, or due to excess zinc ingestion, for instance in denture creams or supplements, which out-competes copper for absorption in the gut. It causes

anaemia which is usually normocytic and may be severe and neutropenia which is often less than 1×10^9/L. Thrombocytopenia is rare. Diagnosis is by detection of low serum copper and caeruloplasmin levels. Bone marrow examination may mimic sideroblastic anaemia as ring sideroblasts may be seen, with increased haemosiderin.

Aging and anaemia

Anaemia is more commonly observed with increasing age. This may be due to the increased prevalence of renal dysfunction, increasing co-morbidity and tendency to development of anaemia of chronic disease. In the absence of such conditions, investigation of anaemia in an older adult should mirror that in younger adults. In the very elderly patient, the particular focus of investigation should be on potentially reversible causes.

Infections

Viral infections

SARS-CoV-2

SARS-CoV-2 infection causes a wide variety of pathology in humans with varying chronicity and severity. Infection may be entirely asymptomatic in some, but fatal in others. It may be an acute and self-limiting illness, but in other patients, symptoms that developed during the initial illness persist beyond 90 days, resulting in post-COVID-19 syndrome which can cause significant long-term physical and psychological morbidity. It typically affects the chest, causing pneumonitis, cough and hypoxia, but can present exclusively with symptoms in other organ systems, for example gastro-intestinal. It increases the tendency for thrombosis, especially in the pulmonary vasculature, and increasing prothrombin and D-dimer levels are a marker of disease severity. Rates of haemorrhage, although less common than thrombosis, are also increased with this disease.

The effects of SARS-CoV-2 on the blood count correlate with disease severity, and are of prognostic significance. During acute infection, the severity of thrombocytopenia and lymphopenia correlate with disease severity, likelihood of admission to intensive care unit and death.

Red cells

Both anaemia, and a positive IgG direct antiglobulin test are common in patients with COVID-19, who may have elevations in lactate dehydrogenase and bilirubin, but treatment specifically directed at AIHA is not usually required.

Patients who are hospitalised with COVID-19 are likely to develop anaemia of chronic disease, but attention should be also paid to the correction of haematinic deficiencies, and to the support of renal dysfunction.

White cells

Lymphopenia is a frequent finding, seen in the majority of patients hospitalised with this infection. A progressive decline in lymphocyte count has been described in non-survivors of COVID-19, compared to survivors. Neutrophilia is common in hospitalised patients, especially if dexamethasone is administered. In patients not taking exogenous steroids, the possibility of bacterial co-infection should be considered.

Platelets

Cases of immune thrombocytopenic purpura have been described following infection with SARS-CoV-2, although this does not appear to be common.

Severe COVID-19 is characterised by widespread immune activation, with similarities to haematological conditions such as macrophage activation syndrome, HLH and DIC. The platelet count often falls with increasing disease severity.

Vaccination against SARS-CoV-2

Vaccine-induced Immune Thrombotic Thrombocytopenia (VITT) may occur very rarely in individuals following vaccination with adenovirus vector-based vaccines. It typically develops 5–10 days after vaccination. Patients with this condition develop activating auto-antibodies to platelet factor 4 (PF4) causing a fall in the platelet count. The same antibodies contribute to the activation of neutrophils, monocytes and endothelial cells which, in combination with the inappropriately activated platelets leads to widespread coagulation. Patients develop a thrombotic syndrome which includes typical sites, such as pulmonary embolism and less often deep vein thrombosis of the legs, but also an increased tendency to affect the cerebral, splanchnic and adrenal veins. Less commonly these patients may develop arterial thromboses. Management of this life-threatening condition should be guided from a specialist centre familiar with the management of pro-thrombotic syndromes.

HIV

HIV infection may lead to cytopenias through a number of causes (Table 56.11), including direct infection of the haematopoietic stem cells, or through secondary mechanisms including co-infection by other pathogens, aberrant immune responses, development of malignancies, or the toxic effects of medications used in the management of patients with HIV. Cytopenias are less commonly seen in the modern era of HIV management, however, due to earlier diagnosis, better disease control, and due to advances in combination anti-retroviral treatments which are less cytotoxic than older treatments.

Table 56.11 Mechanisms of development of cytopenia in patients with HIV.

Mechanism	Notes
HIV infection	Through direct marrow suppression, and induction of apoptosis. Anaemia of chronic disease is common.
Co-infection with other pathogens	
• Viral (Hepatitis A/B/C, CMV, EBV)	May be worsened by development of hypersplenism
• Viral (Parvovirus B19)	Causes an isolated anaemia with reticulocytopenia
• Viral (HHV8)	Associated with lymphadenopathy
• Bacterial/fungal/mycobacterial	Through cytokine-induced marrow suppression, or direct marrow infection (for example mycobacterium avium)
• Protozoal	Depending on travel history, consideration should be given to exclusion of malaria (typically presents with anaemia), and visceral leishmaniasis, which presents with pancytopenia and hepatosplenomegaly.
Auto-immune cytopenia	May affect platelets, red cells or neutrophils
Haemophagocytic lymphohistiocytosis	HIV infection can be the trigger for the development of HLH, which is characterised by cytopenias, unexplained fevers and grossly elevated ferritin levels. Haemophagocytosis may be seen in the bone marrow.
Microangiopathic haemolytic anaemia	This may be directly triggered by the HIV infection, or by medications used in its management. Fragments (schistocytes) will be seen on the peripheral blood smear, and the patient may have neurological symptoms.
Malignancy	
• Lymphoma (Hodgkin or non-Hodgkin), including CLL	Cytopenias arise through auto-immune destruction, or anaemia of chronic disease
• Leukaemia	Cytopenias usually through direct marrow infiltration
• Kaposi's sarcoma	This is associated with HHV8 co-infection, and may cause anaemia and thrombocytopenia
Haematinic deficiency	This is common at diagnosis of HIV, due to poor nutritional intake, and gastrointestinal disease involvement. It may contribute to cytopenias

Cytopenias arising directly through HIV infection

Patients presenting with new HIV infections may be noted to have cytopenias, most often lymphopenia (with reduced CD4 count) or neutropenia. Anaemia and/or thrombocytopenia are less often seen at presentation but become more common in patients presenting at later stages of infection, and are frequent in patients whose disease meets the definition for AIDS. HIV infects the haematopoietic stem cells themselves, and inhibits their proliferation, as well as through the production of pro-inflammatory cytokines (e.g. IFN-γ, TNF-α) that induce apoptosis.

Cytopenias arising through co-infection with other pathogens

In individuals with newly detected HIV infection and low CD4 counts, co-infection with other pathogens is commonly detected, and a full screening panel should be performed. Bacterial or fungal infections may contribute to cytopenias. Evidence of chronic parvovirus (erythrovirus) B19 should be sought if there is marked anaemia (with reticulocytopenia), CMV in patients with colitis or retinitis, EBV in those with symptoms resembling infectious mononucleosis, and EBV and CMV in patients with HLH. Human herpes virus 8 may also complicate HIV infection, causing multicentric Castleman disease, characterised by lymphadenopathy, hepatosplenomegaly and cytopenias.

Viral hepatitis may co-infect patients with HIV, and if chronic liver disease and hypersplenism have developed, could contribute to cytopenias.

Cytopenias arising through immune dysregulation

HIV infection may present with auto-immune cytopenias, such as immune thrombocytopenia, AIHA and auto-immune neutropenia, and HIV serology should always be assessed in patients with unexplained cytopenia.

HIV may trigger the development of haemophagocytic lymphohistiocytosis, and ferritin levels should be measured as a screening test to determine whether this syndrome could be contributing to cytopenias.

MAHAs, such as thrombotic thrombocytopenic purpura can be triggered by HIV infection.

Cytopenias related to the development of malignancy

HIV predisposes patients to the development of malignancies, especially haematological, with lymphomas being the most common. The emergence of malignancy is likely to contribute to cytopenias, either through marrow involvement, hypersplenism or auto-immune destruction.

Other viruses

Anaemia

Haemolytic anaemia due to red cell autoantibody production, usually of the warm type, may occur, although cold antibody syndromes may occur in measles, influenza, infectious mononucleosis and mumps. Paroxysmal cold haemoglobinuria is rare and occurs in children due to Donath–Landsteiner IgG anti-P antibodies. Non-immune micro-angiopathic haemolytic anaemia may be associated with thrombotic thrombocytopenic purpura or disseminated intravascular coagulopathy, which may be the result of viral infection. Pure red cell aplasia occurs with parvovirus (erythrovirus) B19 infection which, in patients with pre-existing conditions causing shortened red cell survival (for example sickle cell disease), may cause a 'transient aplastic crisis'. This virus may also cause erythema infectiosum or fifth disease, in children. It invades and destroys red cell progenitors and the aplasia is terminated when neutralising IgM and IgG antibodies develop. If the virus infects pregnant women, it may cross the placenta and cause miscarriage or hydrops fetalis. Intravenous immunoglobulin has been used for severe cases (e.g. in pregnancy, HIV infection and after stem cell transplantation). Bone marrow aspirate shows characteristic giant erythroblasts.

Pancytopenia occurs in virus-associated bone marrow aplasia, for example with hepatitis viruses. The presence of viruses, either within lymphocytes or on their cell surface, may lead to production of a range of cytokines (including TNF, IFN-α and IFN-γ), which inhibit haemopoietic cell proliferation *in vitro* and *in vivo*. This may cause a substantial reduction in erythropoiesis and is presumably the mechanism underlying neutropenia and lymphopenia in viral infections. In infectious mononucleosis and other viral infections such as viral hepatitis, the virus infects B lymphocytes and the activated lymphocytes seen on the blood film are a reactive population of T cells.

Platelets

Thrombocytopenia may occur due to multiple mechanisms. Children with autoimmune thrombocytopenic purpura frequently give a history of a preceding viral illness, and autoantibody production is well described in infectious mononucleosis, rubella and cytomegalovirus infections. Reduction of bone marrow thrombopoiesis is frequently subclinical, but it is particularly important in virus-associated aplasia and dengue fever. Thrombocytosis can also occur in response to viral infections.

Bacterial, fungal and protozoal infections

Specific microbial infections can be associated with particular effects on the haematological parameters (Table 56.12).

Anaemia

Anaemia of chronic disease can occur in acute infections, overwhelming septicaemia and chronic or suppurative infection. Haemolytic anaemia is less common but can occur through both immune (e.g. cold antibodies with anti-I specificity in *Mycoplasma* infection) and non-immune mechanisms. Direct red cell invasion frequently results in severe haemolysis in infections caused by *Bartonella baciliformis*, with elements of intravascular haemolysis (due to increased red cell fragility) and extravascular haemolysis. *Clostridium perfringens* produces an α-toxin (a lecithinase) and a θ-toxin, and *Staphylococcus aureus* an α-toxin, which act as haemolysins and can cause severe intravascular haemolysis. DIC and MAHA can occur in any severe bacterial, fungal or protozoal infection. HUS is associated with a range of bacterial infections, including *Salmonella*, *Shigella* and *Campylobacter* spp., but most frequently with verotoxin-producing strains of *Escherichia coli*. Hookworm and schistosomiasis are two of the most frequent causes worldwide of iron deficiency anaemia, due to intestinal haemorrhage and in the case of schistosomiasis, haematuria (see Chapter 11).

White cells

Neutrophilia is the most common manifestation. The neutrophil response shows great individual variation, with no clear relationship to the severity of the infection. The term *leukaemoid reaction* is used to describe marked leucocytosis ($>50 \times 10^9$/L), with circulating immature forms occurring in patients with non-leukaemic conditions, typically severe infection or haemolysis or with generalised malignancy. Such reactions are more common in children. Features that distinguish such a reactive leucocytosis from chronic myeloid leukaemia include the presence of toxic granulation, Döhle bodies, and the lack of twin peaks of neutrophils and myelocytes. Neutropenia can also occur with virtually any bacterial infection, although it has been most frequently noted with *Salmonella*, *Rickettsia* and *Brucella*. Defects of neutrophil function may also occur.

Platelets

Thrombocytosis is frequent in patients with chronic infections, especially bacterial abscesses, and during the convalescent phase of acute infections. Thrombocytopenia also occurs during severe bacterial or fungal infection, particularly where there is bloodstream invasion or in intensive care patients. Certain rickettsial infections (e.g. Rocky Mountain spotted fever) are almost always associated with thrombocytopenia. Accelerated platelet

Table 56.12 Haematological changes in bacterial, fungal and protozoal infections.

Anaemia
Anaemia of chronic disease
Haemolytic
Immune: *Mycoplasma*, malaria, syphilis (paroxysmal cold haemoglobinuria), listeriosis
Non-immune: *Clostridium perfringens* (toxin-related), *Bartonella bacilliformis* (Oroya fever)
Malaria/trypanosomiasis with microangiopathy/Disseminated intravascular coagulation, septicaemia
HUS: verotoxin-producing *Escherichia coli* and *Streptococcus pneumoniae*
Sequestration
Splenomegaly (e.g. malaria, schistosomiasis)
Blood loss
Helicobacter pylori, *Ancylostoma (hookworm), schistosomiasis*
White cells
Neutrophilia
Virtually any bacterial/fungal infection
Neutropenia
Salmonella, *Rickettsia*, brucellosis, pertussis, disseminated tuberculosis (TB)
Overwhelming septicaemia
Lymphocytosis
Whooping cough (*Bordetella pertussis*), *Rickettsia*
Lymphopenia
TB, acute bacterial infections, brucellosis, acute viral infections, including *SARS-CoV-2*
Eosinophilia
Aspergillosis, coccidioidomycosis, *Chlamydia*, streptococcal infections, *Ancylostoma*
Eosinopenia
Common in acute *Bacteroides* infections
Monocytosis
Subacute/chronic infections (e.g. disseminated TB, listeriosis)
Pancytopenia
Bone marrow suppression (e.g. disseminated TB, listeriosis)
Haemophagocytosis: septicaemia
Peripheral destruction (e.g. DIC)

destruction is the most frequent mechanism and can arise through DIC or microangiopathy with platelet attachment to damaged endothelium. Immune destruction can also occur. Decreased platelet production is a less common mechanism, but may occur (e.g. in disseminated tuberculosis). The inflammatory and procoagulant responses to infections are related. TNF-α, IL-1α and IL-6 may activate coagulation and inhibit fibrinolysis, whereas thrombin may stimulate inflammatory pathways. In severe infection, the end result may be endovascular injury, DIC, multiorgan failure and death.

Introduction

Most of the information set out in a standard textbook such as this is organised in functional or anatomical systems. This is logical but does not necessarily represent the way problems present themselves in practice. Haematologists specialising in thrombosis and haemostasis will have primary responsibility for a wide group of patients often with hereditary or lifelong disorders but much of their time is spent giving advice in consultation regarding the management of patients with other primary disorders but who have developed bleeding or thrombotic complications or whose history and therapy for these problems complicates their management. Trainee haematologists frequently comment on the high proportion of their calls arising from consultative haemostasis and thrombosis. This chapter is an attempt to give some structure to managing these problems. Some of the information will appear in other chapters but is here organised in a practical way that reflects how problems arise in practice and often complicate each other.

The bleeding patient

The post-operative patient

Surgery is necessarily traumatic, although in many cases much less so than in the past. However, the advent of laparoscopic or keyhole surgery has made it more difficult to detect bleeding when it occurs. The time taken for haemodilution means that a fall in haemoglobin may take 12–24 hours to appear after a bleeding event and so tachycardia and (postural) hypotension should be sought as they can be significant early indicators of blood loss. Major haemorrhage definitions are not useful in a clinical time frame, but significant bleeding (>150 mL/min) without immediate prospect of control or heart rate >110 beats/min and/or systolic blood pressure <90 mm Hg are useful indicators. Drugs, patient age and comorbidity may make these measures more difficult to assess. The contents of surgical drains should also be examined. When visible, the pattern of bleeding may be helpful in diagnosis and management. Local bleeding or bleeding via drains may be anatomical or surgical whereas widespread bleeding from non-surgical sites indicates deranged haemostasis. Widespread ecchymoses and bleeding from intravenous lines may indicate disseminated intravascular coagulation (DIC), purpura may indicate small vessel thrombosis as seen in meningococcal sepsis or pyoderma gangrenosum. Large unstable and friable clots are typical of haemophilia. Delayed bleeding, whilst theoretically typical of fibrinolysis, reactive haemorrhage or infection may actually arise from almost any haemostatic defect.

Routine preoperative coagulation testing is not recommended due to its poor predictive power, but if previous coagulation screens and platelet counts are available, they can be valuable by excluding the presence of a significant hereditary coagulation disorder and identifying any current abnormalities as acquired. This limits the differential diagnosis considerably.

Hoffbrand's Postgraduate Haematology, Eighth Edition. Edited by Adam J Mead, Michael A Laffan, Graham P Collins, Deborah Hay, and A Victor Hoffbrand (Consulting Editor).

Companion website: www.wiley.com/go/mead/HPH8e

Nonetheless, it is not uncommon for an abnormal coagulation screen disclosing undiagnosed von Willebrand disease (VWD) or mild haemophilia to have been overlooked in preoperative assessment and mild coagulation factor deficiencies may not cause prolongation of the standard prothrombin time (PT) and activated partial thromboplastin time (APTT) screening tests. Thrombocytopenia due to an underlying disorder will usually have been detected preoperatively and its development post operatively is likely to indicate consumption.

It is important first to obtain a clear picture of the amount and rapidity of blood loss followed by the amount and type of blood products that have been given. Coagulation tests and a full blood count (FBC) should be sent but will take time to become available and the situation may be urgent. Increasingly, the results of near-patient testing such as thromboelastography (TEG) or rotational thromboelastometry (ROTEM) will be available. The global nature of these viscoelastic tests is useful in the context of acute bleeding and if they are normal then post-operative or traumatic bleeding is unlikely to be due to a defect of haemostasis and more likely to be structural.

The basic viscoelastic profile is shown in Figure 57.1. The initial clotting time (R or CT) reflects the time taken for thrombin generation to increase and is typically prolonged by anticoagulants, inhibitors or coagulation factor deficiency, including fibrinogen. The speed with which the clot then forms can be measured as the rate or the angle (α-angle) at which the trace widens. This is also dependent on thrombin generation but requires fibrinogen and platelets as well. The maximum amplitude or clot firmness is dependent on both fibrinogen and platelet function. Finally, if fibrinolysis is excessively active, the breakdown of the clot will be evident as decrease in the width of the trace. Normal fibrinolysis usually takes too long to be routinely observed. Abnormalities of the viscoelastic trace can therefore be used to generate straightforward algorithms to help guide replacement therapy. An example is shown in Figure 57.1. This approach is approved by NICE for cardiopulmonary bypass (CPB) surgery but it is widely used in other circumstances as well. In general, haematologists are less familiar with these tests but a working knowledge of their interpretation is invaluable for consultative work. Nonetheless, they do not determine the aetiology of any abnormality which requires further investigation with specific laboratory tests.

Viscoelastic devices are in evolution and new ultrasonic methods for detecting clot strength are replacing physical ones and multitest cartridges are being used to avoid errors from pipetting. Moreover, new reagents allow dissection of platelet-fibrinogen, anticoagulant and antiplatelet effects (platelet mapping).

Dilutional coagulopathy

In bleeding patients, resuscitation is usually focussed, quite reasonably, first on simple fluids and then on red blood cells (RBC) to maintain oxygen delivery. However, RBC preparations do not contain any plasma components and so without plasma replacement, dilutional coagulopathy is inevitable. If no coagulation tests are available, then the likelihood of dilutional coagulopathy can be reasonably estimated by counting the number of units of RBC transfused compared to the number of units of plasma, cryoprecipitate and platelets. If more than about 6 units of RBC have been given with 3 units fresh frozen plasma (FFP) or less, then dilution is likely. Remember that in dilutional coagulopathy fibrinogen falls early and platelets late, whilst the reverse is true of DIC. Routine coagulation tests confirm dilutional coagulopathy likely to cause bleeding when the PT ratio is >1.5 and fibrinogen <0.8 g/L. Viscoelastic tests will give similar indications and can be used to direct replacement as above, but dilutional coagulopathy can be prevented by beginning plasma replacement alongside red cell transfusion as soon as it is recognised that the haemorrhage may be large. This realisation has led to development of major haemorrhage protocols which provide RBC, plasma and platelets in fixed proportions from the beginning of resuscitation. A major haemorrhage protocol is now in place in most major hospitals and a suggested example is shown in Figure 57.2.

If dilutional coagulopathy is established and rapid replacement required or volume capacity is limited, then use of concentrates may be considered. A combination of prothrombin complex concentrate (PCC), fibrinogen concentrate or cryoprecipitate and platelets will provide an almost complete haemostatic mechanism (factor VIII and von Willebrand factor (VWF) release from endothelial stores mean that they are rarely depleted). Current guidelines note that evidence for routine use of this approach is limited and also caution against the use of these concentrates as monotherapy for obvious reasons. Thus, in an emergency, concentrates and platelets should be given simultaneously or in rapid succession, since they must all be present at the same time for successful haemostasis. Recombinant factor VIIa (FVIIa) has been used as an adjunct to promote haemostasis and although generally not approved for this purpose it has now been authorised for refractory post-partum haemorrhage.

The trauma patient

The coagulopathy associated with Trauma is dealt with in Chapter 43 'Acquired coagulation disorders'.

The post-partum patient

Parturition is a highly haemorrhagic event. Recent studies have established that the physiological rises in factor VII, factor VIII and fibrinogen during pregnancy are important

	Clot initiation	Clot strength		Clot lysis
Test result shows	Prolonged R, ACT or CT	Reduced MA/MCF, normal fibrinogen†	Reduced MA/MCF, low fibrinogen†	LY-30 >8% Li30 >15%
What does this mean?	Low clotting factors and/or low fibrinogen level Warfarin use Heparin use DOAC use (not Apixaban)	Low platelets	Low fibrinogen	VHA detected fibrinolysis*
Therapy recommended	FFP (PCC might be considered)	Platelets	Cryoprecipitate or fibrinogen concentrate	Consider additional anti-fibrinolytic*
Therapy groups				
Obstetric	FFP if R or CT above the normal range. PCC is not recommended	No data are available to guide platelet transfusion	Cryoprecipitate or fibrinogen concentrate if FIBTEM <7 mm or <12 mm in severe bleeding	No data are available for guiding antifibrinolytic therapy
Liver	FFP if results above normal range (PCC might be considered)	EXTEM MCF <35 mm	FIBTEM <7 mm	Fibrinolysis at reperfusion may correct spontaneously. Anti-fibrinolytics are indicated in most other circumstances.
Cardiac	FFP if>15% above ULN	Platelets	Cryoprecipitate or FgC	
Trauma	FFP if results ≥ULN PCC not recommended	Give platelets if MA/MCF at lower end or below the normal range whilst ff or FIBTEM normal	Cryoprecipitate or FgC if FIBTEM or ff at lower end or below the normal range	TEG LY-30 ≥3% indicates clinically important lysis

The research in the top panel was originally published in *Blood*. Johansson *et al* (2014) © the American Society of Hematology.
ACT, activated clotting time, CT, clotting time, DOAC, direct oral anticoagulant, ff, functional fibrinogen; FFP, fresh frozen plasma; FgC, fibrinogen concentrate; Li30, lysis index at 30 min; LY-30, lysis at 30 min; MA, maximal amplitude, MCF, maximum clot firmness; PCC, prothrombin complex concentrate, R, reaction time; TEG, thromboelastography; ULN, upper limit of normal; VHA, viscoelastic haemostatic assay.

*Do not withhold an anti-fibrinolytic if is it clinically indicated and within 3 h of injury or start of postpartum haemorrhage.
†Clot strength measures are highly dependent on platelets and fibrinogen. To differentiate low clot strength due to loss of platelet function or from that due to low fibrinogen levels, the clot strength of the fibrinogen assay (ff – TEG; FIBTEM – ROTEM) should be compared with the standard TEG or ROTEM EXTEM trace, respectively. A low overall clot strength with a normal ff/FIBTEM would suggest lack of platelets contributing to the clot, whereas a low overall clot strength with a concomitant low ff/FIBTEM would point to lack of fibrinogen.

Figure 57.1 TEG and ROTEM traces. Thromboelastography (TEG) and thromboelastometry (ROTEM) traces can be broadly divided into four main sections: (a) time to first fibrin formation [reaction *time – TEG5000; activated clotting time (ACT) – TEG6s; clotting time (CT) – ROTEM]; (b) kinetics of fibrin polymerisation which has two parameters that are directly interchangeable [alpha angle used by both devices) and additionally, the time it takes from first fibrin formation to when arbitrarily the clot is 20 mm wide (kinetics [K] time – TEG5000; clot formation time [CFT] – ROTEM); (c) measures of clot strength – often demarcated at 5 min intervals (amplitude [A] – A30 – TEG clot strength at 30 min; clot amplitude [CA] – CA30 – ROTEM clot strength at 30 min) and with a peak measurement (maximal amplitude [MA] – TEG; maximum clot formation [MCF] – ROTEM); (d) measures of clot breakdown/lysis, usually presented as a percentage of reduction in the clot strength measure compared to maximal measurement)Lysis (Ly) – TEG; clot lysis/lysis index/maximal lysis (CL/Li/ML) – ROTEM) (Source: Reproduced from: Curry *et al*. 2018/With permission of John Wiley & Sons.)

for peri-partum haemostasis and that non-pregnant normal ranges are not adequate. The major cause of post-partum haemorrhage is uterine atony as well as other placenta-uterine abnormalities. Hence the initial management is largely obstetric but with rapid resuscitation, dilution can easily occur and coagulopathy may be complicated by problems such as amniotic fluid embolism, thrombocytopenia (gestational, pre-eclampsia (PET), haemolysis, elevated liver enzymes and low platelets (HELLP) syndrome), sepsis, abruption. As with other major haemorrhages, fluids should be warmed if possible

Figure 57.2 **Algorithm for the management of major haemorrhage (adapted from the BCSH *Practical Guideline for the Management of Those With, or At Risk of Major Haemorrhage* (2013) with permission)**

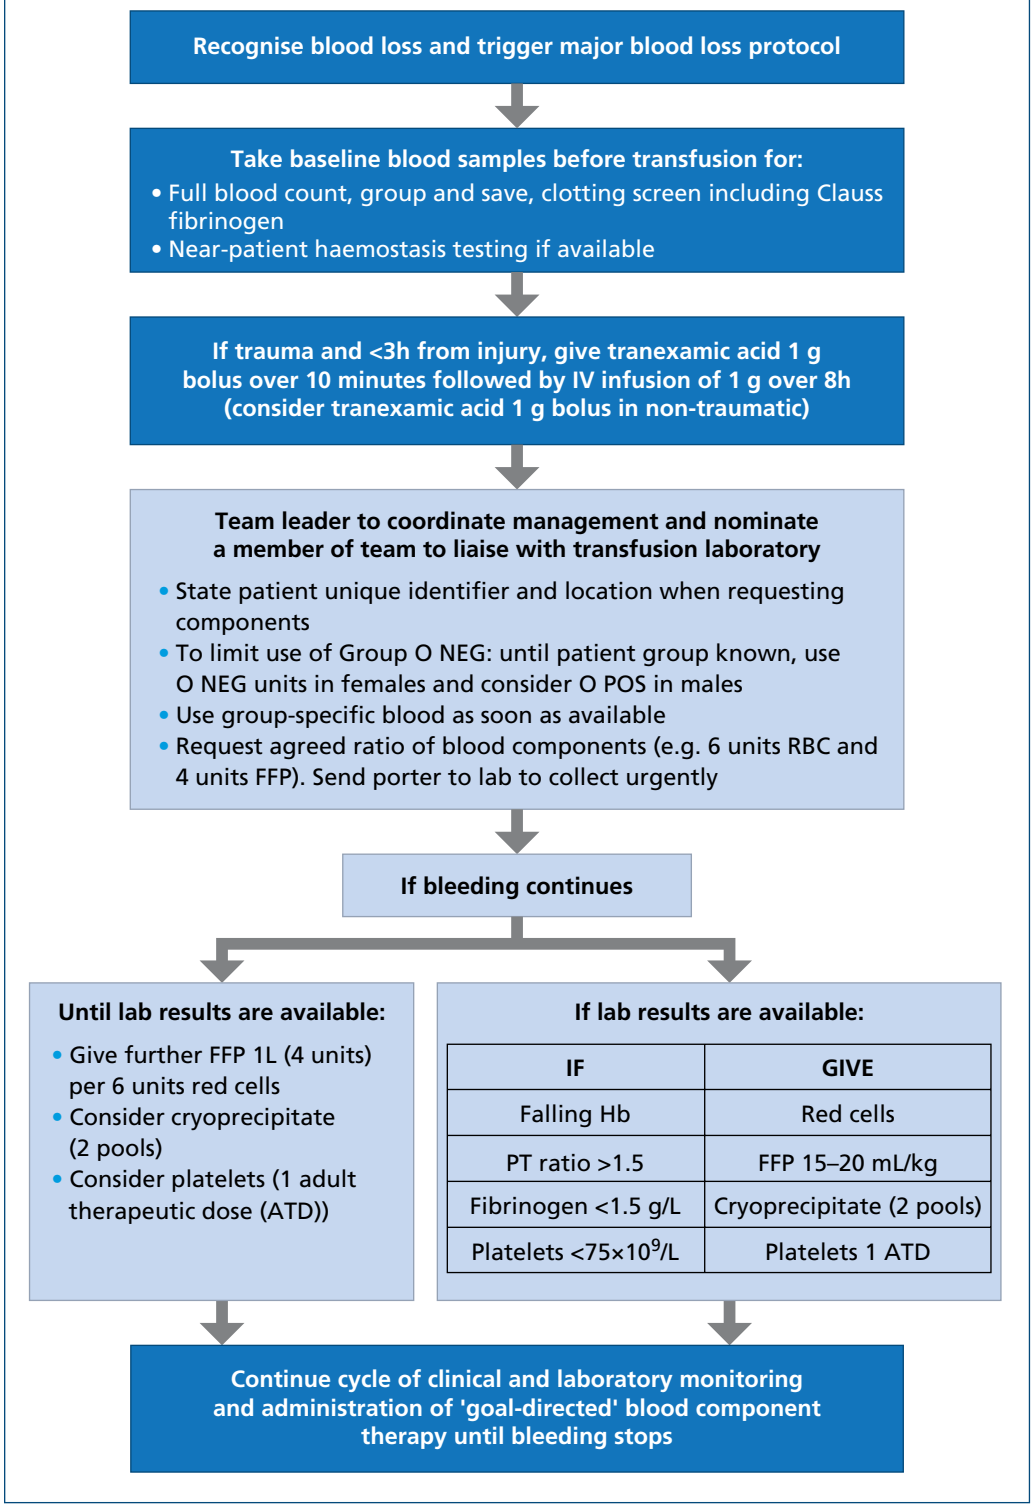

Figure 57.2 Major haemorrhage protocol (Source: Derek Norfolk 2013/TSO/Public Domain OGL.)

to avoid hypothermia and acidosis. Suggested targets (for ROTEM) are

- Normal PT/aPTT (refer to local laboratory ranges)
- Fibrinogen (>2 g/L)
- EXTEM CT (<75 s)
- Fibtem A5 (>11 mm)

Pregnancy-related haemostatic dysfunction is dealt with in more detail in Chapter 43 'Acquired coagulation disorders'.

The patient bleeding with normal coagulation tests

Sometimes post-operative patients appear to have been given adequate replacement therapy and have corrected their standard coagulation tests but continue to bleed or they have bled despite normal tests. Obviously, the first consideration is whether this is structural or surgical and a normal TEG/ROTEM makes this likely. The unrecognised presence of antithrombotic therapy should be considered because anticoagulants, even at therapeutic doses, do not always produce an abnormal coagulation screen or viscoelastic test and nor do anti-platelet agents. Consider that the available analyses may not have tested all haemostatic functions such as platelet capture under shear stress, factor XIII activity, anticoagulant function and fibrinolysis. Some procedures such as prolonged CPB or hypothermic arrest procedures typically result in a platelet dysfunction due to loss of surface glycoproteins not detected by standard tests. Extravascular circuits can cause an acquired von Willebrand syndrome which can be associated with angiodysplasia and refractory bleeding and the factor VIII may not be reduced sufficiently to prolong the APTT.

Additional non-replacement therapies for haemorrhage

Tranexamic acid is a lysine analogue that binds to the lysine binding sites on plasminogen to prevent it from binding to fibrin and being activated by tissue plasminogen activator (tPA). It has been shown to reduce blood loss in major orthopaedic, cardiac and general surgery. Notably in the CRASH II study, early administration within three hours, but most markedly within 1 hour, reduced mortality. This has led to a number of other trials that have shown variable success and in some cases harm. Meta analyses suggest that there is overall no increase in thrombosis associated with tranexamic acid use but this has been increased in some studies. High doses in particular can increase the risk of seizures. The trial results are summarised in Table 57.1.

Aprotonin is a bovine serine protease inhibitor used as a potent anti-fibrinolytic although some of its beneficial effects may result from other effects including inhibition of thrombin platelet activation. After reports of an increase in myocardial infarction and death, it now has a limited indication for cardiac surgery patients at high risk of bleeding.

Desmopressin is a modified form of vasopressin without its pressor effect, that releases stores of von Willebrand factor and Factor VIII from endothelial stores. It is widely used to elevate levels of these factors in suitable patients with forms of haemophilia and VWD. It is also effective in mild platelet function defects and in reversing the primary haemostatic defect in uraemia, but has not been shown to be of general benefit in haemorrhage.

The outpatient with bleeding symptoms

Acute onset bleeding

Sometimes patients present with new-onset bleeding symptoms as the primary problem. Once anticoagulant excess has been excluded, the differential diagnosis in adults is relatively short. A full blood count will demonstrate whether acquired disorders such as immune thrombocytopenic purpura (ITP), thrombotic thrombocytopenic purpura (TTP) or leukaemia are the explanation and the clinical picture of thrombocytopenic bleeding will be typical. Widespread ecchymoses and

Table 57.1 Trial results for tranexamic acid.

Indication	Benefit on blood loss/mortality	Thrombotic risk reported	Additional risk	Comment
Trauma	Yes	No		Timing important
TBI	Yes	No		
ICH	No	No		
GI	No	Yes	Seizures increased	4 g/24 hrs
Post-partum	Yes	No		Timing important
Orthopaedic surgery	Yes	No		
Cardiac surgery	Yes	No	Seizures increased	
HMB	Yes	Possible, but causality uncertain.		

soft tissue bleeding raises the possibility of acquired haemophilia supported by a newly prolonged APTT and confirmed by a low factor VIII level. Typical patients are elderly, sometimes with comorbidity, or younger and post-partum. Acquired deficiencies of other factors can occur but are extremely rare: Factor V and factor XIII are probably the most common and the problem should be evident from coagulation tests of PT and APTT and specific assays.

Acquired von Willebrand syndrome is often asymptomatic and detected on laboratory testing but may present with protracted gum or mucosal bleeding and bruising after minor trauma. A number of disorders including paraproteinemia, aortic stenosis and myeloproliferative neoplasms (with thrombocytosis) can be responsible, each via different mechanisms. There is a well-known association between chronic blood loss from angiodysplasia and acquired von Willebrand syndrome secondary to aortic stenosis. Note that there may be acquired FVIII deficiency but no anti-FVIII antibody or inhibitor.

Some tumours, notably prostatic carcinoma, release excessive profibrinolytic factors (urokinase-plasminogen activator (uPA) or tPA) into the circulation causing a haemorrhagic disorder due to primary fibrinogenolysis. Clinical bleeding from gut or urogenital tract may result but also large subcutaneous or muscular haematomas reminiscent of acquired haemophilia. Blood tests show the expected reduction in fibrinogen, gross elevation of fibrin degradation products (FDPs) and prolongation of clotting times. D-dimer levels are also elevated suggesting there is also a component of DIC.

Bruising

Bruising, often reported to occur with minimal or no trauma, is one of the commonest reasons for referral to the haemostasis clinic. It is usually very clearly distinct from the large soft tissue and subcutaneous ecchymoses seen in acquired haemophilia and also from the large patchy lesions of senile purpura over the back of the hands and forearm in association with delicate sun-exposed skin or prolonged steroid therapy. Easy bruising characterised by small bruises predominantly on the legs and sometimes arms but not the torso is very rarely an indicator of a significant underlying bleeding disorder.

In older patients, the appearance of bruises may follow initiation of antiplatelet therapy, steroid inhalers or over-the-counter (OTC) supplements with anti-platelet activity. Selective serotonin reuptake inhibitors (SSRIs) are widely used and have a clear antiplatelet effect manifest as an increased risk of intracranial haemorrhage but bruising or other bleeding may also be enhanced. A history of surgery without problems is helpful. Some patient groups will be at risk of scurvy and older patients with amyloidosis may present with bruising. Routine investigations are usually warranted as the acquired disorders listed above are significant and others such as paraproteins or myelodysplasia may also be associated with impaired platelet function. Nonetheless, most instances of 'easy bruising' especially when restricted to the limbs do not reflect a significant haemostatic defect and preliminary investigations are normal with no need for further testing. Bruising is a feature of some forms of Ehlers-Danlos syndrome but not of Marfan's or cutis laxa. Bruises preceded by a painful sensation have been described as 'painful bruising syndrome'. The aetiology is not clear but may represent inadvertent self-infliction.

Post-viral bruising in children may be caused by ITP but there is also a syndrome of bruising and prolonged coagulation tests produced by acute but transient antiphospholipid antibodies. It does not require treatment.

Epistaxes

Epistaxes are common in childhood and usually settle in adolescence; this pattern is not indicative of a bleeding disorder. Indicators of a bleeding disorder are prolonged bleeding, usually 15–20 min or more, recurrence after local measures and bleeding from both nostrils. An ENT assessment will be useful at some stage and although cautery may be beneficial, repeated treatments may be counterproductive especially if the underlying problem is haemostatic. Prolonged epistaxes are a typical feature of VWD and platelet disorders, but also remember to check for the telangiectasia of hereditary haemorrhagic telangiectasia (HHT), which is a progressive disorder and so lesions may be less obvious in young patients.

Heavy menstrual bleeding

There is a growing realisation that the problem and impact of heavy menstrual bleeding (HMB) has been underestimated if not ignored, by haematologists and physicians in general. It is highly prevalent and an estimated 30% of women report HMB at some point in their reproductive period and 15–30% of these may have an underlying bleeding disorder. It should always be taken seriously and investigated for both haematological and gynaecological contributory factors. Pictorial assessment tools are available to give quantitative assessment if necessary and Bleeding Assessment Tools, developed primarily for VWD may indicate help the identification of a likely bleeding disorder. Heavy bleeding from menarche and the development of iron deficiency are indicators of severity.

Close collaboration between haematology and gynaecology is essential, firstly because although specific treatments are available for haemostatic support, the first line of therapy is usually hormonal. Combined or progesterone-only contraceptive pills, the mirena coil or loop are all valuable methods for reducing menstrual blood loss. Tranexamic acid may be useful on its own in mild cases or as an adjunct. Severe bleeding disorders such as type 3 VWD or if contraception is unwanted may necessitate intermittent replacement therapy. Secondly, HMB may have a pathological or structural basis requiring gynaecological management. The

National Institute for Health and Care Excellence (NICE) has published guideline https://www.nice.org.uk/guidance/ng88.

Bruising in children

Hereditary disorders of haemostasis generally present at a young age, often with bruising, haemarthrosis, epistaxis or other post-traumatic bleeds which are spontaneous or out of proportion to injury. Careful history-taking and critical examination are essential. Many children with haemophilia have been taken into care erroneously, but it remains important to consider deliberate trauma and to activate safeguarding authorities when appropriate.

The patient with abnormal coagulation tests

The coagulation screen

The coagulation 'screen' routinely requested in hospital almost always comprises a PT and an APTT. In some hospitals, a fibrinogen assay is included or this may be a reflex test only performed if one of the first two is abnormal. Coagulation testing is often performed without any clear purpose and consequently, it frequently reveals abnormal results of uncertain significance resulting in a call to haematology for advice. At the same time, a normal coagulation screen may give unwarranted reassurance that haemostasis is normal. The PT and APTT bear only limited relationship to the *in vivo* process of haemostasis and do not require the elements of primary haemostasis (platelets, VWF and collagen). Nor do they assess clot stability, anticoagulant mechanisms or fibrinolysis. Conversely, they may frequently be rendered abnormal by factors that have no impact on haemostasis such as factor XII deficiency or a lupus anticoagulant. The most important lesson for the haematologist is that a normal coagulation screen does not imply normal haemostasis and an abnormal one does not indicate abnormal haemostasis. It is essential to understand both the limitations and the importance of these tests.

When approaching the patient in hospital with abnormal test(s) some basic steps are always useful:

1 Has the patient ever had normal coagulation tests? If so then this excludes hereditary or congenital coagulation disorders and narrows the differential diagnosis considerably.

2 Has the patient ever had interventional procedures or trauma and were these associated with bleeding? This similarly can help exclude or identify a congenital disorder.

3 Could the abnormality be artefactual due to anticoagulants (including heparin from the sample line or cannula), under filling of the sample tube, elevated haematocrit, prolonged transit or is it a failure of endpoint detection by the analyser rather than a genuine prolongation? If the endpoint was not detected, perform a manual test or inspect the waveform on the analyser. In some laboratory systems, the plasma is separated before shipping to another site for analysis so that an incorrect sample, for example in EDTA, may have been sent.

4 A repeat test with careful collection and transport is always valuable.

5 What is the sensitivity of your APTT reagent to nonspecific/antiphospholipid antibodies?

6 What type of endpoint detection does your analyser use? Optical end-point detection may be affected by other plasma factors such as lipids or haemolysis.

7 Does the patient have liver dysfunction, malabsorption or a prolonged reduction in dietary intake? In which case an injection of vitamin K may improve results significantly within 12–24 hours.

Isolated prolonged PT

This indicates Factor VII deficiency or an inhibitor. Some PT reagents are sensitive to antiphospholipid antibodies. It may also be seen at the beginning of VKA therapy or incipient vitamin K deficiency. A factor VII assay is required, but unless very long it is unlikely to represent a significant bleeding risk because only very low levels of factor VII (<10 iu/dL) are required for normal haemostasis. If the thromboplastin used is animal rather than human then repeat using one containing human tissue factor because rare variants (factor VII Padua) give abnormal results with animal tissue factor.

Isolated prolonged APTT

This is the most frequent problem in hospital. If the situation is urgent then the best diagnostic approach is to perform factor VIII, IX and XI assays. If these are normal then there is unlikely to be a significant bleeding tendency and surgery can proceed. Other explanations such as a lupus anticoagulant or contact factor deficiency can be investigated later.

Mixing tests are often requested but have limited sensitivity and specificity, use up valuable time and sample and are not recommended in the acute setting providing assays are available. The rationale for this is as follows:

> If mixing tests correct you have not excluded a time-dependent inhibitor and if it is a factor deficiency you do not know which one is missing, so assays will be required.
> If the mix fails to correct you will need to exclude acquired haemophilia by performing a factor VIII assay (or rarely some other specific inhibitor).
> The degree of correction is often difficult to assess especially with minor degrees of prolongation.

If there is insufficient time to perform assays, then consideration of history, tests and current clinical situation may allow you to conclude that a significant problem is unlikely. An extremely long APTT makes a contact factor deficiency or heparin contamination

likely. If the analyser fails to detect an endpoint (e.g. reports >180 s) then perform a manual test: the result may well be normal.

A new and significant (not borderline) isolated APTT prolongation raises the possibility of acquired haemophilia which is perhaps the single most significant and important possibility. A factor VIII assay is required to exclude this. A UK study reported that 33% of patients with acquired haemophilia A (AHA) did not require haemostatic treatment so bleeding may not be evident at diagnosis.

Prolonged APTT and PT

Some judgement is required to conclude that this is a combined problem and not (for example) a significantly prolonged APTT with a marginal prolonged PT which might be better treated as an isolated prolonged APTT. If the abnormality is long standing, perhaps with a bleeding history then assays of factor V, X and II will be indicated and review of the fibrinogen level. If the factor V is reduced, remember that this may be part of the autosomal recessive combined factor V and factor VIII disorder. Other combined deficiencies are extremely rare (see Chapter 42).

Acquired prolongation of both tests may indicate liver impairment, DIC, dilution, vitamin K deficiency and drug effects. The need for correction is complicated and depends on the likely cause but it is not usually required unless bleeding is present or surgery planned. These causes are discussed further in the chapter on acquired disorders. (Chapter 43)

The patient on anticoagulants, antiplatelet agents or following fibrinolytic therapy

The initial step in considering a patient who is bleeding on antithrombotic therapy is to assess the severity of bleeding against the background thrombotic risk, which may entail multidisciplinary discussion, and to obtain details of drug administration including the route, timing and dose, and the presence of any relevant co-morbidities including background predisposition to bleeding and recent invasive procedures or trauma. A suitably sited and maintained point-of-care coagulometer in the Emergency Department reduces delays in correction of warfarin-associated coagulopathies. The major haemorrhage protocol should be activated if necessary.

On top of the immediate management, consideration should be given to the underlying cause of the bleeding in addition to antithrombotic therapy and to the co-administration of any medication associated with a pharmacokinetic or pharmacodynamic interaction. Blood samples should be sent to check the FBC, clotting screen, renal and liver function tests and, where available and appropriate, an anti-Xa or drug level. Local measures to control bleeding should be implemented as appropriate.

Heparin

The risk of major bleeding during the initial days of therapeutic heparin administration is about 1–5%. Intravenous unfractionated heparin (UFH) has a short half-life of about 60–90 min, unless administered in considerable excess and it may be sufficient to simply switch off the infusion in the event of minor bleeding. More rapid reversal is achieved by the intravenous administration of protamine sulfate which completely neutralises UFH. Subcutaneous low-molecular-weight heparin (LMWH) has a longer effective half-life of 4–6 hours and, although the anti-IIa component is neutralised by protamine sulfate (normalising the APTT), the predominant anti-Xa component is only partially neutralised.

In the event of major bleeding or risk of bleeding, intravenous protamine sulfate should be administered at a rate not exceeding 5 mg/min and with a maximum dose of 50 mg. As a general rule for reversal of UFH being given by intravenous infusion, 1 mg protamine sulfate should be given for every 100 IU heparin administered in the previous 90 min plus 0.5 mg for every 100 IU administered in the previous 90–180 min. For reversal following an intravenous UFH bolus administered less than 30 min earlier, 1 mg protamine per 100 IU UFH should be given. This dose of protamine should be halved if 30–120 min have elapsed since the UFH bolus and a 25% dose should be considered if 120–180 min have elapsed since the UFH bolus. The half-life of protamine sulfate is short (about 7 min) and the APTT should be re-checked 10 min, 2 hours and 6–8 hours after administration, initially to assess reversal and later to identify possible heparin rebound.

For reversal of LMWH, 1 mg protamine sulfate should be administered per 100 IU of tinzaparin or dalteparin or per 1 mg enoxaparin if the heparin has been administered in the previous 8 hours (maximum dose 50 mg). If 8–16 hours have elapsed since the last dose of LMWH, the dose of protamine sulfate should be 0.5 mg per 100 IU of tinzaparin/dalteparin or 1 mg enoxaparin. The APTT should be rechecked after administration if initially prolonged.

Protamine sulfate may cause hypersensitivity including anaphylactoid reactions with bronchospasm and hypotension. Particular care with close monitoring is required in patients who have recently undergone procedures such as cardiopulmonary bypass that use protamine, those with fish allergy or diabetes treated with isophane insulin, or males with a previous vasectomy or male infertility. In excess, protamine sulfate has an anticoagulant effect.

Warfarin and other vitamin K antagonists (VKAs)

The absolute risk of major bleeding on VKAs is about 2% per year overall but is strongly age-related. Major or life-threatening bleeding requires stopping the VKA and administration of PCC

25–50 U/kg and vitamin K 5 mg intravenously. Vitamin K takes several hours to reverse the coagulopathy of VKAs whereas PCC rapidly corrects it but wears off over some hours in line with the half-lives of the vitamin K-dependent clotting factors. PCC in the UK contains the four vitamin K-dependent clotting factors – factors II, VII, IX and X – as well as protein C and protein S. It also contains a small amount of heparin and should therefore be avoided in patients with heparin-induced thrombocytopenia. As well as measurement before administration, the international normalised ratio (INR) should be checked 10–30 min and 4–6 hours after PCC has been given. If PCC is not available, FFP 10–15 mL/kg should be considered but compared to PCC, VKA reversal with FFP is slower and less complete.

Direct oral anticoagulants

The specific agent as well as the timing and amount of the last dose should be established as soon as possible. In the setting of major haemorrhage, if it is less than 2 hours since ingestion, oral activated charcoal 50 g can be considered. Blood samples should be sent for FBC, clotting screen, renal and liver function tests and, if available, the specific direct oral anticoagulant (DOAC) concentration. The latter can be helpful particularly where there is uncertainty over timing of the last dose and given the insensitivity of clotting screens to factor Xa inhibitor concentrations, although a normal thrombin time effectively excludes the presence of dabigatran. A DOAC concentration threshold of 50 ng/mL is reasonable for consideration of reversal in patients with major bleeding, although a threshold of 30 ng/mL can be considered if bleeding is life-threatening. Further anticoagulation should be interrupted until the bleeding has stopped and an assessment made of appropriateness and timing of restarting.

For patients on dabigatran, a specific monoclonal antibody, idarucizumab, is licensed for reversal. The dose is 5 g intravenously given as two consecutive 2.5 g vials over 5–10 min. In an emergency, the dose can be administered over 3–5 min. Usually, the reversal of dabigatran is complete but if bleeding continues or potential re-bleeding would be life-threatening and the APTT or dabigatran level remain elevated, a second 5 g dose can be considered.

Andexanet alfa is a recombinant human factor Xa protein that has been modified to lack both the active serine site of factor Xa and the Gla domain. By giving it in excess over factor Xa, it serves as a decoy protein to which the Xa inhibitor predominantly binds. Andexanet alfa is licensed for life-threatening or uncontrolled bleeding in association with rivaroxaban or apixaban, but NICE approval in England and Wales is restricted to life-threatening or uncontrolled bleeding in the gastrointestinal tract. It has a short half-life and is administered as an initial intravenous bolus followed by a 120-min infusion.

In settings where urgent reversal of an oral factor Xa inhibitor is desired and andexanet alfa is not available or licensed, PCC 25–50 units/kg can be administered but this should not be considered an antidote and is off-label. Activated PCC (factor VIII inhibitor bypassing activity (FEIBA)) 50 units/kg is a less frequently used alternative. Tranexamic acid (1 g bolus over 10 min followed by 1 g infusion over 8 hours) should also be considered.

Other anticoagulant agents

Neither argatroban nor fondaparinux has a reversal agent available and therefore treatment of bleeding on these agents is largely supportive. Limited anecdotal evidence suggests that recombinant factor VIIa (90 μg/kg) might be of some benefit in the setting of life-threatening bleeding on fondaparinux. Argatroban has a short half-life of approximately 60 min but that of fondaparinux is approximately 20 hours and is dependent on renal function.

Antiplatelet agents

The PATCH trial, a randomised trial that investigated the effects of platelet transfusion in patients with antiplatelet therapy-associated spontaneous intracerebral haemorrhage, found that those who received a transfusion had a significantly worse outcome at 3 months than those who did not receive a transfusion. As a result, platelet transfusions are generally not indicated, at least in patients with intracerebral haemorrhage taking aspirin who formed the majority of participants and received a single pool of platelets. Patients taking P2Y12 inhibitors such as clopidogrel, who received 2 pools of platelets, were under-represented in the trial, and those who were for or were more likely to undergo neurosurgical intervention were not included. Pending results from further trials this suggests that patients on P2Y12 inhibitors or undergoing neurosurgical intervention should be managed on an individual patient basis. Patients with intracerebral haemorrhage on aspirin and/or dipyridamole should generally be managed without platelet transfusion unless there is another indication such as thrombocytopenia (platelet count $<100 \times 10^9$/L). Tranexamic acid 1 g bolus followed by 1 g over 8 hours should be considered although it was not of benefit by day 90 in the TICH-2 trial in patients with spontaneous intracerebral haemorrhage, approximately 25% of whom were on antiplatelet therapy at the time of the bleed.

In general, platelet support is not required for extracranial haemorrhage in patients on antiplatelet therapy except as part of the major haemorrhage protocol or if bleeding is life-threatening.

Thrombolytic therapy

Thrombolysis with recombinant tPA (alteplase) for acute stroke is associated with a 2–7% risk of symptomatic intracranial haemorrhage. The half-life of alteplase is about 4 min but,

despite its relative fibrin specificity, it frequently causes a coagulopathy with reduction in plasma fibrinogen and prolongation of the PT and APTT that may last over 24 hours. Symptomatic intracranial haemorrhage attributed to alteplase occurs within 36 hours of the infusion with median times ranging from 5 to 10 hours. Data on management are limited but cryoprecipitate (2 pools) should be administered and the plasma fibrinogen kept above 1.5 g/L. Plasma should be given as a source of antiplasmin and factor V. Tranexamic acid 1 g intravenous bolus followed by an infusion of 1 g over 8 hours also seems reasonable but evidence of benefit is lacking. The outcome is poor with 50% mortality and significant morbidity in those who survive.

Resumption of anticoagulation following major haemorrhage

Multidisciplinary discussion is often required to discuss the benefits, risks and timing of the reintroduction of anticoagulant therapy and possible alternative approaches. Decisions will depend on the indication for anticoagulation, the site and any local cause of bleeding, and the presence of risk factors for further bleeding. Modifiable risk factors, e.g. hypertension or co-administration of antiplatelet therapy, should be corrected where possible. Patient preferences are an important consideration.

For patients with atrial fibrillation, factors that might favour withholding rather than restarting DOACs after a major gastrointestinal (GI) bleed or intracranial haemorrhage ICH on anticoagulants are shown in Table 57.2. Often it is possible to resume anticoagulation 4–7 days after a GI bleed whereas guidelines favour a delay of at least 4 weeks if anticoagulation is resumed after intracranial haemorrhage. The choice of oral anticoagulant agent should be reviewed, DOACs being associated with a lower risk of intracranial haemorrhage than warfarin. Consideration should be given to the potential role of left atrial appendage occlusion when anticoagulant resumption is contra-indicated.

In patients with venous thromboembolism (VTE), the need to resume anticoagulation will be higher in the initial stages of treatment for a recent event than for those continuing for secondary prevention after three months of initial therapy. If major bleeding occurs within the first three months of treatment, anticoagulation is generally resumed as soon as practical after the bleeding has stopped. This is often with LMWH initially because of its shorter half-life. It may be reasonable to recommence at a prophylactic or intermediate dose and escalate up to a treatment dose if there is no re-bleeding. Insertion of a temporary inferior vena cava (IVC) filter should be considered if early resumption of anticoagulation is unsafe, particularly if the episode of VTE was diagnosed within the previous 4 weeks, although evidence of benefit is lacking.

Factors associated with risk of bleeding in those with VTE are likely similar to those with atrial fibrillation. It should be borne in mind that in patients with previous unprovoked VTE, continuing anticoagulation after the first three months of treatment is associated with a risk of recurrent VTE of about 1.5 per 100 person-years compared to a risk of 10.3 per 100 person-years in the first year after discontinuation of treatment. The risk of major bleeding is about 1.7 per 100 person-years with VKAs and 1.1 per 100 person-years with DOACs. However, the overall

Table 57.2 Factors to consider before re-initiation of anticoagulation following GI bleed or ICH in patients with atrial fibrillation.

Modifiable risk factors for bleeding on anticoagulants	Factors favouring withholding DOACs after GI bleed in patients with AF	Factors favouring withholding DOACs after ICH in patients with AF
Hypertension	Unidentifiable site of bleeding	No reversible cause of bleeding
Concomitant medication – antiplatelet/NSAID/SSRI	Multiple angiodysplasias in GI tract	Multiple cerebral microbleeds
Non-adherence to anticoagulation	No reversible/treatable cause	Severe intracranial bleed
Hazardous occupation/hobbies	Bleeding during treatment interruption	Older age
Choice of anticoagulant	Chronic alcohol abuse	Bleeding during interruption of anticoagulation
Dosing of anticoagulant	Older age	Uncontrolled hypertension
Potentially modifiable:	Careful reassessment of stroke and bleeding risk	Bleed on adequately or under-dosed DOAC
Falls risk		
Anaemia		
Warfarin management		
		Chronic alcohol abuse
		Need for dual antiplatelet therapy after PCI

(*Source:* Adapted from Steffel J *et al.* 2021).

case fatality rate for recurrent VTE is 4% compared to 9% for major bleeding. Where licensed, lower doses of DOACs should be used in long-term treatment.

In patients with mechanical heart valves, resumption of anticoagulation is particularly problematic after intracerebral haemorrhage. In general, resumption of therapeutic anticoagulation should be delayed for 2 weeks to reduce the risk of haemorrhagic complications. However, resumption at day 6 might be considered for patients at high thrombotic risk (mitral or dual valve replacement, cage-ball prosthesis, atrial fibrillation) after taking account of the individual's composite thrombotic and haemorrhagic risks.

The patient with thrombosis

Thrombosis at young age

The overall management of thrombosis at a young age follows similar principles to management in those of older age as discussed in Chapter 49.

In younger populations, thrombophilia testing is more likely to be considered. However, the acute management of lower limb deep vein thrombosis (DVT) and/or pulmonary embolism is generally unaffected by the presence or absence of a laboratory-diagnosed thrombophilic tendency. Moreover, acute phase effects and anticoagulation interfere with coagulation-based assays. Therefore, there is no role for routine thrombophilia testing in the acute setting with the possible exception of solid-phase testing for cardiolipin and β_2-glycoprotein 1 antibodies in selected patients (generally under 50 years) with an episode of venous thrombosis that was unprovoked or provoked by a minor risk factor since, particularly if both are positive, this might suggest a preference for LMWH/warfarin over a DOAC and a need to repeat testing after 12 weeks.

One uncommon but important group is young patients with extensive ilio-femoral DVTs. If left-sided, the May-Thurner syndrome should be considered, i.e. compression of the left common iliac vein by the right common iliac artery, since such patients may be considered for venoplasty and stenting. Some patients, typically in their late teens or twenties, with uni- or bilateral proximal DVTs may have congenital abnormalities of the inferior vena cava and a high risk of recurrent DVT that generally warrants long-term anticoagulation, and vascular surgery input may be considered.

The role of age in the prediction of recurrent venous thrombosis is uncertain as illustrated by its inclusion in different prediction rules for recurrent VTE in those after an unprovoked first event – in the DASH score age $\leq$50 years is regarded as a risk factor, in the HERDOO2 score in women age $\geq$65 years is regarded as a risk factor, and age is not included as a risk factor in the Vienna prediction model.

Haematologists are not infrequently asked about investigation of young patients with arterial thrombotic events. In general, the risk factors that are important in older patients, such as hypertension, diabetes mellitus, dyslipidaemia and cigarette smoking, are also important in younger patients. The finding of a heritable thrombophilia would not alter management and testing for heritable thrombophilias is not recommended. However, testing for antiphospholipid antibodies is recommended when other vascular risk factors are absent as this may influence the choice of antithrombotic therapy.

Thrombosis at unusual sites

Thrombosis at unusual sites is dealt with in Chapter 49.

Recurrent thrombosis or thrombosis despite anticoagulation

The approach to recurrent venous thrombosis depends on whether it occurred after anticoagulation had been discontinued, or was due to sub-therapeutic anticoagulation, or while therapeutically anticoagulated. The mode of anticoagulation is also important. Long-term anticoagulation reduces the relative recurrence risk by 80–90% so occasional recurrences are inevitable. The important first step is senior review of the imaging because the radiological diagnosis of recurrence is often difficult and the potential long-term management implications are significant.

Recurrent thrombosis off anticoagulation generally requires resumption of anticoagulation and lowers the threshold for continuing treatment long-term.

Recurrence may be the result of sub-therapeutic anticoagulation arising from poor compliance or from of factors that result in inappropriate dosing. This is easiest to judge in patients on vitamin K antagonists because of INR measurement, and details should be sought about compliance and interacting drugs and vitamin K intake. A switch to a DOAC might be considered in those with poor INR control because of, for example, difficulties with clinic attendance for INR monitoring. Good compliance is also important in patients on DOACs and LMWH because of their short half-lives. Other possible causes of sub-therapeutic anticoagulation with DOACs are interacting drugs, failure to take therapeutic dose rivaroxaban with food, malabsorption, and possibly obesity with edoxaban and dabigatran where data on use in the obese is lacking.

Prospective studies and randomised trials show a significantly higher risk of VTE recurrence in patients with cancer-associated thrombosis. Antiphospholipid syndrome (APS) is also associated with an increased risk of recurrent thrombosis. Randomised trials have confirmed an increased risk of arterial thrombotic events in those with an initial venous or arterial episode treated with DOACs compared to warfarin, particularly in those who are triple antiphospholipid antibody positive. A falsely increased INR should be excluded in patients

with the antiphospholipid syndrome and recurrent thrombosis on warfarin whose INR is apparently within the therapeutic range. This can be done by using an alternative thromboplastin that is insensitive to the lupus anticoagulant or by a chromogenic factor X assay where an expected level would be 20–40% if the INR is 2.0–3.0. If the INR has been genuinely within the therapeutic range, the target INR should be increased from 2.5 to 3.5, potentially after a period of single agent therapeutic dose LMWH. Alternatively, aspirin and/or hydroxychloroquine could be added. For those with recurrent thrombosis at an INR of 3.0–4.0, possible approaches include the addition of aspirin, a switch to LMWH or fondaparinux, or the adjunctive use of immunosuppressive or immunomodulatory agents such as rituximab, complement inhibitors or mammalian target of rapamycin (mTOR) inhibitors.

In those without APS who have a recurrent thrombotic event on warfarin and a therapeutic INR, the target INR should be increased from 2.5 to 3.5 after a period of LMWH. Aspirin could be added if the recurrence is despite anticoagulation with an INR of 3.0–4.0. If INR control is poor and a DOAC is contraindicated, consideration could be given to long-term parenteral therapy with LMWH or fondaparinux.

Causes of recurrent thrombosis while on therapeutic anticoagulation are listed in Table 57.3.

Thrombosis in presence of bleeding risk or thrombocytopenia

The combination of thrombosis and thrombocytopenia is challenging to manage because of competing thrombotic and bleeding risks. There are a number of causes with cancer being the most frequently encountered, particularly in those with haematological malignancies and/or receiving chemotherapy. Other well-recognised causes include sepsis, cirrhosis, APS, heparin-induced thrombocytopenia (HIT), ITP, DIC, paroxysmal nocturnal haemoglobinuria (PNH) and vaccine-induced immune thrombocytopenia and thrombosis (VITT). The microangiopathies, such as TTP, haemolytic uraemic syndrome (HUS) and HELLP syndrome, usually cause thrombosis limited to small vessels. In view of the disparate nature of these conditions, accurate diagnosis is essential including, when thrombocytopenia is new or unexpected, exclusion of pseudothrombocytopenia with a blood film and citrated FBC. It should be borne in mind that pseudothrombocytopenia in citrated blood can occur during treatment with glycoprotein IIb/IIIa (GPIIb/IIIa) antagonists.

Table 57.3 Causes of recurrent thrombosis while on therapeutic anticoagulation.

Cancer
Myeloproliferative neoplasm with high cell counts
Antiphospholipid syndrome especially if on DOAC treatment and triple-positive antiphospholipid antibodies
Heparin-induced thrombocytopenia
Paroxysmal nocturnal haemoglobinuria
Behçet's syndrome
Antithrombin deficiency (heparin)
Vascular abnormalities – May-Thurner syndrome, thoracic outlet syndrome, congenital abnormalities of the inferior vena cava
Inappropriate choice or dosing of anticoagulant
Poor adherence

In patients with cancer and thrombocytopenia, LMWH is generally the preferred therapeutic option. Guidelines suggest full treatment doses can be safely administered down to a platelet count of 50×10^9/L. In the setting of acute venous thrombosis (within 30 days of the index event), platelet support should be given when necessary to elevate the platelet count to $>50 \times 10^9$/L. If the platelet count cannot be elevated, a 50% treatment dose can be given if the platelet count is $25–50 \times 10^9$/L. Anticoagulation is generally contraindicated if the platelet count is $<25 \times 10^9$/L and insertion of a retrievable IVC filter might then be considered in the setting of acute venous thrombosis and refractory thrombocytopenia. Full-dose anticoagulation should be resumed as the platelet count recovers to $>50 \times 10^9$/L. In those with platelet counts of $25–50 \times 10^9$/L and lower risk acute thrombotic events, such as distal venous thrombosis or subsegmental pulmonary emboli, or those whose VTE event was >30 days earlier, a 50% treatment dose or a prophylactic dose without platelet support are suggested.

In patients with acute lymphoblastic leukaemia receiving asparaginase, International Society on Thrombosis and Haemostasis guidance suggests weekly monitoring of antithrombin levels. If venous thrombosis occurs, LMWH is suggested in preference to a DOAC if a platelet count $<50 \times 10^9$/L is anticipated. Anti-Xa levels should be monitored if plasma antithrombin activity is decreased below 50–60%. For life-threatening VTE, such as cerebral venous sinus thrombosis (CVST) or central pulmonary embolism, concurrent administration of antithrombin concentrate is suggested until therapeutic anticoagulation and clinical stability are established.

In patients with other causes of thrombosis and thrombocytopenia, management depends on the underlying condition.

Thrombosis and cancer

Up to 20% of all cases of VTE occur in patients with cancer and thrombosis is one of the leading causes of death in cancer patients after cancer itself. The 12-month cumulative incidence of VTE after a cancer diagnosis is >3%, the risk varying between cancer sites and increasing as cancer progresses. Outcomes, including recurrent thrombosis, bleeding and mortality, of patients with cancer and thrombosis are worse than the outcomes of either condition on its own. The reasons for the association of cancer and thrombosis are multifactorial and include

the prothrombotic effects of cancer and its treatments, reduced mobility, hospital admission, central lines and surgery.

For two decades, LMWH for 6 months has been the standard treatment of VTE in patients with cancer-associated venous thrombosis because of trial data showing a reduced recurrence risk compared to warfarin without an increased risk of major bleeding. The risks and benefits of continuing anticoagulation should be reviewed at 6 months. Data beyond this are sparse but generally anticoagulation is continued with regular review in those with active cancer, taking account of bleeding risks and patient status and preferences. Recent trial evidence suggests that the direct oral factor Xa inhibitors are as effective and safe as LMWH in the initial treatment of cancer-associated venous thrombosis. Recent national and international guidelines support their use as first-line therapy although LMWH is preferred in those with a high risk of bleeding including those with luminal gastrointestinal cancers with an intact primary, patients at increased risk of bleeding from the genitourinary tract, patients with active gastrointestinal mucosal abnormalities or patients taking potent inhibitors or inducers of P-glycoprotein and/or cytochrome P450 3A4. The increased risk of bleeding from gastrointestinal cancers that was seen in the trials with edoxaban and rivaroxaban was not observed with apixaban. Current guidelines support anticoagulation of incidental venous thrombosis, at least for 6 months.

The risk of recurrent on-treatment thrombosis is increased in patients with cancer-associated venous thrombosis. Non-compliance with treatment should be excluded and a possible diagnosis of HIT should be considered but is unlikely. There are no randomised trials to inform management. Current recommendations are to switch to LMWH if being managed on other anticoagulants, to increase the dose to therapeutic if being managed on a sub-therapeutic dose of LMWH, and to increase the dose by about 25% if currently on a therapeutic dose of LMWH. With enoxaparin the once-daily therapeutic dose regimen may be switched to the twice daily dose.

In other settings, thrombosis occurs together with a significant bleeding concern. For example, VTE is common in patients with primary brain tumours or cerebral metastases. Such patients were largely excluded from randomised trials of anticoagulants and management is complicated by the high rate of spontaneous ICH, particularly in certain tumour types such as non-small cell lung cancer or renal cell cancer. Retrospective data suggest that LMWH does not increase the risk of ICH in those with cerebral metastases but may increase the risk in those with primary brain tumours. Preliminary observational data in patients with primary brain tumours suggest that DOACs may be associated with a lower risk of ICH but LMWH is generally preferred initially because of the shorter half-life. In view of the paucity of data, the management of patients with intracranial lesions and acute VTE should be discussed with a multidisciplinary team including neurosurgeons and oncologists, and treatment decisions individualised.

Bleeding or thrombosis and systemic disease

General effects of inflammation

The underlying mechanisms whereby haemostasis is disturbed in patients with inflammation are outlined in Chapter 43.

Inflammation is such a common feature in patients with thrombosis that in general management is unaffected unless a decompensated state has been reached and there is an associated bleeding tendency as in DIC. The most widely used anticoagulants are LMWH and DOACs and an inflammatory state does not usually alter their efficacy. However, problems may arise in patients in whom intravenous unfractionated heparin is preferred because of its reversibility. In such patients, in particular, the phenomenon of heparin resistance may arise. This is characterised by difficulty in achieving the target APTT ratio using standard doses of heparin. The causes are multifactorial and include elevated acute phase proteins and activated cell surfaces to which an increasing proportion of long-chain heparin molecules non-specifically bind, increased factor VIII and fibrinogen levels that shorten the baseline APTT and therefore result in an increased heparin requirement to prolong the ratio into the therapeutic range, and acquired antithrombin deficiency. Management of this problem can be difficult and it is thought that measurement of anti-Xa levels (typical therapeutic range 0.3–0.7 IU/mL by chromogenic assay) may be superior to APTT monitoring. In patients with acquired antithrombin deficiency and without a history of thrombosis, a role for antithrombin replacement has not been demonstrated outside the setting of cardiac surgery.

Diagnosis and management of DIC are outlined in Chapter 43.

Liver disease

Liver disease is dealt with in Chapter 43.

Amyloidosis

Amyloidosis is dealt with in Chapter 43.

Behçet's syndrome

Behçet's syndrome is an inflammatory multiorgan vasculitis characterised by recurrent oral and genital ulcers, and involvement of the skin, eyes, joints, gut and central nervous system. The overall prevalence is 10 per 100,000 inhabitants but this varies considerably geographically with a prevalence of over 100 per 100,000 in Turkey and 3 per 100,000 in European populations. It affects men and women equally but young men under 30 years have a greater likelihood of a more severe course. Its onset is rare after 40 years.

Behçet's syndrome is unique amongst vasculitides because it predominantly affects veins and probably causes inflammation and activation of the vein wall endothelium as well as activation of neutrophils and platelets. Vascular involvement is usually in the form of thrombosis or aneurysm formation and is present in up to 40% of cases, with 75% of these being venous. Lower extremity venous thrombosis is the most common manifestation although vena cava thrombosis, pulmonary artery aneurysms, cerebral venous sinus thrombosis, Budd-Chiari syndrome, and peripheral artery and abdominal artery aneurysms also occur. The recurrence risk of lower extremity venous thrombosis is high with one study reporting a 45% recurrence risk at 2 years.

Endothelial activation is thought to induce thrombosis through reduced nitric oxide production and increased plasma levels of von Willebrand factor and P-selectin. Fibrinogen structure and function may be altered by reactive oxygen species produced by neutrophil activation and fibrin clots may be less susceptible to plasmin-mediated lysis. Anti-endothelial and antiphospholipid antibodies are seen in some patients. Imaging studies show thickened vessel walls in patients with vascular Behçet's syndrome compared to controls, even in non-thrombotic areas.

Arterial lesions may be occlusive or aneurysmal. The latter results from vasculitic destruction of the media, arterial dilatation, and fibrosis with inflammatory destruction of the vasa vasorum.

European Alliance of Associations for Rheumatology (EULAR) guidelines recommend glucocorticoids and immunosuppressives such as azathioprine, cyclophosphamide or cyclosporine A as the primary therapy for acute venous thrombosis. Other immune therapies are being investigated. The role of anticoagulants is uncertain and there are concerns about their use in patients with associated pulmonary artery aneurysms because of potential bleeding risks. Mechanical thrombectomy should be avoided as it may predispose to aneurysm formation. In view of the uncertainties, it is suggested that patients with significant new thrombotic events should be discussed with an expert in one of the three UK Behçet's syndrome centres (London, Birmingham, Liverpool).

Sickle cell disease

Sickle cell disease (SCD) is associated with an acquired prothrombotic state. This is most evident in the early onset of arterial complications such as stroke in children. It has been observed in epidemiological studies that reported, for example, a 10–15% cumulative incidence of VTE by the age of 40 years and a fivefold increase in the risk of VTE in pregnancy compared to women without SCD. The recurrence risk of VTE in SCD is also high at over 35% at 5 years. The risk of pulmonary embolism appears to be higher than for DVT and this may be partly attributable to *in situ* pulmonary thrombosis. Mortality appears to be higher in people with SCD and a history of VTE compared to those without VTE. Risk factors for VTE in people with SCD include frequent hospital admissions, exposure to erythropoietin or blood transfusions, insertion of central venous catheters and surgical splenectomy.

The molecular and cellular changes in SCD result in two primary pathologies: vaso-occlusion-mediated ischaemia/reperfusion and increased circulating levels of free haem caused by chronic haemolytic anaemia. The former leads to free radical-mediated oxidative stress and increased vascular inflammation. The latter results in depletion of haptoglobin and haemopexin, which scavenge free haemoglobin and free haem respectively, and this leads to reduced nitric acid bioavailability. This in turn causes platelet activation as well as activation of endothelial cells and neutrophils. Monocyte activation leads to increased production of inflammatory cytokines that can induce tissue factor expression and thereby initiate coagulation. Further thrombin generation may result from activation of the contact system through, for example, formation of neutrophil extracellular traps (NETs). Sickle red cells themselves have numerous receptors that interact with the vessel wall and result in post-capillary venule occlusion, and increased numbers of phosphatidylserine-positive sickle red cell-derived extracellular vesicles have been associated with markers of thrombin generation. The coagulation system is activated with increased markers of thrombin generation and fibrin turnover. Thus the prothrombotic tendency of sickle cell disease reflects an underlying thrombo-inflammatory state with numerous factors altering the haemostatic balance.

The cumulative effect of stasis, altered rheology, vascular fibrin deposition and chronic inflammation leads to a chronic vasculopathy and multi-organ damage. Those affected by deep vein thrombosis and/or pulmonary embolism may develop long-term complications such as the post-thrombotic syndrome and chronic thromboembolic pulmonary hypertension.

In general, prospective trials of anticoagulation have not included people with SCD and management of VTE follows guidelines developed for the general population. In view of the high risk of recurrent VTE that has been reported, it seems reasonable to consider long-term anticoagulation after a first event even in those with less severe disease or where the incident event was related to hospitalisation. Based on few data, DOACs seem a reasonable option at this point. However, before embarking on long-term anticoagulation, it is important to consider the underlying risk of bleeding such as from intracranial haemorrhage due to central nervous system vasculopathy as well as other comorbidities associated with an increased bleeding risk and to take account of patient preferences.

Paroxysmal nocturnal haemoglobinuria

Thrombosis is a frequent and feared complication of PNH with historically 29–44% of patients having at least one thrombotic

event during follow-up. The majority of thrombotic episodes (75%) are venous with over 50% of these involving either the hepatic or portal veins. Although more common in those with large PNH clones (>50% PNH granulocytes), the risk is also increased in those with smaller clones compared to the background population.

The pathogenesis of thrombosis in PNH is multifactorial and the efficacy of complement inhibitors in preventing thrombotic events illustrates the central importance of complement activation. Although not fully characterised, it is thought that two main mechanisms are responsible – haemolysis-related and non-haemolysis-related. Complement-mediated destruction of red cells with intravascular haemolysis results in the release of danger-associated molecular patterns (DAMPs), such as cell-free haemoglobin and cell-free haem, into plasma. These have multiple pro-thrombotic effects with activation of platelets, neutrophils, monocytes, endothelial cells and coagulation factors. Haemolysed red cells release phosphatidylserine microvesicles that can support thrombin generation. Recognition that thrombotic episodes occur in patients with low levels of haemolysis suggest that platelet, white cell and endothelial factors likely play a pivotal role. There are multiple bidirectional interactions between the complement and coagulation systems leading to their reciprocal activation and thrombin generation.

In patients who present with a thrombotic event, the initial step is anticoagulation. This is standard with low-molecular-weight or unfractionated heparin followed by warfarin. The DOACs have not been evaluated in PNH although they would seem reasonable options in individual patients. However, the key intervention, ideally within 24 hours, is with a C5 inhibitor such as eculizumab or ravulizumab which prevents thrombosis progression in the acute phase and appears particularly important in the Budd-Chiari syndrome. These agents are also required long-term because anticoagulation alone is insufficient for secondary prevention. There is uncertainty over the duration of anticoagulation in patients on complement inhibitors whose haemolysis is well controlled and who may have bleeding risks due, for example, to thrombocytopenia, and advice in individual cases should be sought from an expert in one of the two UK centres, London and Leeds.

Myeloproliferative Neoplasms (MPN)

Thrombosis

In Philadelphia-negative MPNs, the pooled prevalence of thrombosis at the time of diagnosis is 20%. Arterial events are more common in older patients and venous thrombosis is more common in younger patients. In females thrombosis is more commonly seen in unusual sites such as splanchnic veins, cerebral venous sinuses and in the placenta. During long-term follow-up the increased risk of an arterial thrombotic event is of a similar degree to cigarette smoking and the risk of venous thrombosis is increased to a similar degree as heterozygosity for factor V Leiden. Cardiovascular risk factors in the general population likely also contribute to the thrombotic risks of MPNs. The risk of thrombosis is higher in those over 60 years and/or with a past history of thrombosis and/or who carry the *JAK2V617F* mutation.

There are no randomised trials to inform anticoagulant management following an episode of venous thrombosis. Current management in polycythemia vera involves phlebotomy to a haematocrit of <45% in both males and females and the addition of hydroxyurea or interferon and anticoagulation. Retrospective data suggest that DOACs are as safe and effective as warfarin. Following an arterial event antiplatelet therapy is used in place of anticoagulation and some recommend twice daily low-dose aspirin because of increased platelet turnover. A similar approach following venous and arterial thrombotic events but without phlebotomy is generally taken with essential thrombocythemia. Some authorities add aspirin to anticoagulation in those with venous thrombosis and cardiovascular risk factors but the bleeding risk is increased.

Bleeding

Bleeding is less common than thrombosis in patients with MPNs and mostly involves gastrointestinal, mucosal and cutaneous bleeding. The cause is multifactorial and may of course result from thrombocytopenia or antithrombotic therapy. The most widely accepted mechanism, however, is acquired von Willebrand disease. Although associated with extreme thrombocytosis, evidence for acquired von Willebrand disease is found in over 50% of patients with platelet counts $<1000 \times 10^9$/L. Laboratory diagnosis can be difficult outside a specialist centre. Management is supportive, antithrombotic therapy may require interruption and cytoreduction to normalise the platelet count.

Managing anticoagulation for surgery and procedures

Advice is largely based on the British Society for Haematology guidelines on the peri-operative management of anticoagulation and antiplatelet therapy. Management entails assessment of the procedure-related bleeding risk and potential consequences of bleeding if anticoagulation continues on the one hand and the thrombotic risk and consequences if anticoagulation is interrupted. The assessment also needs to take into account patient-specific clinical factors and of the pharmacological properties of different anticoagulants.

Some procedures such as much dental work, cataract surgery, pacemaker insertion, joint injections and certain endoscopic procedures are of low bleeding risk and do not require anticoagulation to be interrupted. In general, however, the

British Society for Haematology guidelines suggest that the surgeon, dentist or interventional radiologist has to assess the bleeding risk for the individual patient and discuss this and the plan for peri-procedural anticoagulation with them, recording the plan clearly in the notes, including for when the patient is discharged.

Warfarin and other vitamin K antagonists

Warfarin has a half-life of about 36 hours and as its effect subsides γ-carboxylated vitamin K-dependent clotting factors are fully synthesised and secreted by hepatocytes. Therefore, with a starting INR in the therapeutic range a week beforehand, warfarin generally needs to be stopped 5 days before elective surgery to enable the INR to normalise. Ideally, the INR should be rechecked the day before surgery to allow vitamin K to be administered if the INR is still ≥1.5, thereby reducing the need for cancellation. The INR should also be checked on the day of surgery.

Patients who are judged at high risk of thrombosis when VKA treatment is interrupted should be considered for 'bridging', i.e. the administration of therapeutic dose LMWH or UFH during the period of sub-therapeutic oral anticoagulation. LMWH has the advantage over UFH of ease of use with fixed weight-based dosing and outpatient administration. Generally, the heparin is commenced 48 hours after the last dose of warfarin. LMWH is discontinued at least 24 hours and intravenous UFH 4–6 hours before the procedure. Following high-bleeding risk surgery, patients should generally not recommence therapeutic dose of heparin until at least 48 hours after the procedure although thromboprophylactic doses should be given if indicated. Because of its slow onset of action, warfarin can generally be resumed the evening of or the day after surgery but in circumstances where LMWH is more appropriate in the short term, it may be reasonable to delay warfarin's reintroduction. The approach is outlined in Table 57.4.

Settings where bridging doses of heparin might be considered when warfarin is interrupted are shown in Table 57.4.

Although this reflects current practice, it should be acknowledged that evidence showing the benefit of bridging is lacking while increased bleeding risks have been observed in some studies.

Additionally, patients with an episode of VTE within the previous month who require interruption of anticoagulation for surgery that cannot be delayed should be considered for insertion of a retrievable IVC filter until anticoagulation can be safely resumed post-operatively.

In patients requiring emergency surgery who can wait for 6–8 hours, 5 mg intravenous vitamin K can correct the INR. If a delay is not possible, PCC 25–50 IU/kg can be given. Post-operative management is similar to that following elective surgery.

Table 57.4 Settings where bridging doses of heparin might be considered when warfarin is interrupted.

	Consider **bridging with treatment dose heparin in**
VTE	Patients with a VTE within previous 3 months. Very high-risk patients such as patients with a previous VTE whilst on therapeutic anticoagulation who now have a target INR of 35.)
AF	Patients with a previous stroke/TIA in last 3 months. Patients with a previous stroke/TIA and three or more of the following risk factors: • Congestive cardiac failure • Hypertension (>140/90 mmHg or on medication) • Age >75 yrs • Diabetes mellitus
MHV	MHV patients other than those with a bileaflet aortic valve and no other risk factors

AF, atrial fibrillation; INR, International Normalised Ratio; MHV, mechanical heart valve; TIA, transient ischaemic attack; VTE, venous thromboembolism.
(*Source:* Keeling D *et al.* 2016/John Wiley & Sons).

Direct oral anticoagulants

Similar general principles apply to DOACs as to VKAs in considering interruption of anticoagulant therapy before and after elective surgery. However, the shorter half-life of the DOACs means that bridging with heparin is generally not recommended and appears to increase the bleeding risk without reducing the risk of thrombotic events. Again, plans should be discussed in advance with the patient and be clearly recorded in the notes.

As for warfarin, some procedures carry no significant bleeding risk and do not require interruption of anticoagulant therapy. In practice, for such minor procedures, it may be reasonable to schedule the intervention 18–24 hours after the last DOAC intake and restart 6 hours later, thereby skipping one dose of (twice daily) apixaban or dabigatran or timing the intervention at the trough level of (once daily) edoxaban or rivaroxaban.

For procedures associated with high or low bleeding risks, the recommended times to discontinue DOACs in advance are shown in Table 57.5. In patients whose creatinine clearance is <30 mL/min, the interval between the last DOAC dose and elective surgical intervention may need to be extended.

Following low bleeding risk procedures, DOACs can generally resume 12–24 hours later if haemostasis has been fully secured. In those with a high post-procedural bleeding risk, reintroduction of the full dose of the DOAC should be delayed for at least 48 hours. Daily prophylactic heparin should be considered in patients at high risk of venous thrombosis prior to DOAC recommencement.

Table 57.5 DOAC perioperative management scheme.

DOAC	Procedural bleeding risk	Perioperative DOAC management									
		Day −5	Day −4	Day −3	Day −2	Day −1	Day 0	Day +1	Day +2	Day +3	Day +4
Direct Xa Inhibitors *and* Dabigatran (CrCl ≥ 50 mL/min)	Low	✓	✓	✓	✓	OMIT	Day of procedure Do not administer any DOAC	✓	✓	✓	✓
	High	✓	✓	✓	OMIT	OMIT		OMIT	Resume day +2 or day +3		✓

	High	✓	OMIT	OMIT	OMIT	OMIT		OMIT	Resume day +2 or day +3		✓

✓ – DOAC may be taken or administered.
(*Source:* Saja K, 2022/John Wiley & Sons).

When emergency surgery is required, discussion with the surgeon and anaesthetist is necessary to assess the risks and timing of the surgical intervention. Knowledge of the specific DOAC the patient is taking, the timing of the last dose, and the current renal function are of considerable importance in estimating the potential degree of anticoagulation. Other factors such as weight and interacting drugs are generally of less significance. A normal clotting screen (PT and APTT) does not exclude the presence of a significant concentration of a direct oral Xa inhibitor, although a normal thrombin time effectively excludes the presence of dabigatran. Where available, rapid access to individual DOAC concentrations can be helpful in assessing the degree of anticoagulation and the likely timeframe for waning of the effect, in turn assisting with decision-making over the timing of surgery. Where possible, surgery associated with a bleeding risk should be postponed in patients in whom a significant anticoagulant effect is known or is likely, taking into account the half-life of the DOAC and the risks of delaying surgery.

In patients on dabigatran where surgery or urgent procedures cannot be delayed and carry a bleeding risk, idarucizumab is licensed for rapid reversal of its anticoagulant effects. The dose is as for reversal of dabigatran for life-threatening or uncontrolled bleeding. Andexanet alfa has not been evaluated for its efficacy in reversing the direct oral Xa inhibitors prior to emergency surgery and is not licensed for this indication. In clinical practice where surgery cannot be delayed, PCC has been used but it should be appreciated by clinicians that it is not an antidote and its efficacy in this setting is uncertain. British Society for Haematology guidelines suggest that a pragmatic approach might be to proceed with surgery considering PCC only in the event of diffuse coagulopathic bleeding. Tranexamic acid may also be of benefit and should be given.

General notes in consultative haemostasis and thrombosis

Balancing risks and benefits

When practising consultative haemostasis, it is often true that decisions may need to be compromised and represent the best balance between competing risks. In nearly all cases, the intention is to minimise the overall risk and maximise the benefit for the patient. Usually, this means balancing the risks (both the immediate risk and the consequences of unwanted events) of thrombosis against those of bleeding. It is often not easy to compare risks of bleeding with risks of thrombosis. Thrombosis may also have longer, indirect effect such as pulmonary hypertension or postphlebitic syndrome and critical site bleeding may also have long-term consequences. For longer-term decisions, it is important to consider the patient's quality of life and how burdensome a theoretically good solution might be. Many patients intensely dislike taking medication and for others, the shock of a thromboembolic event was so traumatic that any risk of bleeding from anticoagulation is outweighed by the feeling of safety and reassurance it confers.

Making recommendations

Problems in hospital management can arise if advice is not communicated clearly or is too tentative. It is important that unambiguous instructions are given that deal with likely alternative developments. Obviously, these need to be communicated clearly to the consulting team and written in the patient's notes. For surgical management a clear and complete plan should be placed in the patient notes with relevant contact details. It is dangerous to assume that any aspect of management is obvious or self-explanatory.

Genetic consultations

Determining the precise cause of a haemorrhagic or thrombotic tendency often leads to genetic testing. This is increasingly readily available and increasingly useful as more variants are identified and their phenotypic correlates described. In the UK, gene panels for both thrombotic and bleeding disorders, including thrombocytopenia are available via the NHS genomics network. This can be very helpful in predicting the phenotype – for example identifying heparin-binding variants of antithrombin which have a lower thrombotic risk than other forms of deficiency. It may also help interpretation of laboratory results and for example, define the type of VWD and predict the response to therapy. Some guidelines recommend genetic testing over laboratory tests where the latter are poorly standardised or difficult such as for type 2B VWD and platelet-type VWD. However genetic testing rarely identifies an abnormality when a clinical phenotype is not apparent clinically or on laboratory testing.

The largest advances have been where there is a clinical phenotype but no diagnostic test – a good example is thrombocytopenia. Where many possible genetic abnormalities may be responsible then genetic panels can be set up and hundreds of genes analysed at the same time. Multiple genetic variants can be combined to give a propensity score for thrombocytopenia. However, the analysis may reveal genetic variants which have implications beyond those expected. For example, some genetic variants responsible for thrombocytopenia, such as *ACTN1* have no phenotype beyond the low platelet count whereas others, such as *ANKRD26* have a clear association with leukaemia. The risk of leukaemia may be unexpected and unwelcome information for the patient and their family with a significant impact on their lives. At the same time, the doctor in possession of the information has an obligation to pass this on. It is therefore essential to fully explain and counsel patients of all the possible outcomes before obtaining their consent for genetic tests. Another problem for the future is that variants identified today without any known clinical significance may later be found to have important implications and the patient may expect to be updated on the interpretation of their genetic status as information changes. This will be a major task for genetic services.

Genetic testing is also available for family studies where a clear hereditary cause is already identified such as haemophilia or VWD. This is useful for assessing risk of transmission and can be used for antenatal diagnosis either for termination or to plan delivery. Genetic testing is not usually justified in children below the age of competence for consent and should be avoided unless it will have an important effect on management. Phenotypic testing is usually sufficient to direct management.

End-of-life decisions

Thrombosis and haemostasis both increase significantly with age. Moreover, not only are they frequent complications of many other disorders, the therapy, particularly anticoagulants, may have significant interactions with other treatments and may be burdensome to administer. Finding the best balance of risk and benefit without making life miserable due to repeated injections or having to spend a lot of time in or attending hospital becomes a particularly acute and difficult problem towards the end of life. The advent of new anticoagulants have simplified management as have near-patient testing devices and home visits. It is important not to 'strive officiously' and to remember that quality of life is particularly important when there is only little left.

haemopoietic stem cell transplantation, 595
late complications after ATG, 594
predictors of response to ATG, 593
repeat courses of ATG, 593–594
survival after ATG, 593
infections, 590
investigations, 589, 599
iron chelation therapy, 590
leukaemic transformation, 598
management, 589
alemtuzumab, 594
allogeneic HSC, 595–596
alternative donor HSCT, 596
androgens, 595
cyclophosphamide, 594
eltrombopag, 594–595
immunosuppressive therapy, 590–595
indications for treatment, 590
infections, 590
iron chelation therapy, 590
transfusions, 589–590
pathogenesis, 584
haemopoietic defect
immune-mediated defect, 586–588
renal disease, 598
somatic mutations, 588
somatic mutations in AA, detection of, 588
spontaneous remission, 598–599
supportive care, 589–590
thrombosis, 598, 600
treatment, 599–600
treatment of AA, 589
acquired bleeding disorders
haemophilia, 798–801
vonWillebrand disease, 809–812
acquired circulating anticoagulants, 830, *831*
acquired coagulation disorders, 829–847
activated clotting time, 830
acute hepatitis, 837
amyloidosis, 845
APL, 835
arteriovenous malformations, 843–844
hereditary haemorrhagic telangiectasia, 843
Kasabach–Merritt syndrome, 843–844
bruising, 842–843
haemostatic dysfunction associated with vasculitis, 843
inherited disorders of collagen and elastic fibres, 843
non-accidental bruising, 842
painful bruising syndrome (psychogenic purpura), 842–843
purpura simplex (normal easy bruising), 842
scurvy, 843
senile purpura (atrophic or actinic purpura) and steroid-related purpura, 842
cardiopulmonary bypass surgery, 840–841
chronic liver disease
coagulopathy in massive blood loss, 841–842
fibrinogen, 838
fibrinolysis, 838
haemostatic disturbance in renal disease, 839–840
haemostatic dysfunction associated with cardiopulmonary bypass surgery, 840–841
haemostatic dysfunction associated with trauma, 841
haemostatic impairment, management of, 838
hypercoagulability in liver disease, 839
liver transplantation, 839
pregnancy-related haemostatic dysfunction, 840
procoagulant and anticoagulant factors, 838
thrombocytopenia, 837–838
coagulation tests, 829
coagulopathy associated with COVID-19, 834–835
disseminated intravascular coagulation, 830–834
clinical features, 832
diagnosis, 832–833
disseminating and sustaining thrombin generation, 832
endothelial cell activation and dysfunction, 832
links between inflammation and coagulation, 832
neutrophil extracellular traps and histones, 832
pathophysiology, 831
thrombin generation *in vivo,* 831
treatment, 833–834
factor V deficiency, 847
haemophilia, 845–847
haemostatic disturbance in liver disease, 837
haemostatic dysfunction associated with paraproteinaemia and amyloidosis
acquired factor V deficiency, 847
acquired haemophilia A, 845–847
acquired inhibitors of coagulation factors, 845
acquired protein S deficiency, 847
acquired von Willebrand syndrome, 847
amyloidosis, 845
paraproteinaemia, 844
prothrombin deficiency associated with lupus anticoagulant, 847
haemostatic dysfunction in acute promyelocytic leukaemia, 835
liver disease, 837–842
massive blood loss, 841–842
microthromboembolic disease, 844
cholesterol embolism, 844
fat embolism syndrome, 844
warfarin-induced skin necrosis, 844
paraproteinaemia, 844
pregnancy-related, 840
renal disease, 839–840
routine tests of haemostasis, 829
thrombin generation assays, 830
thromboelastometry, 830
trauma, 841
vasculitis, 843
vitamin K, 835–837
vitamin K deficiency, 835–837
vitamin K metabolism, 835
vonWillebrand disease, 847
acquired disorders of coagulation, 1001
acquired DNA mutations, haematological malignancies, 127–129

acquired factor V deficiency, 847
acquired haematological disorders, 113
acquired haemolytic anaemias
  alloimmune haemolytic anaemia with anti-D, 301–302
  clinical management
    first-line treatment, 298–299
    prognosis, 299
    second-line treatments, 299
    splenectomy, 299
    supportive therapy, 298
  cold agglutinin disease
    clinical features of, 299–300
    drug treatments, 301
    supportive therapy, 300–301
  immune haemolytic anaemias
    autoimmune haemolytic anaemia, 292
    cold-acting antibodies, 294
    complement activation, 294
    complement-mediated intravascular haemolysis, 295
    immune red cell destruction, mechanisms for, 294–295
    liver, role of, 295
    pathogenesis of, 292–293
    red cell autoantibodies, characteristics and specificity of, 293
    red cell destruction and production, 295
    spleen, role of, 295
    warm-acting antibodies, 293–294
  non-immune acquired haemolytic anaemias
    abetalipoproteinaemia, 308
    arteriovenous malformation, 305
    babesiosis, 303
    bacterial infections, 304
    bartonella, 303
    blackwater fever, 303
    clostridium perfringens, 303
    fragmentation haemolysis, 304
    haemolysis associated with cardiac surgery, 304–305
    haemorrhagic fevers, 304
    hereditary acanthocytosis, 308
    lead poisoning, 307
    malaria, 302–303
    malignant disease, 305
    March haemoglobinuria, 306
    mechanical haemolytic anaemias, 304

  genotype guided de-escalation, 940–941
  guided and non-guided de-escalation, 940
  platelet function guided de-escalation, 940
  primary lifelong prevention, 937
  single antiplatelet agents, 935–937
  symptomatic coronary artery disease, 937–938
  transient ischaemic attack and ischaemic stroke (non-embolic), 942–943
  unguided de-escalation, 940
arteriovenous malformations, 304, 843–844
  hereditary haemorrhagic telangiectasia, 843
  Kasabach–Merritt syndrome, 843–844
asciminib, 642
asymptomatic disease, management of, 442
atherosclerosis
  and atherothrombosis, 933–935
  physiological defence against, 933
atherothrombosis, different types of, 935
atransferrinaemia, 193
ATTR amyloidosis, 558–559
atypical HUS, 881–883
auditory toxicity, 1011
autoimmune cytopaenia, 435–436
autoimmune disorders
  autoimmune haemolytic anaemia, 980
  neutropenia, 980
autoimmune haemolytic anaemia, 292, 980
  transfusion in, 342–343
autoinflammatory disorders, 34
autologous peripheral blood stem cell transplantation, 555
autologous SCT, 727, 739, 743
autologous stem cell transplantation, 542
  in first remission, 460
autologous transplantation, 725
autosomal dominant (AD)-DC and its link to telomeres, 570–572
autosomal recessive DC, 572
avoidance of triggers, 698
aymmetric dimethylarginine (ADMA), 250

β2-microglobulin
  amyloidosis, **548**
babesiosis, 302, 956–957
bacterial infections, 1034–1035
band 3/Rh molecular macrocomplexes, 323
bartonella, 302
basophilia, **1026**
basophils, 29–30
  granules and their contents, **31**
B-cell ALL (mature), 414
B-cell chronic disorders with leukaemic expression
  splenic marginal zone lymphoma, 446–447
B-cells, 56–59
  anergy process, 57
  development, 57–59, *58*
  pre-B cell, 57
  pro-B cell, 57
  prolymphocytic leukaemia, 365–366
  receptor, 62
  transitional, 57
BCR–ABL1 fusion, 415
BCR-ABL1-like ALL, 416
Behçet's syndrome, 1048–1049
Bernard-Soulier syndrome, **858**
β-thalassaemias, 228–240
  in association with haemoglobin variants, 237
  clinical findings, 232–233
  δβ-thalassaemia, 238–240
  deletions causing, *230*
  distribution, 228
  εγδβ-thalassaemia, 240
  emerging treatments, 236
  gene editing for, 102–104
  genotype–phenotype relationships, 232
  haematopoietic stem cell transplantation (HSCT), 236
  HbC/β-thalassaemia, 237
  HbE/β-thalassaemia, 237
  HbS/β-thalassaemia, 237
  heterozygous, 236–237
  iron overload, 234–235
  laboratory diagnosis, 233, *233*
  management of, 233–236
  molecular pathology, 228–231
    β-globin gene, deletions restricted to, 229–230, *230*
    post-translational stability, 229
    processing, 229
    transcription, 229
  monitoring and annual review of patients, 235
  pathophysiology, *231,* 231–232
  prognosis, 236
  sickle cell disease (SCD), 260
  unusual causes of, 230–231
  variant forms of, 238–240
betibeglogene autotemcel, 99
β-globin, 224
Bilharzia, 963

bioinformatic processing, 111–113
biomarkers, 94
Birbeck bodies, 34
bispecific antibodies, 88
bispecific antibody to mimic factor VIII, 802
bispecific T-cell engagers (BiTEs), 513
bivalirudin, 894–895
blackwater fever, 302
blastic phase, 631–632
bleeding patient, 1036–1040
B-lineage ALL, 396
blood cells, examination of, 662–663
blood coagulation, naturally occurring inhibitors of
  α_1-antitrypsin, 775
  α_2-antiplasmin, 775–776
  α_2-macroglobulin, 776
  antithrombin, 774
  C1-esterase inhibitor, 775
  endothelial protein C receptor, 777
  heparin and heparin-like substances in plasma, 774–775
  heparin cofactor II, 774
  Kunitz-type inhibitor, 773
  physiological anticoagulants, 773
  protease nexin 2, 775
  protein C inhibitors, 777
  protein C pathway, 776–777
  protein S, 777
  protein Z and protein-Z-dependent inhibitor, 775
  serine protease inhibitors (serpins) and heparin, 773–774
  thrombomodulin, 777
blood components
  cryoprecipitate, 338–339
  fresh-frozen plasma, 338
  frozen red cells, 337
  granulocyte concentrates, 338
  irradiated blood components, 339
  platelet preparations, 337–338
  platelets in additive solution, 338
  red cells, 336–337
  washed platelets, 338
  washed red cells, 337
  whole blood, 336
blood count abnormalities, 1007–1010
blood donation, 328–329
  laboratory tests on, 334
blood donor, 328
blood group antibodies
  cold and warm antibodies, 312
  IgM and IgG, 312
  lectins, 312
  monoclonal antibodies, 312
  naturally occurring and immune antibodies, 311–312
blood group antigens, biological significance of, 326–327
blood grouping reagents, 316
blood group system, 308
  molecular techniques for, 316–317
  other, 325–326
blood-inhabiting larvae, 958
blood loss, 180
blood transfusions, 234
  and regulatory aspects, 328
  therapy, for SCD, 263–264
blood vessels
  endothelial cell anticoagulant activities, 767
  endothelial cell-derived fibrinolytic factors, 767
  endothelium, 765
  platelet–vessel wall interaction, 765–767
  von Willebrand factor, 767
B lymphocytes, 56
body iron quantitation, 191–192
bone involvement, 533–535
bone marrow, 206–207, 689
  aspiration, *144,* 144–145, *145,* 177, *177*
  trephine biopsy, 144–148, *146–148*
bone marrow, examination of, 663–665
bone marrow disorders
  aplastic anaemia and paroxysmal nocturnal haemoglobinuria, 987–988
  haematological malignancy, 986–987
  myeloproliferative neoplasms, 986
bone marrow examination, 865
bone marrow failure, 598
bone marrow failure syndromes, 598
  congenital amegakaryocytic thrombocytopenia, 579–580
  congenital dyserythropoietic anaemia
    CDA type I, 576
    CDA type II, 576–578
    CDA type III, 578
    congenital and cyclical neutropenias, 578–579
    treatment, 578
  Diamond–Blackfan anaemia
    cell and molecular biology, 575
    clinical features, 574–575
    treatment, 575
  Dyskeratosis congenita
    autosomal dominant (AD)-DC and its link to telomeres, 570–572
    autosomal recessive DC, 572
    cell biology and link to other diseases, 570
    clinical features, 569–570
    treatment, 572–573
    X-linked DC and Hoyeraal-Hreidarsson (HH) syndrome, 570
  Fanconi anaemia
    cell and molecular biology, 566–568
    clinical features, 563–566
    treatment, 568–569
  Shwachman–Diamond syndrome
    cell and molecular biology, 573
    clinical features, 573
    treatment, 573–574
  thrombocytopenia with absent radii, 579
bone marrow infiltration, 850, **1026**
bone marrow niche dysregulation, 659
Bordetella pertussis infection, 70
bosutinib, 641
branching evolution, 138
breast implant-associated anaplastic large-cell lymphoma, 391
bromodomain and extraterminal (BET) proteins, 131
bruising, 842–843, 1041
  haemostatic dysfunction associated with vasculitis, 843
  inherited disorders of collagen and elastic fibres, 843
  non-accidental bruising, 842
  painful bruising syndrome (psychogenic purpura), 842–843
  purpura simplex (normal easy bruising), 842
  scurvy, 843
  senile purpura (atrophic or actinic purpura) and steroid-related purpura, 842
Bruton's tyrosine kinase (BTK), 62, *63*
bruton tyrosine kinase inhibitors, 867
Burkitt lymphoma, *143,* 379–380, 518–521
burst-forming erythroid units (BFU-E), 45
busulfan, 728

C1-esterase inhibitor, 775
CALR, mutations in, 673–674
Calreticulin (CALR), 133
cancer, 917–918, 1024–1027
cancer-associated fibroblasts (CAFs), 85
cancer genome, 121, 123–124
cancer immunotherapy, 82–94, *83*
  adoptive T cell (ATC) therapy, 88–91
  allogeneic cell therapies, 93
  antibody therapy, 85, 87–88
  cancer vaccines, 91–92
  cytokine therapy, 92–93
  emerging types of, 93
  future of, 93–94
  immune evasion and subversion in, 83–85
  immune system and TME, 83–85
  types of, 85–93

cancer therapy
immune response in, 68–69
cancer vaccines, 91–92
prophylactic, 91–92
therapeutic, 92
cangrelor, 889
carbapenem, **1012**, 1013, **1017**
carcinoma-related warm AIHA, 298
carcinomas, 76
cardiac iron, 195–196
cardiopulmonary bypass surgery, 841–842
cardiovascular disease, 204–205, 480, 933
CAR T-cell therapy, 89–90, *90,* 512
catalytic proteins, **24**
$CD4^+$ T cells and their functions, 66
$CD8^+$ T cells and their functions, 66
cell-extrinsic contribution to HSC fitness, 752–753
cell-intrinsic contribution to HSC fitness, 749
cell signalling
regulation of erythropoiesis, 49–50
cells resisting therapy, 139
cell-surface marker analysis, 396
cellular changes during pregnancy
platelet, 975
red cells, 974
white cells, 974–975
cellular origin of myeloma cells, 524–525
celmods, 546
central macrophages, 49
central memory, 66
central Treg cells, 67
centroblasts, 57, *58*, 59
cerebral vein thrombosis, 679, 910, 930
Chagas disease, 961
Charcot-Marie-Tooth disease, 34, **35**
checkpoint inhibitors/inhibition (CPI), 68, 82, 93
adverse effects of, 88
Chédiak–Higashi syndrome, 34, *38*, 856
chemotherapeutic agents, 670
chemotherapy, 624
chemotherapy-induced nausea and vomiting (CINV), 1022
childhood acute lymphoblastic leukaemia
aetiology
environmental factors, 410
genetic factors, 409–410
clinical features, 411
cytogenetic and molecular classification
ABL-class fusions, 416
BCR–ABL1 fusion, 415
BCR-ABL1-like ALL, 416
ETV6–RUNX1 fusion, 415
fusions involving *KMT2A* (formerly *MLL*), 415
genetic abnormalities in B-ALL, 416
genetic abnormalities in T-cell ALL, 417
high hyperdiploidy (51–65 chromosomes), 414
IGH-DUX4 fusions, 416
intrachromosomal amplification of chromosome 21q (iAMP21), 415–416
JAK-STAT abnormalities, 416
low hypodiploidy (30–39 chromosomes), 415
near-haploidy (<30 chromosomes), 414
TCF3-HLF fusion, 415
TCF3–PBX1 fusion, 415
differential diagnosis, 412
early and late toxicity, 425–426
epidemiology, 409
future strategies, 426–427
immunophenotypic classification
B-cell ALL (mature), 414
early pre-B ALL, 412–414
pre-B ALL, 414
T-lineage ALL, 414
laboratory features, 412
pathogenesis, 410–411
prognostic factors
early response, 417
integrated risk factor analysis, 418
minimal residual disease, 417–418
pharmacogenetic variables, 418
presenting features, 417
relapse, 425
resource poor setting, treatment in, 426
treatment
ALLTogether 1 protocol, 423
current outcomes, 423
current UK strategy, 422
drugs and protocols, 420
historical background, 420–422
primary refractory ALL, 422–423
treatment of distinct subgroups
ABL-class fusions, 423
down syndrome, 425
infants, 424
young people (age 16–25 years), 423–424
chimeric antigen receptors (CARs), 69, 88
chimerism, 595, 622, 718, 729, 732
cholecystectomy, 78, 257, 275
cholesterol embolism, 844
chromosomal aberrations, 656
chromosomal aberrations in myeloma, prognostic significance of, 527
chromosomal *AMP C* β-lactamase, **1017**
chromosomal inversions, 124
chromosomal material, gains and losses of, 526
chromosomal translocations, 124
chromosomes, 207
chromothripsis, 124
chronic eosinophilic leukaemia, 702
chronic graft-*versus*-host disease, 722
chronic granulomatous disease (CGD), 34
chronic GVHD, 738
chronic liver disease, 194
coagulopathy in massive blood loss, 841–842
fibrinogen, 838
fibrinolysis, 838
haemostatic disturbance in renal disease, 839–840
haemostatic dysfunction associated with cardiopulmonary bypass surgery, 840–841
haemostatic dysfunction associated with trauma, 841
haemostatic impairment, management of, 838
hypercoagulability in liver disease, 839
liver transplantation, 839
pregnancy-related haemostatic dysfunction, 840
procoagulant and anticoagulant factors, 838
thrombocytopenia, 837–838
chronic lymphocytic leukaemia (CLL), *144,* 363, 367
clinical features, 430–431
diagnostic criteria, 433
differential diagnosis, 433–434
epidemiology, 430
genetic and molecular features, 432
genetic predisposition, 430
immune defects, 430
laboratory features, 431–432
pathogenesis, 430
pathology features, 432–433
chronic myeloid leukaemia (CML), 121, *145*
accelerated phase, 631
advanced phase diseases, 647–648
asciminib, 642
atypical CML/chronic neutrophilic leukaemia, 649
blastic phase, 631–632
bosutinib, 641
chronic phase, 631
cytogenetics and *BCR::ABL1* RQ-PCR, 635–636
cytogenetics and molecular biology, 632–634
dasatinib, 639–641
epidemiology and aetiology, 630

fertility preservation and pregnancy, 648–649
future prospects, 649–650
haemopoietic stem cell transplantation, 649
imatinib, 636–638
nilotinib, 638–639
ponatinib, 641–642
TKI upfront, 642–643
treatment, 636, 643
chronic myelomonocytic leukaemia, 660–661
chronic neutrophilic leukaemia, 649, 675–676, 702
chronic non-spherocytic haemolytic anaemia, 288–289
chronic pancreatitis, 212
chronic phase, 631
chronic T-cell leukaemias
large granular lymphocyte leukaemia, 454–455
T-prolymphocytic leukaemia, 453–454
chronic thromboembolic pulmonary hypertension, 928
classical Hodgkin lymphoma, 391–393, *393*
classical pathway, 60
class switch recombination, *58*, 59
CLEC-2, 792–793
clinical blood transfusion
allogeneic blood transfusion
clinical decision to transfuse, 352
cryoprecipitate, use of, 354
fresh-frozen plasma, use of, 354
major haemorrhage, 354–355
minimize transfusion of blood and components, strategies to, 352–353
patient blood management, 352
platelet transfusion response and refractoriness, 353–354
platelet transfusions, 353
red cell transfusion triggers, 353
antenatal testing, 342
autoimmune haemolytic anaemia, transfusion in, 342–343
blood components
cryoprecipitate, 338–339
fresh-frozen plasma, 338
frozen red cells, 337
granulocyte concentrates, 338
irradiated blood components, 339
platelet preparations, 337–338
platelets in additive solution, 338
red cells, 336–337
washed platelets, 338
washed red cells, 337
whole blood, 336
blood donation, 328–329
laboratory tests on, 334
blood donor, 328
blood transfusion and regulatory aspects, 328
clinical and laboratory transfusion practice, 339
compatibility testing (cross-match), 340
complications of
delayed haemolytic transfusion reactions, 347
febrile non-haemolytic transfusion reactions, 347
haemolytic transfusion reactions, 344
immediate or acute haemolytic transfusion reactions, 344–346
mild allergic reactions, 349
post-transfusion purpura, 348–349
sensitization to red cell antigens, 344
severe anaphylactic reactions, 349
transfusion-associated circlatory overload, 350–351
transfusion-associated graft-*versus*-host disease, 348
transfusion-related acute lung injury, 347
transfusion-transmitted infection, 349–350
electronic cross-match/electronic issue, 340
EU blood directives, 339
haemato-oncology, 341–342
haemoglobinopathy, 340–341
haemolytic disease of foetus and newborn
fetomaternal haemorrhage, testing for, 359
foetal and neonatal alloimmune thrombocytopenia, 360
foetal RhD screening, 359
prevention of, 358–359
Rh D-positive platelet transfusions, 359
haemovigilance, 351
hospital transfusion practice, 339
neonatal 'top-up' transfusion, 342
pretransfusion group and screen, 339–340
safe administration of blood
patient identification, 343
transfusion reactions, detection and approach to, 343
storage and processing of blood
anticoagulants and optimal additive solutions, 336
leucodepletion, 336
storage changes, 334–336
transfusion-transmitted infection
bacteria, 333
cytomegalovirus, 332
hepatitis viruses, 331
human immunodeficiency virus (HIV-l and HIV-2), 331–332
human T-cell leukaemia viruses, 332
malaria, 332–333
prions, 333–334
syphilis, 332
clinical decision to transfuse, 352
clinical management, haemolytic anaemias
first-line treatment, 298–299
prognosis, 299
second-line treatments, 299
splenectomy, 299
supportive therapy, 298
clinical presentation, 398–399
clonal behaviour through life, 753–754
clonal eosinophilias, 675, 701–702
clonal haematopoiesis, 139
additional classes of driver mutation, 751
cell-extrinsic contribution to HSC fitness, 752–753
cell-intrinsic contribution to HSC fitness, 749
clonal behaviour through life, 753–754
clonal haematopoiesis and myeloid malignancies, 754
clonal haematopoiesis and non-haematological disease, 754–755
DNMT3A and TET2, 749–750
of indeterminate potential, 654–655
inherited factors, 751–752
and myeloid malignancies, 754
and non-haematological disease, 754–755
SF3B1, SRSF2 and U2AF1, 750–751
clostridium perfringens, 303, 1034
clotting factor concentrates, 801–802
CNS-directed therapy, 404–405
CNS prophylaxis, 510–511
coagulation factors
factor IX, 771
factor V, 772
factor VII, 770–771
factor VIII, 771–772
factor X, 771
factor XI, 771
factor XIII, 771
fibrinogen, 772
prothrombin, 772
tissue factor, 769–770
coagulation tests, 829
coagulopathy associated with COVID-19, 834–835
coagulopathy in massive blood loss, 841–842

cobalamin (vitamin B_{12}), 207–214
absorption, 207–208
analogues, 209
congenital intrinsic factor deficiency, 211
dietary sources and requirements, 207
enterohepatic circulation, 208
gastrectomy, 211
inadequate dietary intake adults, 209
serum cobalamin-binding proteins, *208*
structure, *207*
transport, 208–209
cobalamin deficiency, 202
causes of, 209, **209**
diagnosis of, 213
in infants, 209
serum methylmalonate (MMA) and homocysteine levels, 213–214
tests for cause, 214
tissue effects of, 202
treatment of, 218–219
cobalamin–folate relationship, 201–202, *202*
cobalamin malabsorption, gastric causes, 209–211, **210**
antibodies to gastric antigens, 210
diagnosis, 210
gastric biopsy, 210
hypogammaglobulinaemia, 210–211
juvenile pernicious anaemia, 211
pernicious anaemia (PA), 209–210
cobalamin malabsorption, intestinal causes of, 211–212
cobalamin metabolism
acquired abnormality of, 212–213
cobalamin neuropathy, 205
Cohesin complex, 609
cold-acting antibodies, 294
cold agglutinin disease
clinical features of, 299–300
drug treatments, 301
supportive therapy, 300–301
cold antibodies, 312
collagen receptor defect, **858**
colony-forming erythroid units (CFU-E), 45
colony stimulating factor 3 (CSF3), 15
combination therapies, 87
combined oral contraceptive, 913
common genetic lesions, 397
common lymphoid progenitors, 57
comparative genomic hybridization (CGH), 159
compatibility testing (cross-match), 340
complement activation, 294
complementarity-determining regions (CDR), 59
complement blockade, 600–601
complement fixation, 60–61, *61*
complement-mediated intravascular haemolysis, 295
complex karyotype, 607–608
complications of therapy
aging haemophilia population, 806
immune tolerance, 805–806
inhibitors, 804–805
molecular genetics of haemophiia A, 806
molecular genetics of haemophiia B, 806–807
composed of core and shell regions, 787
conditioning regimens
acute graft-*versus*-host disease, 732–733
acute GVHD scoring–MAGIC criteria, 733
allogeneic SCT, 743–744
allogeneic stem cell transplantation (beyond day 100), 738
allogeneic stem cell transplantation (days 0–90), 731–732
autologous SCT, 727, 739, 743
chronic GVHD, 738, *738*
disease relapse, prevention and management of, 742–743
fungal infection, 735–736
growth, puberty and fertility, 739
GVHD prophylaxis in RIC regimens, 730
herpesvirus infection, 734–735
infectious complications, 734
intensive care support, 737–738
myeloablative conditioning regimens in allogeneic SCT
busulfan/cyclophosphamide, 728
fludarabine-based RIC regimens, 729–730
fludarabine/busulphan, 728
GVHD prophylaxis strategies, 728–729
low-dose (200 cGy) TBI-based regimens, 729
reduced-intensity conditioning regimens, 729
TBI/cyclophosphamide, 727–728
in non-malignant diseases, 730
organ toxicity
gastrointestinal toxicity, 736
liver toxicity, 736–737
post-transplant lymphoproliferative disease, 737
pulmonary infections and non-infectious complications, 737
renal toxicity, 737
overall clinical grade, 733
secondary malignancies, 738–739
stem cell infusion and blood product support, 730–731
transplantation, indications for, 740–742
confirming presence of amyloid, 550–551
congenital amegakaryocytic thrombocytopenia, 579–580, **858**
congenital anaemias, 976
congenital dyserythropoietic anaemia
CDA type I, 576
CDA type II, 576, 578
CDA type III, 578
congenital and cyclical neutropenias, 578–579
treatment, 578
congenital erythrocytosis, 681–682
congenital intrinsic factor deficiency, 211
congenital leukaemias, 999
congenital methaemoglobinaemia, 248
congenital methylmalonic acidaemia, 212
congenital methylmalonic aciduria, 212
congenital platelet disorders, **858**
platelet transfusions, 857
thrombocytopenias
alloimmune thrombocytopenia, 849–850
bone marrow infiltration, 850
drugs and chemical agents, 850
infection, 850
inherited thrombocytopenias, 850
inherited thrombocytopenias with increased platelet size, 851–852
inherited thrombocytopenias with normal platelet size, 851
inherited thrombocytopenias with reduced platelet size, 850–851
non-inherited congenital thrombocytopenia, 849
platelet adhesion, disorders of, 853–854
platelet aggregation, disorders of, 854–856
platelet signalling transduction, disorders of, 854
thrombocytopathies, 852–853
treatment, 856–857
congenital transcobalamin deficiency/abnormality, 212
congestive cardiac failure (CCF), 1030–1031
congestive heart failure, 217
congestive liver disease, 217
connective tissue disorders, 1029–1030
consolidation therapy, 404, 621–622
constitutional features, 697
constraint theory, 138
consultative haemostasis/thrombosis, 1036–1053
convergent evolution, 138
copper, 220
copper deficiency, 1031–1032

copy-neutral loss-of-heterozygosity, 126
cord blood transplantation, 726–727
cords of Billroth, 72
core-binding factor leukaemia, 607
corpora cavernosa, 258
corticosteroids, 70, 870
COVID-19, 39, 62
  infection, 254, 255
COVID-19 and vaccine-induced, 864
CpG islands, 131
CPX-351 (Vyxeos), 620
CRISPR/Cas system, 101, 102
Crizanlizumab, 265
cross-presentation, 64, *65*
cryoprecipitate, 338–339, 354
Cushing syndrome, **1031**
cutaneous manifestations, 697
cutaneous T-cell non-Hodgkin lymphomas
  mycosis fungoides, 462–465
  primary cutaneous CD30+ lymphoproliferative disorders, 466
  Sézary syndrome, 465–466
cyanocobalamin, *207*
Cyclic Neutropenia (CyN), 34
cyclic nucleotides, 793
cyclophosphamide, 594, 727–728
cystatin C, amyloidosis, **548**
cytochemistry, 148–149, *149–150*
cytogenetic abnormalities, 606–608, 666
cytogenetic analysis, *152,* 153–154, **153**
cytogenetic and molecular classification
  ABL-class fusions, 416
  BCR–ABL1 fusion, 415
  BCR-ABL1-like ALL, 416
  ETV6–RUNX1 fusion, 415
  fusions involving *KMT2A* (formerly *MLL*), 415
  genetic abnormalities in B-ALL, 416–417
  genetic abnormalities in T-cell ALL, 417
  high hyperdiploidy (51–65 chromosomes), 414
  IGH-DUX4 fusions, 416
  intrachromosomal amplification of chromosome 21q (iAMP21), 415–416
  JAK-STAT abnormalities, 416
  low hypodiploidy (30–39 chromosomes), 415
  near-haploidy (<30 chromosomes), 414
  TCF3-HLF fusion, 415
  TCF3–PBX1 fusion, 415
cytogenetics, 438–439
cytogenetics and *BCR::ABL1* RQ-PCR, 635–636
cytogenetics and molecular biology, 632–635
cytokine release syndrome (CRS), 91
cytokines, *15*
  regulation of erythropoiesis, 50–51
cytokine therapy, 92–93
cytomegalovirus, 332
cytoreductive therapies, 699
cytotoxic T-lymphocyte-associated antigen 4 molecule (CTLA-4), 67

D, C/c and E/e polymorphisms, 323
damage-derived molecular patterns (DAMPS), 22
dasatinib, 639, 641
DC haematopoiesis, 706
deep vein thrombosis, 923
defective haem synthesis, 185
defective mitochondria respiratory chain, 186
defence against oxidative stress, 286
deferasirox (DFX), 192, **195**, 198
deferiprone (DFP), **195**, 197–198
definitive erythropoiesis (DE), 44, *44*
  cellular and molecular pathways, 45
delayed haemolytic transfusion reactions, 347
δβ-thalassaemia, 238–240, *239*
dendrites, 33
dendritic cell deficiency, 706
dendritic cells (DCs), 17, 30–34, 73, 705–706
dengue, 963
dental problems, 1010
desferrioxamine (DFO), 192, **195**, 197
  clinical studies, 197
  pharmacokinetics, 197
  side-effects, 197
desmopressin, 804
developmental haemostasis, 1000
diabetes mellitus, **1031**
Diamond–Blackfan anaemia
  cell and molecular biology, 575
  clinical features, 574–575
  treatment, 575
diapedesis, 19, *22*
differentiation syndrome (DS), 1021
diffuse large B-cell lymphoma, 376
  associated with chronic inflammation, 522
  bispecific T-cell engagers (BiTEs) and bispecific antibodies, 513
  CAR T-cell therapy, 512
  cell-of-origin based typing, 504
  clinical prognostic factors, 505–506
  CNS prophylaxis, 510–511
  high-dose chemotherapy, 511–512
  in HIV-positive patients, 513–514
  microenvironment in, 505
  molecular-based typing, 504–505
  treatment, 506–510
D immunisation, 324
direct agglutination, 313
direct antiglobulin test (DAT), 313
direct oral anticoagulants, 898–900, 1044, 1051–1052
disseminated intravascular coagulation, 830–834
  clinical features, 832
  diagnosis, 832–833
  disseminating and sustaining thrombin generation, 832
  endothelial cell activation and dysfunction, 832
  links between inflammation and coagulation, 832
  neutrophil extracellular traps and histones, 832
  pathophysiology, 831
  thrombin generation *in vivo,* 831
  treatment, 833–834
disseminated intravascular coagulation (DIC), 1001
disseminating and sustaining thrombin generation, 832
divalent metal transporter (DMT)1, 170
DMT1 deficiency, 193
DNA double-stranded breaks (DSB), 137
DNA methylation, in myeloid disorders, *132*
DNA mutations, haematological malignancies, 124–126, *124–126*
  acquired, 127–128
  amplifications, 124
  deletions, 124
  indels, 124
  missense, 124
  nonsense, 124
  substitutions, 124
  synonymous, 124
DNA sequencing technologies, 121
DNMT3A, 749–750
double-hit lymphoma, 514–515
double negative cells, 62
down syndrome, 425
  leukaemia in children without, 999
drug-induced acute haemolysis, 289
drug-related warm AIHA, 297–298
dyskeratosis congenita
  autosomal dominant (AD)-DC and its link to telomeres, 570, 572
  autosomal recessive DC, 572
  cell biology and link to other diseases, 570
  clinical features, 569–570
  treatment, 572–573
  X-linked DC and Hoyeraal-Hreidarsson (HH) syndrome, 570
dysregulation of cyclin D genes, 527

early pre-B ALL, 412–414
early-stage Hodgkin lymphoma, 473
EBMT criteria for response, relapse and progression, 539
Ebola virus, 964
EBV-positive diffuse large B-cell lymphoma, 522
EBV-positive T-cell and NK-cell lymphoproliferative disorders, 381
eculizumab
  administration and dosing, 601–602
  extravascular haemolysis with, 602–603
  future challenges and developments, 603
  infectious risk with complement blockade, 603
  intravascular haemolysis, 601
  pregnancy in PNH, 603
  prognosis, 603
  renal dysfunction, 601
  thrombosis, 601
effector memory, 66
efferocytosis, 26
electronic cross-match/electronic issue, 340
elliptocytosis
  hereditary, 276, *277*
  in neonate, 277
eltrombopag, 594–595
  added to IST in first-line treatment of AA, 603–604
elution tests, 314
embryonic haemoglobins, 222
embryonic macrophages, 17
empiric antibiotic therapy, 1012–1014
Endari, 265
endocrine disorders, 1031
end-of-life decisions, 1053
endogenous processes, 128
endothelial cell activation and dysfunction, 832
endothelial cell anticoagulant activities, 767
endothelial cell-derived fibrinolytic factors, 767
endothelial protein C receptor, 777
endothelium, 765
enterohepatic circulation, 208
  folate, 215
enzyme-linked immunosorbent assay (ELISA), 218
Eosinophil cationic proteins (ECP), 29
Eosinophil-derived neurotoxin (EDN), 29
eosinophilia, **1026,** 1030
  chronic eosinophilic leukaemia, 702
  clonal eosinophilia, 701–702
  eosinophivlia, management of, 700–701
  idiopathic hypereosinophilia and idiopathic hypereosinophilic syndrome (HES), 702
  lymphocytic variant of hypereosinophilic syndrome, 702
eosinophils, 16, 17
  granules, **29**
  primary granules, 29
  proteins, **30**
  respiratory burst in, *30*
eosinophivlia, management of, 700–701
epigenetics, 658
  and leukaemia, 130–132, *131, 132*
  modifications, 526
epinephrine receptor defect, **858**
epistaxes, 1041
Epstein–Barr virus (EBV), 91–92, 129
Erdheim Chester disease, 712–714
erythroblasts, 48, 174
erythrocytes, SID effects on, 250
erythrocytosis, 676
erythroferrone (ERFE), 171–172, 234
erythroid cells
  iron uptake by, 174–175
  negative feedback loop controlling, *51*
  positive and negative cytokines act, *50*
erythroid macrophage protein (EMP), 47
erythroid niche, *48,* 48–49
erythroid proteins, 47–48
erythroid-stimulating agents (ESA), 1007
erythro-myeloid progenitor (EMP) cells, 44
erythropoiesis, 43–55
  apoptosis, regulation of, 50–51
  assessment, 54–55
  developmental origins, 43–44
  differentiation and terminal maturation, 45–46
  erythroid niche, *48,* 48–49
  erythroid proteins, changes in expression, *47,* 47–48
  and iron metabolism, 51–52, *52*
  mature red cell, senescence and clearance, 53–54
  oxygen-sensing system in, 52–53, *53*
  process of, *46*
  regulation of, *54*
erythropoietic protoporphyria, 183
erythropoietin (Epo)., 49
E-selectins, 20
essential thrombocythaemia, 683–684, 918–919
ET, mutations in, 673–675
ethylenediaminetetraacetic acid, 107
ETV6–RUNX1 fusion, 415
EU blood directives, 339
Evans syndrome, 296, 877, 1030
excess parenteral iron, 194
exogenous plasminogen activators, 779
extended spectrum β-lactamases, **1017**
extended thromboprophylaxis, 922–923
extramedullary haemopoiesis, 74–75, 689
extramedullary plasmacytoma, 533
extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, 371–372
extranodal NK/T-cell lymphoma, nasal type, 382
extranodal peripheral T-cell non-Hodgkin lymphomas
  hepatosplenic T-cell lymphoma, 459
  primary intestinal T-cell lymphomas, 459
extravascular aemolysis, 250
extravascular haemolysis with, 602–603
ex-vivo editing, 98
ex vivo genetic modification, 12

*F2*G20210A, 907, 911
factor V deficiency, 847
familial platelet disorder with propensity to myeloid malignancy (FPD/AML), 126
Fanconi anaemia
  cell and molecular biology, 566–568
  clinical features, 563–566
  treatment, 568–569
fate-mapping, 8–9, 12–13, *13*
fat embolism syndrome (FES), 259, 844
favism, 288
Fc-Fc receptor-mediated interactions, 60, 68
FcγRIIA, 793
Fc receptors, 60
febrile non-haemolytic transfusion reactions, 347
ferritin, 166, *172,* 189, 190
ferroportin, 170–171
fetal haemoglobin (HbF), 222
  hereditary persistence of, 238–240, *239*
fetomaternal haemorrhage, 996
  testing for, 359
fibrin generation and clot retraction, 787
fibrinogen, 20, 772, 838
fibrinogen α chain amyloidosis, **548**
fibrinogen deficiency, 824
fibrinolysis, 764–765, 838, 908
  fibrin and fibrinogen, 778–779
  fibrinolytic system, components of, 778
  plasminogen and plasmin, 778
fibrinolysis, inhibitors of, 779
fibroblast activation protein alpha (FAP), 91
filariasis, 957–958
  diagnosis of, 958–959
  haematological abnormalities in, 958
  haematological implications of treatment for, 959
first-line treatment in children, 869–870
flow cytometric immunophenotyping, 149–151, *150*

flow cytometry, 665–666
fludarabine-based RIC regimens, 729–730
fludarabine/busulphan, 728
fluid balance, 1018–1020
fluorescence *in situ* hybridization, 154–156, *155–157,* **155**
fluorescent activated cell sorting (FACS), 9
focused abdominal sonography for trauma (FAST), 77
foetal neonatal alloimmune thrombocytopenia, 360, 981
foetal RhD screening, 359
foetal Rh genotype, 324
folate, 214–215
  absorption, 215
  biochemical functions, 215
  body stores and requirements, 214–215
  dietary, 214
  enterohepatic circulation, 215
  structure of, *214*
  transport, 215
folate co-enzymes, biochemical reactions of, **203**
folate deficiency, **216,** 975
  antifolate drugs, 217
  congenital abnormalities of folate metabolism, 217
  congestive heart failure, liver disease, 217
  diagnosis of, 218
  excess utilization/loss, 216–217
  haematological disorders, 217
  homocystinuria, 217
  inflammatory conditions, 217
  long-term dialysis, 217
  malabsorption, 216
  nutritional, 215–216
  in pregnancy, 216–217
  prematurity, 217
  tissue effects of, 202
  treatment of, 219
folate metabolism, congenital abnormalities of, 217
folates
  in DNA synthesis, *204*
  SAM formation, *204*
folic acid, 187
  fortification of diet with, 219
  before and during pregnancy, 219–220
  structure of, *214*
folinic acid (5-formyl-THF), 219
follicular dendritic cells (FDC), 57
follicular helper T-cell lymphoma, 387
follicular helper T cells (TFH) cell, 67
follicular lymphoma (FL), 373–375, 450, 482
  asymptomatic low tumour burden advanced-stage, 485–486
  clinical and pathological features of, 483
  early-stage, management of, 485
  induction therapy, 486–487
  management of relapsed, 489–490
  management of transformed, 491
  marginal zone lymphomas, 492
  novel therapies for, 490–491
  pathogenesis of, 483
  prognostic markers in, 483–485
  staging and baseline investigations in, 483
  symptomatic high tumour burden advanced-stage, 486
  transplantation in relapsed, 490
food cobalamin malabsorption, 211
formalin fixation followed by paraffin embedding (FFPE), 107
5-formyl-THF, 219
fortification of diet with folic acid, 219
fostamatinib, 867
fragment, antigen binding (Fab) fragment, 60
fragment, crystallisable (Fc) fragment, 60
fragmentation haemolysis, 304, **304**
frameshift mutation, 124
frataxin, **168**, 175
fresh-frozen plasma (FFP), 338
  use of, 354
frozen red cells, 337
fructose diphosphate aldolase A deficiency, 284
functional iron deficiency, 178
fungal infections, 735–736, 1034–1035
fusions involving *KMT2A* (formerly *MLL*), 415
fusion tyrosine kinases, *133*
FVIII assays, 801
FVR506Q (FV), 907
FVR506Q and APC resistance, 911

G6PD deficiency, 995
  in infancy, 288
gain-of-function changes, 132
gastrointestinal infections, 1015
gastrointestinal toxicity, 736
gelsolin, amyloidosis, **548**
gemtuzumab ozogamicin, 620
gene editing, 96–104
  for β-thalassaemias and sickle cell disease, 102–104
  delivery of, 102
  general principles of, 96–98
  for haemophilia, 100–102, *101*
  safety of, 104
gene mutations, 439
gene therapy, 96
  general principles of, 96–98
  for haemoglobinopathies, 98
  for haemophilia, 100, 807–809
  in haemopoietic stem cells, 98–100
  safety and efficacy concerns, 99–100
  for sickle cell disease, 99
  for thalassaemia, 98–99
  vectors used for, 98
genetic abnormalities
  in B-ALL, 416–417
  in T-cell ALL, 417
genetic haematological mechanisms, 954, 956
genetic iron deficiency, 180
genetic predisposition, 588
  to AA and short telomeres, 588–589
genetics
  common genetic lesions, 397
  minimal residual disease, 397–398
  prognostic and predictive factors in ALL, 398
genome-wide association studies (GWAS), 126, 226
genomic abnormalities, 525
genomic instability, 127
genotoxin, 126
genotype guided de-escalation, 940–941
germinal centres (GC), 57
germline mutations, 124
germline predispositions, 675
germline predisposition to myeloid neoplasms, 653–654
Giemsa-stained chromosomes, karyogram of, *152, 154*
Glanzmann's thrombasthenia, **858**
global haemostasis tests, 823
glucose-6-phosphate dehydrogenase deficiency, 287–288
glucose phosphate isomerase deficiency, 284
glutathione, 289–290
glutathione cycle, 287
glycogen storage disease type II, 972
glycolytic pathway (Embden-Meyerhof pathway), disorders of, 281, *282*
glycoprotein, 208
glycosaminoglycans (GAGs), 548
glycosylphosphatidylinositol defect, 597
GPIb-IX-V, 788–789
GPIIb/IIIa antagonists, 889
G protein-coupled adhesion receptors (GPCRs), 20
G protein-coupled receptors
  5-HT_{2A} receptors, 792
  $P2Y_1$ and $P2Y_{12}$ ADP receptors, 790–791
  PAR1 and PAR4 thrombin receptors, 791–792
  thromboxane TP receptor, 791
GPVI-FcRγ, 792

graft-*versus*-host-disease (GvHD), 10, 595
graft-*versus*-leukaemia effect, 722–724
gram-negative bacteria, **1012**
gram-positive bacteria, **1012**
granule secretion and TxA_2 formation, 787
granulocyte
  concentrates, 338
  development and proliferation, 15
granulocyte colony-stimulating factor (G-CSF), 6, 15, 1009
granulocyte/macrophage colony-stimulating factor (GM-CSF), 65
  in juvenile myelomonocytic leukaemia, 134–135
granulocyte-monocyte colony-stimulating factor (GM-CSF), 6
granulocytes, 15, 16
  transfusions, 1009
group O as universal donor, 318–319
guided and non-guided de-escalation, 940
GVHD prophylaxis in RIC regimens, 730
GVHD prophylaxis strategies, 728–729

haematological abnormalities, 953–954, 960, 962
haematological abnormalities, in filariasis, 958
haematological disorders, 217
haematological implications of treatment, 961–963
haematological malignancies, 121–140
  acquired DNA mutations in, 127–128, *128*
  clonal evolution of, 138–139
  clonal structure on treatment and relapse, 139, *140*
  DNA mutations, classes of, 124–126, *124–126*
  endogenous processes, 128
  epigenetics and leukaemia, 130–132, *131, 132*
  exogenous processes, 129
  from genotype to phenotype, 129
  GM-CSF and RAS signalling in juvenile myelomonocytic leukaemia, 134–135
  infiltration by, 75
  inherited predisposition to, 126–137
  multiple myeloma, 137
  NOTCH-signalling and lymphoid malignancies, 129–130, *130*
  P53 network, 135
  Ras pathway mutations in, 135
  splicing factors, 135–137, *136*
  tyrosine kinases and myeloproliferation, 132–134, *133*
haematological malignancy, 986–987
haematological neoplasm, diagnosis of, 142–151
  blood count and film, 142–144, *143, 144*
  bone marrow aspirate, *144,* 144–145, *145*
  bone marrow trephine biopsy, 144–148, *146–148*
  cytochemistry, 148–149, *148–149*
  cytogenetic analysis, *152,* 152–154, **153**
  flow cytometric immunophenotyping, 149–151, *150*
  fluorescence *in situ* hybridization, 154–156, *154–157,* **155**
  histology, 149
  immunohistochemistry, 151–152
  microarray analysis of gene expression, 159–160
  molecular genetic analysis, 157–158, *158*
  next-generation sequencing, 160
  whole-genome scanning, 158–159, *160*
haemato-oncology, 341–342
haematopoiesis, *15*, 33
haematopoietic stem cell transplantation (HSCT), 236
haem iron, 174
haemoglobin, 222–248
  breakdown, and iron recycling, 176
  β-thalassaemias, 228–240
  classification of disorders, 227–228
  electrophoresis, 261, *262*
  genetic control, 222–227, *225*
  haem and globin in, *47*
  prototype globin gene, *225*
  regulation, 224–226
  structure, 222–227, *223*
  switches, 224
  synthesis of, 222–227
  thalassaemia intermedia, 244–246
  α-thalassaemias, 240–244
  thalassaemias and related disorders, 228
  transcription and processing of mRNA, 226–227
  translation, 227
  variants related to thalassaemia, 246–248
haemoglobin Bart's hydrops syndrome, 243
haemoglobin H disease, 243
haemoglobinopathies
  gene editing for, 102–103, *103*
  non transfusion dependent thalassamia, 978
  sickle cell disease, 976–977
  thalassaemia carriage/trait, 977
  thalassemia, 977
  through direct correction of gene, 103–104
  through elevation of fetal haemoglobin levels, 102–103, *103*
  transfusion-dependent thalassaemia major, 978
  UK haemoglobinopathy screening service, 976
haemoglobinopathy, 340–341
haemolyic hereditary elliptocytosis, *277*, *277*
haemolysis, 250–251, 269–270, 314, 597–598

side-effects, 198
iron-containing enzymes, 165–166
iron deficiency, 178–181, 975–976
absolute, 178
anaemia, 178
anaemia of inflammation, 178–179
defective mitochondria respiratory chain, 186
functional, 178
management of, 181–182
sideroblastic anaemia, 184–187
tissue effects of, 179
iron-induced organ damage, **195**
iron metabolism
diagnostic methods, 176–178
divalent metal transporter (DMT)1, 170
erythroferrone, 171–172
and erythropoiesis, 51–52, *52*
ferritin and haemosiderin, 166
ferroportin, 170–171
haem proteins and iron-containing enzymes, 165–166
hepcidin, 171
intracellular iron homeostasis, 172
matriptase-2, 172
proteins in, 165–172, **167**–**169**
iron overload, 176, 188–199
acaeruloplasminaemia, 193
anaemia, associated with, 193–194
atransferrinaemia, 193
body iron burden, test of, 194–196
β-thalassaemias, 234–235
causes of, **189**
chronic liver diseases, 194
DMT1 deficiency, 193
hereditary haemochromatosis (HH), 188–193
hereditary hyperferritinaemia-cataract syndrome, 194
neonatal haemochromatosis, 193–194
iron refractory iron deficiency anaemia (IRIDA), 180
irradiated blood components, 339
irreversibly sickled cells (ISCs), 261
islet amyloid polypeptide, amyloidosis, **548**
isolated 5q deletion, 659–660
isolated calf DVT, 925
ITIM receptors, 793

Jacobsen and Paris-Troussau syndromes, **858**
JAK2, mutations in, 673–674
JAK2–STAT5 pathway, 49
JAK-STAT abnormalities, 416
juvenile myelomonocytic leukaemia (JMML)
GM-CSF and RAS signalling in, *134,* 134–135
juvenile pernicious anaemia, 211
juvenile xanthogranuloma, 714–715

Kaposi's sarcoma, 92
Kasabach–Merritt syndrome, 843–844
kataegis, 128
Kell blood group system, 325
Kit ligand, 49
KMT2A rearrangements, 607
Kunitz-type inhibitor, 773

langerhans cell histiocytosis, 709–712
langerhans cells, 34
large-cell lymphomas of terminally differentiated B cells, 378
large granular lymphocyte, 66
large granular lymphocyte leukaemia, 454–455
Lassa fever, 964
late complications after ATG, 594
late genetic events, 526–527
lead poisoning, 184, 307
lectins, 312
leg ulcers, 259
leishmaniasis, 961
lenalidomide, 669
Lepore, *240*
leucocyte adhesion deficiency (LAD), 34
leucocyte changes, 80
leucocyte chemotactic factor II (LECT2) amyloidosis, 558
leucocyte chemotactic factor II in amyloidosis, **548**
leucocytes, 16, 20, 1026
leucodepletion, 336
leukaemia
epigenetics and, 130–132, *131, 132*
with prominent nucleoli, 450–451
risk factors for, **126**
transformation, 679
leukaemic MCL, 449–450
leukaemic transformation, 598
leukostasis, 1009
Lewis antibodies, 321
Lewis system
antigens and their biosynthesis, 320
I and i antigens and antibodies, 321–322
Lewis antibodies, 321
Lewis antigens on red cells, development of, 320–321
P1, P^k and P blood group antigens and antibodies, 321
L-Glutamine, 265
Li Fraumeni syndrome, 135
lineage markers, 9
linear evolution, 138
links between inflammation and coagulation, 832
lipoprotein A, 780–781
liver, role of, 295
liver disease, 837–842, 1028
liver iron, 194–195
liver toxicity, 736–737
liver transplantation, 839
loa loa, 958
localised AL amyloidosis, 557–558
locomotion, 18
long-read technologies, 111
long-term complications of HSCT, 595–596
long-term haematopoietic stem cells (LT-HSC), 15
long-term in vitro assays, 6–8
long-term treatment, 866
loss-of-heterozygosity (LOH), 108, 125
low-dose (200 cGy) TBI-based regimens, 729
low-expression genes, 277
low hypodiploidy (30–39 chromosomes), 415
low-oxygen-affinity haemoglobin variants, 248
low-risk patients, 686
L-selectins, 20
lupus anticoagulant tests, 915–916
luspatercept, 236, 669
lymphocyte chemoattractant factor (LCF), 29
lymphocytes, 32
antibodies, 59–60
antigen-experienced, 57
B cell receptor, 62
B cells, 57–59
blood, counts in, **69,** 69–70
$CD4^+$ and $CD8^+$ T cells and their functions, 66
complement fixation, 60–61, *61*
co-stimulatory and inhibitory molecules, 68
development and function, 56–70
Fc-Fc receptor-mediated interactions, 60
natural killer cells, 67–68
natural killer T (NKT) cells, 68
neutralising activity, 62
primed T cells into effector cells, 66–67
regulatory $CD4^+$ T cells, 67
lymphocytic variant of hypereosinophilic syndrome, 702

lymphocytosis, **1026**
lymphocytosis, non-malignant causes of, **70**
lymphoid malignancies, 129–130, *130*
lymphoid tissues, laboratory techniques and WHO classification, 160–161
lymphomas, classification of
  Hodgkin lymphoma
    classical Hodgkin lymphoma, 391–393
    nodular lymphocyte-predominant B-cell lymphoma/nodular lymphocyte-predominant Hodgkin lymphoma, 391
  mature B-cell neoplasms
    adult T-cell leukaemia/lymphoma, 381–382
    aggressive NK-cell leukaemia, 380–381
    anaplastic large-cell lymphoma, ALK$^-$, 389–391
    anaplastic large-cell lymphoma, ALK$^+$, 387–389
    B-cell prolymphocytic leukaemia, 367–368
    breast implant-associated anaplastic large-cell lymphoma, 391
    Burkitt lymphoma, 379–380
    chronic lymphocytic leukaemia/small lymphocytic lymphoma, 363–367
    diffuse large B-cell lymphoma, 376
    EBV-positive T-cell and NK-cell lymphoproliferative disorders, 381
    extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, 371–372
    extranodal NK/T-cell lymphoma, nasal type, 382
    follicular helper T-cell lymphoma, 387
    follicular lymphoma, 373–374
    hepatosplenic T-cell lymphoma, 383
    high grade B-cell lymphomas, 380
    intestinal T-cell lymphomas, 382
    large-cell lymphomas of terminally differentiated B cells, 378–379
    lymphoplasmacytic lymphoma/Waldenström macroglobulinaemia, 369
    mantle-cell lymphoma, 375–376
    mediastinal grey zone lymphoma, 380
    mycosis fungoides, 384–385
    nodal marginal zone lymphoma, 372–373
    peripheral T-cell lymphoma, 386–387
    plasma cell neoplasms, 369–371
    predominant extranodal location, 378
    primary cutaneous CD30-positive T-cell lymphoproliferative disorders, 385
    primary cutaneous peripheral T-cell lymphoma, rare types disorders, 385–386
    primary mediastinal large B-cell lymphoma, 377–378
    Sézary syndrome, 385
    splenic marginal zone lymphoma, 368–369
    subcutaneous panniculitis-like T-cell lymphoma, 383–384
    T-cell/histocyte-rich large B-cell lymphoma, 377
  risk factors for, **126**
lymphomatoid papulosis, 466
lymphopenia, **1026**
lymphopenias, 70
lymphoplasmacytic lymphoma/Waldenström macroglobulinaemia, 369
lymphoproliferative diseases, 296–297
lysosomal storage diseases, 76
lysosomal storage disorders
  diagnosis of, 966–967
  enzyme replacement therapy, 968
  Fabry disease, 972
  Gaucher disease, 969
  genetic therapies, 968
  laboratory features, 970–971
  Niemann–Pick disease, 972–973
  pharmacological chaperone therapy, 968
  Pompe disease, 972
  prevalence of, 966
  prognosis, 969
  stem cell transplantation, 967
  substrate reduction therapy, 968
  treatment, 971–972
lysozyme, amyloidosis, **548**
lytic enzymes
  phagocytosis, 23–24

macrophage-restricted mannose receptors (MMR), 18
macrophages, 30–34, 74, 704–705
  cytokines, 49
  disorders of, 34, 39–41
  plasma membrane antigens and receptors, *32*
maintenance therapy, 404, 624–625
major basic protein (MBP), 29
major haemorrhage, 354–355
major histocompatibility complex (MHC), 84
malabsorption, 180
malaria, 301–302, 332–333, 950–951
malaria chemoprophylaxis, 956
malaria rapid diagnostic tests, 956
malignancy, 205
malignant clone factors, 537–538
malignant disease, 304
malignant histiocytosis, 715
mannose-binding lectin pathways, 61
mansonella ozzardi, 958
mansonella perstans, 958
mantle cell lymphoma (MCL), 373–374, 498
  first-line management of, 499
  prognosis of, 498–499
  relapsed disease and novel treatments, 499–500
MAPK pathway activation, 707–708
Marburg virus, 964
March haemoglobinuria, 305
marginal zone lymphomas (MZL), 492
  first-line systemic therapy for, 492
  for symptomatic advanced-stage, 494–495
massive blood loss, 841–842
massive life-threatening PE, 986
massively parallel sequencing. *see* next-generation sequencing
mast cell progenitors, 28
mast cells, 16–17, 29–30
  granules and their contents, **31**
  two-signal, *33*
mastocytosis
  investigations, 695–697
matriptase-2, 172
mature B-cell neoplasms
  adult T-cell leukaemia/lymphoma, 381–382
  aggressive NK-cell leukaemia, 380–381
  anaplastic large-cell lymphoma, ALK, 389–391
  anaplastic large-cell lymphoma, ALK$^+$, 387–389
  B-cell prolymphocytic leukaemia, 365–366
  breast implant-associated anaplastic large-cell lymphoma, 391
  Burkitt lymphoma, 379–380
  chronic lymphocytic leukaemia/small lymphocytic lymphoma, 361–365
  diffuse large B-cell lymphoma, 374
  EBV-positive T-cell and NK-cell lymphoproliferative disorders, 381
  extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, 369–370
  extranodal NK/T-cell lymphoma, nasal type, 382
  follicular helper T-cell lymphoma, 387
  follicular lymphoma, 371–373
  hepatosplenic T-cell lymphoma, 383
  high grade B-cell lymphomas, 380
  intestinal T-cell lymphomas, 382–383
  large-cell lymphomas of terminally differentiated B cells, 378–379

lymphoplasmacytic lymphoma/Waldenström macroglobulinaemia, 367
mantle-cell lymphoma, 373–374
mediastinal grey zone lymphoma, 380
mycosis fungoides, 384–385
nodal marginal zone lymphoma, 370–371
peripheral T-cell lymphoma, 386–387
plasma cell neoplasms, 367–369
predominant extranodal location, 376
primary cutaneous CD30-positive T-cell lymphoproliferative disorders, 385
primary cutaneous peripheral T-cell lymphoma, rare types disorders, 385–386
primary mediastinal large B-cell lymphoma, 375–376
Sézary syndrome, 385
splenic marginal zone lymphoma, 366–367
subcutaneous panniculitis-like T-cell lymphoma, 383–384
T-cell/histocyte-rich large B-cell lymphoma, 375
May Grunwald Giemsa stain, 46
May-Hegglin anomaly and Sebastian, Epstein, Fetchner syndromes, **858**
May–Hegglin anomaly with Döhle bodies, *38*
McLeod phenotype, 280, *280*
MDS/MPN-NOS, 661
MDS/MPN with SF3B1 mutation and thrombocytosis (MDS/MPN-SF3B1-T), 661
measurable residual disease (MRD), 106, 118, 150
mechanical haemolytic anaemias, 303
mediastinal grey zone lymphoma, 380
Mediterranean macrothrombocytopenia, **858**
medullary thymic epithelial cells (mTEC), 64
megakaryocytes, 9
megaloblastic anaemia, 201–221
altered metabolism, 220
biochemical basis of, 201
causes of, **202**
clinical feature, 202–205
cobalamin–folate relationship, 201–202
general management of, 218
haematological findings, 205–207
megaloblastic anaemia, syndromic sideroblastic anaemia with, 186
megaloblastic anaemia Type 1 (MGA1), 211
megative selection, 62
membrane lipids, abnormalities of, 279–280
mesenteric vein thrombosis, 930
methaemoglobinaemia, 306
methicillin, **1017**
methotrexate, 205, 217
MHC
class I, antigen presentation, 65
class II, 65
cross-presentation, *65*
microangiopathic haemolytic anaemias, 304
microarray analysis of gene expression, 159–160
microbiota, 174
microcolumn tests (gel and beads), 314–315
microplate techniques, 315
MicroRNA expression, 527
microthromboembolic disease, 844
cholesterol embolism, 844
fat embolism syndrome, 844
warfarin-induced skin necrosis, 844
midostaurin and FLT3 inhibition, 620
mild allergic reactions, 349
mild common hereditary elliptocytosis, *276,* 276–277
minimal residual disease, 397–398, 417–418, 441–442
minimize transfusion of blood and components, strategies to, 352–353
missing self recognition, 68
mitochondrial glycine importer, mutations of, 185
mitochondrial iron metabolism, 175
mitochondrial myopathy, lactic acidosis and sideroblastic anaemia (MLASA), 186
mitochondria respiratory chain, defective, 186
mixed lineage leukaemia (MLL), 129, 131, *131*
MNS system
antibodies of, 325
antigens of, 324–325
modified vaccinia virus Ankara (MVA), 92
molecular abnormalities, 666–667
molecular basis of D variants, 324
molecular genetic analysis, 157–158, *157*
molecular genetics of haemophiia A, 806
molecular genetics of haemophiia B, 806–807
molecular pathology, 228
moloney leukaemia virus-derived γ-retroviral vectors, 98
monoclonal antibodies, 59, 312
monoclonal antibodies (mAbs), 82
monoclonal B-cell lymphocytosis (MBL)
asymptomatic disease, management of, 442
autoimmune cytopaenia, 435–436
clinical stages, 438
cytogenetics, 438–439
disease transformation (Richter's syndrome), 437
gene mutations, 439–440
IGHV gene mutational status, 439
infections, 436–437
minimal residual disease, 441–442
objectives of treatment, 442
predictive biomarkers, 441
pre-treatment evaluation, 441
prognosis, 436–438
prognostic assessment in daily practice, 440
second neoplasias, 436
treatment, 436, 440–441
treatment approaches, 442
monoclonal gammopathy of undetermined significance, 530
monoclonal gammopathy of unknown significance (MGUS), 137
monoclonal immunoglobulin light chain (AA) amyloidosis, **548**
monocyte, 17, 706
disorders of, 34, 39–41
rudimentary granules in, 23
swarming, *28*
monocyte colony-stimulating factor (M-CSF), 6
monocytopenia, **1026**
monocytosis, **1026**
monogenetic interferonopathies, **41**
monogenic autoinflammatory syndromes, **39**–**40**
monomeric immunoglobulin molecules, *59*
mononuclear phagocyte system (MPS), 15, 17
disorders, 973
moulds, **1012**
Moyamoya disease, 255
MPL in PV, mutations in, 673–674
MPS-monocytes, 30–34
MRD risk-adapted therapy, 622–624
mRNA
transcription and processing of, 226–227
multiagent chemotherapy, 475
multinucleated cells, 30–34
multiple myeloma (MM), 137, *147*
anaemia and bone marrow failure, 536
bone involvement, 533–535
celmods, 546
epidemiology and aetiology, 524
immune-based treatments
bispecific antibodies, 545
chimeric antigen receptor T-Cells, 545
infection, 536
monoclonal gammopathy of clinical significance
smouldering multiple myeloma, 531–532
monoclonal gammopathy of undetermined significance, 530
nervous system involvement, 536–537
pathogenesis

multiple myeloma (MM) (*Continued*)
cellular origin of myeloma cells, 524–525
chromosomal aberrations in myeloma, prognostic significance of, 527
clinical features of MM and the development of bone lesions, 528–530
dysregulation of cyclin D genes, 527
epigenetic modifications, 526
gains and losses of chromosomal material, 526
genomic abnormalities, 525
IGH translocations, 525–526
late genetic events, 526–527
MicroRNA expression, 527
multistep pathogenesis of multiple myeloma, 527
mutations detected by whole-genome sequencing, 526
plasma cells and their microenvironment, 527–528
plasma cell dyscrasia
extramedullary plasmacytoma, 533
IgM multiple myeloma, 533
non-secretory multiple myeloma, 533
osteosclerotic myeloma, 533
plasma cell leukaemia, 532–533
POEMS syndrome, 533
prognostic factors
criteria of response, 539
EBMT criteria for response, relapse and progression, 539
host factors, 537
IMWG response criteria, 539
malignant clone factors, 537–538
response to therapy, 538–539
tumour burden and disease complications, 538
renal failure, 535–536
treatment
allogeneic stem cell transplantation, 543
autologous stem cell transplantation, 542
consolidation and maintenance, 542–543
induction therapy, 541–542
newly diagnosed elderly and non-transplant candidate patients, 541
promising new drugs, 545
at relapse, 543–544
side-effects associated with novel agents, 544–545
venetoclax, 545–546
multistep pathogenesis of multiple myeloma, 527
multisystemic disorders with neutropenia, 34
mutational signatures, 128
mutations detected by whole-genome sequencing, 526
mutual exclusivity, 129
mycophenolate mofetil, 867
mycosis fungoides, 384–385, 462–466
myeloablative conditioning regimens in allogeneic SCT
busulfan/cyclophosphamide, 728
fludarabine-based RIC regimens, 729–730
fludarabine/busulphan, 728
GVHD prophylaxis strategies, 728–729
low-dose (200 cGy) TBI-based regimens, 729
reduced-intensity conditioning regimens, 729
TBI/cyclophosphamide, 727–728
myelodysplasia, α-thalassaemias associated with, 244
myelodysplasia of childhood
juvenile myelomonocytic leukaemia, 662
myelodysplastic/myeloproliferative neoplasm with neutrophilia (MDS/MPN-N), 661
myelodysplastic syndrome (MDS), 34, *147*
age, 655
allogeneic stem cell transplantation, 600
apoptosis, 656
blood cells, examination of, 662–663
bone marrow, examination of, 663–665
bone marrow niche dysregulation, 659
chemotherapeutic agents, 670
chromosomal aberrations, 656
chronic myelomonocytic leukaemia, 660–661
clonal haemopoiesis of indeterminate potential, 654–655
cytogenetic abnormalities, 666
demographics and clinical presentation, 653
epigenetics, 658
flow cytometry, 665–666
future directions, 671
germline predisposition to myeloid neoplasms, 653–654
haemopoietic growth factors, 669
history and classification, 652–653
hypomethylating agents, 669–670
hypoplastic MDS, 660
immune dysregulation, 659
immunosuppression, 669
intensive chemotherapy, 670
international prognostic scoring systems, 667
IPSS-molecular (IPSS-M) risk assessment score, 667–668
iron chelation, 668–669
lenalidomide, 669
low blasts and isolated 5q deletion, 659–660
low blasts and SF3B1 mutation (MDS-SF3B1), 660
luspatercept, 669
MDS/MPN-NOS, 661
MDS/MPN with SF3B1 mutation and thrombocytosis (MDS/MPN-SF3B1-T), 661
molecular abnormalities, 666–667
myelodysplasia of childhood
juvenile myelomonocytic leukaemia, 662
myelodysplastic/myeloproliferative neoplasm with neutrophilia (MDS/MPN-N), 661
myeloid neoplasms post cytotoxic therapy, 654
somatic mutations, 657–658
stem cells and differentiation, 656
supportive care, 668
therapeutic options, 668–671
myelofibrosis, 679
myeloid neoplasms post cytotoxic therapy, 654
myeloid stem cell disorders, 76–78
non-haematological malignancies, infiltration by, 76
splenic lesions, diagnostic evaluation of, 76–77
splenomegaly, diagnostic evaluation of, 76–77
tumour-like lesions, infiltration by, 76
vascular congestion, 76
myeloid transcription factors, 609
myeloperoxidase (MPO) deficiency, 34
myeloproliferation, 132–134
myeloproliferative, **817**
8p 11 myeloproliferative syndrome, 133
myeloproliferative disease, thrombotic risk in, 918–919
myeloproliferative neoplasms, 986
myeloproliferative neoplasms (MPNs)
acquired secondary erythrocytosis
abnormal EPO production, 682
hypoxia driven, 682
idiopathic erythrocytosis, 682
chronic neutrophilic leukaemia, 675–676, 702–703
clonal eosinophilias, 675
congenital erythrocytosis, 681–682
eosinophilia
chronic eosinophilic leukaemia, 702

clonal eosinophilia, 701–702
eosinophivlia, management of, 700–701
idiopathic hypereosinophilia and idiopathic hypereosinophilic syndrome (HES), 702
lymphocytic variant of hypereosinophilic syndrome, 702
erythrocytosis, 676
essential thrombocythaemia, 683–684
germline predispositions, 675
high-risk patients, 685–686
leukaemia transformation, 679
low-risk patients, 686
mastocytosis
investigations, 695–697
mutations in *JAK*44, *CALR* and *MPL* in PV, ET and PMF, 673–674
mutations in PV, ET and PMF, 674–675
myelofibrosis, 679
polycythaemia vera, 676–678
polycythaemic transformation, 685
prefibrotic myelofibrosis, 687
primary myelofibrosis
bone marrow, 689
epidemiology, 687–688
extramedullary haemopoiesis, 689
laboratory features, 688–689
prognosis, 689–691
systemic symptoms, 689
treatment, 691–694
reactive thrombocytosis, 682–683
systemic mastocytosis, 675
constitutional features, 697
cutaneous manifestations, 697
systemic disease, 697
thromboembolic events, 678–679
treatment, 685
avoidance of triggers, 698
cytoreductive therapies, 699
symptomatic management of mediator release, 698–699
uncommon causes of thrombocytosis, 686–687
vascular complications and risk stratification, 684–685

NADPH oxidase, 24
components of, *25*
natural anticoagulants, 907
natural killer (NK) cells, 56, 67–68, 93
natural killer T (NKT) cells, 68
near-haploidy (<30 chromosomes), 414
Necator americanus, 963
negative feedback loop, *50,* 51
neonatal haematology
developmental haemopoiesis, 989
haemostasis and thrombosis in newborn, 999–1004
neonatal anaemia, 989–990
anaemia of prematurity, 997
due to increased red cell destruction (haemolysis), 992–993
due to red cell membrane disorders, 993–994
due to reduced red cell production, 990
genetic red cell aplasia, 990
neonatal polycythaemia, 997–998
parvovirus B19 and foetal/neonatal anaemia, 990
pearson syndrome, 991–992
white cell disorders, 998–999
neonatal haemochromatosis, 193–194
neonatal jaundice, in infancy, 288
neonatal stroke, 909–910
neonatal 'top-up' transfusion, 342
NETosis, 28
neural tube defects, 203–204
fortification of diet with folic acid, 219
neurological manifestations, 205
neutropenia, 980, 998, 1009, **1026,** 1030
neutropenic fever, 1011–1012
neutrophil extracellular traps (NETs), 28, 251
neutrophil extracellular traps and histones, 832
neutrophilia, **1026,** 1030
neutrophils, 17, 24–28
activation receptors in, 26
congenital disorders, 34
defensive functions, 26
diameter, 24

dysfunction disorders, 34
efferocytosis, 26
granules and their contents, *27*
life span, 26
maturation stages, *25,* 26
microbicidal proteins, **24**
and monocyte swarming, *28*
morphology, variations in, *38*
NETosis, 28
progenitors, *25,* 26
quiescent state, 26
respiratory burst in, *30*
retention, 26
new drugs, 461
newly diagnosed elderly and non-transplant candidate patients, 543
next-generation sequencing (NGS)
amplicon *vs.* hybridization panel, 108–109, *109,* **110**
assay breadth and depth, 108
bioinformatic processing and data interpretation, 111–113, *112*
cost of, 118–119
diagnostic, 113, **114**
discovery, 118
ethical considerations, 119–120
future of, 120
germline predisposition, 118
haematological neoplasm, diagnosis of, 160
in haematology, 106–119
input substrate, 106–108, *107*
interpretation complexities, 119
library preparation, 109–110
long-read technologies, 111
measurable residual disease, 118
practical considerations, 118–120
prognostic, 113–114, **116**
short-read technologies, 110–111
therapeutic testing, 114, **116**–114**,** **117**–118
turn-around-times, 119
utility of, 113–118
nicotinic acid deficiencies, 220
Niemann-Pick diseases, 76
nilotinib, 638–639
nitric oxide synthase (NOS), 24
nitrous oxide inhalation, 212–213
nivolumab, 87
nivolumab plus ipilimumab, 87
NK CAR therapy, 93
NLRP3 inflammasome, *23*
nodal marginal zone lymphoma, 370–371
nodal peripheral T-cell non-Hodgkin lymphomas
anaplastic large-cell lymphoma, 458
angioimmunoblastic T-cell lymphoma, 457
peripheral T-cell non-Hodgkin lymphoma, 456–457
nodular lymphocyte-predominant B-cell lymphoma/nodular lymphocyte-predominant Hodgkin lymphoma, 391
non-accidental bruising, 842
non-enzymatic proteins, **24**
non-haematological malignancies, infiltration by, 76
non-haem iron, 174
non-Hodgkin lymphoma (NHL), 75–76, 146
non-immune acquired haemolytic anaemias
abetalipoproteinaemia, 307
arteriovenous malformation, 304
babesiosis, 302
bacterial infections, 303
bartonella, 302
blackwater fever, 302

non-immune acquired haemolytic anaemias (*Continued*)
clostridium perfringens, 302
fragmentation haemolysis, 303
haemolysis associated with cardiac surgery, 303–304
haemorrhagic fevers, 303
hereditary acanthocytosis, 307
lead poisoning, 306
malaria, 301–302
malignant disease, 304
March haemoglobinuria, 305
mechanical haemolytic anaemias, 303
methaemoglobinaemia, 306
microangiopathic haemolytic anaemias, 304
oroya fever, 302
oxidative haemolysis, 305
severe burns, 306
thermal injury, 306
thrombotic thrombocytopenic purpura, 305
toxoplasmosis, 303
vitamin E deficiency, 307
Wilson disease, 307
Zieve syndrome, 306
non-immune haemolysis, 1025
non-inherited congenital thrombocytopenia, 849
non-integrating iral vectors, 97
non-nodal MCL, 449–450
non-secretory multiple myeloma, 533
nonsense codons, 227
nonsense-mediated mRNA decay (NMD), 227
non-transferrin-bound iron (NTBI), 175–176, 196, 234
non-transfusion-dependent thalassaemia (NTDT), 199, 244–246
non transfusion dependent thalassamia, 978
non-transplant chemotherapy for AL amyloidosis, 555–556
normal haemostasis
amplification of initial stimulus, 761–763
blood vessels
endothelial cell anticoagulant activities, 767
endothelial cell-derived fibrinolytic factors, 767
endothelium, 765
platelet–vessel wall interaction, 765–767
von Willebrand factor, 767
coagulation factors
factor IX, 771
factor V, 772
factor VII, 770–771
factor VIII, 771–772
factor X, 771
factor XI, 771
factor XIII, 771
fibrinogen, 772
prothrombin, 772
tissue factor, 769–770
feedback inhibition of procoagulant response, 763–764
fibrinolysis, 764–765
fibrin and fibrinogen, 778–779
fibrinolytic system, components of, 778
plasminogen and plasmin, 778
naturally occurring inhibitors of blood coagulation
α_1-antitrypsin, 775
α_2-antiplasmin, 775–776
α_2-macroglobulin, 776
antithrombin, 774
C1-esterase inhibitor, 775
endothelial protein C receptor, 777
heparin and heparin-like substances in plasma, 774–775
heparin cofactor II, 774
Kunitz-type inhibitor, 773
physiological anticoagulants, 773
protease nexin 44, 775
protein C inhibitors, 777
protein C pathway, 776–777
protein S, 777
protein Z and protein-Z-dependent inhibitor, 775
serine protease inhibitors (serpins) and heparin, 773–774
thrombomodulin, 777
plasminogen activation
α_2−antiplasmin, 780
inhibitors of plasmin, 780
lipoprotein A, 780–781
plasminogen activator inhibitor type 33, 779–780
plasminogen activator inhibitor type 44, 780
thrombin-activatable fibrinolysis inhibitor, 781
plasminogen activators
exogenous plasminogen activators, 779
inhibitors of fibrinolysis, 779
tissue plasminogen activator, 779
urinary plasminogen activator, 779
tissue factor initiates blood coagulation, 761
NOTCH-signalling, 129–130, *130*
NSAIDs, 259
nucleic acid amplification tests (NAATs), 956
nucleotide metabolism, 290–291
obinutuzumab, 60
obstetric haematology
alloimmune disorders
foetal neonatal alloimmune thrombocytopenia, 981
haemolytic disease of foetus and newborn, 981
anaemia
congenital anaemias, 976
folate deficiency, 975
iron deficiency, 975
vitamin B12 deficiency, 975–976
autoimmune disorders
autoimmune haemolytic anaemia, 980
neutropenia, 980
bone marrow disorders
aplastic anaemia and paroxysmal nocturnal haemoglobinuria, 987–988
haematological malignancy, 986–987
myeloproliferative neoplasms, 986
cellular changes during pregnancy
platelet, 975
red cells, 974
white cells, 974–975
haemoglobinopathies
non transfusion dependent thalassamia, 978
sickle cell disease, 976–977
thalassaemia carriage/trait, 977
thalassemia, 977
transfusion-dependent thalassaemia major, 978
UK haemoglobinopathy screening service, 976
inherited bleeding disorders, 982
massive life-threatening PE, 986
obstetric haemorrhage, 982–985
patient blood management in, 985
thrombocytopenia in pregnancy
foetus/neonate, 979
gestational thrombocytopenia, 978–979
immune thrombocytopenia, 979
maternal considerations, 979
venous thromboembolism (VTE) in pregnancy, 985–986
obstetric haemorrhage, 982–985
oedema, 259
off-target effects, 104
oncogenes, 129
oncolytic viruses, 93
opioid therapy, 259
opportunity theory, 138
oral anticoagulants, 895–898
oral iron therapy, 181–182
organ damage, test for, 196

organ involvement, assessment of, 552–553
organ toxicity
  gastrointestinal toxicity, 736
  liver toxicity, 736–737
  post-transplant lymphoproliferative disease, 737
  pulmonary infections and non-infectious complications, 737
  renal toxicity, 737
oroya fever, 302
orthotopic liver transplantation, 1029
osmotic fragility test, 274, *274*
osteoporosis, 196, 894
osteosclerotic myeloma, 533
overwhelming pneumococcal sepsis, *254*
overwhelming postsplenectomy infection (OPSI), 275
overwhelming post splenectomy sepsis (OPSS), 78
oxidative haemolysis, 305
oxygen-sensing system, 52–53, *53*

P1, P^k and P blood group antigens/antibodies, 321
$P2Y_1$ and $P2Y_{12}$ ADP receptors, 790–791
P53 network, 135
painful bruising syndrome (psychogenic purpura), 842–843
pain management, 264
paired-end sequencing, 110
palliative care, 1022
pantothenic acid deficiencies, 220
pappenheimer bodies, *149*
PAR1 and PAR4 thrombin receptors, 791–792
paraproteinaemia, 844–847
parenteral direct thrombin inhibitors, 894
parenteral iron therapy, 182
paroxysmal cold haemoglobinuria, 300
paroxysmal nocturnal haemoglobinuria, 583–604, 919, 987–988, 1049–1050
pathogen-derived molecular patterns (PAMPS), 22
pathogenesis of, 292–293
pathophysiology, 831
patient blood management, 352, 985
patient education, 78–79
pattern recognition receptors (PRRs), 22
Pearson syndrome, 991–992
Pelger–Huët anomaly with a bilobed nucleus, *38*
pembrolizumab, 87, 93
pentose phosphate pathway, 286–287
perforins, 66
periodic acid–Schiff and acid phosphatase reactions, 149
peripheral blood, 205–206, **206,** *206*
peripheral/inducible Treg cells, 67
peripheral T-cell lymphoma, 386–387
peripheral T-cell non-Hodgkin lymphoma, 456–457
  allogeneic transplantation, 460–461
  autologous stem cell transplantation in first remission, 460
  induction chemotherapy, 459
  innovative frontline combinations, 460
  new drugs, 461
  relapsed and refractory disease, 460
periprocedural management, 897–899
pernicious anaemia (PA), 209–210
phaeochromocytoma, **1031**
phagocytes, 15–42
  basophils, 28–30
  chemotactic factors controlling, **22**
  circulating, origin and morphology of, *19*
  DCs, 30–34
  disorders of, 34–41
  eosinophils, 28–29, **29**
  identification and quantification, 17
  lineage at glance, 15–17
  macrophages, 30–34
  mast cells, 28–30
  morphology of, *18*
  MPS-monocytes, 30–34
  multinucleated cells, 30–34
  neutrophils, 24–28
  opsonic and non-opsonic receptors of, **20**
  phagocytosis, 17–24
  secretion, 23
phagocytosis, 17–24
  adhesion, 18–22, **21**
  chemotaxis, 18–22, *22*
  lytic enzymes, killing via, 23–24
  pattern recognition receptors and inflammation, 22–23
  reactive radicals production, killing via, 23–24
pharmacogenetic variables, 418
philadelphia chromosome-positive (Ph+) disease, 405–406
phlebotomy, 192
Ph-like ALL, 406
phosphatidylserine, 53
phosphofructokinase deficiency, 284
phosphoglycerate kinase deficiency, 286
physiological anticoagulants, 773
plasmablastic lymphoma, 522
plasmablasts, 59
plasma cell dyscrasia, 549
  extramedullary plasmacytoma, 533
  IgM multiple myeloma, 533
  non-secretory multiple myeloma, 533
  osteosclerotic myeloma, 533
  plasma cell leukaemia, 532–533
  POEMS syndrome, 533
plasma cell leukaemia, 532–533
plasma cell myelomas, *147*
plasma cell neoplasms, 367–369
plasma cells and their microenvironment, 527–528
plasmacytoid dendritic cells (pDC), 17
plasmin, inhibitors of, 780
plasminogen activation
  α_2—antiplasmin, 780
  inhibitors of plasmin, 780
  lipoprotein A, 780–781
  plasminogen activator inhibitor type 33, 779–780
  plasminogen activator inhibitor type 44, 780
  thrombin-activatable fibrinolysis inhibitor, 781
plasminogen activator inhibitor type 33, 779–780
plasminogen activator inhibitor type 44, 780
plasminogen activators
  exogenous plasminogen activators, 779
  inhibitors of fibrinolysis, 779
  tissue plasminogen activator, 779
  urinary plasminogen activator, 779
plasminogen and plasmin, 778
Plasmodium falciparum, 952–953
Plasmodium knowlesi, 953
Plasmodium malariae, 953
platelet
  based bleeding problems, 793–794
  formation, 784
  function disorders, genetics of, 796

    foetal Rh genotype by molecular methods, 324
    immune antibodies, 324
    molecular basis of D variants, 324
    naturally occurring antibodies, 324
    probable Rh genotype, 322
    Rh antigens, 322
    Rh genes and proteins, 322–323
    variants of D, 323
red cell membrane and chemistry of blood group antigens, 308–311
red cell membrane disorders, *270–273*
  clinical course and complications, 274–275
  clinical phenotypes of, 273
  elliptocytosis, in neonate, 277
  haemolyic hereditary elliptocytosis, 277
  hereditary elliptocytosis, 276
  hereditary spherocytosis, 273, *273*
  integral proteins and vertical interaction, 271–273
  laboratory diagnosis, 274
  laboratory investigation, 277–279
  low-expression genes, 277
  management, 275
  membrane lipids, abnormalities of, 279–280
  mild common hereditary elliptocytosis, 276–277
  molecular pathology, 273
  osmotic fragility test, 274
  poikilocytosis, in neonate, 277
  protein abnormalities or gene defects, 274
  silent carriers, 277
  Southeast Asian ovalocytosis, 279, *280*
  splenectomy, 275–276
  stomatocytosis related disorders, 278
  treatment, 278, 279
red cell metabolism, defects of
  chronic non-spherocytic haemolytic anaemia, 288–289
  clinical features, 282–283
  defence against oxidative stress, 286
  drug-induced acute haemolysis, 289
  favism, 288

red cell metabolism, defects of (*Continued*)
fructose diphosphate aldolase A deficiency, 284
G6PD deficiency, in infancy, 288
glucose-6-phosphate dehydrogenase deficiency, 287–288
glucose phosphate isomerase deficiency, 284
glutathione, 289–290
glycolytic pathway (Embden–Meyerhof pathway), 281
glycolytic pathway, disorders of, 281
hexokinase deficiency, 284
hexose monophosphate shunt, 286–287
laboratory diagnosis, 283, 289
management, 283–284, 289
neonatal jaundice, in infancy, 288
nucleotide metabolism, 290–291
pentose phosphate pathway, 286–287
phosphofructokinase deficiency, 284
phosphoglycerate kinase deficiency, 286
pyrimidine 5′-nucleotidase, 291
pyruvate kinase deficiency, 281–282
Rapoport–Luebering shunt, 281
triose phosphate isomerase deficiency, 286
red cells, 336–337
antibodies, clinical significance of, 312–313
autoantibodies, characteristics and specificity of, 293
destruction and production, 295
folate assay, 218
protoporphyrin, 177
sickling, induction of, *251*
transfusion triggers, 353
reduced-intensity conditioning regimens, 729
refractory anaemia with ring sideroblasts, 185–187
regulatory $CD4^+$ T cells, 67
regulatory T (Treg) cells, 67
Relatlimab, 85
renal disease, 598, 839–840, 1027
renal dysfunction, 601
renal failure, 535–536
renal toxicity, 737
reproductive aspects, 1006–1007
repulsive guidance molecules (RGM), 171
resource poor setting, treatment in, 426
respiratory infections, 1014–1015
reticulocyte haemoglobin content, 178
reticulocytes, 46
retinal vein thrombosis, 930
retroviruses, 97
reverse transcriptase polymerase chain reaction (RT-PCR), 157, *159*
reversible terminator deoxynucleotide triphosphate molecules (RT-dNTPs), 110
Rh antigens, 322
Rh D-positive platelet transfusions, 359
Rh genes and proteins, 322–323
Rh system
band 3/Rh molecular macrocomplexes, 323
D, C/c and E/e polymorphisms, 323
D immunisation and immunoprophylaxis, 324
foetal Rh genotype by molecular methods, 324
immune antibodies, 324
molecular basis of D variants, 324
naturally occurring antibodies, 324
probable Rh genotype, 322
Rh antigens, 322
Rh genes and proteins, 322–323
variants of D, 323
Richter's syndrome, 437
Rituximab, 85
rituximab, 866
RNA splicing, 135–136
Rosai Dorfman Destombes disease, 715
routine tests of haemostasis, 829
ruling out hereditary amyloidosis, 552

S-adenosylmethionine (SAM), *204,* 205
safe administration of blood
patient identification, 343
transfusion reactions, detection and approach to, 343
saline or directly agglutinating antibodies, 312
SARS-CoV-2, 1032
schistosomiases, 963
Schulman-Upshaw syndrome, **858**
Schwachman–Diamond–Oski syndrome, 34
sclerosing angiomatoid nodular transformation (SANT), 76
scurvy, 220, 843
secondary lymphoid organs, 56
secondary malignancies, 480, 738–739
secondary sideroblastic anaemias, 187
second hits, 708
second-line treatment for paediatric ITP, 870
second neoplasias, 436
secretory granule and lysosome disorders, 34
senile purpura (atrophic or actinic purpura) and steroid-related purpura, 842
sensitization to red cell antigens, 344
serine protease inhibitors (serpins) and heparin, 773–774
serum amyloid A protein (SAA), amyloidosis, **548**
serum cobalamin, measurement of, 213
serum ferritin, 176–177, 194
serum folate, 218
serum gastrin, 210
serum holotranscobalamin (holoTCII, holoTC), 213
serum homocysteine, 218–220
serum iron and iron-binding capacity, 177
serum methylmalonate (MMA) levels, 213–214
serum transferrin receptors, 177
severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), 62
severe anaphylactic reactions, 349
severe burns, 306
severe combined immunodeficiency (SCID), 98
Severe Congenital Neutropenia (SCN), 34
Sézary syndrome, 385, 465–466
SF3B1, 750–751
SF3B1 mutation (MDS-SF3B1), 660
short-read technologies, 110–111
short-term haematopoietic stem cells (ST-HSC), 15
short-term in vitro assays, 6
short-term treatment, 866
Shwachman–Diamond syndrome
cell and molecular biology, 573
clinical features, 573
treatment, 573–574
sibling donor transplantation, 725–726
sickle cell disease (SCD), 96, 249–267, 976–977, 1049
acute painful episode, 253
anaemia, 252–253
bone complications, 259
β-thalassaemia, 260
clinical manifestations, 251–259
with coexistent α-thalassaemia, 260
complications of, *256*
disease-modifying therapies, 264–265, **266**
erythrocytes, effects on, 250
gene editing for, 102–104
gene therapy for, 99
geographic distribution of, 249
growth and development, 253
haemoglobin electrophoresis, 261, *262*
haemolysis, 250–251, *252*
haemopoietic stem cell transplantation (HSCT), 265, 267, *267*
HbD disease, 261
HbE disease, 261
Hb Lepore disease, 261
HbO Arab disease, 261
HbSC disease, 259
hepatobiliary complications, 257
HPFH, 260–261
infections, 253–254, 263

laboratory tests, 261
leg ulcers, 259
management of, **266**
molecular basis of sickling, 249–250
neurological complications, 254–255
newborn screening, 261–262
ocular complications, 259
pain management, 264
peripheral blood findings, 261
pregnancy, risk in, 257–258
prenatal diagnosis, 262–263
priapism, 258–259
psychosocial issues, 267
pulmonary complications, 255–257
renal complications, 258
routine healthcare for, 263, *263*
sickle cell trait, 259
sickle mutation, areas of high prevalence, **250**
therapy, 263–267
transfusion therapy, 263–264
vaso-occlusion, 251
sickle cell intrahepatic cholestasis syndrome (SCIC), 257
sickle cell trait, 259
sickling syndromes, **250**
sideroblastic anaemias, 184–187, *185*
acquired, 186–187
classification of, **184**
defective haem synthesis, 185
inherited, 185
mitochondrial glycine importer, mutations of, 185
proteins of iron–sulfur cluster biogenesis, mutations of, 185–186
syndromic forms of, 186
X-linked sideroblastic anaemia (ALAS2 mutations), 185
silent carriers, 277
simple atrophic gastritis, 211
single antiplatelet agents, 935–937
single chain variable fragment (ScFv), 90, *90*
single nucleotide polymorphism (SNP), 108
skin infections, 1015
skin necrosis, 897
sleeping sickness, 959–960
smouldering multiple myeloma, 531–532
solid organ transplantation, 557
solid-phase assays, 916
somatic hypermutation, 57
somatic mutations, 124, 588, 657–658
somatic mutations, sequence of, *124*
somatic mutations in AA
detection of, 588
somatic point mutations, 608–609
Southeast Asian ovalocytosis, 279, *280*
specialized antiglobulin techniques, 314
spherocytosis, hereditary, 273
spleen, 71–81
antibiotics, 79–80
blood flow and red pulp, 71–73
blood pooling within, 73
closed system, 72
in ensuring quality control of red cells, 73
Hodgkin lymphoma (HL), 76
hypersplenism, 74–75
hyposplenism, 80–81
immunological function, 73–74
myeloid stem cell disorders, 76
non-Hodgkin lymphoma (NHL), 75–76
open circulation, 72
patient education, 78–79
role of, 295
size, 74
splenomegaly, 74–75
structure and function, 71
vaccination, 79
vascular and lymphatic organization, *72*
spleen tyrosine kinase inhibitor, 867
splenectomy, 77–78, 187, 275–276, 867–869
changes in peripheral blood, 80
complications of, 78
leucocyte changes, 80
platelet changes, 80
POSS, 78
red cell changes, 80
splenic angiosarcomas, 76
splenic B-cell lymphoma, 450–451
splenic diffuse red pulp small B-cell lymphoma, 451
splenic injury, *77*
splenic lesions, diagnostic evaluation of, 76–77
splenic marginal zone lymphoma, 366–367, 446–447
splenic pooling, **1026**
splenic thromboemboli, 76
splenic vein thrombosis, 931
splenomegaly, 74–75
causes of, 74, **75**
diagnostic evaluation of, 76–77
infections, 75
management of, 77–78
splenectomy, 77–78
spliceosome, 136
spliceosome regulators, 609
splicing factors, 135–137, *136*
spontaneous remission, 598–599
sporadic porphyria cutanea tarda (PCT), 183
spreading, 785–787
SRSF44, 750–751
staging and risk stratification
advanced-stage Hodgkin lymphoma, 474–475
Ann Arbor staging system, 473
early-stage Hodgkin lymphoma, 473
standard intensive chemotherapy, 619–620
stem cell factor (SCF), 8, 11, 28, 50
stem cell factor receptor (SCFR), 16
stem cell infusion and blood product support, 730–731
stem cells
and differentiation, 656
memory cells, 66
mobilization, 724–725
therapy, 33
transplantation, 405, 624
stem cell transplantation
acute graft-*versus*-host disease, 722
autologous transplantation, 725
chronic graft-*versus*-host disease, 722
cord blood transplantation, 726–727
graft-*versus*-leukaemia effect, 722–724
haploidentical stem cell transplantation, 726
HLA matching for transplantation, 721–722
human leucocyte antigen system, 719–721
immune reconstitution, 724
sibling and unrelated donor transplantation, 725–726
stomatocytes, 278
stomatocytosis related disorders, 278
storage and processing of blood
anticoagulants and optimal additive solutions, 336
leucodepletion, 336
storage changes, 334–336
storage changes, 334–336
Streptococcus pyogenes bacilli, 82
subcutaneous panniculitis-like T-cell lymphoma, 383–384
sulfamethoxazole, 217
superficial thrombophlebitis, 931
supportive care, 401, 589–590
supportive treatment, 556
suspected myeloid malignancy, 143
swarming
monocyte, *28*
neutrophil, 26, *28*
symptomatic coronary artery disease, 937–938
symptomatic disease, management of
front-line treatment, 442–443
relapsed/refractory disease, 444–445
response categories, 446
targeted therapies, 443–444
symptomatic management of mediator release, 698–699
syndromic sideroblastic anaemia, 185, 186
with immunodeficiency, 186
with megaloblastic anaemia, 186
with mitochondrial myopathy, 186

syphilis, 332
systemic AL amyloidosis
  AL Amyloidosis, treatment of, 554–555
  AL fibrils and monoclonal light chains, 549
  autologous peripheral blood stem cell transplantation, 555
  clinical features, 549–550
  clone, assessment of, 552
  confirming presence of amyloid, 550–551
  diagnosis and investigation of AL amyloidosis, 550
  differential diagnosis, 553
  goals of treatment, 554
  identifying fibril type, 551–552
  management, 554
  natural history, 553–554
  non-transplant chemotherapy for AL amyloidosis, 555–556
  organ involvement, assessment of, 552–553
  plasma cell dyscrasia, 549
  ruling out hereditary amyloidosis, 552
  solid organ transplantation, 557
  supportive treatment, 556
systemic amyloidosis
  AA amyloidosis, 558
  future directions, 559
  hereditary systemic amyloidoses, 559
  leucocyte chemotactic factor II (LECT2) amyloidosis, 558
  transthyretin amyloidosis (ATTR amyloidosis), 558–559
systemic disease, 697
systemic diseases, 1027–1031
systemic mastocytosis, 675
  constitutional features, 697
  cutaneous manifestations, 697
  systemic disease, 697
systemic symptoms, 689

    FVR506Q and APC resistance, 911
    heparin-induced thrombocytopenia, 913–914
    hormone-replacement therapy, 913
    hospital-acquired thrombosis, 912–913
    immobility and venous thromboembolism, 912
    indwelling venous devices, 913
    lupus anticoagulant tests, 915–916
    paroxysmal nocturnal haemoglobinuria, 919
    polycythaemia rubra vera, 918–919
    preanalytical variables, 910
    pregnancy and venous thromboembolism, 911–912
    protein C assays, 910–911
    solid-phase assays, 916
    thrombosis, 916, 918–919
    thrombotic risk in myeloproliferative disease, 918–919

venous thromboembolism (VTE) (*Continued*)
vaccine induced immune thrombocytopenia and thrombosis, 914
venous thromboembolism and cancer, 917–918
heritable thrombophilia and thrombosis-prone families, 909
initial anticoagulant therapy, 926
intra-abdominal vein thrombosis
hepatic vein thrombosis, 930
mesenteric vein thrombosis, 930
portal vein thrombosis, 930
splenic vein thrombosis, 931
superficial thrombophlebitis, 931
isolated calf DVT, 925
natural anticoagulants, 907
neonatal stroke, 909–910
post-thrombotic syndrome, 927–928
in pregnancy, 985–986
procoagulant factors, 907–908
protein C deficiency, 906
protein S deficiency, 906–907
pulmonary embolism, 925
purpura fulminans, 909
retinal vein thrombosis, 930
risk, 78
risk assessment, 922
thrombectomy, 929
thrombolytic therapy, 926–927
upper limb DVT, 930
vena caval filters, 929
vitamin K antagonist-induced skin necrosis, 909
venous thromboembolism and cancer, 917–918
viral haemorrhagic fevers, 963
viral infections, 298, 1032
viral vectors, integrating vs. non-integrating, *97*
visual toxicity, 1011
vitamin B12 deficiency, 975–976
vitamin E deficiency, 307
vitamin K, 835–837
antagonist-induced skin necrosis, 909
deficiency, 835–837, 1001
dependent coagulation factors deficiency, 827–828
metabolism, 835
vitamin K antagonists (VKAs), 1044
von Willebrand disease (vWD), 847
acquired von Willebrand syndrome, 817
clinical course and complications, 816
clinical features, 811–812
molecular genetics, 816–817
preliminary diagnosis, 812
pseudo von Willebrand disease (platelet-type), 817
secondary tests for classification, 812–815
treatment, 815–816
type-1, 815
von Willebrand factor, 809–811
von Willebrand factor (VWF), 767, 809–811
vorapaxar, 890
voxelotor, 265

Waldenström macroglobulinaemia (WM)
management of, 496–497
stem cell transplantation for, 497–498
Warfarin, 1043–1044
warfarin, 895–898, 1051
warfarin-induced skin necrosis, 844
warm-acting antibodies, 293–294
warm AIHA, clinical features of
carcinoma-related warm AIHA, 298
drug-related warm AIHA, 297–298
Evans syndrome, 296
idiopathic, 296
lymphoproliferative diseases, 296–297
viral infections, 298
warm antibodies, 312
washed platelets, 338
washed red cells, 337
watch and wait policy, 869
Weibel–Palade bodies, 20
white cell abnormalities, 964
whole blood, 336
whole exome sequencing (WES), 123, 160
whole genome sequencing (WGS), 106, 108, 158–159, *160*
whole transcriptome sequencing (WTS), 160
Wilms tumor 1 (WT1) gene product peptide vaccination, 92
Wilms tumour, **817**
Wilson disease, 307
Wip-1, 135
Wiskott–Aldrich syndrome (WAS), 98, **858**

xenotransplantation assay, 8
x-linked DC, 570
x-linked intellectual disability syndromes, α-thalassaemias with, 244
x-linked sideroblastic anaemia (ALAS2 mutations), 185
x-linked thrombocytopenia, **858**
x-linked transcription, 126

yeasts, **1012**
yellow fever virus, 963

Zieve syndrome, 306
Zollinger–Ellison syndrome, 212
ZRSR2 gene, 137
